Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

This edition is dedicated to our esteemed colleague and close friend, Harry N. Herkowitz, MD, who passed away, too early, in June 2013. In a humble attempt to honor him and his legacy, we list Harry's name along with our mentors, thus changing the title of this book to *Rothman-Simeone and Herkowitz's The Spine.* Harry abruptly and unintentionally left the editorship of this great work, of which he truly was the lead and driving force for the first six editions. We present this seventh edition proudly and with the hope that our departed friend would approve. To fill the void left by this one man, we have added two new editors whom Harry respected immensely.

Harry was a luminary in spine. Orthopedic surgeons and neurosurgeons worldwide have benefited from his extensive and significant contributions to the field. Harry worked incredibly hard and accomplished much during his career, rising to the presidency of multiple organizations. He was an excellent and exceptionally active surgeon. He was a surgeon's surgeon, as we say, who was respected as a superb educator, a leader among leaders, and a shining example of a clinical researcher. Harry emphasized and fostered patient-oriented care long before it was in vogue. His manner of practice and teaching epitomized evidence-based medicine, once again before it became a defined process. With an intrinsic drive, he continued to search for excellence. His accomplishments, for a single person, were extraordinary.

Unlike most of us, Harry did not begin his career in a university setting with its attendant peer pressure to publish and produce; his was an internal force. Ultimately he surpassed his original goals. "Don't worry, I will get it done," was a consoling and affirming phrase he used often. And after he uttered those words, we didn't worry, and he would always get it done. Today, it would be unusual to get through a round of fellowship candidate interviews without hearing the word "privademics," and it is to this type of practice that many of our young colleagues aspire. Harry, under the guidance of our mentor Richard Rothman, MD, PhD, blazed a trail into this heretofore unknown hybrid world brilliantly and selflessly, setting aside his and his group's personal finances and time.

In so many ways and in so many settings, Harry changed the lives of patients, colleagues, and trainees. He rewarded those who lived up to his expectations with a lifetime of honor and friendship. He changed the course of contemporary spine surgery through his research and his leadership of numerous professional organizations, not the least of which was the American Board of Orthopaedic Surgery.

Harry was cordial to everyone, tough when needed, and extremely loyal to his friends. His professional and personal life was about giving and sharing with others what he had learned along the way (much of which was from Richard Rothman). Those of us who knew him well saw his softer side. Besides being a great, loyal, and true friend, he was, most importantly, a devoted family man. He adored his wife, Jan, and children, Seth (and wife Lauren) and Rachel (and husband Michael). Sadly, he never met his granddaughter.

We all strive to move forward, improving on the past when possible and appropriate. But the spine world, and the friends Harry left behind, are not the same without him. He bound contemporary orthopedic and spine communities together.

Thank you to Harry's mentors, and family, who shared this giant with us.

Contributors

Muhammad M. Abd-El-Barr, MD, PhD
Resident Neurosurgeon
Harvard Medical School
Brigham and Women's Hospital
Boston Children's Hospital
Boston, Massachusetts

Steven S. Agabegi, MD
Assistant Professor
Department of Orthopaedic Surgery and Sports Medicine
Division of Spine Surgery
University of Cincinnati College of Medicine
Cincinnati, Ohio

Staff Psychologist
Chronic Pain Rehabilitation Section
Center for Neurological Restoration
Cleveland Clinic
Cleveland, Ohio

Scott Delp, PhD
James H. Clark Professor
Departments of Bioengineering, Mechanical Engineering, and Orthopaedic Surgery
Schools of Engineering and Medicine
Stanford University
Stanford, California

Richard Derby, MD
Medical Director
Spinal Diagnostics and Treatment Center
Daly City, California

Peter B. Derman, MD
Orthopedic Surgery Resident
Hospital for Special Surgery
New York, New York

Clinton J. Devin, MD
Associate Professor of Orthopaedic Surgery and Neurosurgery
Vanderbilt University Medical Center
Nashville, Tennessee

Elizabeth A. Dugan, PhD
Postdoctoral Associate
Miami Project to Cure Paralysis
University of Miami Miller School of Medicine
Miami, Florida

Alexandra Miller Dunham, MD
Resident
Orthopaedic Surgery
Johns Hopkins University School of Medicine
Baltimore, Maryland

Richard W. Easton, MD
Assistant Professor
Department of Orthopaedic Surgery
Oakland University William Beaumont School of Medicine
Rochester Hills, Michigan;
Section Head
Orthopaedic and Spine Surgery
Beaumont Hospital
Troy, Michigan

Jason C. Eck, DO, MS
Spine Surgeon
Center for Sports Medicine and Orthopaedics
Chattanooga, Tennessee

Frank J. Eismont
Leonard M. Miller Professor and Chairman
Department of Orthopaedic Surgery
University of Miami Miller School of Medicine
Miami, Florida

Todd M. Emch, MD
Staff
Division of Neuroradiology
Imaging Institute
Cleveland Clinic
Cleveland, Ohio

Sanford E. Emery, MD, MBA
Professor and Chairman
Department of Orthopaedics
West Virginia University
Morgantown, West Virginia

Yashar Eshraghi, MD
Assistant Clinical Professor
Department of Anesthesiology and Perioperative Care
School of Medicine
University of California, Irvine
Irvine, California

Saif Aldeen Farhan, MD
Research Spine Fellow
Department of Orthopaedic Surgery
University of California, Irvine
Irivine, California

Timothy J. Furnish, MD
Associate Clinical Professor of Anesthesiology
Center for Pain Medicine
Pain Fellowship Program Director
University of California, San Diego Medical Center
San Diego, California

Shyam Gajavelli, PhD
Associate Scientist
Department of Neurosurgery
Miami Project to Cure Paralysis
University of Miami Miller School of Medicine
Miami, Florida

Steven R. Garfin, MD
Distinguished Professor and Chair
Department of Orthopaedic Surgery
University of California, San Diego
San Diego, California

Bhavuk Garg, MD
Associate Professor
Department of Orthopaedics
All India Institute of Medical Sciences
New Delhi, India

Matthew F. Gary, MD
Assistant Professor of Neurosurgery and Orthopaedic Surgery
Emory Spine Center
Emory University School of Medicine
Atlanta, Georgia

Joseph P. Gjolaj, MD
Assistant Professor
Orthopaedic Surgery
University of Miami Miller School of Medicine;
Orthopaedic Spine Surgeon
Orthopaedic Surgery
Jackson Memorial Hospital
Miami, Florida

Paul Glazer, MD
Spine Specialists of Boston
Chestnut Hill, Massachusetts

Michael P. Glotzbecker, MD
Assistant Professor
Department of Orthopaedic Surgery
Boston Children's Hospital
Boston, Massachusetts

Vijay K. Goel, PhD
Distinguished University Professor
Endowed Chair and McMaster-Gardner Professor of Orthopaedic Bioengineering
Co-Director, Engineering Center for Orthopaedic Research Excellence (E-CORE)
Departments of Bioengineering and Orthopaedic Surgery
Colleges of Engineering and Medicine
University of Toledo
Toledo, Ohio

Jonathan N. Grauer, MD
Associate Professor
Department of Orthopaedics and Rehabilitation
Yale University School of Medicine
New Haven, Connecticut

Barth A. Green, MD
Professor of Neurological Surgery
University of Miami Miller School of Medicine
Miami, Florida

Ajay Gupta, MD
Head, Pediatric Epilepsy
Director, Tuberous Sclerosis Program
Associate Professor, Cleveland Clinic Lerner College of Medicine
Cleveland Clinic Foundation
Cleveland, Ohio

Richard D. Guyer, MD
Past President
Director, Spine Fellowship
Texas Back Institute
Plano, Texas;
Clinical Associate Professor
Department of Orthopaedic Surgery
University of Texas Southwestern School of Medicine
Dallas, Texas

Aldric Hama, PhD
Study Director
Hamamatsu Pharma Research
Hamamatsu, Japan

Hamid Hassanzadeh, MD
Assistant Professor
Department of Orthopaedic Surgery
University of Virginia
Charlottesville, Virginia

Spencer Hauser, MD
Fellow, Orthopaedic Surgery
Duke University School of Medicine
Durham, North Carolina

Robert F. Heary, MD
Professor of Neurosurgery
Rutgers New Jersey Medical School
Director, Spine Center of New Jersey
Newark, New Jersey

Daniel J. Hedequist, MD
Associate Professor
Department of Orthopaedic Surgery
Boston Children's Hospital
Boston, Massachusetts

Stanley A. Herring, MD
Clinical Professor
Rehabilitation Medicine, Orthopaedics and Sports Medicine and Neurological Surgery
University of Washington;
Director, UW Medicine Sports Health and Safety System
Co-Medical Director, UW Medicine Sports Concussion Program
Harborview Medical Center and Seattle Children's Hospital
Seattle, Washington

Kenneth A. Hood, DO
Assistant Clinical Professor, Spine Surgery
Department of Orthopaedic Surgery
University of Arizona
Tucson, Arizona

Wellington K. Hsu, MD
Clifford C. Raisbeck Distinguished Professor of Orthopaedic Surgery
Director of Research
Department of Orthopaedic Surgery
Northwestern University Feinberg School of Medicine
Chicago, Illinois

Serena S. Hu, MD
Professor and Vice Chair
Chief, Spine Service
Department of Orthopedic Surgery
Stanford University
Stanford, California

Xiaobang Hu, PhD
Research Director
Scoliosis and Spine Tumor Center
Texas Back Institute
Texas Health Presbyterian Hospital
Plano, Texas

Kevin T. Huang, MD
Department of Neurosurgery
Boston Children's Hospital
Harvard Medical School
Boston, Massachusetts

Andre M. Jakoi, MD

Medical Director, Ferguson Laboratory
Associate Program Director, Orthopedic Residency
University of Pittsburgh Medical Center
Pittsburgh, Pennsylvania

Scott I. Lee, MD
Orthopedic Spine Surgeon
Adventist Health
White Memorial Medical Center
Los Angeles, California;
Glendale Adventist Medical Center
Glendale, California

Yu-Po Lee, MD
Clinical Professor
Department of Orthopaedic Surgery
University of California, Irvine
Irvine, California

Ronald A. Lehman Jr, MD
Professor of Orthopaedic Surgery
Chief, Degenerative, MIS, and Robotic Spine Surgery
Director, Athletics Spine Center
Director, Spine Research
Co-Director, Adult and Pediatric Spine Fellowship
Advanced Pediatric and Adult Deformity Service
The Spine Hospital
New York–Presbyterian/The Allen Hospital
New York, New York

Lawrence G. Lenke, MD
Professor and Chief of Spinal Surgery
Chief of Spinal Deformity Surgery
Department of Orthopedic Surgery
Columbia University College of Physicians and Surgeons;
Surgeon-in-Chief
The Spine Hospital
New York–Presbyterian/The Allen Hospital
New York, New York

Dante Leven, MD
Total Orthopedics and Sports Medicine
Associate Professor
Nassau University Medical Center
East Meadow, New York

Allan D. Levi, MD, PhD
Chair, Department of Neurological Surgery
Professor of Neurological Surgery, Orthopedics, and Rehabilitation Medicine
University of Miami Miller School of Medicine
Chief of Neurosurgery
Jackson Memorial Hospital
Miami, Florida

Richard L. Lieber, PhD
Senior Vice President and Chief Scientific Officer
Rehabilitation Institute of Chicago;
Professor of Physiology and Biomedical Engineering
Northwestern University
Chicago, Illinois

Isador H. Lieberman, MD
Director
Scoliosis and Spine Tumor Center
Texas Back Institute
Texas Health Presbyterian Hospital
Plano, Texas

Richard A. Lindtner, MD, PhD
Trauma Surgeon
Department of Trauma Surgery and Sports Medicine
Medical University of Innsbruck
Innsbruck, Austria

Gregory Lopez, MD
Assistant Professor of Spine Surgery
Rush University
Chicago, Illinois

J. Diego Lozano, MD
Interventional Neuroradiologist
Providence Little Company of Mary Medical Center
Mechanical Thrombectomy-Ready Advanced Primary Stroke Center
Torrance, California

Prasath Mageswaran, PhD
Research Associate
Spine Research Institute
Ohio State University
Columbus, Ohio

Kamran Majid, MD
Physician
Orthopedic Spine Surgery
Kaiser Permanente
Oakland, California

Antonios Mammis, MD
Assistant Professor, Neurological Surgery and Anesthesiology
Director, Center for Neuromodulation
Director, Functional and Restorative Neurosurgery
Senator, Rutgers University
Rutgers New Jersey Medical School
Newark, New Jersey

Satyajit Marawar, MD
Orthopedic Spine Surgeon
Veterans Affairs Medical Center
Syracuse, New York

William S. Marras, PhD, CPE
Honda Chair Professor
Integrated Systems Engineering/Spine Research Institute
Ohio State University
Columbus, Ohio

Eric A.K. Mayer, MD
Associate Director, Clinical Transformation
Cleveland Clinic Center for Spine Health
Cleveland, Ohio

Tom G. Mayer, MD
Harvard College

Preface

As can be seen from the Dedication and Acknowledgment pages, the Editorial Board for this seventh edition of *The Spine* has undergone some changes. With the passing of Harry N. Herkowitz, MD, and the fact this may be the last edition for some of the remaining long-term editors, two new editors—Christopher N. Bono, MD, and Jeffrey S. Fischgrund, MD—have stepped in, and up, to help us create this new edition of *Rothman-Simeone and Herkowitz's The Spine*. We hope readers will find this edition—as well as future editions—as important and useful as previous ones.

This edition of *The Spine* comes 7 years after the sixth edition. We have strived to continue the original concepts of Richard H. Rothman, MD, PhD, and Frederick A. Simeone, MD, which was to correlate basic science, knowledge of the natural history, and clinical course of spinal disorders with current treatments based on established scientific principles and evidence-based literature. This edition, as in those of the past, provides a comprehensive look at spinal disorders affecting adults and children. It is directed at clinicians of all levels and specialties who treat spinal conditions and who need and appreciate our underlying principles, which ultimately lead to enhanced quality of care for patients.

Since this may be the last edition for some of the editors, we feel it is important to briefly describe the background for this seventh edition of *The Spine*. In our Preface to the sixth edition, we highlighted each of the previous editions by choosing important wording from the Prefaces. We have followed the same pattern here so that new readers, as well as long-term ones, can put this edition in historical perspective.

The forerunner to *The Spine* was *The Intervertebral Disc* by Drs. Rothman and DePalma. In their preface written in 1970, the authors wrote: "The role of the intervertebral disc in the production of neck and back pain, with or without radiation into one of the extremities, has been the subject of much investigation for many decades…The disc has been attacked from every conceivable angle, the most important of which is its biochemical nature and its response to physiologic aging and trauma. In spite of the exhaustive studies recorded in the literature, it is alarming to find how little of this knowledge has been acquired by those concerned with neck and back disorders…We are sure that much that is recorded in this book is still very controversial. Yet, we believe that our approach to this complex problem will be helpful and rewarding to others." This comprehensive monograph on the disc totaled 373 pages. It crystallized concepts of the disc for spine physicians of the day and served as the forerunner of many books to follow.

In the Preface to the first edition, Rothman and Simeone stated, "*The Spine* had as its genesis a strong feeling on the part of its editors that a need existed for a comprehensive textbook to include all aspects of diagnosis and treatment of spinal disease. Our goals were to lower the traditional disciplinary barriers and biases and to present a uniform guideline to problem solving in this area…This book has been designed to include all facets of disease related to the spine, whether orthopedic, neurosurgical, or medical in nature… An attempt has been made to achieve completeness without exhaustive and burdensome details. The contributing authors have not merely recorded the possibilities in diagnosis and treatment of spinal disorders, but have relied on their personal experience to offer concrete recommendations." The first edition of *The Spine,* following the dictates of the editors, covered the full range of knowledge of spinal disorders known at the time and became an essential component of the libraries of all medical personnel who dealt with spinal disorders. The authors, one a neurosurgeon (F.A.S.) and one an orthopedic surgeon (R.H.R.), combined their efforts to teach the world not only diseases of the spine, but also the importance of working together in an attempt to understand and treat the disease processes. Their spinal fellowship, as well as personal fellowship, was based on this multidisciplinary yet regimented approach to the spine and has been the model that we have sought to achieve in our own clinical and teaching environments.

The Preface to the second edition of *The Spine* stated, "Advancements in medicine generally follow broader scientific and even social trends. The treatment of spine diseases is no exception. Consequently, increments of new information have been added to the general body of knowledge in spotty, but predictable, areas. These new developments constitute the raison d'être for this second edition. The dramatic progress in radiologic imaging stands out as the most useful innovation [at that time, computed tomography]. Each contributor has demonstrated his commitment to summarizing the most recent information in a manner useful to students and clinicians alike, and for this the editors are proud and appreciative."

The Preface to the third edition included the following: "The current edition has new editorial leadership. Those of us involved in the direction of this project have tried to follow the model previously established by Drs. Rothman and Simeone in finding the best authors for each chapter. We, hopefully, have emphasized, as in the past editions, the importance of understanding the basic science in a concise manner, which leads to the ability to make appropriate decisions and

manage patients with simple or complex spinal problems. We have attempted to update each section, have eliminated those areas that are not current, and have separated some components of the basic science from the clinical to aid readers in locating pertinent information in the ever-increasing body of knowledge related to the spine."

The Editorial Board for the fourth edition of *Rothman-Simeone The Spine* carried over from the third edition. "It provided expanded information on magnetic resonance imaging and laparoscopic and endoscopic surgery. It contained a comprehensive discussion of disc degeneration and its treatment. This edition also introduces a chapter on outcomes research and its importance to our assessment of functional outcome in addition to the more traditional measurements of success, including radiographic parameters."

The fifth edition of *The Spine* added much new information, along with significant updates in content and references. This edition introduced Key Points, which were four or five important concepts and facts contained at the end of many of the clinical chapters. A Key References section was added for each chapter that highlighted the most significant references. Chapters new to the fifth edition included surgical management of osteopenic fractures, disc and nuclear replacement, management of flat back deformity, use of transforaminal lumbar interbody fusion, and use of bone graft extenders and bone morphogenetic protein in the lumbar spine. Other new chapters included thoracoscopic surgery and its clinical applications and intraoperative monitoring, including motor-evoked potentials. A new chapter on genetic application and its exciting role for future treatments of degenerative disease was included in the basic science section. Minimally invasive posterior approaches to the lumbar spine were also introduced in that edition.

The sixth continued under the same Editorial Board as the fifth edition. The editors were charged with ensuring that the chapters within their sections contained the latest evidence-based information whenever available. New chapters included those devoted to arthroplasty for cervical and lumbar degenerative disorders. In addition, revision strategies for failed disc replacements highlighted the potential difficulties in dealing with this complex surgical problem. The sixth edition also significantly expanded the discussion of minimally invasive techniques with six chapters devoted to the rationale for minimally invasive surgery and the surgical techniques, results, and complications. A chapter devoted to soft stabilization for lumbar fixation was also added. Also new to that edition were a chapter devoted to anulus repair and a chapter devoted to the basic science of spinal cord injury. As had been done in previous editions, chapter updates were incorporated throughout the book whenever appropriate.

This, the seventh edition of *The Spine*, includes many of the chapters and authors from the sixth edition. However, all have been updated to include what is new in the basic and clinical sciences related to the topic, with relevant references and updates on clinical outcomes where warranted. In essence, as in all other editions, these chapters epitomize the newer academic catchphrase of "clinical translational research."

We have also expanded international authorship, including adding new contributors. The genetics chapters have been enhanced with both basic and clinically relevant information. Even more content on minimally invasive surgery has been added, with updates on outcomes, approaches, and techniques. We have eliminated some topics (e.g., facet replacement) that have fallen out of favor and/or use. We have added discussion on the sacroiliac joint, since that is one of the newest areas in spine care. We have updated the current status on motion-sparing techniques, including disc replacement with now longer-term follow-up and experiential updates in complications and their treatment. Although this is specifically important to disc replacement, it is the crux of change in most preexisting chapters.

The current Editorial Board remains committed to the broad-based appeal of this book. The authors include basic scientists, neuroradiologists, neurologists, physiatrists, and rheumatologists, along with orthopedic surgeons and neurosurgeons. In addition, this book remains unique in providing comprehensive sections on pediatric disorders and adult disease. Its comprehensive content ranges from degenerative disease to deformity to trauma and tumor. Afflictions of the spinal cord, along with detailed discussions of complications and their management, contribute to this book's broad appeal.

We feel this edition of *The Spine* continues to be the primary reference resource for all physicians and other clinicians with an interest in spinal disorders and treatments.

Steven R. Garfin
Frank J. Eismont
Gordon R. Bell
Jeffrey S. Fischgrund
Christopher M. Bono

Acknowledgment

In the past six editions, the editors have always dedicated this book to our mentors Drs. Rothman and Simeone, our families, and our associates, who have given us the time, support, love, and energy to pursue our careers as well as to coordinate, write, and edit this tome, which in fact was a dedication of love toward Drs. Rothman and Simeone. All of this is still true today. This edition, however, represents our feelings toward Harry N. Herkowitz, MD, our deceased lead editor and organizer, colleague, and close, close friend (see Dedication). The senior editors would like to thank and acknowledge our new "junior" editors, Christopher M. Bono, MD, and Jeffrey S. Fischgrund, MD, who have accepted this responsibility for now and the future—carrying on the spine care educational lineage provided by Drs. Rothman, Simeone, and Herkowitz. They stepped in as if they had been with us since the first edition. In addition, the full editorial team would like to thank all of the authors and contributors, some who have done this many times before and accepted our request to submit an updated chapter because it was dedicated to Harry, as well as the new contributors, who did the same thing. It is a monumental effort on everyone's part. We truly appreciate all of them and their hard work. We also thank the readers and the publishers, who have made this one of, if not the, longest-lasting and most-read complete texts on spine care in the world.

Contents

VOLUME 1

Section I
BASIC SCIENCE

1 **Development of the Spine** 3
Christopher M. Bono, Amandeep Bhalla, Steven R. Garfin

2 **Applied Anatomy of the Spine** 17
Christopher M. Bono, Amandeep Bhalla, Steven R. Garfin

3 **Skeletal Muscle: Architectural Design, Physiology, and Function** 57
Samuel R. Ward, Anita Vasavada, Scott Delp, Richard L. Lieber

4 **Spinal Musculature: Anatomy and Function** 65
Anita Vasavada, Samuel R. Ward, Scott Delp, Richard L. Lieber

5 **The Intervertebral Disc: Normal, Aging, and Pathologic** 79
Adam S. Olsen, James D. Kang, Nam Vo, Gwendolyn Sowa

6 **Biomechanics of the Spinal Motion Segment** 91
William S. Marras, Prasath Mageswaran, Safdar N. Khan, Ehud Mendel

7 **Nerve Root Pain in Disc Herniation and Spinal Stenosis** 119
Robert R. Myers, Björn Rydevik, Kjell Olmarker, Shinichi Kikuchi

8 **Basic Concepts in Genetics and Intervertebral Disc Degeneration and Scoliosis** 133
Jason Pui Yin Cheung, Kenneth M.C. Cheung

9 **Twin Studies: Elucidating Genetic and Environmental Influences** 145
Michele C. Battié, Jaakko Kaprio

10 **Outcomes Research for Spinal Disorders** 155
Dipak B. Ramkumar, Adam M. Pearson, Kevin Spratt, James N. Weinstein

11 **Finite Element Analysis** 167
Emily Walsh, M. Saeid Asadollahi, Raj Nangunoori, Jie Zheng, Daniel Cook, Boyle C. Cheng, Vijay K. Goel

Section II
DIAGNOSIS

12 **Patient History and Physical Examination: Cervical, Thoracic, and Lumbar** 183
Christopher J. Standaert, Stanley A. Herring, J. David Sinclair

13 **Spine Imaging** 201
Todd M. Emch, Jeffrey S. Ross, Gordon R. Bell

14 **Electrodiagnostic Examination** 241
Jinny Tavee

15 **Intraoperative Neurophysiologic Monitoring of the Spine** 257
Dileep R. Nair, Ajay Gupta

16 **Targeting Pain Generators** 265
Richard Derby, Lee Wolfer, Zachary McCormick

17 **Discography** 301
Eugene Carragee, Michael Stauff

Section III
SURGICAL ANATOMY AND APPROACHES

18 **Cervical Spine: Surgical Approaches** 317
Hamid Hassanzadeh, Varun Puvanesarajah, Howard S. An

19 **Anatomy of the Anterior Cervicothoracic Spine** 339
Kenneth A. Hood, Shyam Shridharani

20 **Lateral and Posterior Approaches to the Lumbosacral Spine** 357
Yu-Po Lee, Saif Aldeen Farhan, Nitin N. Bhatia

21 **Lateral Lumbar Interbody Fusion** 367
Sina Pourtaheri, R. Todd Allen, John Attenello, Steven R. Garfin

22 **Anatomy, Nonoperative Results, Preoperative Injections, and Prescriptions** 383
Jeffrey L. Chen, Timothy J. Furnish, Mark S. Wallace

23 **Sacroiliac Joint Pain: Pathophysiology and Diagnosis** 397
Alexandra Schwartz, Vinko Zlomislic, W. Carlton Reckling, Daniel Cher

24 **Outcomes of Nonsurgical and Surgical Treatment of Chronic Sacroiliac Joint Pain** 405
Alexandra Schwartz, Vinko Zlomislic, W. Carlton Reckling, Daniel Cher

Section IV
PEDIATRICS

25 **Back Pain in Children and Adolescents** 417
Lori A. Karol, Lauren LaMont, Megan Mignemi

26 **Congenital Scoliosis** 435
Alexandra Miller Dunham, Paul D. Sponseller

27 **Idiopathic Scoliosis** 451
Lawrence G. Lenke, Fernando E. Silva, Ronald A. Lehman Jr

28 **Neuromuscular Scoliosis** 469
Peter O. Newton, Pawel P. Jankowski, Burt Yaszay, Dennis R. Wenger, Scott J. Mubarak

29 **Thoracoscopic Approach for Spinal Conditions** 509
Peter O. Newton, Kuan Wen Wu, Burt Yaszay

30 **Pediatric Kyphosis: Scheuermann Disease and Congenital Deformity** 525
Steven S. Agabegi, Dinesh P. Thawrani, Alvin H. Crawford

31 **Spondylolysis and Spondylolisthesis** 549
Suken A. Shah

32 **Cervical, Thoracic, and Lumbar Spinal Trauma of the Immature Spine** 565
Jesse E. Bible, J. Alex Sielatycki, Joon Yung Lee, Clinton J. Devin

33 **The Immature Spine and Athletic Injuries** 589
Jennifer J. Beck, Lyle J. Micheli

34 **Congenital Anomalies of the Cervical Spine** 609
Robert F. Murphy, Daniel J. Hedequist, Michael P. Glotzbecker

35 **Congenital Anomalies of the Spinal Cord** 641
Muhammad M. Abd-El-Barr, Kevin T. Huang, R. Michael Scott, Mark R. Proctor

Section V
CERVICAL DEGENERATIVE DISORDERS

36 **Cervical Spinal Disorders Associated With Skeletal Dysplasias and Metabolic Diseases** 663
Bruce V. Darden II, Christopher O'Boynick, Jose Manuel Casamitjana

37 **Pathophysiology, Natural History, and Clinical Syndromes of Cervical Disc Disease** 677
Sreeharsha V. Nandyala, A. Jay Khanna, Hamid Hassanzadeh

38 **Medical Myelopathies** 689
Brandon L. Raudenbush, Olga Selioutski, Lawrence Samkoff, A. Jay Khanna, Addisu Mesfin

39 **Nonoperative Management of Disc and Degenerative Disorders** 705
Daniel Park, Jad G. Khalil, Michael P. Planalp

40 **Surgical Management of Axial Neck Pain** 715
Raj Rao, Satyajit Marawar

41 **Cervical Radiculopathy: Surgical Management** 727
Sheeraz A. Qureshi, Steven J. McAnany, Dante Leven

42 **Management of Cervical Myelopathy: Surgical Treatment** 739
Brett D. Rosenthal, Barrett S. Boody, Wellington K. Hsu, Alpesh A. Patel

43 **Ossification of the Posterior Longitudinal Ligament** 763
Bhavuk Garg, Alok Sharan

44 **Cervical Disc Replacement** 771
Abhishek Kannan, Wellington K. Hsu, Rick C. Sasso

Section VI
THORACIC AND LUMBAR DISC DISEASE

45 **Thoracic Disc Disease** 787
Bradford L. Currier, Jason C. Eck, Frank J. Eismont, Barth A. Green

46 **Lumbar Disc Disease** 807
Makarand V. Risbud, Gunnar B.J. Andersson

47 **Lumbar Disc Herniations** 839
Amandeep Bhalla, Christopher M. Bono, Andrew J. Schoenfeld, Steven R. Garfin

48 **Annular Repair** 869
Gregory Lopez, Gunnar B.J. Andersson

49 **Lumbar Disc Degeneration: Anterior Lumbar Interbody Fusion, Degeneration, and Disc Replacement** 873
Robert Johnson, Richard D. Guyer

50 **Posterior Lumbar Interbody Fusion** 891
William J. Molinari III, Nathan H. Lebwohl

51 **Posterolateral and Lateral Corpectomies** 907
Raghav Badrinath, T. Barrett Sullivan, Steven R. Garfin, R. Todd Allen

52 **Dynamic Stabilization: What's Current and What's the Potential** 917
Dilip K. Sengupta

VOLUME 2

Section VII
MINIMALLY INVASIVE SURGERY

53 **Rationale of Minimally Invasive Spine Surgery** 935
Choll W. Kim, Steven R. Garfin

54 **Minimally Invasive Posterior Approaches to the Spine** 945

CHAPTER 1

Development of the Spine

SECTION I

Christopher M. Bono
Amandeep Bhalla
Steven R. Garfin

The embryologic development of the human spine is an enormously complex process that is only partially understood. Differentiation of the pluripotent tissues of the embryo leads to early formation of a repetitive segmented vertebral structure. Because the embryo is exquisitely susceptible to malformation and developmental error, each step of formation is critical.[1-4] Familiarity with these various steps can be helpful in understanding not only congenital syndromes, but also the possible developmental role concerning predisposition to some degenerative spinal processes, typically considered "wear and tear" conditions.[5,6] The continuously expanding understanding of the genetic basis of life, with the genetics of spinal development no exception, has aided the understanding of these syndromes.[7-13]

Fundamental to understanding spinal embryology is the concept of metamerism. In principle, *metamerism* is the development of a highly specialized organism, with multifunctional organ systems, from many anatomically similar segments arranged in a linear fashion. This is particularly easy to conceptualize in the spine because the fully developed spine comprises numerous units with similar shape, arrangement, and function. Metamerism also pertains to the development of the appendages from the metameres, however, which do not have such repetitive arrangement of consecutive units.

In embryonic development, the metameric segments are called *somites*. Primitively, all somites have the same developmental potential. Genetic signaling, specific to the species, determines the degree of regional specialization, such as limbs in mammals versus fins in fish or the lack thereof in snakes. Using these comparative examples, one can also understand the concepts of isomerism and anisomerism. *Isomerism* is characteristic of more primitive animals, in which the number of somites is greater but more uniform and not so highly specialized. This is akin to the snake, which has a great number of vertebral units sustaining its long body, but no limbs. In contrast, *anisomerism* is present in more developed species, such as mammals, in which many of the somites have been deleted (resulting in a lesser number of vertebrae), whereas the remaining somites are more highly specialized so that complex, specialized appendages can be developed.

Although the mature vertebral column is composed of numerous similar units, the tissues within each of those units are highly specialized. The vertebrae, discs, nerves, and blood vessels have embryologic precursors that form according to rapidly dynamic interstructural relationships. This chapter provides the essentials of human spinal development as they relate to the fully developed structure to understand its form, function, and various pathologic possibilities better.

Early Embryologic Spine Precursors: Day 17 to Week 4

The development of the human spine begins on the seventeenth day of gestation. This is within the triploblastic stage of the embryo, during which it is shaped as a disc (Figs. 1.1 and 1.2). On one side of the disc is the amnion cavity, and on the other is the yolk sac. On the dorsal layer (which is in contact with the amnion) of the disc, there are epiblastic cells that converge and invaginate into the disc to form the primitive pit or node. When embedded within the tissue, it forms a tubelike structure that extends craniad, "burrowing" deep to the embryonic disc along its ventral surface. The tube cavity is in continuity with the amniotic fluid. This extension is known as the *notochordal tube*.

At this point, the ventral wall of the notochordal tube is in contact with the yolk sac, which causes disintegration of these cells. A flat remnant of dorsal wall cells from the notochordal tube forms the notochordal plate on the nineteenth day. This plate matures and thickens to form a solid round structure known as the *notochord*. The yolk sac reforms, which obliterates the temporary communication between the amnion and the yolk sac (persistence of this yolk sac/amnion communication is lethal). The presence of the notochord induces a thickening in the overlying ectodermal cells, which are fated to become neuroectodermal cells. The thickening forms the neural plate. At this time, the neural plate is in continuity with the amniotic cavity. On the eighteenth day, the sides of the plate begin to curl up to form a tube. When the edges have

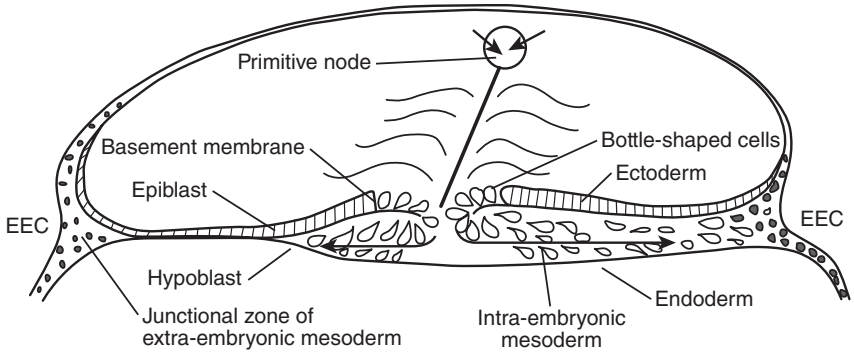

FIG. 1.1 During triploblastic stage (seventeenth day of gestation), the embryo is shaped as a disc. *EEC,* extraembryonic coelom. (From Brooks M, Zietman AL. *Clinical Embryology: A Color Atlas and Text.* Boca Raton, FL: CRC Press; 1998:57.)

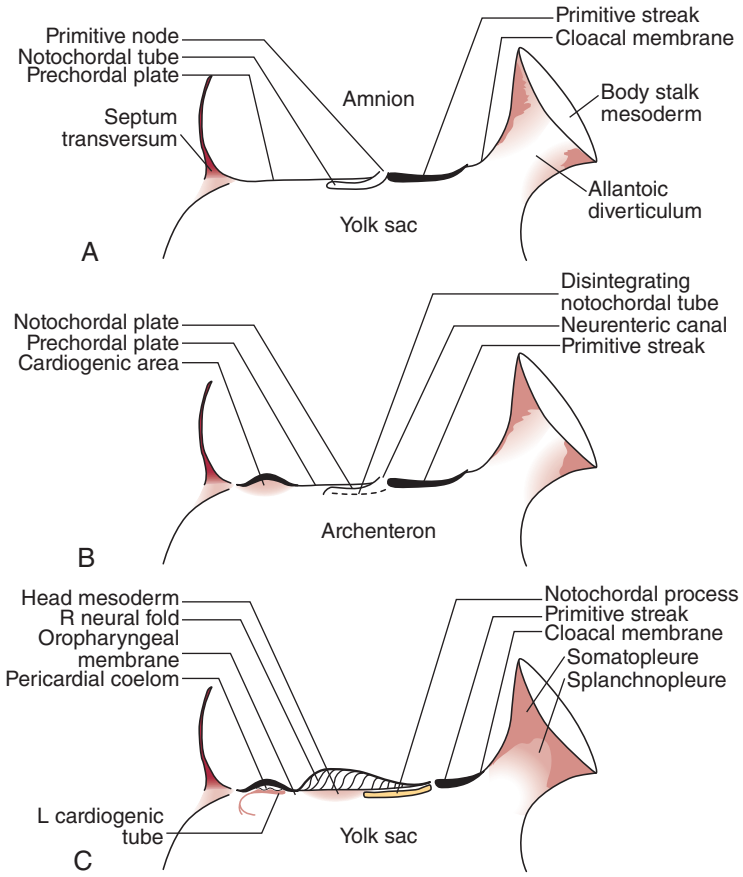

FIG. 1.2 (A) On one side of the disc is the amniotic cavity, and on the other is the yolk sac. The notochordal tube "burrows" deep into the embryonic disc. (B) When the ventral wall of the notochordal tube contacts the yolk sac, it disintegrates. (C) Remaining dorsal wall cells thicken to form the notochordal plate; this matures and thickens to become the notochord. *L,* left; *R,* right. (From Brooks M, Zietman AL. *Clinical Embryology: A Color Atlas and Text.* Boca Raton, FL: CRC Press; 1998:57.)

fused together, it is known as the *neural tube*. The amniotic fluid trapped inside is the precursor to spinal fluid.

The notochord lies ventral to the neural tube in the midline. Mesodermal tissues on either side of these structures condense to form longitudinal columns. By the nineteenth day, there are three distinct columns on either side of the midline: (1) medial paraxial columns, which give rise to the somites; (2) intermediate mesodermal columns, which form the urogenital organs; and (3) lateral mesodermal plates, which form the gut cavities. In considering the development of the spine, attention is focused on the medial paraxial columns. The juxtaposition to the intermediate columns may help explain, however, why abnormalities of the urogenital tract are frequently associated with vertebral anomalies.[1]

The somites are arranged in consecutive fashion along the dorsal aspect of the embryo. They are first formed in the rostral (or cranial) aspect of the embryo, continuing caudad to form 42 to 44 individual segments over a period of days

where the medial paraxial columns previously existed. Because they are close to the dorsal surface, they are visibly apparent as a series of beaded elevations (Fig. 1.3).

Within the somite different regions have specialized fates (Figs. 1.4 and 1.5). The dorsolateral cells become the dermomyotomes. These eventually give rise to the skin (lateral) and muscle (medial) overlying the spine. The ventromedial cells within the somite become the sclerotomes. These are the precursors of the skeletal components (vertebrae) of the spine. The neural tube is fated to become the spinal cord.

From Somites to Spinal Column

The sclerotomes, myotomes, notochord, and neural tube eventually develop into the discoligamentous vertebral complex, paraspinal musculature, nucleus pulposus, and neural elements. This development is achieved through numerous sequential steps and stages.

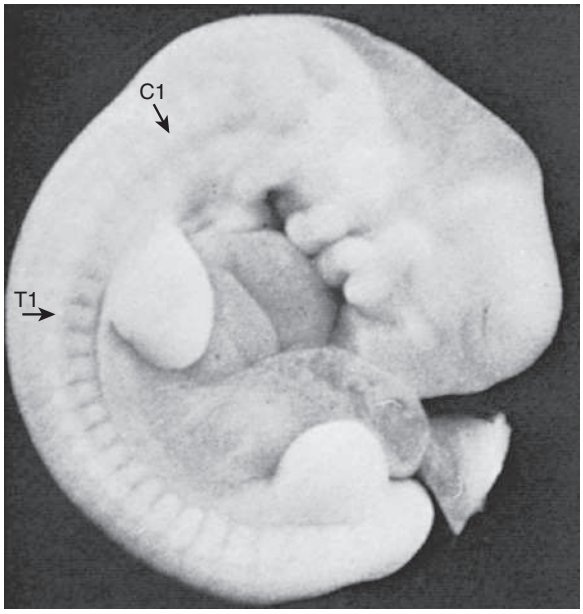

FIG. 1.3 Somites of the human embryo are externally represented as a series of dorsolateral swellings.

Precartilaginous (Mesenchymal) Stage: Weeks 4 and 5

The mesenchymal cells within the sclerotome divide into three main regions. One immediately surrounds the notochord. This region is the precursor for the vertebral bodies and the anulus fibrosus portion of the intervertebral discs. A second region surrounds the neural tube; this is destined to develop into the posterior arch of the vertebra. The third region of cells is within the body wall and is related to extraspinal tissue.

In metameric fashion, the sclerotomes are organized into a consecutively stacked arrangement. The next step in spinal development has been explained by the "resegmentation" theory.[14-18] *Resegmentation* describes the division of each sclerotome into a cranial and caudal half. The cranial half is loosely arranged, whereas the caudal half is composed of densely packed cells. A small portion of the densely packed

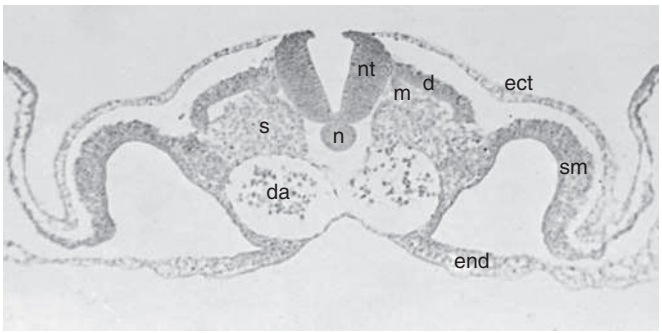

FIG. 1.4 Cross section of thoracic somite in a chick embryo. The notochord (n) underlies the neural tube (nt). The somite is divided into dermatome (d), myotome (m), and sclerotome (s). Lateral to this, the somatic mesoderm (sm), endoderm (end), and ectoderm (ect) are shown. Ventral to the sclerotomes lie the paired dorsal aortae (da).

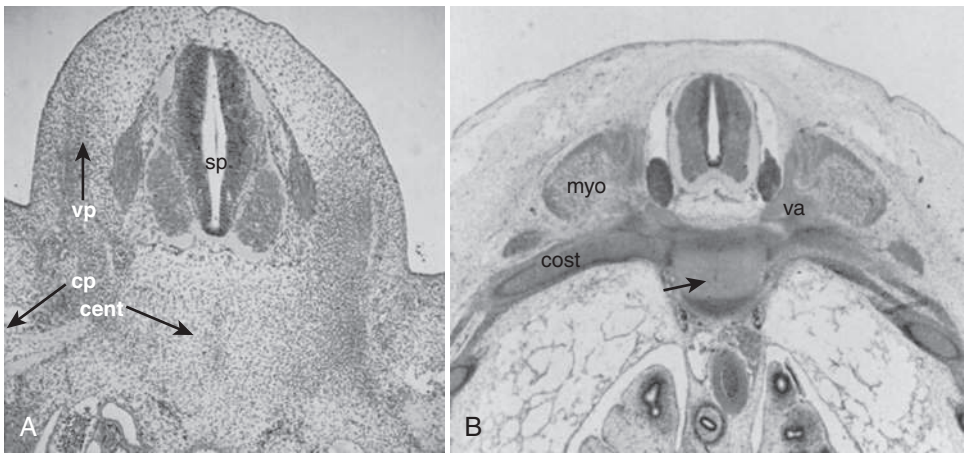

FIG. 1.5 (A) Cross section of pig embryo. *Arrows* indicate the direction of somite cell migration to form the vertebral process (vp), costal process (cp), and centrum (cent). The neural tube shows the anterior horn masses and the dorsal root ganglia. (B) Cartilaginous vertebral arch (va) and costal process (cost) are evident, as is the myotomic precursor to the spinal muscles (myo). *Arrow* indicates the intracentral vestige of the notochord, called the mucoid streak.

cells migrate superiorly to form the annular portion of the intervertebral disc, surrounding the notochord. Most of the densely packed cells fuse with the loosely packed cells of the adjacent caudal sclerotome. This fusion creates the centrum, the precursor of the vertebral body. The centrum develops from portions of two neighboring sclerotomes. This has significance on the anatomy of the fully developed spinal column. Initially, the segmental nerve precursors are located at the midportion of each sclerotome, whereas the segmental artery lies at the junction between two adjacent levels. After resegmentation, the nerve lies at the level of the disc and the artery lies at the mid-centrum, where one would expect to find them in the fully developed specimen.

Experimental data support the resegmentation theory.[8,19-22] The crux of these experiments includes implanting a quail somite (from a quail embryo) within a chick embryo's native somites. The quail somite is juxtaposed to a chick somite, and they develop together as the embryo grows. The quail tissue can be differentiated from the chick tissue using special staining techniques. Eventually, the somites give rise to sclerotomes that develop into centra. With the use of this model, it has been shown that the centrum does arise from the caudal and cranial halves of adjacent sclerotomes. The posterior arches (i.e., laminae) appear to follow this same pattern of growth.

This process seems to be highly influenced by the *Pax1* and *Pax9* genes.[22] It is unclear whether the spinous process develops from one sclerotome or two adjacent levels.[8,22] Other investigators have produced evidence of resegmentation using genetic labeling techniques.[20] These studies involved injection of retroviral particles containing the lacZ transducing vector BAG into a single somite of a chick embryo. In other words, a single somite was genetically altered so that its cells would produce the lacZ gene product—the protein β-galactosidase. When the investigators evaluated the developed embryo, they detected β-galactosidase in the caudal and cranial halves of two adjacent vertebrae, suggesting that cells from the labeled somite were incorporated into two neighboring vertebrae.

Cartilaginous Stage: Weeks 6 and 7

Before the sixth week, the embryonic spinal precursor is composed of mesenchymal cells. Starting in the sixth week, cartilage-producing centers, or chondrification centers, form within each developing vertebra. Although type II collagen production within the extracellular matrix has been detected in the fifth week, it is most active during the cartilaginous stage; it tapers off during the ossification stage, but its production persists within the notochordal remnants of the nucleus pulposus.[12] Two chondrification centers form in each half of the centrum, which eventually fuse into a solid block of cartilage. A hemivertebra is formed because of a failure of chondrification in one half of the vertebral body. The segmental arteries from either side of the centrum fuse at its middle aspect. Chondrification centers also form within each half of the vertebral arch and eventually fuse with each other in the midline and to the posterior aspect of the centrum.

Next, primitive cartilaginous transverse processes and spinous processes develop from the vertebral arch. More recent evidence has shown that the cartilaginous spinous process is formed from Msx1 and Msx2 (two embryologic proteins), producing mesenchymal cells, which require BMP4 to differentiate.[23] These relationships highlight the important interactions of primordial proteins in governing further development of the spine.

The developing centrum and vertebra have the notochord as a central axis. Intervening segments of loosely packed cells are present between the regions of densely packed cells. The outer disc is formed by these loosely packed cells of the sclerotome, which are fated to become the anulus fibrosus. The notochord disintegrates within the centrum during resegmentation and chondrification except in the region of the intervertebral disc, where some of its cells remain. The nucleus fibrosus is the replacement of the embryologic notochord.

Ossification Stage: Week 8 and Beyond

Primary ossification centers develop in utero. In the spine, ossification centers form within the cartilaginous template. There are three primary ossification centers in the typical embryonic vertebra: one in the center of the centrum and one in each of the vertebra arch halves. At about the ninth week, the preparation for ossification of the centrum is heralded by anterior and posterior excavations of the cartilaginous centrum produced by the invasion of pericostal vessels.[24] These vessels produce ventral and dorsal vascular lacunae, which support the initial ossification (Fig. 1.6). Ossification of the centra starts first at the lower thoracic spine working craniad and caudad from that point.[25]

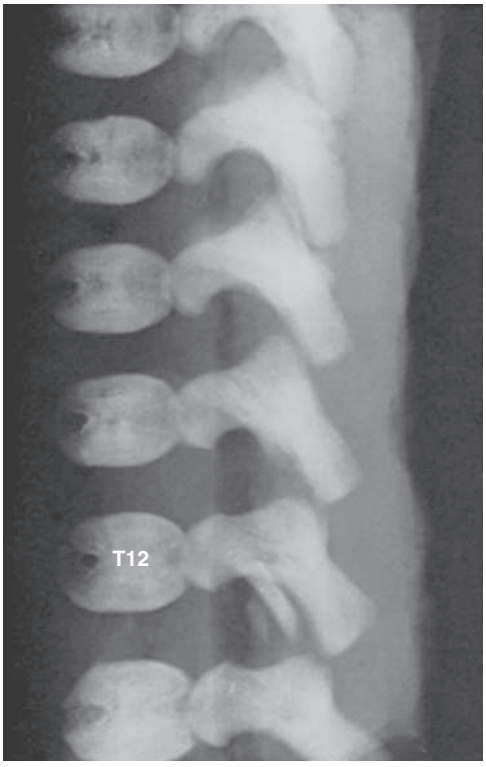

FIG. 1.6 Lateral radiograph of a 34-week spine. Ossification of the centra starts first at the lower thoracic spine, working craniad and caudad from that point.

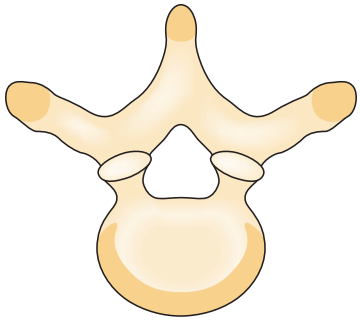

FIG. 1.7 Secondary centers of ossification of a thoracic vertebra. The centers at the tips of the spinous and transverse processes appear at 16 years and fuse at approximately 25 years. The ring apophysis of the centrum ossifies at around 14 years and fuses at about 25 years.

Secondary ossification centers develop after birth. In the spine, these appear after puberty. There are five centers: one in the tip of the spinous process, one in each transverse process tip, and one ring epiphysis in the superior and inferior endplates of the vertebral bodies. This development occurs at about 15 or 16 years of age, but eventually these ossification centers fuse in the middle of the third decade (Fig. 1.7).[26] The transverse processes of the lower cervical vertebrae, particularly C7, may show an additional costal center of ossification that produces the troublesome cervical rib; this reinforces the concept that all vertebrae primitively had the potential of forming ribs.

A pair of embryologic joints, known as *neurocentral joints,* is not present in the fully developed spine. These are located at the junction of the vertebral arches and the centrum but are anterior to the site of the future pedicle. Although not true "joints," they allow expansion of the vertebral arch and spinal canal along with growth of the vertebral body. This expansion is most rapid between 18 and 36 weeks of gestation.[2] At birth, the spinal canal diameter at L1 through L4 is approximately 70% of adult size, whereas at L5 it is only 50%.[2] This indicates differential growth within regions of the vertebral column during fetal development. Full adult dimensions are reached by 1 year of life at L3 and L4 levels. The neurocentral joints persist until 3 to 6 years of age. The fusion of the fetal vertebral arches to the centra occurs well anterior to the pedicles, at the site of the neurocentral joints. The definitive vertebral body includes more than just the bone derived from the ossification center of the centrum, so the terms *body* and *centrum* are not accurately interchangeable (Figs. 1.8 and 1.9).

It is commonly thought that isthmic spondylolysis occurs because of a stress-type fracture within the pars interarticularis of the lower lumbar vertebrae, most commonly L5. Specific anatomic features of the adult lumbar spine, such as variation of the dimensions of the "lateral buttress" within the lumbar spine, have been described. Prenatal factors have been sought, but with limited success. Sagi and colleagues[5] analyzed histomorphologically the lumbar spines of fetal spines aged 8 to 20 weeks to determine the sequence and location of ossification of the pars interarticularis of the various levels. They reported several findings. First, the pars begins to ossify in the twelfth to thirteenth week of gestation. In the upper lumbar levels,

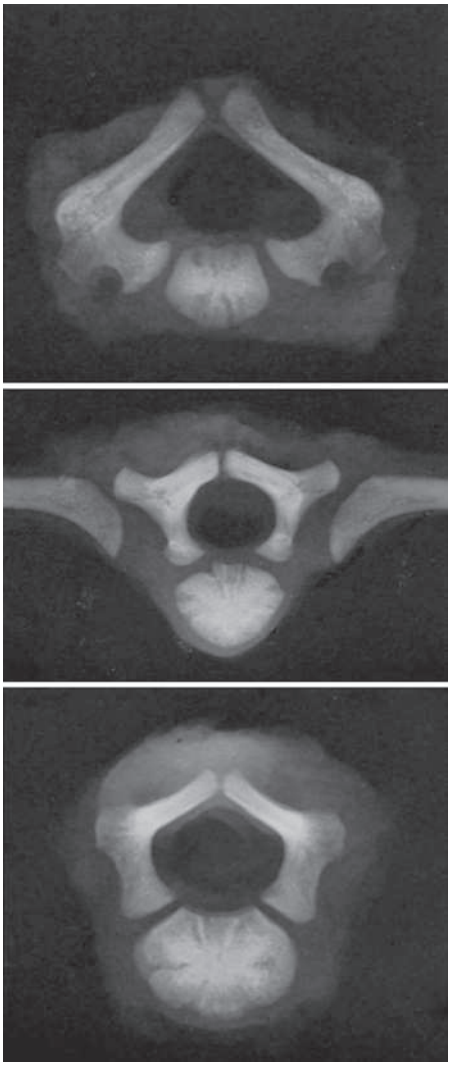

FIG. 1.8 Fusion of the fetal vertebral arches to the centra occurs well anterior to the pedicles, at the site of the neurocentral joints. The contributions of the vertebral arches to the dorsolateral parts of the bodies are apparent. The definitive vertebral body includes more than just the bone derived from the ossification center of the centrum, so that the terms *body* and *centrum* are not accurately interchangeable.

ossification begins at the posterior portion of the pedicle and continues caudad, creating uniform ossification and trabeculation of the pars interarticularis. In contrast, the pars of the lower lumbar levels begins within the center of the pars itself, extending from this point to connect to the neighboring structures. Sagi and colleagues[5] found that this resulted in uneven ossification. This finding may help explain areas of weakness within the pars interarticularis of the lower lumbar levels and may suggest that there is a prenatal predilection for a stress fracture in most individuals.

Fate of the Notochord

In the early embryo, the notochord serves as a rigid template around which the future vertebral column develops. It is a uniform structure that is present throughout the entire length

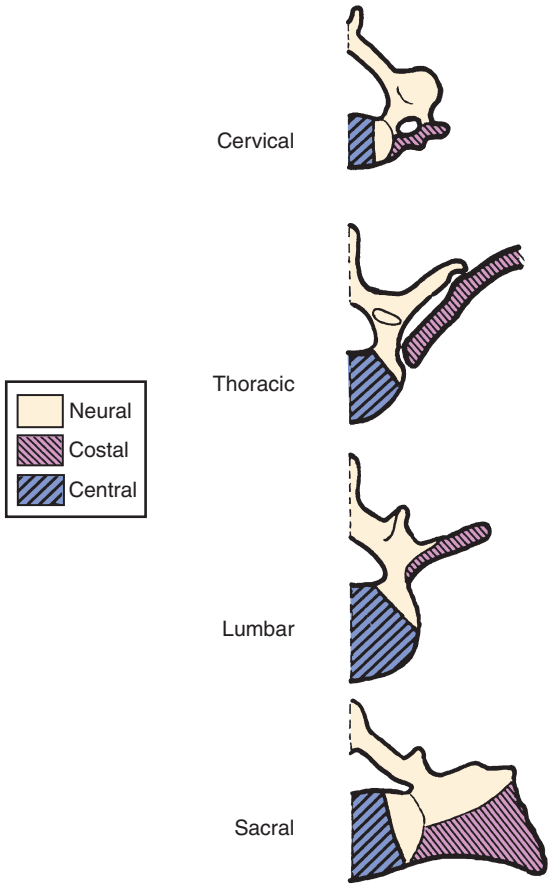

FIG. 1.9 Neurocentral synchondroses lie well within the vertebral body in all cases. Normally, costovertebral synchondroses develop a true diarthrodial joint only in the thoracic region.

of the primordial spinal column. A sheath exists around the notochord in its early stages. Immunohistochemical staining studies of 4- and 5-week embryos identified that a complex of extracellular matrix molecules is already present within this sheath, including sulfated glycosaminoglycans, hyaluronic acid, fibronectin, laminin, tenascin, and collagen II.[27] Aggrecan, keratan sulfate, and other large aggregating proteoglycans (present in the mature spine) were not detected at this stage, suggesting that these appear later in development. The notochordal cells themselves showed reactivity to transforming growth factor-β (TGF-β), suggesting an early influence of this growth factor on the developing extracellular matrix, and the formation of vasculature, cartilage, and bones.[27,28] Disruptions in the TGF-β signaling pathways have been implicated in the abnormal bone morphology and ligamentous laxity found in Loeys-Dietz syndrome, an autosomal dominant mutation of TGF-BR1 or TGF-BR2. Patients with this syndrome, first described in 2005, may have cervical osseous deformity and instability.[29]

In the 20-mm embryo, the notochord becomes an intrinsically segmented structure in the thoracic and lumbar region; in the 30-mm embryo, this structure is evident in the cervical region as well. Segmentation leads to areas of fusiform enlargements in the region of the intervertebral disc, while the notochord is slowly obliterated in the region of the developing vertebral bodies. Within the developing vertebral body, the notochord is stretched into a "mucoid streak" (see Fig. 1.5B). With continued growth, the mucoid streak disappears, leaving behind only bone.

The notochord expands in the region of the intervertebral disc to form the nucleus pulposus. This was originally described in detail by Luschka.[30] The notochord is a major source of the nucleus pulposus, and it has been shown histochemically and autoradiographically that notochordal cells proliferate and remain vital several years after birth.[31] Although notochordal cells generally do not seem to be demonstrable in the human nucleus pulposus of individuals older than 5 years of age, Schwabe[32] reported their survival in the incarcerated discs of the sacrum in a series of specimens ranging from 22 to 45 years in age. A chordoma is abnormal neoplastic growth of notochord cells that remain within the spine in adult life. This suggests that notochordal rest cells can persist well into middle age in some individuals. These neoplasms may develop at any point along the original notochordal track but are usually in the rostral (basisphenoid or basiocciput) and caudal (sacral) regions.

As a theme of development of the spine, the region of the previous notochord lies anterior to the center of the fully developed vertebral body. This has been verified by Nolting and colleagues,[25] who detected remnants of notochordal tissue anterior to the cartilaginous body center in 13 fetal spines aged 10 to 24 weeks. This finding further reinforces that using the terms *centrum* and *vertebral body* interchangeably is inaccurate.

From Neural Tube to Spinal Cord

On the twentieth day, ectodermal tissues on either side of the neural plate become thick and "pucker up." This area is known as the *neural crest,* which contains cells that eventually compose the neural elements. The mesenchymal tissue beneath the neural crest is the neural fold. As the folds grow toward the midline, the two neural crests meet and fuse on day 22. The underlying neural plate forms a tube, known as the *neural tube,* whose walls are composed of the previous neural plate. The neural tube invaginates itself within the dorsum of the embryo. On the twenty-sixth day, the fused neural crest cells invaginate into the embryo and divide into right and left globules. They are termed the *dorsal root ganglia*. They are oval and appear before ossification of the spine.[33]

By the fifth week, the neural tube has changed into a diamond shape and is termed the *neural canal*. A sulcus limitans forms between its anterior (basal) and posterior (alar) halves, which are destined to become motor and sensory tracts. The dorsal root ganglion is composed of sensory cells alone. It develops two "arms." One arm is an extension toward the posterior aspect of the neural canal, which eventually joins the future site of the posterior column of the spinal cord. The other arm is a lateral extension that projects from the dorsal ganglion to reach peripheral tissues.

During the sixth week, the sulcus limitans disappears, and the basal and alar halves join together, while keeping their

respective motor and sensory functions. Ventral horns form in the basal portion, which appear as gray matter because they are composed of motor cell bodies. Axons grow out from the ventral horns to peripheral structures. These axons join with the dorsal root ganglion to form the spinal nerves, which exit the vertebral column as a single unit.

In the seventh to eighth week, white matter finally develops within the spinal cord, representing myelin formation along axon sheaths; this occurs in ascending and descending tracts. The central part of the spinal cord retains a small cavity lined with ependymal cells that allows the transfer of fluid. This cavity was previously filled with amnion, the early embryologic analogue of cerebrospinal fluid.

Development of the Costal Elements

The costal elements persist only in the thoracic spine of the fully developed normal spinal column. During the fifth week, costal processes are formed and project from either side of the centrum. By the seventh week, they become sequestrated, or separated, from the centrum, by forming costovertebral and costotransverse joints. The cartilaginous structures begin to ossify in the eighth week, recognizable as ribs. In the cervical spine, the primordial costal processes fuse with transverse processes to form the costotransverse bar. Eventually, the unique cervical transverse processes form, which contain the transverse foramen for the vertebral artery. In the lumbar spine, the costal processes do not fully form. They persist only partially as the transverse processes of the fully developed spine. The embryonic transverse process forms the mammillary process (not the transverse process). The transverse and mammillary processes eventually fuse. In the sacrum, the costal processes fuse with the embryonic transverse processes and merge to become the anlage of bone of the lateral sacral mass.

Development of the Intervertebral Disc

The intervertebral disc warrants special attention because it is the pathologic focus of many spinal conditions. In the early stages of embryonic development, there are an increasing number of cells in the peripheral portion of the disc and a decreasing number adjacent to the notochord. As the embryo grows beyond a crown-rump length of 10 mm, the cells in the peripheral zone become elongated and are arranged in a lamellar pattern. When it reaches a length of 20 to 40 mm, collagen fibers begin to be synthesized and are exported from the cells, forming a collagen-rich extracellular matrix. The collagen fibers follow the pattern of the cells and are arranged in a lamellar pattern as well, giving the peripheral disc (or anulus fibrosus) its characteristic composition of circumferential bands of tissue. No fully continuous fibers span the entire periphery of the disc; rather, multiple strands interdigitate to create a highly tensile structure. These lamellar bundles appear to be more densely arranged in the anterior anulus and less dense in the posterior anulus of the developing spine, which may explain the propensity for posterior disc rupture in young patients.[6] As the embryo passes into the fetal stage at 2 months, the cells begin to decrease in number, and the production of extracellular matrix is increased.

By the start of the fetal period, the disc has three distinct regions: (1) an external fibrous zone, (2) an internal hyaline zone surrounding the notochord, and (3) a fibrocartilaginous zone. The disc grows by interstitial and appositional growth.[34] *Interstitial growth* refers to growth that occurs at the outer attachment of the anulus to the cartilaginous endplates. *Appositional growth* refers to growth that occurs longitudinally between the vertebra and the disc. Lamellar fibers form attachments to the cartilaginous endplates in the region of the nucleus pulposus, which completely encases the gel-like structure. The outer layers of the anulus become deeply embedded into the peripheral portion of the endplate cartilage.

As the endplate ossifies, forming the ring apophysis, the inserted annular fibers become tightly fixed. The "weak link" in this complex is between the ring apophysis and its corresponding vertebral body, so that apophyseal separation fractures are more common than rupture of the intervertebral disc in the immature spine. The interval between the apophysis and the vertebral ossification center provides an entrance for vessels to supply nutrition to the endplate and to the intervertebral disc by diffusion. This supply is obliterated after union of the ring apophysis to the vertebral body.

There is a lack of agreement regarding the extent of the vascularity of the fetal intervertebral disc. In the fetal disc, the anulus pulposus seems to be vascularized. Taylor and Twomney[35] found that a plexus of vessels around the circumference of the disc sent branches deep within the anulus. In contrast, Whalen and colleagues[36] reported that these vessels entered only the outermost lamellae of the anulus fibrosus. In addition to vessels within the anulus, regularly spaced vascular channels within the cartilage have been shown within the interface between the cartilaginous endplate and the disc (Fig. 1.10). These channels most likely do not act as blood vessels but rather as a sinusoidal "cul-de-sac" system that delivers nutritional factors by diffusion. The deep regions of the disc

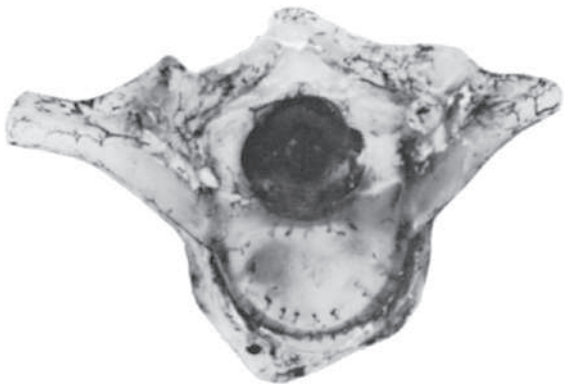

FIG. 1.10 Section through cartilaginous vertebra of 30 weeks after vascular injection. Note the coronal vascular pattern. Each tuft consists of a central artery entwined by recurrent veins that end in a chondrous lacuna as a terminal arteriovenous anastomotic sinusoid (cul-de-sac). Nutrients diffuse from the sinusoid into the surrounding tissues.

are probably not vascularized at any point in development. The adult intervertebral disc is avascular, receiving nutrition only through diffusion through the endplates aided by the flux of fluid to and from the nucleus pulposus. This avascularity may be present at 17 to 24 weeks.[24]

Spinal Ligament Development

There is a paucity of literature concerning the development of the spinal ligaments in the human fetus. Misawa and colleagues[37] dissected 25 human fetuses 6 to 24 weeks of age. They found that, at 6 to 7 weeks, "light zones" represented areas of low cell density that correlated with vertebral bodies, whereas "dark zones" were areas of high cell density and corresponded to the intervertebral regions. The posterior longitudinal ligament was first recognized at 10 weeks, whereas the appearance of the ligamentum flavum was concomitant with that of the lamina at 12 weeks. The fibers of the ligamentum flavum became discernible only at 15 weeks.

Influence of Fetal Movement

Development of the human skeleton seems to be strongly influenced by the interaction of its immature moving parts. In the appendicular skeleton, the opposing surfaces of the femoral head and acetabulum are codependent on each other for normal development into a highly mobile, but stable, weight-bearing joint. In the spine, the development of facet joints is thought to be influenced by torsional loading. It is commonly thought, however, that these demands are placed on the spine only postnatally during upright posture.

The importance of fetal spinal movement has been recognized only more recently. Boszczyk and colleagues[38] used ultrasonography to study the movements of 52 normal fetal spines in utero. They found that rotational movements of 4 to 10 degrees were measurable in fetuses at 9 to 36 weeks. These investigators concluded that this amount of rotation influenced the ultimate morphology of the joint and that torsional stresses are present prenatally and postnatally. Functional demands on the spine may begin even before birth.

Development of Specialized Vertebral Regions

Most of the spine develops in a very uniform manner. The more particular mechanical requirements of the cranial and caudal extremes of the spine have led to unique development processes, however, enabling functional transition between the head and lower limbs.

Occipitocervical Complex

Four occipital myotomes can be readily identified in the human embryo of 4-mm crown-rump length.[39] The first is small, the second is of intermediate size, and the third and fourth are equivalent to the succeeding cervical segments. The first cervical nerve and the hypoglossal artery clearly delimit the most caudal occipital segment. Eight rootlets of the hypoglossal nerve can be discerned rostral to the hypoglossal artery, and these usually unite into four, but no less than three, main roots. This confirms the involvement of at least three precervical segments in the formation of the occiput. DeBeer[40] claimed that a total of nine segments might be involved in skull formation. The first four appear very primitive but contribute to the preotic cranium, whereas the fifth is rudimentary, without a myotome. The last four segments are definite precursors of the occipital complex.

The definitive hypoglossal nerve shows some retention of its multisegmental origins. Its rootlets usually coalesce into two distinct fascicles that exit through separate openings in the dura, and occasionally these do not unite until they have left the skull. The formation of the hypoglossal canal may also indicate a multisegmental relationship. The usual single aperture has been regarded in some texts as homologous to the intervertebral foramen between the neural arch equivalents of two occipital somites, but during chondrification a membranous strut that separates the two main fascicles of the nerve may be observed. By further chondrification and ossification, a double hypoglossal canal accommodating both strands of the nerve may result. Most likely, this mesenchymal strut is a representative of the membranous neural arch process of an intervening segment and is a good indicator that at least three somitic levels were involved in forming the part of the occipital bone surrounding the hypoglossal canal.

Atlantoaxial Complex

The axis and atlas, although considered two vertebral levels in the fully developed spine, actually arise from three different centra. Sensenig[41] first described this in detail in 1937, and later O'Rahilly and Meyer[42] provided a description. These three centra have been named the *X, Y,* and *Z* components. The apical *X component* at first projects into the early foramen magnum and forms an occipitoaxial joint. It has come to be known as the *proatlas* and constitutes the main portion of the odontoid process. Although it is commonly written that the odontoid process develops from the centrum of C1, this is probably not entirely true.[43] Remains of the occipitocervical syndesmosis are apparent by the formation of the alar ligaments. The *Y component* becomes the centrum of the atlas, and the *Z component* becomes the centrum of the axis (C2). The X, Y, and Z components are related to the first, second, and third cervical nerves, which explains the redundancy of the numbering of the upper cervical nerves. Muller and O'Rahilly[44] determined that these three components actually develop from only two and a half sclerotomes in the chick embryo.

Considering the segmental complexities involved in the development of the normal human craniocervical articulations, the occasional occurrence of anomalous separations, fusions, and intercalated ossicles should not be surprising. The odontoid process has origins from the axial portion of the

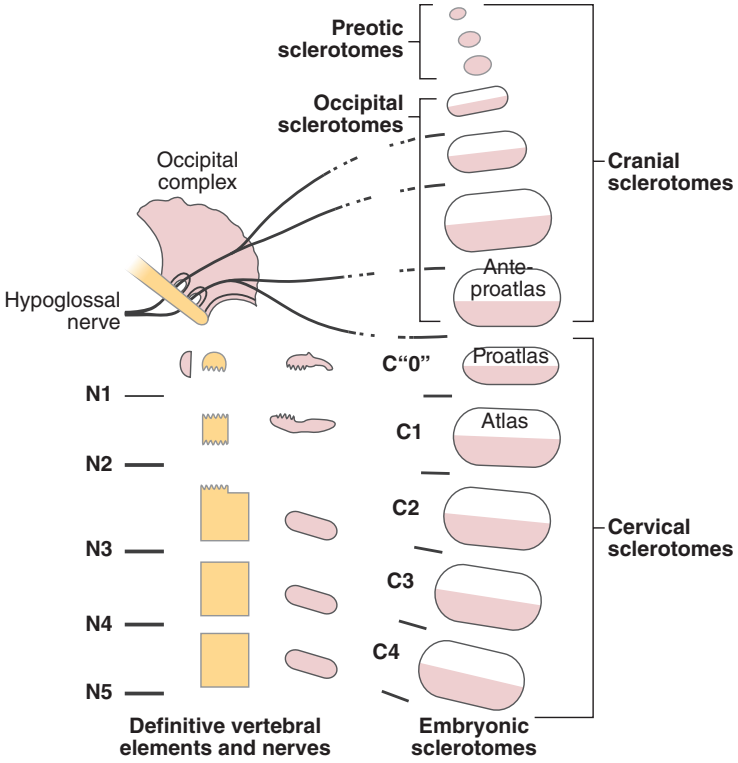

FIG. 1.11 Schematic representation of craniocervical sclerotomes and their segmentally related definitive cranial and vertebral elements and nerves. The cranial and cervical sclerotomes originally formed a continuum. The axis incorporates three sclerotomic elements. The caudal four cranial sclerotomes contribute to the occiput, and their nerves coalesce to form the hypoglossal nerve.

occipital and upper two cervical sclerotomes and is formed from two separate ossification centers that fuse by the seventh month of gestation.[45] A second ossification center, forming the tip of the odontoid, appears by age 3 to 6 and fuses by puberty. Because the odontoid process develops from its own centrum, it can be better understood how an os odontoideum may arise. This anomaly is manifested as a spherule of bone suspended between the two alar ligaments without any apparent bony connection to the C2 body. Os odontoideum has been theorized to be related to prior injury to the odontoid process, but its etiology may also be developmental. Os odontoideum can manifest clinically as neck pain, myelopathy, or even sudden death.[45] Its embryologic development also helps explain the region at the base of the odontoid process that predisposes to nonunion after displaced fractures.

Morphologic anomalies of the odontoid have been described and are attributable to early development. With absence of the midline integration of the primary ossification centers, bifid odontoid process may result, which may lead to craniocervical instability. Furthermore, inclination of the odontoid process may be influenced by traction of the apical ligament on the tip of the odontoid process during development of the craniocervical junction.[46] Retroflexion of the odontoid has been described in patients with Chiari I malformations.[47]

The most frequent manifestation of variant segmentation is the appearance of a third (midline) occipital condyle, also known as a *basilar tubercle*. This structure occurs as a projection on the basion (anterior central point) of the foramen magnum. Sometimes it is expressed as a simple rounded tubercle, but in better developed cases there is actually an articular facet that receives the tip of the odontoid process forming a true diarthrosis (joint). Occasionally, accessory facets lateral to the central projection are present. In a series of 600 skulls, some suggestion of a third condyle was present in 14% of specimens.[48]

Toro and Szepe[49] observed that the third condyle often occurs with occipitalization of the atlas. They also thought that it may be the expression of the hypochordal arch of the "ante-proatlas." As they used this term, it seems to designate the most caudal occipital somite (Fig. 1.11). A more complete separation of this ante-proatlas may form a true occipital vertebra. First described by Meckel in 1815, this malformation forms a more or less complete ring inferior to the foramen magnum, and its anterior arch is often fused to the skull, bearing a third condyle. This condition is distinguished from occipitalization of the atlas by the radiologic identification of the true atlas beneath it. Transverse processes of variable relative size may be present in occipital vertebrae, but these do not show a transverse foramen.[50] Because bony eminences on either side of the third condyle are common to these structures, they may encroach on the foramen magnum, causing neurologic sequelae.

Occipitalization of the atlas occurs in 0.1% to 0.8% of the population according to the series of skulls examined. If the occipitalization is complete, there is no movable atlanto-occipital articulation, and the atlas ring is more constricted. Also, the level of the odontoid tip shows a higher relative

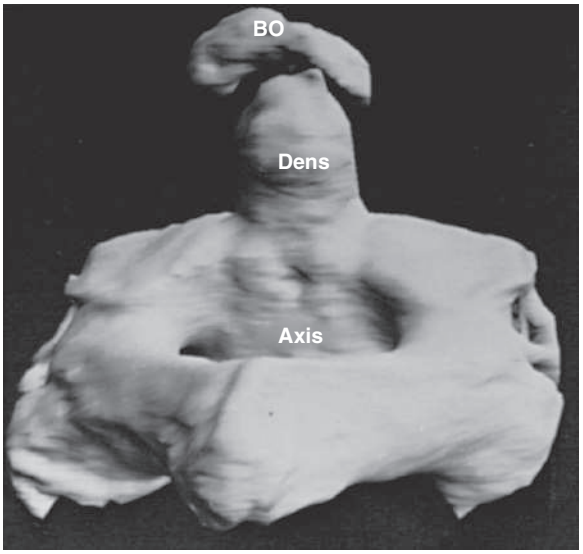

FIG. 1.12 Nonfused "floating" ossicles may occur within craniocervical syndesmoses. A variably shaped, usually pea-sized ossification that occurs between the basion and the tip of the odontoid (in the presence of a complete odontoid process) has been labeled Bergmann ossicle (BO).

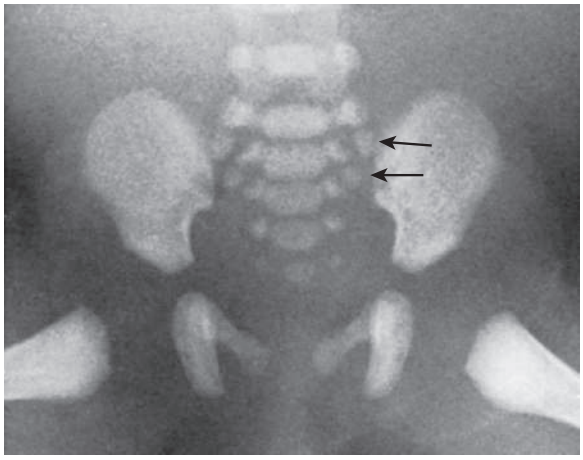

FIG. 1.13 Anteroposterior radiograph of a 34-week fetal pelvis showing two of the eventual three ossific centers (*arrows*) of the costal contributions to the alae. These form in the cartilage that anchors the fetal sacrum to the auricular processes of the iliac wings.

position, and the fusion is often asymmetrical. Inglemark's series of skulls showed that in 78% of the true congenital cases the posterior arch was fused to the posterior rim of the foramen magnum; the anterior arch was fused in 54%, and lateral fusions occurred in 23%.[51] Toro and Szepe[49] suggested that the variable expressions of fragments of the proatlas arch, which normally form parts of the atlas, may enhance the predilection of this segment to fuse to the skull.

Nonfused "floating" ossicles may occur within the craniocervical syndesmoses. A variably shaped, usually pea-sized ossification that occurs between the basion and the tip of the odontoid (in the presence of a complete odontoid process) has been labeled Bergmann ossicle (Fig. 1.12)[52] and is most likely a variant derivative of the ante-proatlas mesenchyme. Putz[53] also recorded the incidence of a small ossicle between the anterior lip of the foramen magnum and the anterior arch of the atlas and within the anterior atlanto-occipital membrane. He was convinced that this was a manifestation of the hypochordal potential of the last occipital (ante-proatlas) somite.

Sacrum

Ossification of the bodies of the sacral vertebrae is unique in that, in addition to the single central ossific zone, two true epiphyseal plates later provide accessory ossification to the superior and inferior surfaces of each segment. The central centers for the superior three sacral vertebrae are evident at week 9, whereas these centers for the fourth and fifth segments do not appear until after week 24. Each vertebral arch of the sacrum shows the conventional bilateral centers, but in addition six centers produce the sacral alae. Between weeks 24 and 32, these centers appear anterolateral to the anterior sacral foramina of the upper three sacral vertebrae. They are expressions of the ever-present potential of the vertebral anlagen to produce costal equivalents (Fig. 1.13).

In the early part of the first year after birth, the sacral vertebrae are still separated by intervertebral discs, and the lower two are the first to fuse in late adolescence. Before this, the ossific centers for the superior and inferior epiphyseal plates of the bodies appear, and between 18 and 20 years of age, lateral epiphyseal plates form on the auricular surfaces of the sacral alae. By the middle of the third decade, the entire sacrum should be fused, although internal remnants of the intervertebral plates remain throughout life. These may be visualized in a sagittal section or in radiographs taken at the appropriate anteroposterior angle.

The coccygeal segments lack neural arch equivalents and form a single ossific center for their bodies. The first usually appears before 5 years of age, and the succeeding three ossify during consecutive 5-year intervals.

Genetic Control of Spinal Segmentation

In the previous edition, an extensive discussion of the genetic control of segmentation was presented. This discussion focused on the wealth of information provided by studies performed on the fruit fly, *Drosophila*. The most essential concept provided by these studies is the fact that the individual aspects of the advanced stages of development are the result of a sequential action of numerous genes, and the mutation of single-effect genes, whose phenotypic expressions have provided the classic mendelian patterns of heredity, usually show errors in only a single step in this concatenation of events. *Drosophila* development shows that a set of maternal effect genes (so labeled because they are exclusively derived from the maternal genome) initially establishes the axial symmetry of the body within the ovum. A group of approximately 20 segmentation genes guides cellular construction of the defined segments. Mutations of these genes are manifest as deletions

affecting the normal segment number. Most mutations of the segmentation genes are lethal, and knowledge of them has been obtained from the doomed larval forms. Because they are commonly recessive, however, the mutant strain can be propagated for continuous study. The equivalent genetic effects would not be so readily observable in vertebrates, but comparative evidence strongly indicates that similar genetic mechanisms are operable.

Only after the segmental boundaries have been established can the structures characteristic of each segment be determined. These designations are effected by the homeotic selector genes. The term *homeotic* (from the Greek *homoeos,* meaning "similar") was originally used by Bateson[54] to label the mutant substitution of segment appendages because he surmised that they indicated a similarity (genetic homology) in their underlying developmental mechanisms. In contrast to the segmentation genes whose mutations affect the whole segment, mutations of the homeotic genes are expressed as homologous structures (e.g., legs and wings) grotesquely appearing on inappropriate segments. It is now known that these homeotic genes are closely grouped in two locations on the third chromosome of *Drosophila*'s four chromosomes.

Another significant outcome of *Drosophila* genetic research has been the identification of a sequence of nucleotide base pairs that is common to the homeotic selector genes.[10] Intergenetic cross homologies of certain gene regions are not unusual, but the relatively small sequence common to these homeotic genes contained only a 180–base pair unit that could easily be used as a probe to identify the locations of its homologues. This compact genetic fragment was called the *homeobox* by McGinnis and associates,[55] and the protein it encodes is known as the *homeodomain*.[10]

Links Between Fly and Human

Evolution recognized a fundamental advantage in deriving a body plan from the regional diversification of a series of basically similar modules because virtually all higher organisms develop from some type of segmental organization. Although vertebrate segmentation is not externally obvious in the postembryonic stages, the sclerotomic contributions to the axial skeleton retain the original metameric organization; the common neurologic examination based on a knowledge of the myotomic and dermatomic distribution of the cranial and spinal nerves pays perpetual homage to the truth that humans and the other vertebrates are segmentally constructed animals.

As would be expected, the homeobox-containing genes discovered in humans[9] do not act in exactly the same manner as they do in *Drosophila* because the types of segmental organization are quite different. Nevertheless, the nucleotide sequence cognates of the *Drosophila* homeobox genes found in mammals seem to have considerable influence in the early establishment of brainstem and spinal cord formation.[13] As in the more primitive forms, malfunctions of the genes controlling the more fundamental aspects of segmentation most likely produce early lethal mutations. Because higher vertebrates do not have an autonomous larval stage, the occurrence of such mutations would be lost to general observation. Nevertheless, some gross errors of segmentation that may reach parturition do show genetic implication.

Congenital Syndromes: Genetic Evidence of Segmentation in Humans

Klippel-Feil Syndrome

In humans, congenital vertebral fusions, most commonly manifested in the various types of Klippel-Feil syndrome, serve as a prime example of segmentation. Many instances of this syndrome seem to result from spontaneous mutations or individual teratogenic accidents in the early developmental sequences because most reports present single case histories without examination of the extended family and the family's pedigree. Gunderson and colleagues[11] provided substantial evidence, however, that many cases of Klippel-Feil syndrome are probands of a familial history of the condition. These authors provided the pedigrees of 11 probands. Of particular interest is their type II of the syndrome, which exhibits fusions limited to the cervical regions at C2–C3 and C5–C6. Gunderson and colleagues[11] concluded that this disorder, which produced segmentation errors at consistent spine levels through several successive generations, strongly indicated a dominant mutant defect of a gene that controls these specific levels of segmentation.

Caudal Dysplasias

Another class of segmental spinal malformations that indicates genetic import is grouped under the generic term of *caudal dysplasias*.[4] This malformation complex has proved to be heritable and has a marked association with maternal diabetes. From this complex, certain insights into genetic mechanisms of mammalian spinal development may be derived. That some degree of caudal segment regression is a natural phenomenon is shown by the reduction of the original postsacral somites from eight (±2) to four (±1) in normal human development. In more severe forms of lumbosacral agenesis, all vertebral elements as far cephalad as the upper lumbar region may fail to develop. The association with maternal diabetes has been attributed to a teratogenic effect of hyperglycemia because experimental elevations of blood glucose have produced varying degrees of caudal deficiencies in animals.[53] Similar effects have been induced by various toxic insults during embryogenesis of the spine.

Because caudal agenesis is not a consistent occurrence in the offspring of diabetic mothers, a more complex genetic association has been suspected, particularly as diabetes mellitus and spine defects have been associated with human leukocyte antigen (HLA)-type histocompatibility genes.[4] This inference has been supported by studies of the T-locus genes in the mouse. This locus apparently is a segment of the mouse chromosomes with a collection of genes that have a profound effect on spine development and other aspects of embryogenesis.[56] There is evidence that a gene complex, functionally similar to the mouse T locus, may be operable in humans because an association between histocompatibility antigens of

the HLA type and the inheritance of human spina bifida has been reported.[57]

The HLAs are controlled by a cluster of contiguous genes located on the human chromosome 6. As in the mouse T locus, each gene in this group has several alleles, and numerous serologically discrete forms of cell surface antigens may be coded by the gene complex. The total ensemble of the HLAs produced within an individual determines its HLA "personality."[57] The comparative evidence suggests that the HLA complex, because of its defined chromosomal localization, its coding for the antigen complex, and its effect on spine development, is a reasonable candidate for the human analogue of the mouse T locus.

In vertebrates, as in other forms of segmented animals, a definite sequence of genetically controlled events establishes the basic aspects of segment formation. When this has been accomplished, some analogue of the homeotic system of genes most likely determines the regional specializations of the individual segments. This system provides an early determination within the vertebrate sclerotome because these embryonic cell masses exhibit a marked "position effect" before any regional differentiation of the somite is visibly evident. This effect has been shown in the chick embryo, in which the transplantation of an early thoracic sclerotome into the cervical region results in a rib-bearing thoracic vertebra whose specific character development was not modified by its heterotopic location.[58] This early position identity may be because vertebrate embryonic patterns are mostly established through early cell-to-cell interactions subsequent to cell cleavages, and these involve the antigen-mediated cell surface recognitions and adhesions as shown by the HLAs. Nevertheless, some analogues of the homeotic mechanisms in *Drosophila,* although differing in their modes of expression, must determine whether a given vertebra exhibits cervical, thoracic, or sacral characteristics.

The range of anomalies observed in the human spine well support the concept that regional vertebral specification may be the result of a homeotic type of selective repression. In addition to the obvious articulated ribs of the thoracic region, each human vertebral level shows some expression of the costal element potential, but it is usually incorporated as an immovable projection. Anomalous free or articulated rib components have been observed at virtually every vertebral level, including the sacrum and coccyx.[59] The hypochordal potential may best indicate the existence of early segmental totipotency in the vertebrates, however. This component is normally expressed at only the C1 level in humans and in the caudal region in other mammals. If there is some interference in the normal control mechanisms, it may also arise at other levels because hypochordal elements have been observed to occur below the last normal vertebra in some cases of lumbosacral agenesis.

2 CHAPTER Applied Anatomy of the Spine

Christopher M. Bono
Amandeep Bhalla
Steven R. Garfin

The spine is a segmental column of similar formed bones that constitutes the major subcranial part of the axial skeleton. Its individual elements are united by a series of intervertebral articulations that form a flexible, although neuroprotective, support to the trunk and limbs. The spinal column typically consists of 33 vertebrae. The mobile section of the spine comprises 7 cervical, 12 thoracic, and 5 lumbar vertebrae; 5 fused vertebrae form the inflexible sacrum that offers a relatively rigid connection to the innominate bones. Caudad to the sacrum, four or five irregular ossicles compose the coccyx.

Vertebrae

The movements of the spine involve 97 diarthroses (i.e., synovial joints, having substantial motion) and an even greater number of amphiarthroses (i.e., fibrocartilaginous joints, having less motion). The individual vertebrae bear multiple processes and surface markings that indicate the attachments of the numerous ligaments that stabilize these articulations. Despite an appreciable degree of regional variation of these characteristics, the embryologically homologous segmental origin of the spine provides a basic uniformity so that a single generalized description can be applied to the basic morphology of all but the most superior and inferior elements.

The typical vertebra consists of two major components: a roughly cylindrical ventral mass of mostly trabecularized cancellous bone, called the *body,* and a denser, more cortical posterior structure, called the *dorsal vertebral arch*. The vertebral bodies vary considerably in size and sectional contour but exhibit no salient processes or unique external features other than the facets for rib articulation in the thoracic region. In contrast, the vertebral arch has a more complex structure. It is attached to the dorsolateral aspects of the body by two stout pillars, called the *pedicles*. These are united dorsally by a pair of arched flat laminae that are surmounted in the midline by a dorsal projection, called the *spinous process*. The pedicles, laminae, and dorsum of the body form the vertebral foramen, a complete osseous ring that encloses the spinal cord.

The transverse processes and the superior and inferior articular processes are found near the junction of the pedicles and the laminae. The transverse processes extend laterally from the sides of the vertebral arches, and because all vertebrae are phyletically and ontogenetically associated with some form of costal element, they either articulate with or incorporate a rib component. In the thoracic spine, the costal process persists as a rib proper. In the cervical spine, the costal process becomes the anterior part of the transverse process that encloses the vertebral artery foramen, and in the lumbar spine it becomes the mature transverse process; the immature posterior (neural arch) component becomes the mammillary process.

The articular processes (zygapophyses) form the paired diarthrodial articulations (facet joints) between the vertebral arches. The superior processes (prezygapophyses) always bear an articulating facet, whose surface is directed dorsally to some degree, whereas the complementary inferior articulating processes (postzygapophyses) direct their articulating surfaces ventrally. Variously shaped bony prominences (mammillary processes or parapophyses) may be found lateral to the articular processes and serve in the multiple origins and insertions of the spinal muscles.

The superoinferior dimensions of the pedicles are roughly half that of their corresponding body, so that in their lateral aspect the pedicles and their articulating processes form the superior and inferior vertebral notches. Because the base of the pedicle arises superiorly from the dorsum of the body, particularly in the lumbar spine, the inferior vertebral notch appears more deeply incised. In the articulated spine, the opposing superior and inferior notches form the intervertebral foramina that transmit the neural and vascular structures between the corresponding levels of the spinal cord and their developmentally related body segments.

Pars Interarticularis

The pars interarticularis defines the parts of the arch that lie between the superior and inferior articular facets of all subatlantal movable vertebral elements (Fig. 2.1). The term *pars interarticularis* arose to designate that area of the arch that is most stressed by translational movement between adjacent

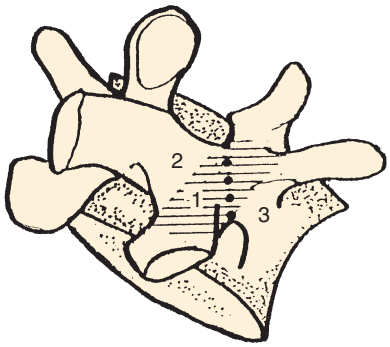

FIG. 2.1 Rendering of the oblique dorsal view of the L5 vertebra showing the parts of the vertebral arch: (*1*) pars interarticularis as the *cross-hatched area,* (*2*) pars laminalis, and (*3*) pars pedicularis. *Dotted line* indicates the most frequent site of mechanical failure of the pars interarticularis.

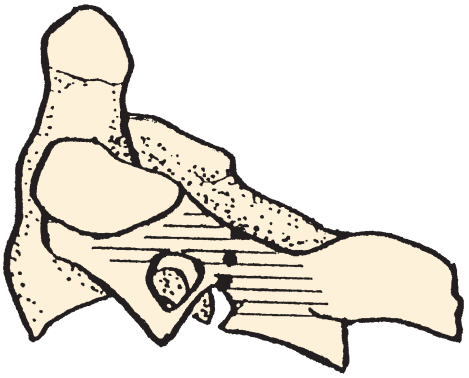

FIG. 2.2 Depiction of lateral view of C2 (axis) vertebra. The offset relationship of the superior facet to the inferior facet elongates the pars interarticularis (*cross-hatched area*). *Dotted line* indicates the most frequent site of failure in upper cervical hyperextension injury (hangman's fracture).

segments, particularly in the second cervical and fifth lumbar vertebrae, which are susceptible to traumatic and stress fractures in this region (i.e., hangman's fracture of C2 and isthmic spondylolysis of L5).[1] In sequential alternation with the intervertebral facet joints, it roofs the lateral recesses of the spinal canal and contributes to the dorsal margins of the intervertebral foramina. In the subcervical vertebrae, it also provides the dorsal part of the base of the transverse process.

Biomechanical forces on the pars interarticularis place it in a position to receive the shearing stresses that occur when translational (spondylolisthetic) forces tend to displace, in a dorsoventral plane, the superior articular processes with respect to their inferior counterparts on the same vertebra. The usual site of failure in the pars interarticularis permits the superior articular facets, pedicles, and vertebral body to be ventrally displaced as a unit, while the inferior articular facets remain attached to the dorsal arch components. These tend to retain their articular relationships with the superior facets of the next lower vertebra.

In the case of the second cervical vertebra (axis) there is a unique anterior relationship of its superior articular facets with the more posteriorly positioned inferior processes that elongates the C2 pars interarticularis. As this offset area receives the greatest leverage between the "cervicocranium" and the lower cervical spine, the indicated line in the illustration in Fig. 2.2 shows the common site of mechanical failure in hyperextension injuries to the upper cervical spine.

In the case of the lumbar vertebrae, the pars interarticularis has been subdivided further. McCulloch and Transfeldt[2] referred to the "lateral buttress," which they believed offered particular structural support to the intervening structures. They described it as the bony bridge that connects the superolateral edge of the inferior facet to the junction of the transverse process and the pedicle. In a follow-up anatomic study, Weiner and colleagues[3] measured the surface area of the lateral buttress in human cadaveric lumbar spines. They found the greatest areas (about 80 mm^2) from L1 to L3, whereas area averaged 50 mm^2 at L4 and only 15 mm^2 at L5. These investigators thought that the broadness of the buttress in the upper lumbar spine can obscure or confuse landmarks for placement of pedicle screws, and its relative thinness (or nonexistence) in the lower lumbar spine can be a predisposing factor to stress

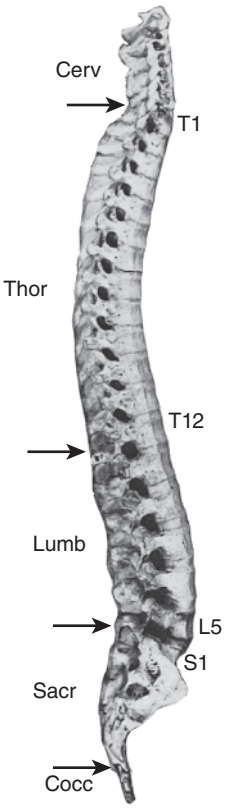

FIG. 2.3 Lateral view of dried preparation of the spine with anterior longitudinal and supraspinous ligaments intact.

fractures or iatrogenic injury to the pars interarticularis. Cadaveric study of L5 pedicle morphology in patients with L5-S1 isthmic spondylolisthesis has shown greater L5 pedicle length compared to that of unaffected subjects, which increases with age.[4]

Regional Characteristics

Although the 24 vertebrae of the presacral spine are divided into three distinct groups (Fig. 2.3), in which the individual members may be recognized by one or two uniquely regional

features, there is a gradual craniocaudal progression of morphologic changes. The vertebrae found above and below the point of regional demarcation are transitional and bear some of the characteristics of both areas. There may be variations in the number of vertebrae, particularly with adolescent idiopathic scoliosis, where up to 10% of individuals can have atypical number of thoracic or lumbar vertebrae.[5]

Cervical Vertebrae

Of the seven cervical vertebrae, the first two (Fig. 2.4A–D) and the last require special notation, but the third to the sixth are fairly uniform, and a common description suffices (Fig. 2.4E–F). Because the cervical vertebrae bear the least weight, their bodies are relatively small and thin with respect to the size of the vertebral arch and vertebral foramen. In addition, their diameter is greater transversely than in the anteroposterior direction. The lateral edges of the superior surface of each body are sharply turned upward to form the uncinate processes that are characteristic of the cervical region. The most obvious diagnostic feature of the cervical vertebrae is the transverse foramina that perforate the transverse processes and transmit the vertebral arteries. The anterior part of the transverse processes represents fused costal elements that arise from the sides of the body. The lateral extremities of the transverse processes bear two projections, the anterior and posterior tubercles. The former serve as origins of anterior cervical muscles; the latter provide origins and insertions for posterior cervical muscles. A deep groove between the upper aspects of the tubercles holds the cervical spinal nerves.

The cervical pedicles connect the posterior vertebral arch to the vertebral body. Anatomic studies have shown that the cervical pedicle height ranges from 5.1 to 9.5 mm, and width ranges from 3 to 7.5 mm.[6,7] The pedicle is angled medially between 90 and 110 degrees.[7]

The superior and inferior articular processes appear as obliquely sectioned surfaces of short cylinders of bone that, when united with the adjacent vertebrae, form two osseous shafts posterolateral to the stacked vertebral bodies. The

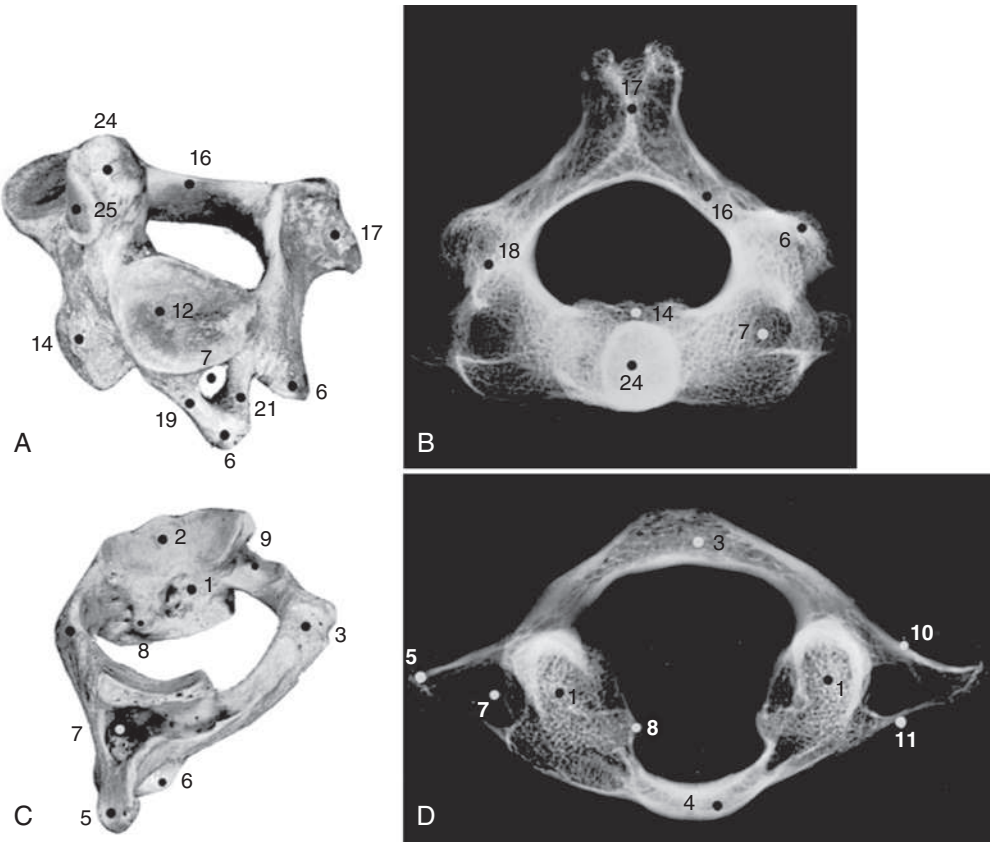

FIG. 2.4 Atlas, axis, and a typical vertebra of each region are illustrated photographically and radiographically. The following numerical key is applicable to all subdivisions of this figure. FIG. 2.4, cont'd (E) Oblique view of typical (fourth) cervical vertebra. (F) Vertical radiographic view of typical cervical vertebra. (G) Oblique view of typical (fifth) thoracic vertebra. (H) Vertical radiographic view of thoracic vertebra. The plane of the articular facets would readily permit rotation. (I) Oblique view of typical (third) lumbar vertebra. (J) Vertical radiographic view of lumbar vertebra. The plane of the articular facets is situated to lock the lumbar vertebrae against rotation.

cervical vertebrae present a tripod of flexible columns for the support of the head. As in the upper cervical spine, the combination of the articular processes and the intervening bone is often referred to as the lateral mass in the subaxial region. It is a common site for screw insertion during internal fixation of the cervical spine.[8]

The laminae are narrow and have a thinner superior edge. At their mid-dorsal junction, they bear a bifid spinous process that receives the insertions of the semispinalis cervicis muscles. The height of the lamina of C4 is 10 to 11 mm, whereas the lamina thickness at C5 is about 2 mm.[9] The lamina is thickest at T2, where it measures an average of 5 mm.

Atlantoaxial Complex

The first two cervical vertebrae are structurally and developmentally different. Together, they form a complex articular system that permits the nutational (i.e., nodding) and rotational movements of the head. The first cervical vertebra, or atlas, is a bony ring consisting of an anterior and a posterior arch, which are connected by the two lateral masses. It has all the homologous features of a typical vertebra with the exception of the body. The lateral masses correspond to the combined pedicles and articular pillars of the lower cervical vertebrae, but the superior and inferior articular facets are concave. The superior articular surfaces face upward and internally to receive the occipital condyles of the skull, whereas the inferior articulating surfaces face downward and internally to rotate on the sloped "shoulders" of the axis. This slope helps prevent lateral translation while permitting rotation.

The posterior arch consists of modified laminae that are more round than flat in their sectional aspect and a posterior tubercle that represents an attenuated spinous process that gives origin to suboccipital muscles. Immediately behind the lateral masses on the superior surface of the posterior arch of C1, two smooth grooves house the vertebral arteries as they penetrate the posterior atlanto-occipital membrane. These arteries take a tortuous course from the transverse processes of the atlas, making an almost 90-degree turn medially as they exit the foramen and a subsequent 90-degree turn superiorly to enter the dura and subsequently the foramen magnum. The vertebral artery courses over the posterior ring of the atlas 10 to 15 mm from the midline in adults and, although the arteries are closer to the midline in the pediatric population, 97% are located at least 1 cm from the midline.[10] Dissection further lateral risks injury to these vessels.

The transverse foramen also houses a venous system. In an anatomic and radiologic study to characterize the venous system within the transverse foramen, Magro and colleagues[11] found ventral longitudinal veins that may also exist in a plexus arrangement. Anastomosis between the plexus transverse veins and vertebral veins can be present. An understanding of venous anatomy in the transverse foramen may help contextualize false-positive diagnoses of vertebral artery dissection from magnetic resonance angiography caused by slow flow vertebral veins.

The anterior arch forms a short bridge between the anterior aspects of the lateral masses. It bears an anterior tubercle that is the site of insertion of the longus colli muscle. On the posterior surface of the anterior arch, a semicircular depression marks the synovial articulation of the odontoid process. Internal tubercles on the adjacent lateral masses are the attachment sites of the transverse atlantal ligaments that hold the odontoid against this articular area. Cadaveric studies have shown that the right-sided tubercles tend to be of larger caliber and that the mean angle formed between both tubercles and the dental facet is 75 degrees.[12]

The second cervical vertebra, or axis, provides a bearing surface on which the atlas may rotate. Its most distinctive characteristic is the vertically projecting odontoid process that serves as a pivotal restraint against horizontal displacements of the atlas. This bony prominence represents the phyletically purloined centrum of the first cervical vertebra. It exhibits a slight constriction at its neck and an anterior facet for its articulation with the anterior arch of the atlas. Posteriorly, a groove in the neck of the odontoid marks the position of the strong transverse atlantal ligament.

The apex of the odontoid process is slightly pointed. It is the attachment site of the apical ligament. Posterior to the apex, two lateral roughened prominences indicate the attachments of the alar ligaments. These structures and the apical ligament connect the odontoid process to the base of the skull at the basion, the anterior aspect of the foramen magnum. The occipital attachments of the alar ligaments are on the medial surface of the occipital condyles, adjacent to the atlanto-occipital joints. Atlantal attachments of the alar ligaments have also been described, but these are more likely to be anatomic variants and not essential components of craniovertebral junction stability.[13] The superior articulating surfaces of the axis are convex and are directed laterally to receive the lateral masses of the atlas. The inferior articulating surfaces are typical of those of the cervical vertebrae and serve as the start of the articular columns. The transverse processes of the axis are directed downward. Anteriorly, the inferior aspect of the body of the axis forms a liplike process that descends over the first intervertebral disc and the body of the third cervical vertebra.

The seventh cervical vertebra is transitional. The inferior surface of its body is proportionately larger than the superior surface. It has a long, distinct spinous process that is usually easily palpable (the vertebra prominens). The superior and inferior articulating facets are more steeply inclined and presage the form of these structures in the thoracic region. Blunt transverse processes have heavy posterior struts and much lighter anterior struts that surround transverse foramina that are often bilaterally unequal and seldom pass the vertebral arteries. Frequently, one or both of the anterior struts realize their true potential as a costal element and develop into a cervical rib.

Thoracic Vertebrae

All 12 thoracic vertebrae support ribs and have facets for the diarthrodial articulations of these structures. The first and last four have specific peculiarities in the manner of costal articulations, but the second to the eighth are similar (Fig. 2.4G–H).

The body of a mid-thoracic vertebra is heart-shaped. Its length and width are roughly halfway between that of the cervical and lumbar bodies. Often a flattening of the left side of the body indicates its contact with the descending aorta. In the mid-thorax, the heads of the ribs form a joint that spans the intervertebral disc, so that the inferior lip of the body of one vertebra and the corresponding site of the superior lip of the infrajacent element share in the formation of a single articular facet for the costal capitulum. The typical thoracic vertebra bears two demifacets on each side of its body. The thoracic vertebral arch encloses a small, round vertebral foramen that would not admit the tip of an index finger, even

when the specimen is from a large adult. This limited space for the spinal cord predisposes to severe spinal cord injury with minimal dimensional compromise.

Because the pedicles arise more superiorly on the dorsum of the body than they do in the cervical region, the inferior vertebral notch forms an even greater contribution to the intervertebral foramen. The pedicle height increases from T1 to T12, but the transverse pedicle width (which is more critical for transpedicular screw containment) does not follow this same craniocaudal pattern.[14] Cinotti and colleagues[15] found that the pedicles in the T4 to T8 region had the smallest transverse diameter. Scoles and colleagues[16] documented similar findings in 50 cadaveric human spines, with the smallest diameters measured at T3 to T6. On average, the transverse pedicle diameter at T3 is 3.4 mm in women and 3.9 mm in men. At T6, it averages 3 mm in women and 3.5 mm in men. At T1, however, the mean diameter is 6.4 mm in women and 7.3 mm in men. Lehman and colleagues described key morphologic characteristics to facilitate safe medial-lateral starting points for placement of thoracic pedicle screws.[17] The ventral lamina is an anatomically reproducible structure consistently located medial to the superior articular facet in the thoracic spine. They also noted the center of the pedicle lays 2 to 3 mm lateral to the midline of the superior articular facet.

The superior articular facets form a stout shelflike projection from the junction of the laminae and the pedicles. Their ovoid surfaces are slightly convex, are almost vertical, and are coronal in their plane of articulation. They face dorsally and slightly superolaterally, and in bilateral combination they present the segment of an arc whose center of radius lies at the anterior edge of the vertebral body. They permit a slight rotation around the axis of this radius. The inferior articular facets are borne by the inferior edges of the laminae. The geometry of their articular surfaces is complementary to the superior processes.

On the ventral side of the tip of the strong transverse processes, another concave facet receives the tuberculum of the rib whose capitulum articulates with the superior demifacet of the same vertebra. The spinous processes of the thoracic vertebrae are long and triangular in section. The spinous processes of the upper four thoracic vertebrae are more bladelike and are directed downward at an angle of about 40 degrees from the horizontal. The middle four thoracic spinous processes are longer but directed downward at an angle of 60 degrees, so that they completely overlap the adjacent lower segment. The lower four resemble the upper four in direction and shape.

The first thoracic vertebra has a complete facet on the side of its body for the capitulum of the first rib and an inferior demifacet for the capitulum of the second rib. The costal articulations of the 9th to 12th thoracic vertebrae are confined to the sides of the bodies of their respective segments. On the last two thoracic vertebrae, transitional characteristics are evident in the diminution of the transverse processes and their failure to buttress the last two ribs. Because the ribs are disconnected from the sternum, they are frequently referred to as "floating ribs."

Lumbar Vertebrae

The lumbar vertebrae are the lowest five vertebrae of the presacral column (see Fig. 2.4I–J). All their features are expressed in more massive proportions. They are easily distinguished from other regional elements by their lack of a transverse foramen or costal articular facets. The body is large, having a width greater than its anteroposterior diameter, and is slightly thicker anteriorly than posteriorly. All structures associated with the vertebral arch are blunt and stout. The thick pedicles are widely placed on the dorsolaterosuperior aspects of the body, and with their laminae they enclose a triangular vertebral foramen. Although the inferior vertebral notch is deeper than the superior, both make substantial contributions to the intervertebral foramen. The transverse processes are flat and winglike in the upper three lumbar segments, but in the fifth segment they are thick, rounded stumps. The fourth transverse process is usually the smallest.

Aside from their relative size, the lumbar vertebrae can be recognized by their articular processes. The superior pair arise in the usual manner from the junction of the pedicles and laminae, but their articular facets are concave and directed dorsomedially, so that they almost face each other. The inferior processes are extensions of the laminae that direct the articulating surfaces ventrolaterally and lock themselves between the superior facets of the next inferior vertebra in an almost mortise-and-tenon fashion. This arrangement restricts rotation and translation in the lumbar region. The lumbar segments also have pronounced mammillary processes, which are points of origin and insertion of the thick lower divisions of the deep paraspinal muscles.

Sacral Vertebrae

The sacrum consists of five fused vertebrae that form a single triangular complex of bone that supports the spine and forms the posterior part of the pelvis (Figs. 2.5 and 2.6). It is markedly curved and tilted backward, so that its first element articulates with the fifth lumbar vertebra at a pronounced angle (the sacrovertebral angle).

Close inspection of the flat, concave ventral surface and the rough, ridged convex dorsal surface reveals that, despite their fusion, all the homologous elements of typical vertebrae are still evident in the sacrum. The heavy, laterally projecting alae that bear the articular surfaces for articulation with the pelvis are fused anterior costal and posterior transverse processes of the first three sacral vertebrae. These lateral fusions require that separate dorsal and ventral foramina provide egress for the anterior and posterior divisions of the sacral nerves. The ventral four pairs of sacral foramina are larger than their dorsal counterparts because they must pass the thick sacral contributions to the sciatic nerve. The ventral surface of the sacrum is relatively smooth. There are four transverse ridges that mark the fusions of the vertebral bodies and enclose remnants of the intervertebral discs. Lateral to the bodies of the second, third, and fourth elements, the ridges of bone that

FIG. 2.5 Composite anteroposterior view of sacrum. The roughened crests on the dorsum (*left side*) indicate longitudinal fusions of vertebral arch structures. The articular process is directed backward to buttress the vertebral arch of the fifth lumbar vertebra. *Art crest,* articular crest; *Art pro,* articular process; *Cost proc,* costal process; *Lat crest,* lateral crest; *Sarc tub,* superior articulating tubercle; SC, sacral comua; *Spin crest,* spinous crest.

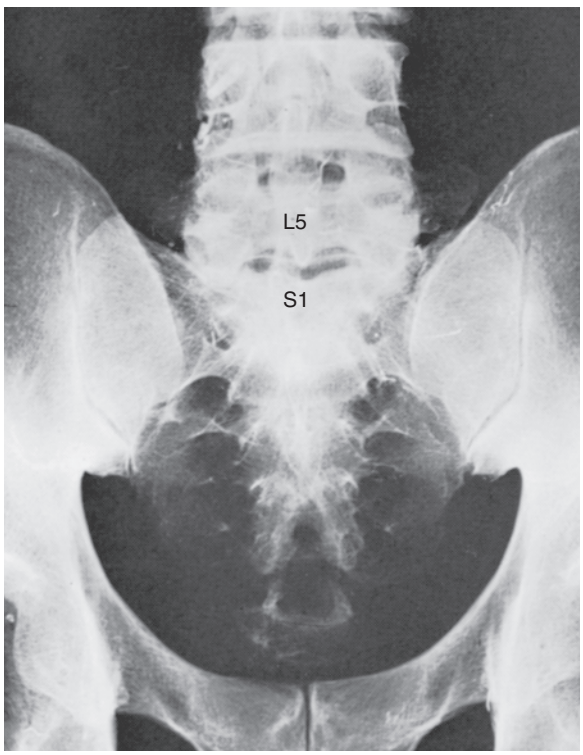

FIG. 2.6 Anterior radiographic view of lumbosacral and sacroiliac articulations. Load transfer from the lumbar spine to the iliac bones via the costal processes of the first and second sacral segments is obvious.

separate the anterior sacral foramina are quite prominent and give origin to the piriformis muscle.

The dorsal aspect of the sacrum is convex, rough, and conspicuously marked by five longitudinal ridges. The central one, the middle sacral crest, is formed by the fusion of the spinous processes of the sacral vertebrae. On either side, a sacral groove separates it from the medial sacral articular crest that represents the fused articular process. The superior ends of these crests form the functional superior articular processes of the first sacral vertebra, which articulate with the inferior processes of the fifth lumbar vertebra. They are very strong, and their facets are directed dorsally to resist the tendency of the fifth lumbar vertebra to be displaced forward. Inferiorly, the articular crests terminate as the sacral cornua, two rounded projections that bracket the inferior hiatus where it gives access to the sacral vertebral canal. More laterally, the lateral crests and sacral tuberosities form uneven elevations for the attachments of the dorsal sacroiliac ligaments.

The sacrum and its posterior ligaments lie ventral to the posterior iliac spines and form a deep depression that accommodates, and gives origin to, the inferior parts of the paraspinal muscles. The grooves between the central spinous crest and the articular crests are occupied by the origins of the multifidus muscles. Dorsal and lateral to these are attached the origins of the iliocostal and iliolumbar muscles.

Coccyx

The coccyx is usually composed of four vertebral rudiments, but one fewer or one greater than this number is not uncommon. The coccyx is the vestigial representation of the tail. The first coccygeal segment is larger than the succeeding members and resembles to some extent the inferior sacral element. It has an obvious body that articulates with the homologous component of the inferior sacrum, and it bears two cornua, which may be regarded as vestiges of superior articulating processes. The three inferior coccygeal members are most frequently fused and present a curved profile continuous with that of the sacrum. They incorporate the rudiments of a body and transverse processes but possess no components of the vertebral arch.

The coccyx contributes no supportive function to the spine. It serves as an origin for the gluteus maximus posteriorly and the muscles of the pelvic diaphragm anteriorly.

Arthrology of the Spine

The articulations of the spine include the three major types of joints: synarthroses, diarthroses, and amphiarthroses (Figs. 2.7 to 2.9). The *synarthroses* are found during development and the first decade of life. The best examples are the neurocentral joints of the immature spine, which are the two unions between the centers of ossification for the two halves of the vertebral arch and that of the centrum. Until they are obliterated during the 2nd decade, they possess a thin plate cartilage between the two apposed bony surfaces. Another example is

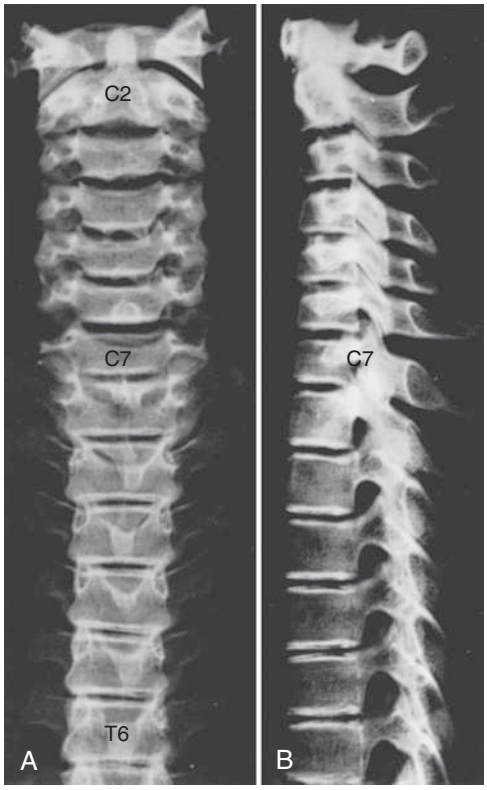

FIG. 2.7 (A) Anteroposterior radiograph of dried preparation of cervical and upper thoracic spine. Note greater relative thickness of cervical discs and more lateral disposition of cervical articular pillars. (B) Lateral view of preceding specimen. The normal curvatures did not survive the preparation, but the gradual increase in size of the bodies and the intervertebral foramina is well illustrated.

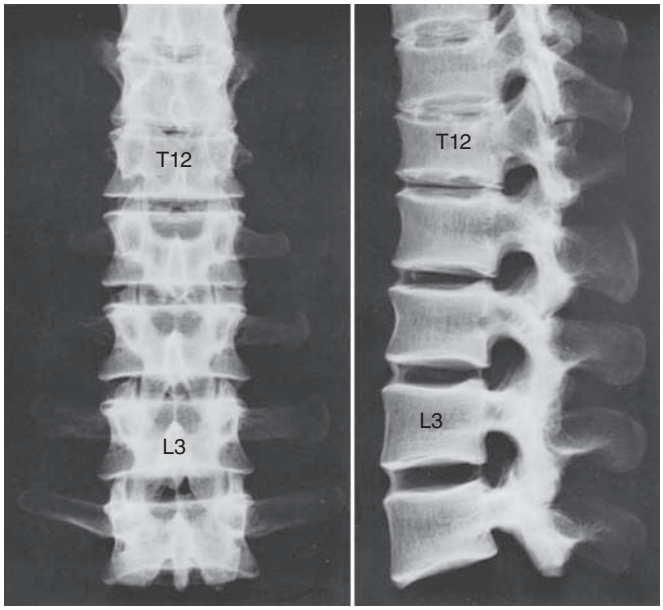

FIG. 2.8 Anteroposterior *(left)* and lateral *(right)* radiographs of lower thoracic and upper lumbar region of articulated dried preparation.

the early union between the articular processes of the sacral vertebrae, known as *ephemeral synchondroses*.

The *diarthroses* are true synovial joints, formed mostly by the facet joints and costovertebral joints, but also include the atlantoaxial and sacroiliac articulations. All the spinal diarthroses are of the arthrodial or gliding type, with the exception of the trochoid or pivot joint of the atlantodens articulation.

The *amphiarthroses* are nonsynovial, slightly movable connective tissue joints. They are of two types: the symphysis, as exemplified by the fibrocartilage of the intervertebral disc, and the syndesmosis, as represented by all the ligamentous connections between the adjacent bodies and the adjacent arches.

Articulations of the Vertebral Arches

The synovial facet joints formed by the articular processes of the vertebral arches possess a true joint capsule and are capable of a limited gliding articulation. The capsules are thin and lax and are attached to the bases of the engaging superior and inferior articulating processes of opposing vertebrae. Because it is mostly the plane of articulation of these joints that determines the types of motion characteristic of the various regions of the spine, it would be expected that the fibers of the articular capsules would be longest and loosest in the cervical region and become increasingly taut in an inferior progression.

The syndesmoses between the vertebral arches are formed by the paired sets of ligamenta flava, the intertransverse ligaments, the interspinous ligaments, and the unpaired supraspinous ligament. The ligamenta flava bridge the spaces between the laminae of adjacent vertebrae from the second cervical to the lumbosacral interval. The lateral extent of each half of a paired set begins around the bases of the articulating processes and can be traced medially where they nearly join in the midline. This longitudinal central deficiency serves to transmit small vessels and facilitates the passage of a needle during lumbar punctures. The fibers of the ligamenta flava are almost vertical in their disposition, but are attached to the ventral surface of the cephalad lamina and to the superior lip of the subjacent lamina.

This shinglelike arrangement conceals the true length of the ligaments because of the overlapping of the superior lamina. Their morphology is best appreciated from the ventral aspect as in Fig. 2.9B. The yellow elastic fibers that give the ligamenta flava their name maintain their elasticity even in embalmed specimens. It has been stated in some texts that the elasticity of the ligamenta flava serves to assist in the maintenance of the erect posture. A more probable reason for this property is simply to keep the ligament taut during extension, where any laxity would permit redundancy and infolding toward the ventrally related nervous structures, as occurs in degenerative lumbar spinal stenosis.

There are two separable layers of the ligamentum flavum, one superficial and one deep, that have distinct attachments to the inferior lamina.[18] The superficial component inserts at the classically described location along the posterosuperior aspect of the lamina. The deep component inserts along the anterosuperior surface of the lamina.[18] This attachment can have significance during surgical removal of the ligamentum flavum for exposure of the neural elements.

The intertransverse ligaments are fibrous connections between the transverse processes. They are difficult to distinguish from extensions of the tendinous insertions of the segmental muscles and in reality may be just that in some regions.

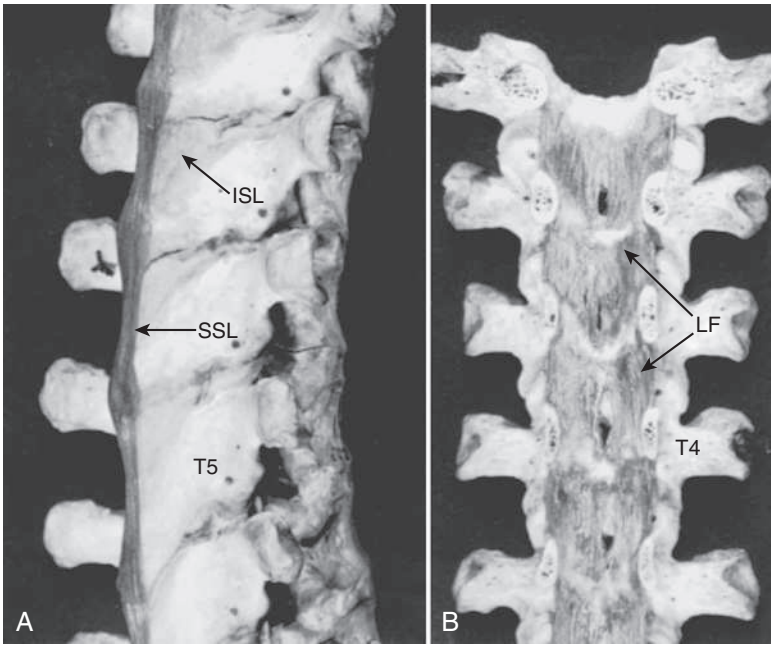

FIG. 2.9 (A) Dried preparation of thoracic vertebrae showing the supraspinous ligament (SSL) and interspinous ligaments (ISL). (B) Anterior view of upper thoracic vertebral arches showing the disposition of the ligamenta flava (LF).

They appear as a few tough, thin fibers between the cervical transverse processes, and in the thoracic area they blend with the intercostal ligaments. Being most distinct between the lumbar transverse processes, the intertransverse ligaments may be isolated here as membranous bands.

The interspinous ligaments (see Fig. 2.9A) are membranous sets of fibers that connect adjoining spinous processes. They are situated medial to the thin pairs of interspinal muscles that bridge the apices of the spine. The fibers of the ligaments are arranged obliquely as they connect the base of the superior spine with the superior ridge and apex of the next most inferior spinous process. These midline ligaments are found in pairs with a distinct dissectible cleft between them.

The supraspinous ligament (see Fig. 2.9A) is a continuous fibrous cord that runs along the apices of the spinous processes from the seventh cervical to the end of the sacral spinous crest. Similar to the longitudinal ligaments of the vertebra, the more superficial fibers of the ligament extend over several spinal segments, whereas the deeper, shorter fibers bridge only two or three segments. In the cervical region the supraspinous ligament assumes a distinctive character and a specific name, the *ligamentum nuchae*. This structure is bowstrung across the cervical lordosis from the external occipital protuberance to the spine of the seventh cervical vertebra. Its anterior border forms a sagittal fibrous sheet that divides the posterior nuchal muscles and attaches to the spinous processes of all cervical vertebrae. The ligamentum nuchae contains an abundance of elastic fibers. In quadrupeds, it forms a strong truss that supports the cantilevered position of the head.

Special Articulations

The atlanto-occipital articulation consists of the diarthrosis between the lateral masses of the atlas and the occipital condyles of the skull and the syndesmoses formed by the atlanto-occipital membranes. The articular capsules around the condyles are thin and loose and permit a gliding motion between the condylar convexity and the concavity of the lateral masses. The capsules blend laterally with ligaments that connect the transverse processes of the atlas with the jugular processes of the skull. Although the lateral ligaments and the capsules are sufficiently lax to permit nodding, they do not permit rotation.

The anterior atlanto-occipital membrane is a structural extension of the anterior longitudinal ligament that connects the forward rim of the foramen magnum, also known as the *basion,* to the anterior arch of the atlas and blends with the joint capsules laterally. It is dense, tough, and virtually cordlike in its central portion.

The posterior atlanto-occipital membrane is homologous to the ligamenta flava and unites the posterior arch of the atlas. It is deficient laterally where it arches over the groove on the superior surface of the arch. Through this aperture, the vertebral artery enters the neural canal to penetrate the dura. Occasionally, the free edge of this membrane is ossified to form a true bony foramen (called the *ponticulus posticus*) around the artery.

The median atlantoaxial articulation is a pivot (trochoid) joint (Figs. 2.10 and 2.11). The essential features of the articulation are the odontoid process (dens) of the axis and the internal surface of the anterior arch of the atlas. The opposition of the two bones is maintained by the thick, straplike transverse atlantal ligament. The ligament and the arch of the atlas have true synovial cavities intervening between them and the odontoid process. Alar expansions of the transverse ligament attach to tubercles on the lateral rims of the anterior foramen magnum, and a single, unpaired cord, the apical odontoid ligament, attaches the apex of the process to the

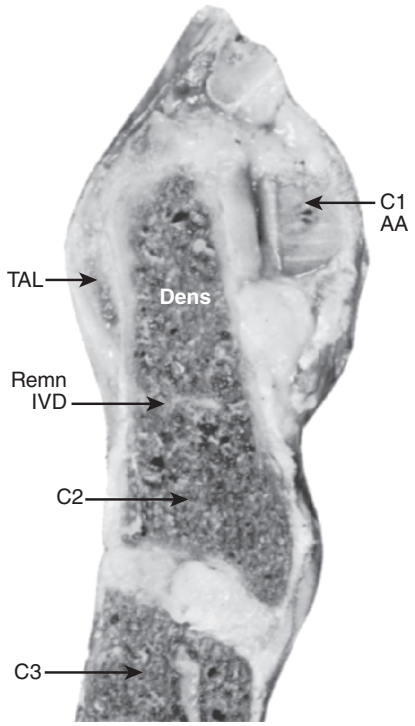

FIG. 2.10 Sagittal section through adult odontoid process showing articular relationships with anterior arch of the atlas (AA) and transverse atlantal ligament (TAL). Despite the fact this patient was older than 50 years, a cartilaginous remnant of the homologue of an intervertebral disc (Remn IVD) may be discerned. Radiologically, this might be confused with fracture or a nonunion status.

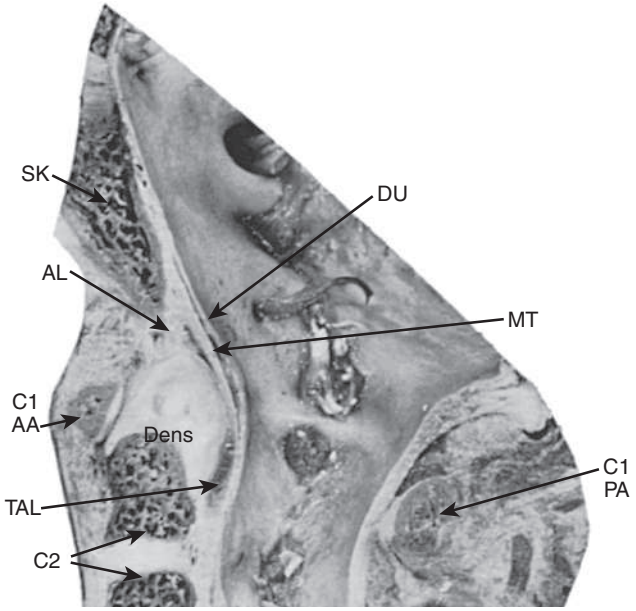

FIG. 2.11 Sagittal section through atlanto-occipital articulation of a 4-year-old child. The major ossification centers of the odontoid process are still separated from the body of C2 by a well-differentiated disc. The cartilaginous apex of the process shows a condensation marking the apical ossific center. C1 AA and C1 PA mark the anterior and posterior atlantal arches. The dura (DU) overlies the membrana tectoria (MT), which is a superior extension of the posterior longitudinal ligament. The transverse atlantal ligament (TAL) and apical ligament (AL) are also indicated. SK, skull.

basion. The entire joint is covered posteriorly by a cranial extension of the posterior longitudinal ligament, which is named *tectorial membrane* in this region. Because the atlas freely glides over the superior articulating facets of C2, the atlantoaxial pivot is essential for preventing horizontal displacements between C1 and C2. Fracture of the odontoid or, less likely, rupture of the transverse ligament produces a very unstable articulation.

Articulations of the Vertebral Bodies

The vertebral bodies are connected by the two forms of amphiarthroses. Symphyses are represented by the intervertebral discs, and syndesmoses are formed by the anterior and posterior longitudinal ligaments.

Intervertebral Disc

In view of the semiliquid nature of the nucleus pulposus and the vacuities that may be shown in the nucleus of aging specimens, von Luschka[19] attempted to classify the intervertebral disc as a diarthrosis, in which the vertebral chondral plates were the articular cartilages, the anulus provided the articular capsule, and the fluid and ephemeral spaces within the nucleus corresponded to the synovia and the joint cavity. Although the intervertebral disc forms a joint that should be classified in its own exclusive category because its development, structure, and function are generally different from those of any other joint, it most closely conforms to an amphiarthrosis of the symphysis type.

The intervertebral disc is the fibrocartilaginous complex that forms the articulation between the bodies of the vertebrae. Although it provides a very strong union, ensuring the degree of intervertebral fixation that is necessary for effective action and the protective alignment of the neural canal, the summation of the limited movements allowed by each disc imparts to the spinal column as a whole its characteristic mobility. The discs of the various spinal regions may differ considerably in size and in some detail, but they are basically identical in their structural organization. Each consists of two components: the internal semifluid mass, called the *nucleus pulposus,* and its laminar fibrous container, known as the *anulus fibrosus*.

Nucleus Pulposus

Typically, the nucleus pulposus occupies an eccentric position within the confines of the anulus, usually being closer to the posterior margin of the disc. Its most essential character becomes obvious in either transverse or sagittal preparations of the disc in which, as evidence of internal pressure, it bulges beyond the plane of section. Palpation of a dissected nucleus from a young adult shows that it responds as a viscid fluid under applied pressure, but it also exhibits considerable elastic rebound and assumes its original physical state on release. These properties may still be shown in the spine of a cadaver that has been embalmed for many months.

Histologic analysis provides a partial explanation for the characteristics of the nucleus. As the definitive remnant of the

embryonic notochord, it is similarly composed of loose, delicate fibrous strands embedded in a gelatinous matrix. In the center of the mass, these fibers show no geometric preference in their arrangement but form a felted mesh of undulating bundles. Only the fibers that are in approximation to the vertebral chondral plates display a definite orientation. These approach the cartilage at an angle and become embedded in its substance to afford an attachment for the nucleus. Numerous cells are suspended in the fibrous network. Many of these are fusiform and resemble typical reticulocytes, but vacuolar and darkly nucleated chondrocytes are also interspersed in the matrix. Even in the absence of vascular elements, the profusion of cells should accentuate the fact that the nucleus pulposus is composed of vital tissue. There is no definite structural interface between the nucleus and the anulus. Rather, the composition of the two tissues blends imperceptibly.

Anulus Fibrosus

The anulus is a concentric series of fibrous lamellae that encase the nucleus and strongly unite the vertebral bodies (Fig. 2.12). The essential function of the nucleus is to resist and redistribute compressive forces within the spine, whereas one of the major functions of the anulus is to withstand tension, whether the tensile forces be from the horizontal extensions of the compressed nucleus, from the torsional stress of the column, or from the separation of the vertebral bodies on the convex side of a spinal flexure. Without optical aid, simple dissection and discernment reveals how well the anulus is constructed for the performance of this function.

FIG. 2.12 A dissected third lumbar disc. Lamellar bands are still visible when the section is cut deep into bony apophyseal ring. A layer of spongiosa was left attached to the superior surface of the disc to show that only a thin chondral plate intervenes between the vascular trabeculae and the disc. The inward buckling of the lamellae near the cavity of the extirpated nuclear material is well shown. The specimen is from a 52-year-old man.

On horizontal section, it is noted that an individual lamella encircling the disc is composed of glistening fibers that run an oblique or spiral course in relation to the axis of the vertebral column. Because the disc presents a kidney-shaped or heart-shaped horizontal section, and the nucleus is displaced posteriorly, these lamellae are thinner and more closely packed between the nucleus and the dorsal aspect of the disc. The bands are stoutest and individually more distinct in the anterior third of the disc, and here when transected they may give the impression that they are of varying composition because every other ring presents a difference in color and elevation with reference to the plane of section. Teasing and inspection at an oblique angle shows in the freed lamellae, however, that this difference is due to an abrupt change in the direction of the fibers of adjacent rings. Previous descriptions of the anulus have claimed that the alternating appearance of the banding is the result of the interposition of a chondrous layer between each fibrous ring.[20] In reality, the alternations of glistening white lamellae with translucent rings result from differences in the incidence of light with regard to the direction of the fiber bundles. This repeated reversal of fiber arrangement within the anulus has implications in the biomechanics of the disc, which are discussed later.

The disposition of the lamellae on sagittal section is not consistently vertical. In the regions of the anulus approximating the nucleus pulposus, the first distinct bands curve inward, with their convexity facing the nuclear substance. As one follows the successive layers outward, a true vertical profile is assumed, but as the external laminae of the disc are approached, they may again become bowed, with their convexity facing the periphery of the disc.[21,22]

The attachment of the anulus to its respective vertebral bodies warrants particular mention. This attachment is best understood when a dried preparation of a thoracic or lumbar vertebra is examined first. In the adult, the articular surface of the body presents two aspects: a concave central depression that is quite porous and an elevated ring of compact bone that appears to be rolled over the edge of the vertebral body. Often a demarcating fissure falsely suggests that the ring is a true epiphysis of the body, but postnatal studies of ossification have indicated that it is a traction apophysis for the attachment of the anulus and associated longitudinal ligaments.[23]

In life, the depth of the central concavity is filled to the level of the marginal ring by the presence of a cribriform cartilaginous plate. In contrast to other articular surfaces, there is no closing plate of compact osseous material intervening between this cartilage and the cancellous medullary part of the bone. The trabeculations of the spongiosa blend into the internal face of the chondrous plate, whereas fibers from the nucleus and inner lamellae of the anulus penetrate its outer surface. As intimate as this union between the central disc and vertebra may appear, the outer bony ring affords the disc its firmest attachment because the stoutest external lamellar bands of fibers actually penetrate the ring as Sharpey fibers. Scraping the disc to the bone shows the concentric arrangements reflecting the different angles at which the fibers insert (see

Fig. 2.12). The fibers of the outermost ring of the anulus have the most extensive range of attachment. They extend beyond the confines of the disc and blend with the vertebral periosteum and the longitudinal ligaments.

Regional Variations of the Disc

The discs in aggregate make up approximately one-fourth of the length of the spinal column, exclusive of the sacrum and coccyx. Their degree of contribution is not uniform in the various regions. According to Aeby,[24] the discs provide more than one-fifth of the length of the cervical spine, approximately one-fifth of the length of the thoracic column, and approximately one-third of the length of the lumbar region.

The discs are smallest in the cervical spine. Their lateral extent is less than that of the corresponding vertebral body because of the uncinate processes (Fig. 2.13). Here, as in the lumbar region, they are wedge-shaped, the greatest width being anterior, producing lordosis. The thoracic discs are heart-shaped on section, with the nucleus pulposus being more centrally located than in the lumbar region. The thickness and the horizontal dimensions of the thoracic disc increase caudad with the corresponding increase in size of the vertebral bodies. The normal thoracic kyphosis results from a disparity between the anterior and posterior heights of the vertebral bodies because the discs are of uniform thickness. The lumbar discs are reniform and are relatively and absolutely the thickest in the spine. The progressive caudal increase in the degree of lumbar lordosis is due to the equivalent increase in the differential between the anterior and posterior thickness of the disc. In a study of lumbar disc morphology, Zhong and colleagues noted that disc length increased from upper to lower lumbar levels, although the L4–L5 disc, and the L5-S1 discs had similar lengths.[25] The L4–L5 nucleus pulposus height was tallest of the lumbar levels. The authors concluded that the geometry of the anulus fibrosus and nucleus pulposus show segment-dependent properties.

The cervical intervertebral discs have been a source of controversy because of the so-called joints of Luschka, or uncovertebral joints. These articular modifications are found on both sides of the cervical discs as oblique, cleftlike cavities between the superior surfaces of the uncinate processes and the corresponding lateral lips of the interior articular surface of the next superior vertebra. Because they initially appear in the latter part of the first decade and are not universally demonstrable in all cervical spines, or even in all subaxial discs of the same cervical spine, it is preferable to call them "accommodative joints" that have developed in response to the shearing stresses of the torsions of cervical mobility (see Fig. 2.13).

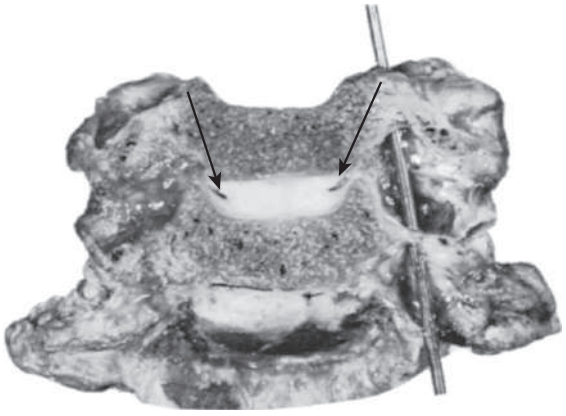

FIG. 2.13 Frontal section through fourth to fifth cervical vertebrae showing typical cervical disc and its joints of Luschka (*arrows*). A probe has been passed through the vertebral arterial canal to show its relationships to the uncovertebral joints.

Spinal Ligaments

Anterior Longitudinal Ligament

The anterior longitudinal ligament is a strong band of fibers that extends along the ventral surface of the spine from the skull to the sacrum. It is narrowest and cordlike in the upper cervical region, where it is attached to the atlas and axis and their intervening capsular membranes. It widens as it descends the column to the extent, in the lower lumbar region, of covering most of the anterolateral surfaces of the vertebral bodies and discs before it blends into the presacral fibers. The anterior longitudinal ligament is not uniform in its composition or manner of attachment. Its deepest fibers, which span only one intervertebral level, are covered by an intermediate layer that unites two or three vertebrae and a superficial stratum that may connect four or five levels. Where the ligament is adherent to the anterior surface of the vertebra, it also forms its periosteum. It is most firmly attached to the articular lip at the end of each body. It is most readily elevated at the point of its passage over the midsection of the discs, where it is loosely attached to the connective tissue band that encircles the anulus (Fig. 2.14).

Posterior Longitudinal Ligament

The posterior longitudinal ligament differs considerably from its anterior counterpart with respect to the clinical significance of its relationships to the intervertebral disc. Similar to the anterior ligament, it extends from the skull to the sacrum, but it is within the vertebral canal. Its central fiber bundles diminish in breadth as the size of the spinal column increases. The segmental denticulate configuration of the posterior longitudinal ligament is one of its most characteristic features. Between the pedicles, particularly in the lower thoracic and lumbar regions, it forms a thick band of connective tissue that is not adherent to the posterior surface of the vertebral body. Instead, it is bowstrung across the concavity of the dorsum of the body. The large vascular elements enter and leave the medullary sinus located beneath its fibers.

In approximating the dorsum of the disc, the posterior longitudinal ligament displays two strata of fibers. The superficial, longer strands form a distinct strong strap whose filaments bridge several vertebral elements. A second, deeper stratum spans only two vertebral articulations and forms lateral curving extensions of fibers that pass along the dorsum of the disc and out through the intervertebral foramen. These

FIG. 2.14 Bodies of third and fourth lumbar vertebrae from a 58-year-old man. The spiral course of fibers of the outer lamellae is evident. The periosteal attachment of the reflected anterior longitudinal ligament is well shown, in addition to the delineation of the loosely attached area raised from the surface of the disc.

FIG. 2.15 Posterior longitudinal ligament traversing the bodies of third and fourth lumbar vertebrae. The central strap of long fibers can be seen passing over the hemostat. The lines of strong attachment of the fibers at the lateral expansions are indicated by the *black dots* as they outline the rhomboid area, where the fibers are readily dissected from the dorsal surface of the disc. In this case, the instrument was inserted into an actual fascial cleft, and the points show the weakest area of the lateral expansion.

deeper intervertebral expansions of the ligament have the most significant relationship with the disc.

These fibers are most firmly fixed at the margins of their lateral expansions. This produces a central rhomboidal area of loose attachment, or in some cases an actual fascial cleft of equivalent dimensions, on the dorsolateral aspect of the disc. At dissection, this characteristic may be readily shown by inserting a blunt probe beneath the intervertebral part of the longitudinal ligament and exploring the area to define the margins of the space where the fibers are strongly inserted (Fig. 2.15). This situation is particularly pertinent to problems involving dorsal or dorsolateral prolapse of the nucleus pulposus. With a dorsocentral protrusion of a semifluid mass, the strong midline strap of posterior longitudinal fibers tends to restrain the herniation. If an easily dissectible cleft offers a space for lateral expansion, however, the mass can extend to either side, dissecting the loose attachments.

Trabeculations of connective tissue bind the dura to the dorsal surface of the posterior longitudinal ligament. This attachment is firmest along the lateral edges. Numerous venous cross connections of the epidural sinuses pass between the dura and the ligament. The venous elements are the most ubiquitous structures among the components related to the vertebral articulations.

Although not frequently included in anatomic discussions of the spine, an additional structure travels deep to the posterior longitudinal ligament, extending laterally and posteriorly to surround the dura of the cauda equina. It has been termed the *peridural membrane,* first by Dommissee in 1975[26] and later by Wiltse.[27] The basivertebral veins cross the peridural membrane because it offers no obstruction to vascular communication between the intraosseous vessels of the vertebral body and the epidural space. Its possible clinical significance is that it may provide a containing membrane for herniated discs or hematomas, which may be noted on advanced imaging such as computed tomography (CT) or magnetic resonance imaging (MRI) as a delimiting barrier to the pathology.

Relationships of the Roots of the Spinal Nerves

The dorsal and ventral nerve roots pass through the subarachnoid space and converge to form the spinal nerve at approximately the level of its respective intervertebral foramen. Owing to the ascensus spinalis—the apparent cranial migration of the distal end of the spinal cord during development that actually arises from differential growth of the lower parts of the vertebral column—the course of the nerve roots becomes longer and more obliquely directed in the lower lumbar segments. In the cervical region, the nerve root and the spinal nerve are posteriorly related to the same corresponding intervertebral disc; in other words, the nerve root exits the spinal canal at the same level it branches from the spinal cord.

In the lumbar region, a different situation prevails. The nerve roots contributing to the cauda equina travel an almost vertical course over the dorsum of one intervertebral disc to exit with the spinal nerve of the foramen one segment lower. In the cervical and lumbar regions, dorsal or dorsolateral (i.e., paracentral) protrusions of disc material affect the descending rather than exiting nerve root. When the meningeal coverings

(dura) blend with the epineurium, the nerve components become extrathecal. The actual point of this transition is variable but usually occurs in relation to the distal aspect of the dorsal root ganglion.

The nerve root is intimately related to the pedicle of the vertebra. Ugur and colleagues[28] found no distance between the upper cervical pedicles and their corresponding nerve roots in 20 cadaveric spines, whereas there was a slight distance in 4 of the 20 specimens in the lower cervical region. For all specimens, the distance from the nerve root to the inferior aspect of the upper pedicle ranged from 1 to 2.5 mm. The distance from the medial aspect of the pedicle to the dural sac ranged from 2.4 to 3.1 mm. A similar relationship between the thoracic nerve roots and pedicle exists.[29] The distance from the pedicle to the superior nerve root in the thoracic spine ranges from 1.5 to 6.7 mm, and the distance from the pedicle to the inferior nerve root, 0.8 to 6 mm. Ebraheim and colleagues[30] measured these distances in the lumbar spine, finding a mean distance of 1.5 mm from the pedicle to the inferior nerve root, 5.3 mm from the pedicle to the superior nerve root, and 1.5 mm from the medial pedicle wall to the dura.

Of particular interest is the distribution of epidural fat around and within the intervertebral foramen. This fat has a firm character and forms a mechanically supportive "bushing" for structures entering and leaving the spinal canal. A prominent extension of this fat body also follows the inferior and ventral surfaces of each lumbar nerve. It is interposed between the root and the external surfaces of the pedicle and vertebral body that define the inferior part of the intervertebral foramen. Its amelioration of the downward and ventral distraction of the nerve that accompanies the spine and lower limb motions is obvious. Histologically, it is composed of uniform cells that are contained within a fine membrane (perhaps the elusive peridural membrane).[31] There is no fibrous tissue in normal epidural fat and only tenuous attachments to the dura.

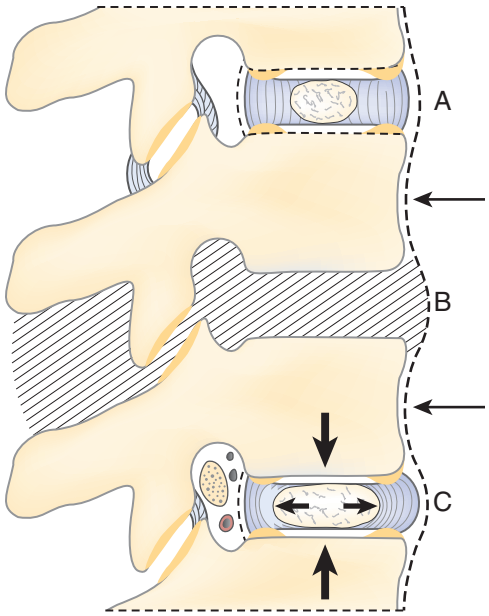

FIG. 2.16 Three aspects of the relational anatomy of the disc. *A* shows the topographic arrangement of the normal disc with the apophyseal ring and perforated chondral plate in relation to the nucleus pulposus and the anulus. *B* indicates the inclusions of the motor segment as originally described by Junghanns *(cross-hatched area)*. *Arrows* define the limits of the motor segment proposed here. *C* indicates the dissipation by the lateral thrust in a compressed disc. Related anatomy of the intervertebral foramen is also indicated. The two structures passing ventral to the spinal nerve are the sinuvertebral nerve and the artery. The other vessels are veins.

Intervertebral Foramen

The intervertebral foramen is the aperture that gives exit to the segmental spinal nerves and entrance to the vessels and nerve branches that supply the bone and soft tissues of the vertebral canal. It is superiorly and inferiorly bounded by the respective pedicles of the adjacent vertebrae. Its ventral and dorsal components involve the two major intervertebral articulations. The dorsum of the intervertebral disc, covered by the lateral expansion of the posterior longitudinal ligament, provides a large part of its ventral boundary, whereas the joint capsule of the articular facets and the ligamentum flavum contribute the major parts of its dorsal limitation. Along with the root, the remaining space is filled with loose areolar tissue and fat (Fig. 2.16).

However ample the overall dimensions of the intervertebral foramen may be, its elliptical nature is responsible for many of its relational problems. In the lumbar region, the vertical diameter of the foramen ranges from 12 to 19 mm; this undoubtedly accounts for the fact that a complete collapse of the disc may produce little or no evidence of nerve compression. The sagittal diameter may be only 7 mm, however, making this dimension exquisitely sensitive to changes. Because the diameter of the fourth lumbar nerve can be just slightly less than 7 mm, the tolerance for pathologic alteration of the bony or connective tissue relationships is restricted.[32]

The existence of additional ligamentous elements in relation to the intervertebral foramen could limit further the space for the exiting spinal nerve. These structures, known as the *transforaminal ligaments,* are frequently found in the lumbar region.[33,34] The transforaminal ligaments are strong, unyielding cords of fibrous tissue that pass anteriorly from various parts of the neural arch to the body of the same or the adjacent vertebra and may be 5 mm wide. Grimes and colleagues[35] found these ligaments span from the nerve root itself. These investigators noted four different bands, the most significant of which spread from the nerve root to the anterior aspect of the facet capsule. Other bands spanned from the nerve root to the superior pedicle, the inferior pedicle, and the intervertebral disc anteriorly.

In the cervical spine, the space available for the exiting nerve root may be compromised by structures just lateral to the foramen. In 10 adult human cadaveric specimens, Alleyne and colleagues[36] found the dorsal root ganglia of the C3 to C6 spinal nerves to be slightly compressed by the ascending vertebral artery. This compression was most pronounced at the C5 level, which the authors suggested as a possible explanation for the greater susceptibility of this nerve to iatrogenic injury during procedures such as laminoplasty.

Lumbosacral Nerve Root Variations

Numerous anatomic variations in the relationships of the lumbosacral nerve roots can exist. These variations may help explain seemingly anatomically inconsistent neurologic findings with compressive disorders such as herniated discs or lateral stenosis.

The most common variation involves atypical origins, or foraminal exits, of individual lumbosacral roots. Although myelographic studies indicated only a 4% incidence of lumbosacral root anomalies, an anatomic study by Kadish and Simmons[37] reported an incidence of 14%. The L5-S1 level is the most commonly involved. Observations by these authors provided four types of variations: (1) intradural interconnections between roots at different levels, (2) anomalous levels of origin of nerve roots, (3) extradural connections between roots, and (4) extradural division of nerve roots. Furthermore, nerve roots may be conjoined, in which two adjacent roots share a common dural envelope as they leave the dural sac.[38] The bifurcation of conjoined roots can occur close to the intervening pedicle, creating a secondary axilla, which may be involved in the etiology of neuropathy. The L5-S1 segment is the most common for presence of a conjoined nerve root. Although the diagnosis of a conjoined nerve root is often made during surgery, clinical suspicion should be raised in a patient with a herniated disc with symptoms corresponding to two dermatomes.

A source of confusing neurologic findings may relate to the variant anatomy of the furcal nerve. The name *furcal nerve* has been applied to the fourth lumbar nerve because it exhibits a prominent bifurcation to contribute to the lumbar plexus (femoral and obturator nerves) and sacral plexus (lumbosacral trunk). Kikuchi and Hasue[39] found that it is often indefinite in its intradural affinities, frequently exhibiting two dorsal root ganglia that have distinct root sources at the conus medullaris. They proposed that when symptoms indicate the involvement of two levels, suspicion should be directed toward four possible causes: (1) two roots compressed by a single lesion, (2) the presence of two lesions, (3) the anomalous emergence of two roots through the same foramen, or (4) the existence of the peculiarly doubled components of the furcal nerve (Fig. 2.17).

Infrequently, variant "fixation" alters the expected sequences of nerve root exit. In a *prefixed* lumbosacral plexus, the furcal nerve (the division between the lumbar and sacral plexuses) exits through the third lumbar foramen, and the preceding and subsequent nerves exit one vertebral level higher than in the conventional distribution. Conversely, in the *postfixed* plexus, the furcal nerve exits the L5-S1 foramen, and the lumbosacral nerve sequence is all one level lower than usually described.[40]

Although Kadish and Simmons[37] noted that the existence of anomalous interconnections between nerve root levels dispels any notion of "absolute innervation," Parke and Watanabe[41] showed that there is a consistent system of intersegmental connections between the roots of the lumbosacral nerves. They described an epispinal system of motor axons

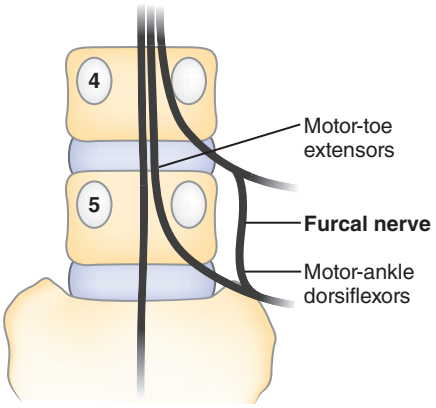

FIG. 2.17 Cross connection L4 and L5 nerve roots (spinal nerves) in the extraforaminal region through the furcal nerve. (Modified from McCulloch JA, Young PH. *Essentials of Spinal Microsurgery.* Philadelphia: Lippincott-Raven; 1998:390.)

that courses among the meningeal fibers of the conus medullaris and virtually ensheathes its ventral and lateral funiculi between the L2 and S2 levels. These nerve fibers apparently arise from motor neuron cells of the ventral horn gray matter and join spinal nerve roots caudal to their level of origin. In all the spinal cords studied, many of these axons commingled at the cord surface to form an irregular group of ectopic rootlets that could be visually traced to join conventional spinal nerve roots at one to several segments inferior to their original segmental level (Figs. 2.18 and 2.19). Occasionally, these ventral ectopic rootlets course dorsocaudad to join a dorsal (sensory) nerve root. Although the function and the clinical significance of this epispinal system of axons have yet to be explained, a given segmental level of motor nerve cells may contribute fibers not only to an adjacent segment, but also to nerve roots of multiple inferior levels.

An additional variant aspect of the lumbosacral nerve roots concerns the relative location of their dorsal root ganglia. Almost all anatomic illustrations depict the lumbosacral dorsal root ganglia in an intraforaminal position, the central part of the ganglion lying between the adjacent pedicles. Hasue and colleagues[42,43] found, however, that the lumbosacral dorsal root ganglia may also be positioned internal or external to their foramina. They designated the internal positions as *subarticular* or *sublaminar,* depending on their relationship to these structures roofing the spinal canal, and found that approximately one-third of the L4 and L5 ganglia are in the subarticular position. If the ganglion is subarticular, it is in the lateral recess and subject to the direct consequences of a lateral stenosis.

Innervation of the Spine

The distribution of the medial branches of the dorsal ramus of the spinal nerve to the external periosteum, facet joints, and ligamentous connections of the neural arches (and the general ramification of the "recurrent" sinuvertebral nerve, known as the nerve of Luschka or *ramus meningeus,* to structures related

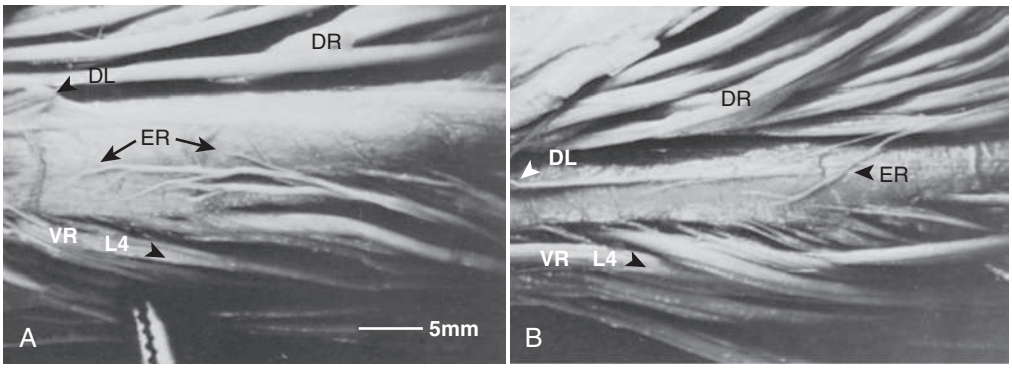

FIG. 2.18 (A) Photomicrograph of the lateral surface of human conus medullaris showing ectopic rootlets (ER) that receive axons from cells in the ventral horn nuclei. Note origin of some fibers at the level of L4 motor nuclei extends caudad to join S1 root. (B) Photomicrograph showing ER passing posteriorly to join a dorsal (sensory) nerve root (DR). DL, last denticulum of denticulate ligament; VR, ventral root.

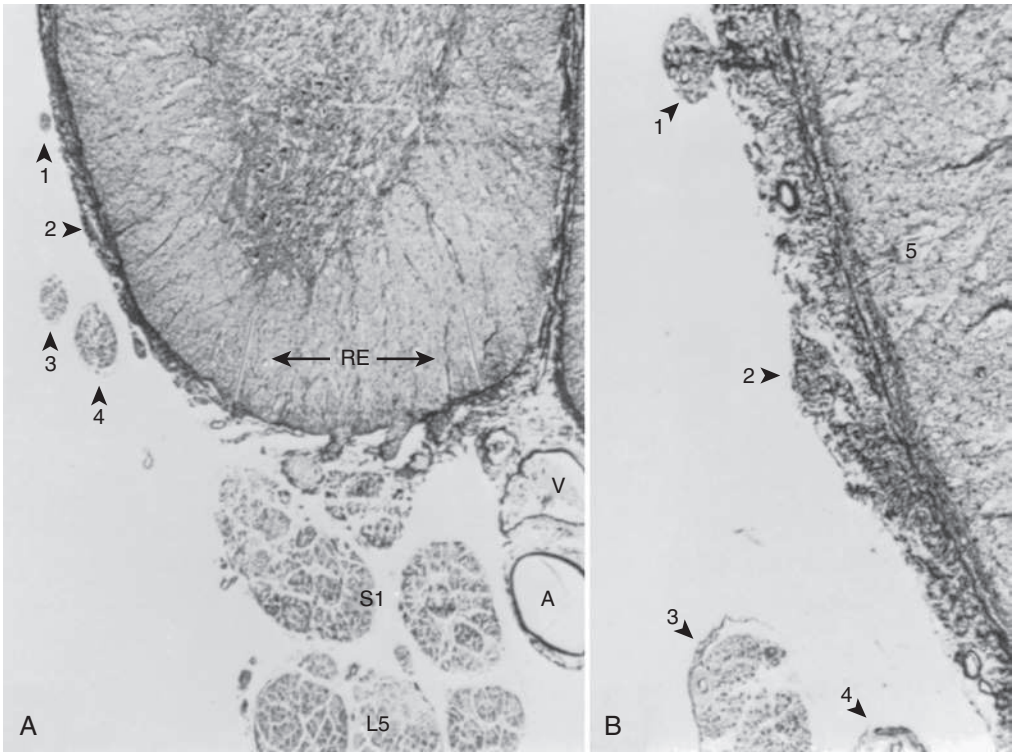

FIG. 2.19 Photomicrographs of a 5-μm cross section from the conus medullaris at the S1 level showing ectopic rootlets in various stages characteristic of their emergence from the ventrolateral surface of the cord. (A) Rootlets just appearing on the pial surface (*1, 2*) eventually join free rootlets (*3, 4*) that have originated from higher levels. The conventional roots of L5 and S1 nerves have emerged from the typical zone of rootlet emergence (RE). *A and V,* Anterior spinal artery and vein. (B) Higher power photomicrograph of (A) shows greater detail of rootlet emergence. The entire ventrolateral pia is intertwined with epispinal axons, of which only a few form ectopic rootlets. Dense circular band of pial straps (*5*) is characteristic of the region of the epispinal fibers. ([A], ×33. [B], ×133.) (From Parke WW, Watanabe R. Lumbosacral intersegmental epispinal axons and ectopic ventral nerve rootlets. *J Neurosurg.* 1967;67:269-277.)

to the spinal canal) has been known for more than a century. The recognition that degenerative disease of the intervertebral disc and its consequences is a major cause of low back pain has stimulated more inquiries, however.

Many investigations have attempted to delineate the origins, terminal ramifications, and nerve ending types of the sinuvertebral nerve, often with contradictory results. More comprehensive works[22,44-51] have agreed on the general source and composition of this nerve and have described it as variously branching from the distal pole of the dorsal root ganglion, the initial part of the spinal nerve, or the dorsal sections of the rami communicantes. It was recognized that a multiple origin is common, especially in the lumbar region, and small autonomic branches often have a separate course, entering the intervertebral foramen independently. The extent and complexity of the relationships of the sinuvertebral nerve

within the spinal canal have engendered much argument, however, particularly concerning the segmental range of the individual nerve ramifications.

In illustrations based on dissections, Bogduk and colleagues[44] and Parke[52] agreed that each nerve supplies two intervertebral discs via superiorly and inferiorly directed branches—the inferiorly directed branch ramifying over the dorsum of the disc at the level of entry and the longer, superiorly directed branch coursing along the edge of the posterior longitudinal ligament to reach the disc of the next superior level (Fig. 2.20). Dissections identify mainly the larger ramifications. Smaller fibers are usually localized with staining techniques. Conventional methods of staining using silver or lipotrophic stains have given controversial results, however, because of a lack of specificity.

Groen and colleagues,[53] using a highly specific acetylcholinesterase staining method on large cleared sections of fetal human spines, resolved many conflicts concerning the ramifications of the nerves supplying spinal structures. They found that, in contrast to most previous reports, the human sinuvertebral nerves were almost exclusively derivatives of the rami communicantes close to their connections with the spinal nerves. These origins were fairly consistent throughout the length of the thoracolumbar sympathetic trunk, but in the cervical region they were also derived from the perivascular plexus of the vertebral artery.

Five sinuvertebral nerves have been observed passing into one intervertebral foramen. Typically, the group consists of one thick nerve (perhaps the one seen in most conventional dissections) and several fine fibers. The thick, or predominant, sinuvertebral nerve is often absent, however, in the upper cervical and sacral regions. The major sinuvertebral element enters the foramen ventral to the spinal ganglion and gives off some fine branches at this point. As the nerve enters the spinal canal, the major branch usually divides into rami that course in approximation to the distribution of the posterior central branches of the segmental artery, with a long ascending element and a shorter descending one. From these branches, one to three coiled rami supply the ventral dura.

The acetylcholinesterase technique used by Groen and colleagues[53] made it possible to delineate details of the plexus of the posterior longitudinal ligament. The work of these authors supports the idea that the posterior longitudinal ligament is highly innervated by an irregular plexiform distribution of fibers that have a greater density in the ligament expansions dorsal to the discs. These authors were able to note the primary direction, length, and "termination area" of the branches of a single segmental sinuvertebral nerve. They classified the variations of individual nerves as follows: (1) ascending one segment, (2) descending one segment, (3) dichotomizing toward one segment caudal and one segment cranial or horizontal, (4) ascending two or more segments, and (5) descending two or more segments (see Fig. 2.20). The existence of the latter two categories, although they are not as common as the others, shows that the sinuvertebral nerve can supply more than two adjacent segmental levels. A basis for the poor pain localization of an offending disc may be related to the generous distribution possible in the individual sinuvertebral nerve. The large totomounts treated with acetylcholinesterase also showed that the patterns of sinuvertebral nerve distribution to the posterior longitudinal ligament did not display significant regional variations apart from an expected pronounced diminution in the plexus density in the immovable lower sacral region.

The posterior longitudinal ligament is highly innervated with complex encapsulated nerve endings and numerous low-myelinated free nerve endings (Fig. 2.21). The lateral expansion of the posterior longitudinal ligament extends through the intervertebral foramen covering all the dorsal and most of the dorsolateral aspects of the disc. The elevation of this thin, highly innervated strap of connective tissue may provide a significant component of the pain manifest in acute disc protrusions.

The probable range of diverse functions of the sinuvertebral nerve may be indicated by the analysis of its cross-sectional composition. Stained preparations taken from a section near

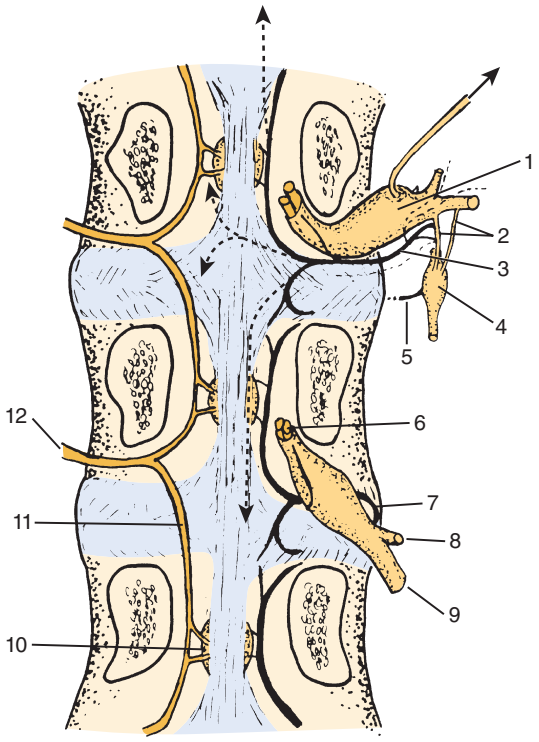

FIG. 2.20 Schema of major intraspinal distribution of dorsal central branches of segmental vertebromedullary arteries and distribution and source of the sinuvertebral nerves. The pattern of the nerve shown entering the superior foramen is derived from the data provided by Groen and colleagues.[53] *Dotted lines* show a composite of the variant ranges (*arrows* indicate two or more segments) and ramifications tabulated by these authors. The nerve entering the inferior foramen shows the extent and distribution described in previous reports. *1,* Dorsal root ganglion. *2,* Rami communicantes. *3,* Sinuvertebral nerve and its origin according to Groen and colleagues. *4,* Autonomic ganglion. *5,* Nerve to anterior longitudinal ligament. *6,* Spinal nerve roots. *7,* Sinuvertebral nerve arising from distal pole of ganglion (thought to be its most common source before report of Groen and colleagues). *8,* Dorsal primary ramus of spinal nerve. *9,* Ventral primary ramus of spinal nerve. *10,* Arteries entering basivertebral sinus to supply cancellous bone. *11,* Descending dorsal central branch of vertebromedullary (spinal) artery. *12,* Ventral branch of vertebromedullary artery.

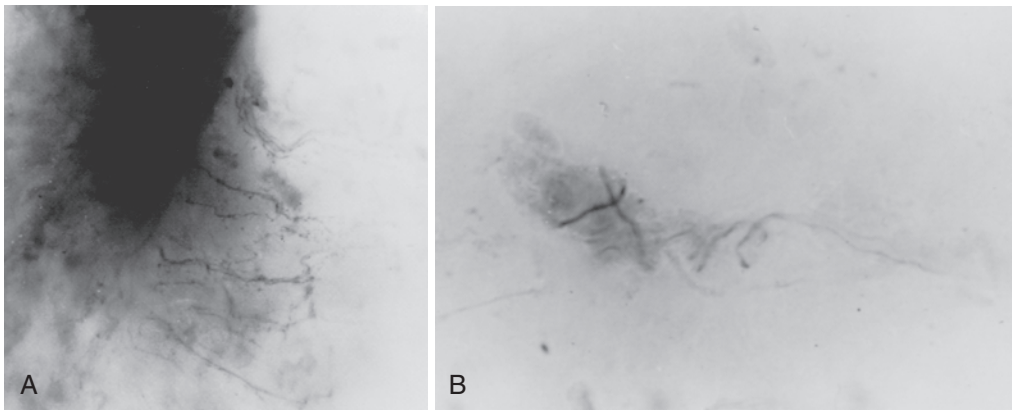

FIG. 2.21 Photomicrographs of nerve endings in posterior longitudinal ligament of a dog. (A) Section of ligament dorsal to a lumbar intervertebral disc. The dark area is the central strap of the ligament, and the light area is the thin lateral expansion over the dorsum of the disc. These fine nerve endings are characteristic of those in known nociceptors. (B) Complex nerve ending from posterior longitudinal ligament. This type of ending is believed to be a transducer of mechanical deformation for postural senses. (Methylene blue vital tissue stain: [A], ×300; [B], ×500.)

the nerve origin show many small myelinated fibers, although some myelin sheaths are greater than 10 µm in diameter.[54] Many of the smaller fibers are postganglionic efferents from the thoracolumbar autonomic ganglia that mediate the smooth muscle control of the various vascular elements within the spinal canal, and many of the larger fibers are involved in proprioceptive functions. Concerning the latter, Hirsch and colleagues[46,55] found numerous complex encapsulated nerve endings in the posterior longitudinal ligament (see Fig. 2.21B). It is assumed that these may be associated with the larger myelinated fibers whose postganglionic axons enter the cord to mediate postural reflexes because similar fibers in the cervical region of cats have been shown to be important in tonic neck reflexes.[56] It seems, however, that the smaller fibers making up the bulk of the sinuvertebral nerve are afferents, associated with simple, nonencapsulated, or "free" nerve endings that are generally regarded as nociceptive (see Fig. 2.21A).

The fact that the sinuvertebral nerve carries pain fibers has been amply shown by clinical and laboratory experimentation. Direct stimulation of tissues known to be served by the nerve elicits back pain in humans. Pedersen and colleagues[54] showed that stimulation of these tissues in decerebrate cats resulted in blood pressure and respiratory changes similar to those elicited by noxious stimuli to known pain receptors in other areas of the body.

Disagreement exists over whether the anulus itself is innervated and, if so, how extensively. The classic work of Hirsch and colleagues[55] claimed that nerve endings are only in the dorsal aspect of the most superficial layer of the anulus, and these presumably are from branches of the same nerve fibers that innervate the overlying expansions of the posterior longitudinal ligament.

Pedersen and colleagues,[54] Stilwell,[57] and Parke[52] have failed to show nerve endings in the anulus. Because the connective tissue structures intimately related to the disc show a profusion of nerve endings, Parke[52] assumed that their disruption could account for discogenic pain. Inappropriate methodology may account for the failure to show intradiscal nerves. Malinsky,[49] Bogduk and colleagues,[44,45] and Yoshizawa and colleagues[58] published accounts showing nerve fibers in the outer lamina of the anulus. This work has now been supported by the highly specific acetylcholinesterase method of Groen and colleagues.[53]

Most descriptions of the sinuvertebral nerve indicate that the major meningeal fibers to the spinal dura are distributed to its ventral surface.[59] The median dorsal dural surface has been regarded as virtually free of nerve fibers, a convenience that permits its painless penetration during needle puncture. Although Cyriax[60] claimed that irritation of the ventral dura during protrusion of the nucleus may contribute to discogenic pain, a sufficient distortion of the nerve fibers on the movable or unattached dura does not seem likely. The coiled configuration of these dural contributions of the sinuvertebral nerve, noted by Groen and colleagues,[61] may indicate a compensation to permit a degree of dural movement without placing traction on these nerves.

Parke and Watanabe[62] observed that the ventral lower lumbar dura is often fixed to the ventral canal surface by numerous connective tissue fibers, most firmly fixed at the margins of the lower lumbar discs. These apparently acquired adhesions are not to be confused with the ligaments of Hofmann, which are normal straps of tissue connecting the dura to the ventral canal surface that have been obliquely positioned by the developmental cranial traction of the dura and its contents. This observation has been supported by a series of dissections by Blikra,[63] who was seeking a rationale for lower lumbar intradural disc protrusions. His analysis showed that in some cases the dura may be sufficiently fixed to the ventral surface of the canal, particularly at the L4–L5 level, for protruding nucleus material to rupture the ventral dura. Parke and Watanabe,[62] by microscopic analysis of sections of the dura that had been forcibly freed from these adhesions overlying the fourth or fifth lumbar disc, showed disruption of the nerve fibers bound in the adhesion. In the numerous cases in which such adhesions are present, the

forceful elevation of the dura by a disc protrusion may provide an adjunctive source of the discogenic pain.

Spinal Motion Segment

The inclusion of all articular tissue, the overlying spinal muscles, and the segmental contents of the vertebral canal and intervertebral foramen into a single functional and anatomic unit was first suggested by Junghanns.[64,65] Originally called the "motor" segment, this unit represents a useful concept that stresses the developmental and topographic interdependence between the fibrous structures that surround the intervertebral foramen and the functioning of the structures that pass through it. Although the 23 or 24 individual motion segments must be considered in relation to the spinal column as a whole, no congenital or acquired disorder of a single major component of a unit can exist without affecting first the functions of the other components of the same unit and then the functions of other levels of the spine.

Although Junghanns[64] defined the unit primarily in terms of the movable structures making up the intervertebral articulations, a logical, if not necessary, extension of the motion segment concept should include some aspect of the vertebral elements. DePalma and Rothman[66] included both adjacent vertebrae in their illustration of the unit, but depiction of the unit concept is improved by incorporating only the opposing superior and inferior halves of each vertebra, eliminating redundancy (see Fig. 2.16). In visualizing the motion segment unit as a musculoskeletal complex surrounding a corresponding level of nervous structures, it must be realized that the intervertebral disc and the facets are but two of the articulations involved. The interosseous fibrous connections that include the interspinous, intertransverse, costovertebral, and longitudinal ligaments and the ligamentum flavum are varieties of syndesmoses.

Nutrition of the Intervertebral Disc

Most descriptive accounts of the intervertebral disc dismiss the subject of its vascular nutrition with a brief mention of the general agreement that the normal adult disc is avascular. The demonstrable truth of this statement may give the impression that the substance of the disc is inert biologically. Experimental evidence has indicated that the normal disc tissue is quite vital and has a demonstrable rate of metabolic turnover.[67,68] In contrast to the nonvascular cartilage in the diarthroses, the cellular elements of the disc cannot receive the blood-borne nutrients through the mediation of the synovial fluid but must rely on a diffusional system with the vessels that lie adjacent to the disc. Diffusion is also the mechanism for removal of products of metabolism from the disc, such as lactic acid.[69]

The qualitative and quantitative aspects of the diffusional nutrition of the disc have been studied.[68-72] The peripheral vascular plexus of the anulus and the vessels adjacent to the hyaline cartilage of the bone-disc interface provide the two sources for the diffusion of metabolites into the disc. Although the interface shows an average permeability of 40%, there is a decreasing centrifugal gradient that starts with an 80% permeability at the center. Because diffusion is the major mechanism that carries small solutes through the disc matrix, the two main parameters affecting this flow are the *partition coefficient,* which defines the equilibrium between the solutes within the plasma and the solutes within the disc, and the *diffusion coefficient,* which characterizes the solute mobility.

The partition coefficient varies with the size and charge of the solute particle. Small uncharged solutes show a near-equilibrium between their plasma and intradiscal concentrations, but because the disc matrix has a predominantly negative charge, anionic solutes have a lower intradiscal concentration in relation to the plasma, whereas the reverse is true for positively charged solutes, whose intradiscal concentration is greater than that of the plasma. Because the range of these effects depends on the concentration of the fixed, negatively charged, larger molecular aggregates (proteoglycans), the partition coefficient is regionally variable within the disc matrix and especially pronounced in the inner annular lamellae and nucleus, where the concentration of proteoglycans is the highest.

Solute mobility (the diffusion coefficient) within the disc is slower than in the plasma because the presence of solids in the form of collagen and proteoglycans impedes diffusional progress. Without regard to charge, the diffusion coefficient within the disc is 40% to 60% of free diffusion within water, and mobility is greatest in the inner anulus and nucleus where the water concentrations are the highest.

Because of the regional differentials in the densities of the fixed charges within the disc, the two vascular sources for disc nutrition vary in their significance in the supply of certain solutes. With respect to the small uncharged particles, there is little difference in the transport potential of either the peripheral or the endplate vascular routes, but because of the greater collective negative charge within the central substances of the disc (from proteoglycans), the interface vasculature is a greater source of cationic solutes, whereas the anions would gain easier access through the peripheral vessels.

The effect of fluid "pumping" under changes in the load applied to the disc is minimal with respect to the transport of small solutes because the matrix has a low hydraulic permeability relative to their higher rates of diffusion. With regard to the larger solutes, however, the pumping may have a more substantial effect.

Metabolic turnover, as indicated by proteoglycan synthesis in discs in dogs, is variable according to age within the range of 2 to 3 years. It is roughly equivalent to that of articular cartilage. The central disc tissues have a low oxygen tension and a high concentration of lactic acid, indicating that the inner disc cell respiration is primarily anaerobic. Because this type of respiration is heavily dependent on glycolytic energy requirements, the interface vasculature must deliver the needed glucose to maintain the central disc cell viability.

Because this interface exchange is precariously dependent on the integrity of the fine vasculature subjacent to the cartilaginous endplate, any change from the optimal state occasioned by age-dependent vagaries in the intrinsic vertebral

vasculature may partly explain the marked predisposition to degenerative changes characteristic of the aging disc. Calcification and sclerosis of the endplate decrease permeability and contact area with the disc space, further contributing to disc degeneration. MRI studies following the movement of contrast medium into the disc have demonstrated a decreased ability of a degenerated disc to accept solutes, both in speed and quantity.[69]

Blood Supply of the Vertebral Column

The descriptions and terminology of the nutritional vessels of the vertebrae vary considerably in anatomy texts. In general, the texts illustrate and discuss the vascularity of a typical thoracic or lumbar vertebra, with a lack of agreement on such basic issues as to whether the vertebral body does[73] or does not[74] receive an anterior supply. In addition, discussions of the vascularization of the atypical (craniocervical, cervical, and sacral) vertebral regions are either superficial or entirely lacking. Much of the information presented here is the result of a de novo investigation by Parke and colleagues,[77] and the terminology ascribed to the vessels is derived from a selection of what seem to be the most descriptive names previously used in the literature.[75-77]

Despite the fact that regional variations may at first seem to thwart the perception of a common pattern of vertebral vascularization, the homologous origin of all vertebral elements nevertheless provides a certain constancy. From a segmental artery, or its regional equivalent, each vertebra receives several sets of nutritional vessels, which consist of anterior central, posterior central, prelaminar, and postlaminar branches. The first and last of these are derived from vessels external to the vertebral column, whereas the posterior central and prelaminar branches are derived from spinal branches that enter the intervertebral foramina and supply the neural, meningeal, and epidural tissues as well. In the mid-spinal region, the internal arteries (i.e., the posterior central and prelaminar branches) provide the greater part of the blood supply to the body and vertebral arch, but reciprocal arrangements may occur, particularly in the cervical region.

This general pattern of the vasculature is best shown in the area between the second thoracic and fifth lumbar vertebrae, where the segments are associated with paired arteries that arise directly from the aorta (Fig. 2.22). Typically, each segmental artery leaves the posterior surface of the aorta and follows a dorsolateral course around the middle of the vertebral body. Near the transverse processes, it divides into a lateral (intercostal or lumbar) and a dorsal branch. The dorsal branch runs lateral to the intervertebral foramen and the articular processes as it continues backward between the transverse processes eventually to reach the spinal muscles. Because the segmental artery is closely applied to the anterolateral surface of the body, its first spinal derivatives are two or more anterior central branches that directly penetrate the cortical bone of the body and that may be traced radiologically into the spongiosa (Figs. 2.23 and 2.24). The same region of the segmental

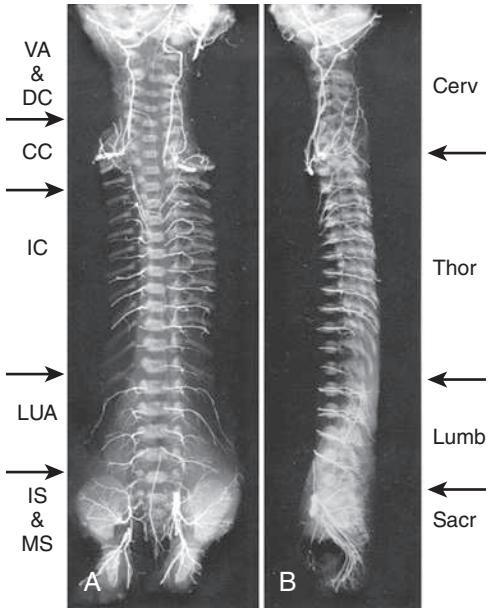

FIG. 2.22 (A) Anteroposterior and (B) lateral radiographs of spine of an 8-month fetus injected with finely divided barium sulfate. Traditional regional subdivisions of the spine are indicated on the *left,* and regional arteries that provide the segmental branches to the individual vertebrae are shown on the *right*. The upper cervical region is supplied by vertebral and deep cervical arteries (VA & DC), the lower cervical and upper two thoracic segments are supplied by the costocervical trunk (CC), and the remaining thoracic vertebrae receive intercostal vessels (IC). The lumbar arteries (LUA) supply their regional vertebrae, and the sacral segments are provided with branches from lateral sacral (LS) and middle sacral (MS) arteries.

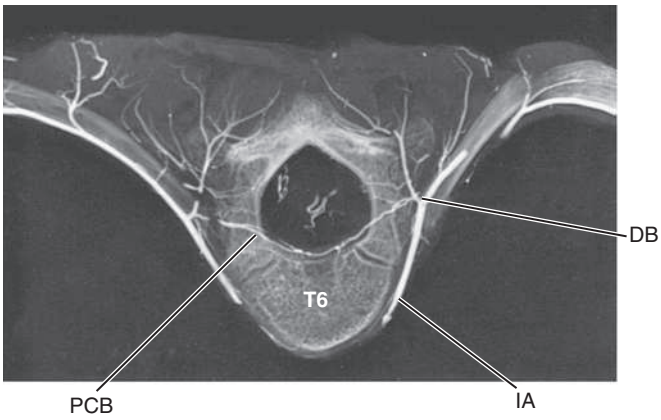

FIG. 2.23 Ventral radiograph of section through T6 of a specimen from a 6-year-old child injected with barium sulfate. The intercostal arteries (IA) give rise to dorsal branches (DB) that provide spinal branches to the vertebral canal and posterior branches to the arch and dorsal musculature. The posterior central branches (PCB) are well shown as they send vessels into the vertebral body. Fine anterior central and anterior laminar and posterior laminar vessels can be seen. Note the neurocentral synchondrosis.

artery also supplies longitudinal arteries to the anterior longitudinal ligament (Fig. 2.25).

After the segmental artery divides into its dorsal and lateral branches, the dorsal component passes lateral to the intervertebral foramen, where it gives off the spinal branch that provides the major vascularity to the bone and contents of the vertebral canal. This branch may enter the foramen as a

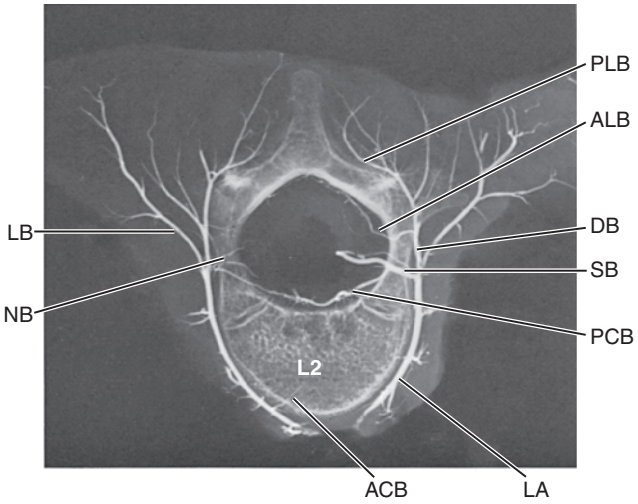

FIG. 2.24 Vertical radiograph of section through lumbar vertebra of a 6-year-old child. The vascularity of the lumbar vertebra may be regarded as the archetypal pattern from which other regions evolved variations. The segmental lumbar artery (LA) gives rise to numerous anterior central branches that penetrate the cortical bone of the body. The spinal branch (SB) sends prominent posterior central branches to the dorsum of the body, whereas the dorsal branch (DB) supplies the anterior (ALB) and posterior (PLB) laminar branches. Neural branches (NB) follow the nerve roots to the cord. In this section, the arteria radicularis magna is seen as a neural branch on the right side. ACB, anterior central branches; LB, lumbar branches; PCB, posterior central branches.

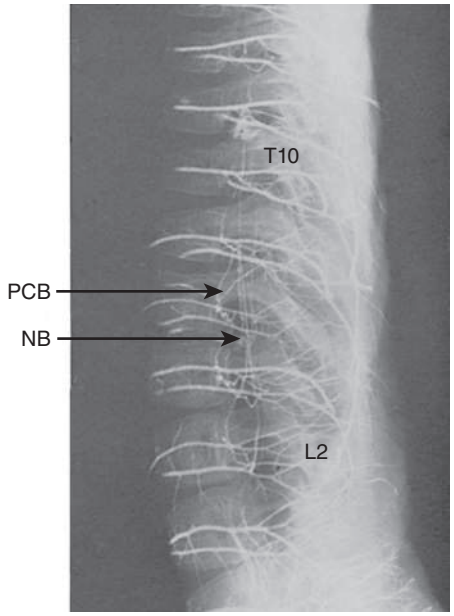

FIG. 2.25 Lateral view of lumbar vertebra shown in Fig. 2.24. Longitudinal anastomoses of posterior central branches (PCB) can be appreciated, and the disposition of neural branches (NB) is clarified. The lumbar arteries also supply small longitudinal branches to the anterior longitudinal ligament.

single vessel, or it may arise from the dorsal segmental branch as numerous independent rami. In either case, it ultimately divides into a triad of posterior central, prelaminar, and intermediate neural branches. The posterior central branch passes over the dorsolateral surface of the intervertebral disc and divides into a caudal and a cranial branch, which supply the two adjacent vertebral bodies.

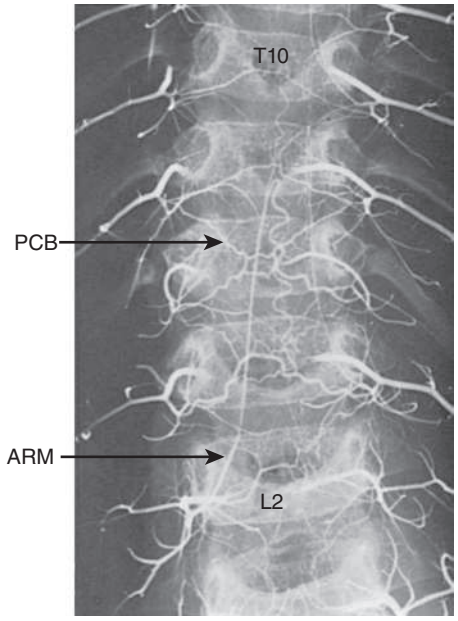

FIG. 2.26 Anteroposterior arteriogram of lower thoracic and upper lumbar vertebrae in a 6-year-old child. The interlocking anastomotic pattern formed by the posterior central branches (PCB) and the manner in which four branches converge over the center of the dorsum of the body of each vertebra are well shown. The arteria radicularis magna (ARM), which forms a major contribution to the anterior spinal artery of the cord, can be seen arising at L2.

Coursing in the same plane as the posterior longitudinal ligament, these branches vascularize the ligament and the related dura before entering the large concavity in the central dorsal surface of the vertebral body. The dorsum of each vertebral body is supplied by four arteries derived from two intervertebral levels. As these vessels tend to converge toward the dorsal central concavity, where they are cross-connected with their bilateral counterparts, their connections with other vertebral levels give the appearance of a series of rhomboid anastomotic loops (Fig. 2.26) that illustrate the extent of collateral supply to a single vertebra.

The prelaminar branch of the spinal artery follows the inner surface of the vertebral arch, giving fine penetrating nutrient branches to the laminae and ligamenta flava, while also supplying the regional epidural and dorsal tissue. The neural branches that enter the intervertebral foramen with the above-described vessels supply the pia-arachnoid complex and the spinal cord itself. In the fetus and the adult, the neural or radicular branches are not segmentally uniform in their size or occurrence. Although all spinal nerves receive fine twigs to their ganglia and roots, the major contributions to the cord are found at irregular intervals. Several larger radicular arteries may be discerned in the cervical and upper thoracic regions, but the largest, the arteria radicularis magna (artery of Adamkiewicz[76]), is an asymmetrical contribution from one of the upper lumbar, or lower thoracic, segmental arteries. It travels obliquely upward with a ventral spinal root to join the anterior spinal artery in the region of the conus medullaris. Radicular contributions to the dorsal spinal plexus may usually be distinguished by their more tortuous course (see Figs. 2.25 and 2.26).

After the dorsal branch of the segmental artery has provided the vessels to the intervertebral foramen, it passes between the transverse processes, where it gives off a fine spray of articular branches to the joint capsule of the articular processes. Immediately distal to this point, it divides into dorsal and medial branches; the larger, dorsal branch ramifies in the greater muscle mass of the erector spinae, whereas the medial branch follows the external contours of the lamina and the spinous process. This postlaminar artery supplies the musculature immediately overlying the lamina and sends fine nutrient branches into the bone. The largest of these branches penetrates the lamina through a nutrient foramen located just dorsomedial to the articular capsule.

Regional Variations in Spinal Vasculature

Only vertebrae that are related to the aorta have access to direct segmental branches. The cervical, upper thoracic, and sacral regions have different patterns in their segmental supply that affect to various extents the arrangements of the finer vessels. In an arteriogram of the entire fetal spine (see Fig. 2.22), it can be seen that the greater part of the cervical region is supplied by the vertebral arteries and the deep cervical arteries. An intermediate area that usually includes the lower two cervical and upper two thoracic vertebrae is supplied by costocervical branches of the subclavian artery that are of variable pattern and often bilaterally dissimilar. From T2 to L3, the typical segmental arrangement prevails, but in the sacral area lateral sacral branches of the hypogastric artery and middle sacral branches assume the function of supporting the nutritional vasculature to the vertebral elements.

Cervical Region

The general patterns of the arterial supply with respect to the typical cervical vertebrae are schematically represented in Figs. 2.27A and 2.28.[77] The vertebral arteries represent a lateral longitudinal fusion of the original segmental vessels and provide a ventrally coursing anterior central artery and a medially directed posterior central artery to each subaxial vertebral element. The anterior spinal plexus is best developed in the cervical region, where it exhibits a rectangular mesh of vessels in which the transverse members (anterior central arteries) run along the upper ventral edges of their respective intervertebral discs. The conspicuousness of this plexus reflects the fact that it also serves the cervical prevertebral musculature. The thyrocervical and costocervical trunks assist in the lower cervical region, and the upper cervical part of the plexus receives contributions from the ascending pharyngeal arteries (Fig. 2.29).

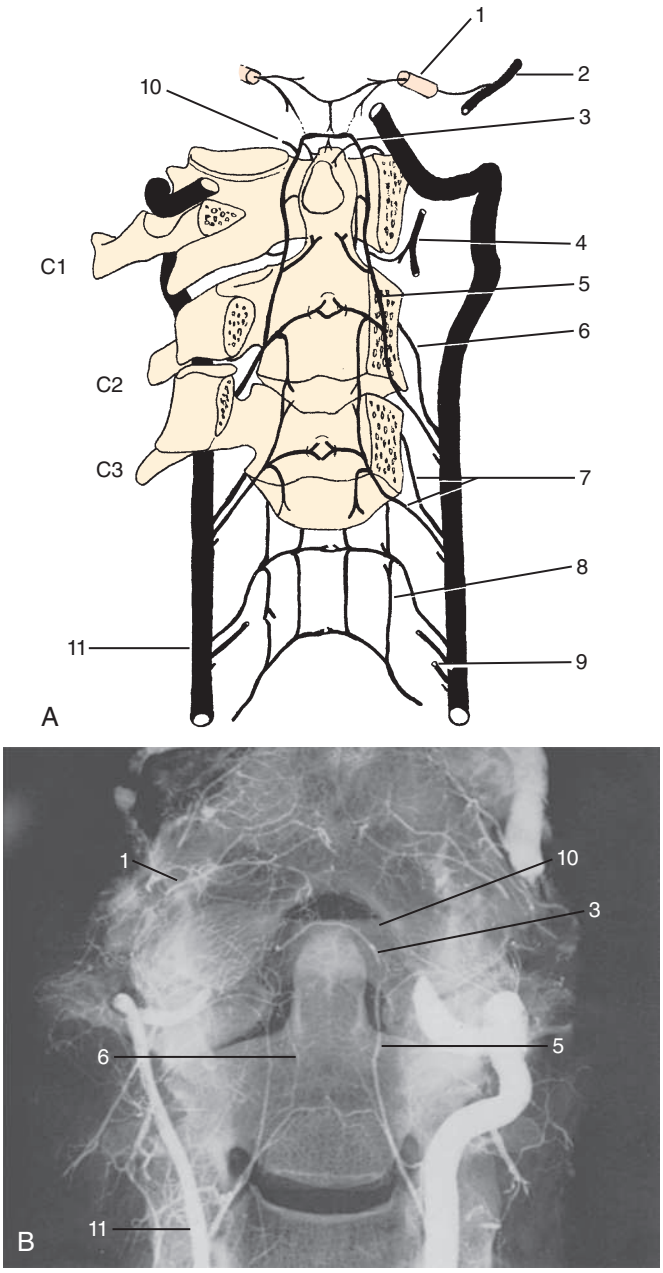

FIG. 2.27 (A) Schema of arterial supply to bodies of the upper cervical vertebrae and the odontoid process. Numerical designations apply to the same structures in (B). *1,* Hypoglossal canal passing meningeal artery. *2,* Occipital artery. *3,* Apical arcade of odontoid process. *4,* Ascending pharyngeal artery giving collateral branch beneath anterior arch of atlas. *5,* Posterior ascending artery. *6,* Anterior ascending artery. *7,* Precentral and postcentral arteries to typical cervical vertebral body. *8,* Anterior spinal plexus. *9,* Medullary branch of vertebral artery; radicular, prelaminar, and meningeal branches are also found at each level. *10,* Collateral to ascending pharyngeal artery passing rostral to anterior arch of atlas. *11,* Left vertebral artery.

Atlantoaxial Complex

With their complex phyletic and developmental history, the components of the atlantoaxial articulation display the most atypical vascular pattern of all the vertebrae. Although the odontoid process represents the definitive centrum of the first cervical vertebra, it develops and remains as a projecting process of the axis that is almost completely isolated from the rest of the atlas by synovial joint cavities. Its fixed position relative to the rotation of the atlas and the adjacent sections of the vertebral arteries prevents formation of major vascularization by direct branches at its corresponding segmental level.

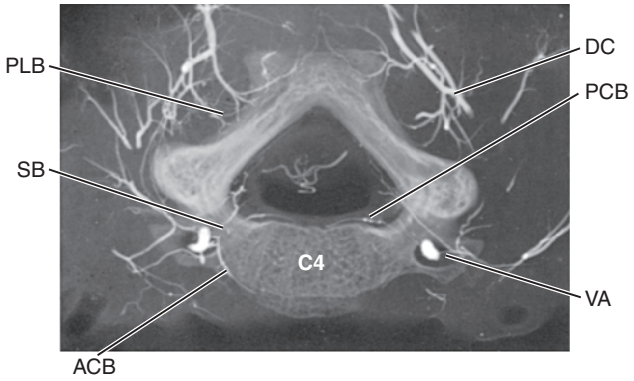

FIG. 2.28 Vertical radiograph of section through fourth cervical vertebra of a 6-year-old child, showing vascularity. The deep cervical artery (DC) provides the posterior laminar branches (PLB). Vertebral arteries show numerous anastomoses with other cervical arteries and send spinal branches (SB) that form posterior central branches (PCB) of the body and anterior lamina branches of the arch. Anterior central branches (ACB) may arise independently from the vertebral arteries (VA).

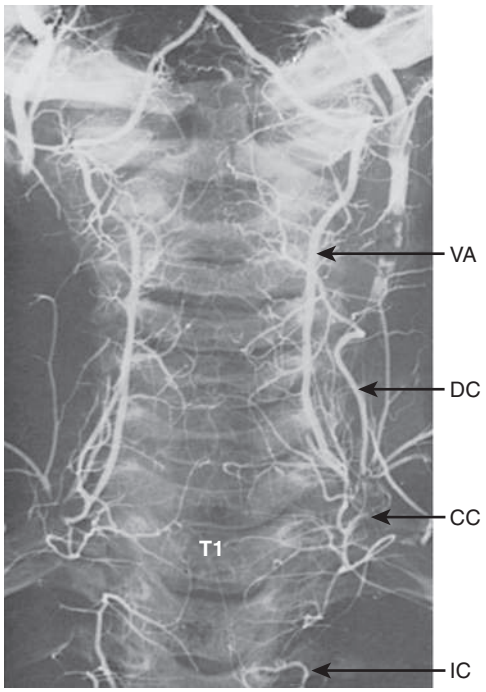

FIG. 2.29 Arteriogram of cervical and upper thoracic regions of the 6-year-old spine seen in Figs. 2.23 and 2.24. The vertebral artery (VA) and deep cervical branch (DC) of the costocervical trunk (CC) supply segmental branches to each vertebra. The costocervical artery also typically supplies T1 and T2, but in this case T2 receives a high intercostal (IC) branch on the left side.

One might assume that the nutrition of the dens would easily be accomplished by interosseous vessels derived from the spongiosa within the supporting body of the axis. It is axiomatic, however, that the vascular patterns of bones were developmentally established to supply the original ossification centers within the nonvascular cartilage matrices, and despite the eventual obliteration of the separating cartilage, the original patterns of vascularity generally prevail throughout life. The transient cartilaginous plate, which represents an incipient intervertebral disc between the atlas and axis, does not calcify until the latter half of the first decade and effectively prevents the development of any significant vascular communication between the axis centrum and the odontoid process. Occasionally, noncalcified remnants of this plate may persist in adults; although there may be a stable union between the two elements, a radiolucent area may suggest a fracture nonunion or a "false" os odontoideum.

In light of the foregoing facts, it was not unexpected that the investigations of Schiff and Parke[78] revealed that the odontoid process was supplied primarily by pairs of anterior and posterior central branches that coursed upward from the surfaces of the body of the axis and were derived from the vertebral arteries at the level of the foramen of the third cervical nerve. The posterior ascending arteries are the larger members of these two sets of vessels and usually arise independently from the posteromedial sides of their respective vertebral arteries. The individual artery enters the vertebral canal through the foramen between the second and third vertebrae and trifurcates on the dorsum of the axis body. The typical posterior central perforators course medially passing deep to the posterior longitudinal ligament (called the *tectorial membrane* in the craniocervical region) to penetrate into the spongiosa of the axis. A small descending branch anastomoses distally with vessels of the next lower segment.

The major part of the posterior ascending artery crosses the dorsal surface of the transverse ligament of the atlas about 1.5 mm lateral to the neck of the odontoid process (see Fig. 2.27). Dorsal to the alar ligament, it sends an anterior anastomotic branch over the cranial edge of this ligament to form collateral connections with the anterior ascending artery. The posterior ascending artery continues on a medial course to meet its opposite counterpart and forms the apical arcade that arches over the apex of the odontoid process.

The smaller anterior ascending arteries arise from the anteromedial aspect of the vertebral arteries and pass to the ventral surface of the axis body. Fine medial branches send perforators into the substance of the vertebral body and meet in a median anastomosis typical of the anterior central branches of the lower cervical region. The rostral continuance of the anterior ascending arteries brings them dorsal to the anterior arch of the atlas. Here each artery sends numerous fine perforators into the anterolateral surfaces of the neck of the odontoid process and terminates in a spray of vessels that supply the synovial capsule of the median atlantoaxial joint.

Fine branches from the anterior and posterior ascending arteries also assist in the nutrition of the syndesmotic relations of the atlantoaxial and craniovertebral articulations. The main blood supply to the atlanto-occipital joint is provided by a complex of vessels derived from the vertebral and occipital arteries.

Collateral vessels pass over and under the anterior arch of the atlas to anastomose with the apical arcade and ascending arteries.[79] These are derived from some component of the external carotid system. These vessels are branches of the ascending pharyngeal artery, which has a nearly ubiquitous distribution in the upper pharyngeal region and sends a branch along the inner aspect of the carotid sheath that, on

reaching the base of the skull, becomes recurrent and descends deep to the prevertebral fascia to supply the upper prevertebral cervical muscles and anastomose with the anterior spinal plexus. Numerous small-bore vessels that descend from the rim of the foramen magnum to anastomose with the apical arcade are derivatives of a meningeal branch of the occipital artery that enters the skull through the hypoglossal canal (see Fig. 2.27). Its descending branches supply the periforaminal dura, the tectorial membrane and alar and apical ligaments, and the fine anastomoses to the arcade.

Sacroiliolumbar Arterial System

From the second thoracic vertebra to the fourth lumbar vertebra, the spine and its regionally related structures are supplied by pairs of segmental arteries that are direct branches of the aorta. Because the aorta terminates in a bifurcation ventral to the fourth lumbar vertebral body, the vertebrae and the associated tissues caudad to this point rely on an arterial complex derived mostly from the internal iliac (hypogastric) arteries. This "sacroiliolumbar system" consists of contributions from the fourth lumbar artery, the iliolumbar artery, and the middle and lateral sacral arteries.

With the increasing use of percutaneous approaches to the lower lumbar discs, this infra-aortic system of vessels has assumed some surgical significance, particularly because, in contrast to the conventional segmental supply to the more superior vertebrae, its major components are longitudinally related to the dorsolateral surfaces of the discs most frequently involved in these procedures.[79]

Fourth Lumbar Arteries

The peculiarities of the sacroiliolumbar system of arteries may best be understood if compared with the pattern of distribution of the typical aortic segmental branches. The ramifications of the fourth lumbar arteries were selected for this purpose because they not only exemplify the conventional segmental distribution, but often are involved in the nutrition of the next lower segments by variable contributions to the iliolumbar vessels. These vessels often may be twice the caliber of their more cephalad homologues because of a greater muscular and intersegmental distribution.

As depicted in Figs. 2.30 and 2.31, the distribution of the major ramifications is similar to that of the thoracic segmental vessels, with the exception of additional branches that supply the psoas and quadratus lumborum muscles. The lateral muscular branch (equivalent of the thoracic intercostals) may be quite large at the fourth lumbar level, where, in contrast to the other lumbar laterals, it passes anterior, rather than posterior, to the quadratus lumborum. It then continues to supply the lower posterolateral abdominal wall as it courses superior to the crest of the ilium. As can be seen in Fig. 2.30, it may be equivalent in size to the iliac branch of the iliolumbar artery. Its position superior to the crest indicates that it is more likely to be encountered by percutaneous instrumentation than the latter vessel.

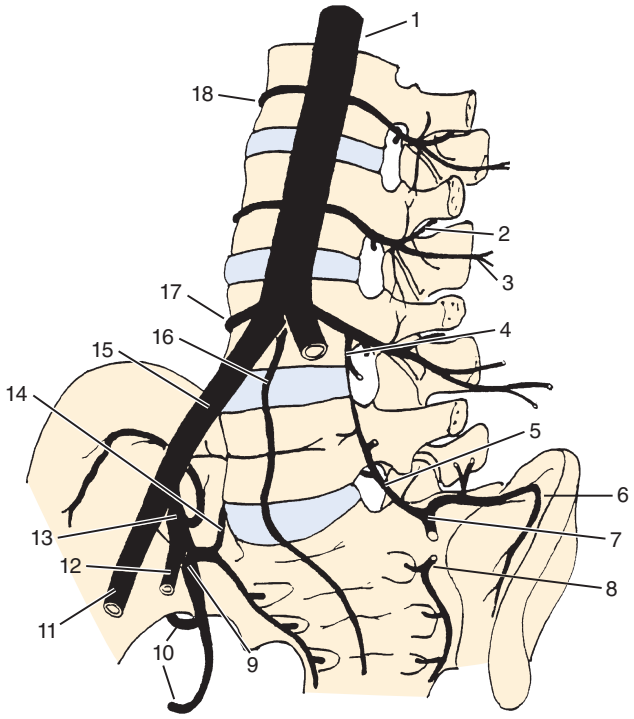

FIG. 2.30 Distribution and major variations of sacroiliolumbar system of arteries that supply the vertebrae and their associated structures inferior to the fourth lumbar vertebra. These patterns of the vessels were derived from radiographs of perinatal specimens and dissections of adults and drawn against a tracing of the lumbosacral region taken from a left anterior oblique radiograph of a man. The aorta lies to the left of center as it approaches the bifurcation ventral to the fourth lumbar vertebra. This schema shows the more frequent arrangement of the sacroiliolumbar system on the right side of the illustration, where the iliolumbar vessel (*7*) has a single origin from the dorsum of the posterior division of the (removed) internal iliac artery. The left side shows the common variation where the iliac artery and the lumbar artery (*14*) are derived separately. The middle sacral artery (*16*) is in its typical position, and the anastomotic contribution from the fourth lumbar artery (*4*) shows its most frequent form. *1,* Aorta. *2,* Musculocutaneous branch of third lumbar artery. *3,* Muscular branch to posterior abdominal wall. *4,* Anastomotic contribution of fourth lumbar artery to sacroiliolumbar system. *5,* Lumbar branch of iliolumbar artery. *6,* Iliac branch of iliolumbar artery. *7,* Iliolumbar artery. *8,* Left lateral sacral artery. *9,* Posterior division of internal iliac artery. *10,* Superior and inferior gluteal arteries. *11,* External iliac artery. *12,* Anterior (visceral) division of internal iliac artery. *13,* Internal iliac artery. *14,* Variant origin of lumbar branch of iliolumbar artery from lateral sacral artery. *15,* Common iliac artery. *16,* Middle sacral artery. *17,* Left fourth lumbar segmental artery. *18,* Left second lumbar segmental artery.

The dorsal musculocutaneous branch of the fourth lumbar artery is equivalent in distribution to other thoracolumbar segmental arteries. It usually has a medial branch that supplies the external aspects of the facet joints and neural arch components and the transversospinal group of muscles and a lateral branch to the transversocostal group of the erector spinae. The vertebromedullary (spinal) branches of the fourth lumbar artery are also similar to those of other segmental arteries (see Fig. 2.24). They are a group of vessels of variable caliber that may generally be sorted into three divisions: (1) the ventral periosteal and osseous branches that supply the posterior longitudinal ligament, the periosteum, and the

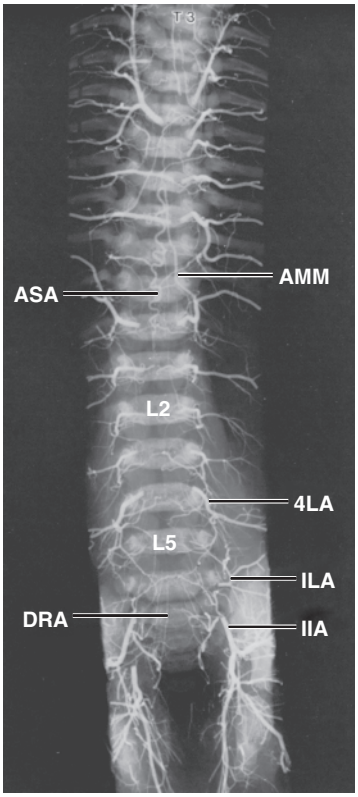

FIG. 2.31 Anteroposterior radiograph of spine from a perinatal cadaver injected with barium sulfate. The aorta and common iliac vessels have been removed before radiography. This specimen shows considerable variation between the two sides of the sacroiliolumbar system. On the *right,* a small lumbar branch and a descending branch from the fourth lumbar artery (4LA) enter the L5-S1 intervertebral foramen. On the *left,* there is no lumbar branch, and a descending branch of the L4 artery supplies all of the vessels to the L5-S1 foramen. The middle sacral artery is also absent, and other branches of the system supply its domain. The radicular branches of the vertebromedullary vessels supply the distal radicular arteries (DRA) and reveal the positions of the lower ends of the lumbosacral nerve roots. *AMM,* Arteria medullaris magna; *ASA,* anterior spinal artery; *IIA,* internal iliac artery; *ILA,* iliolumbar artery.

cancellous bone of the vertebral body; (2) the radiculomedullary division that provides the irregularly located medullary arteries of the cord and the constant distal radicular arteries to all the roots; and (3) the dorsal division that supplies fine articular branches to the deep aspects of the facet joints and the periosteum of the deep surfaces of the laminae and their associated ligaments. The first two divisions usually originate from a common branch of the segmental artery and enter the intervertebral foramen just rostral to their respective vertebral pedicle and ventral to the dorsal root ganglion, whereas the dorsal division arises from the musculocutaneous branch of the segmental artery and enters the foramen dorsal to the nerve components. All the vertebromedullary branches may provide fine branches to the spinal dura.

The aortic segmental arteries course around their respective vertebral body at its narrowest circumference and are positioned almost equidistant between the adjacent discs. These parts of the arterial distribution are relatively safe from instrumentation properly positioned to enter the discs.

A major peculiarity of the fourth lumbar artery is its proclivity toward providing a relatively large, caudally directed intersegmental branch that arises near the level of the intervertebral foramen and becomes reciprocally involved with the lumbar branch of the iliolumbar artery. When this latter vessel is small or absent, the descending branch of the fourth lumbar artery may be sufficiently large to provide the predominant nutritional system to two vertebral segments caudad to its origin (see Figs. 2.30 and 2.31).

Iliolumbar Artery

As opposed to the mostly visceral distribution of the anterior division of the internal iliac (hypogastric) artery, the posterior division is essentially a somatic artery giving rise to gluteal, iliolumbar, and lateral sacral branches. The iliolumbar artery most frequently is the first branch of this dorsal division. It is directed dorsosuperiorly, passing close to the ventrolateral surface of the first sacral vertebral segment. It courses superiorly, dorsal to the obturator nerve and ventral to the lumbosacral trunk. Lateral to the inferior margin of the L5-S1 disc, the iliolumbar artery usually divides into a laterally directed iliac artery and an ascending lumbar artery. The first of these crosses the sacroiliac joint to reach the iliac fossa of the pelvis, where it courses inferior to the iliac crest and usually deep to the muscle to provide muscular branches to the iliac muscle and articular twigs to the acetabulum and eventually anastomoses with the deep circumflex branch of the femoral artery.

The lumbar artery ascends posterolateral to the L5-S1 disc, still between the obturator nerve and the lumbosacral trunk, to provide the vertebromedullary vessels to the L5-S1 intervertebral foramen (Fig. 2.32; also see Figs. 2.30 and 2.31). In most cases, a branch of this vessel continues rostrally to anastomose with the descending branch of the fourth lumbar artery. The lumbar branch of the iliolumbar artery provides regional branches to the psoas and quadratus lumborum muscles.

Sacral Arteries

Lateral Sacral Arteries

Lateral sacral arteries usually form the second branch of the dorsal division of the internal iliac arteries and course down the pars lateralis on each side of the sacrum. Opposite the sacral foramina, they give off medial branches that dorsally enter the foramina. After providing the typical vertebromedullary derivatives, their dorsal muscular branches exit through the dorsal sacral foramina to supply the sacral origins of the erector spinae muscles.

Middle Sacral Artery

The middle sacral artery is an unpaired vessel that is the last branch of the aorta, usually derived from its dorsal median surface just above the carina of the bifurcation (Fig. 2.33; also see Fig. 2.30). It descends down the ventral surface of the anterior longitudinal ligament over the fourth and fifth lumbar

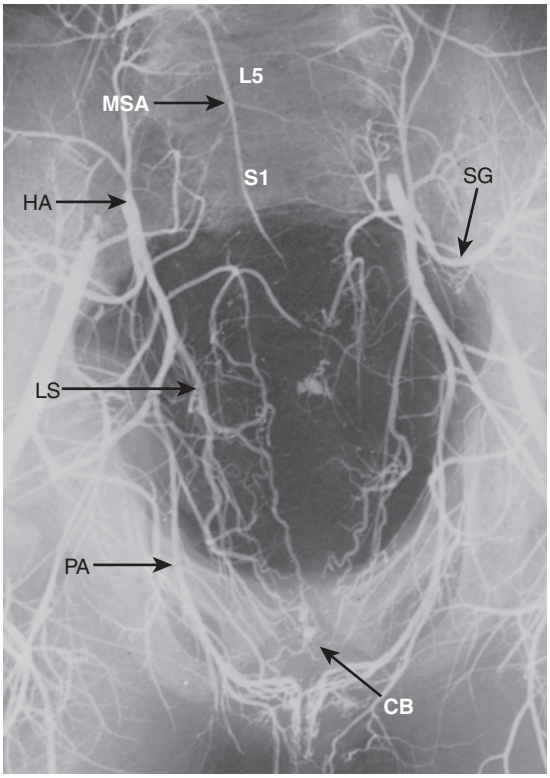

FIG. 2.32 Anteroposterior arteriogram of sacral region in a 7-year-old child. The lateral sacral arteries (LS) can be seen coming from the hypogastric vessels (HA). The middle sacral artery (MSA) is atypical in this specimen because it stops at S1. Just anterior to the coccyx, the coccygeal bodies (CB) are indicated as small knots of arteriovenous anastomoses. Pudendal arteries (PA) are well injected.

bodies and down the ventral sacrum to terminate at the sacrococcygeal junction in a vascular glomus (sacrococcygeal body) in tail-less mammals or continues ventral to the coccygeal (caudal) vertebrae in tailed mammals as the caudal artery. In humans, this is a variable vessel, being totally absent in some cases or replaced by a branch of one of the lateral sacral arteries. Where it is a significant component of the sacroiliolumbar system, its first lateral branches on the ventral surface of the fifth lumbar body may entirely replace this segment's contributions from the iliolumbar or fourth lumbar vessels and provide its osseous, muscular, and vertebromedullary requirements.

Where it is conspicuously present in the sacral region, the middle sacral artery may also contribute a vertebromedullary branch to each anterior sacral foramen. When it is absent, these ventral sacral territories are provided with segmental medial branches from the lateral sacral arteries.

Functional Significance

The sacroiliolumbar system, despite its complexity and seemingly endless combinations of reciprocal substitutions, supplies the lower lumbosacral elements of the spine and the inferior half of the lumbosacral spinal nerve roots (cauda equina) and the back musculature inferior to the L4 level. It is also a major contributor to the vasa nervorum of the lumbosacral plexus. The distal radicular arteries define the positions of the lumbosacral roots (see Fig. 2.25). Although significant medullary branches to the spinal cord are seldom found below L4, they do occur, and from the preceding descriptions it is obvious why the ligation of both internal iliac arteries during radical cystoprostatectomy can result in spinal cord ischemia.[80]

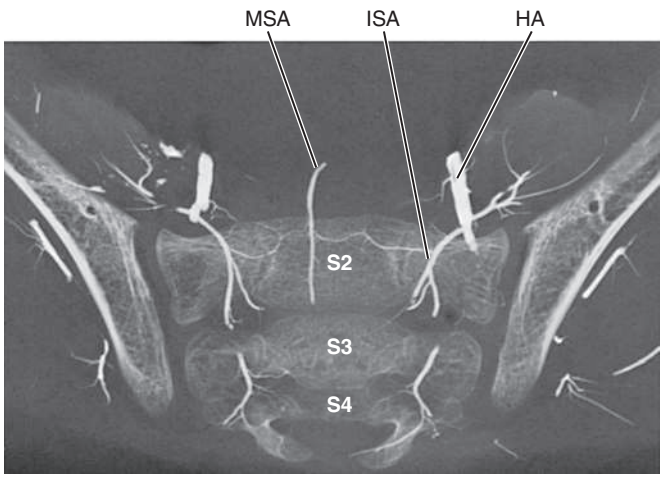

FIG. 2.33 Radiograph of horizontal section through sacroiliac joint. The natural curvature of the sacrum provided oblique sections through segments 2, 3, and 4. The hypogastric artery (HA) gives off the lateral sacral artery (LSA) that sends anastomotic branches to join the middle sacral artery (MSA); from these, the sacral segments receive the penetrating anterior central branches. The dorsal branches pass into the anterior sacral foramina to provide posterior, central, neural, and prelaminar branches. The dorsal branches leave through the posterior sacral foramina to supply the muscles and posterior laminar branches.

Venous System of the Vertebral Column

An external plexus and an internal plexus of veins are associated with the vertebral column. The distribution of the two systems roughly coincides with the areas served by the external and internal arterial supplies. The external venous plexus also consists of an anterior and a posterior set of veins. The small anterior external plexus is coextensive with the anterior central arteries and receives tributaries that perforate the anterior and lateral sides of the vertebral body.

The more extensive posterior external veins drain the regions supplied by posterior (muscular and postlaminar) branches of the segmental artery. The posterior external veins form an essentially paired system, which lies in the two vertebrocostal grooves, but has cross anastomoses between the spinous processes. It is a valveless venous complex that receives the draining segmental tributaries of the internal veins through the intervertebral foramina and communicates ultimately with the lumbar and intercostal tributaries of the caval and azygos system. The posterior external plexus becomes most extensive in the posterior nuchal region, where it receives the intraspinous tributaries via the vertebral veins and drains into the deep cervical and jugular veins.

The internal venous plexus is of more functional and anatomic interest. This plexus is essentially a series of irregular, valveless epidural sinuses that extend from the coccyx to the foramen magnum. Its channels are embedded in the epidural fat and are supported by a network of collagenous fibers, but their walls are so thin that their extent or configuration cannot be discerned by gross dissection. This latter property may account for the fact that the epidural venous sinuses have been periodically "rediscovered." The epidural vertebral veins were known to Vesalius and his contemporaries and were described and illustrated in the first part of the 19th century by Breschet.[81] Batson,[82] Clemens,[83] and others made the functional and pathologic significance of these vessels apparent (Fig. 2.34).

The plexus does not entwine the dura in a completely haphazard fashion but is arranged in a series of cross-connected expansions that produce anterior and posterior ladderlike configurations up the vertebral canal. The main anterior components of the epidural plexus consist of two continuous channels that course along the posterior surface of the vertebral bodies just medial to the pedicles. These channels expand medially to create cross anastomoses over the central dorsal area of each vertebral body and are thinnest where they overlie the intervertebral discs. When injected with a contrast medium, the main channels may appear as a segmental chain of rhomboid beads. Chaynes and colleagues[84] studied the internal venous plexus using silicon injection techniques. They found that anterior longitudinal veins were located in a "dehiscence" within the periosteum along the lateral aspect of the spinal canal and that veins of each side communicated with each other through a retrocorporeal vein. In the cervical spine, the retrocorporeal vein was found deep to the posterior longitudinal ligament, whereas it was superficial to the ligament in the thoracic and lumbar regions.

Where the main anterior sinuses cross connect, they receive the large unpaired basivertebral sinus that arises within the dorsal central concavity of the spongiosa and drains the intraosseous labyrinth of sinusoids. Regional visualization of the epidural plexus can be accomplished by introducing a radiopaque medium directly into the spongiosa or the cancellous bone of the spinous process (intraosseous venography).

The major external connections of the epidural plexus consist of the veins that pass through the intervertebral foramen and eventually empty into the segmentally available intercostal or lumbar veins (Fig. 2.35). Because these sinuses are valveless, one cannot refer accurately to directions of drainage and flow. The greatest functional significance of these vessels lies in their ability to pass blood in any direction according to the constantly shifting intraabdominal and intrathoracic pressures. Breschet[81] surmised that the epidural plexus served as a collateral route for the valveless caval and azygos systems. This ability has been shown by experimental ligation of either the superior vena cava or the inferior vena cava. In addition, the Queckenstedt maneuver, which tests the patency of the spinal subarachnoid space by compressing the jugular or intraabdominal veins, causes an increase in cerebrospinal fluid pressure through dural compression from the expansion of the collaterally loaded epidural plexus.

The plexus is evidently capable of passing large quantities of blood without developing varices. Clemens claimed that this feature was due to the intricate network of collagenous fibers that supports the thin walls of the sinuses. Also, passive

congestion of the spinal cord is prevented by minute valves in the radicular branches draining the spinal cord.[83] This latter fact is anatomically unique because valves exist nowhere else in the venous channels associated with the central nervous system. An ancillary function of the epidural plexus may be to act in a mechanical capacity as a hydraulic shock-absorbing sheath that helps buffer the spinal cord during movements of the vertebral column, similar to the epidural fat.

The vertebral sinuses are largest in the suboccipital and upper cervical region. Here they also receive numerous nerve endings from the sinuvertebral nerves and are associated with glomerular arteriovenous anastomoses, which suggests a possible baroceptive function.[85] The patency of these anastomoses is most easily shown in the fetus, in which arterial injections of a contrast medium may also fill the upper cervical epidural sinuses. Similarly, the coccygeal bodies of the same specimen pass the arterial injection directly into the epidural veins of the lower sacral region.

The detrimental aspects of the vertebral epidural veins have been well stated by Batson.[82] Retrograde flow from venous connections to the lower pelvic organs provides an obvious route of metastasis for pelvic neoplasms to the spine itself and to the regions of the trunk associated with valveless connections to the plexus. Batson[82] claimed that direct metastatic transfer can occur between the pelvic organs and the brain via the vertebral epidural route.

Another extraspinal-intraspinal venous connection implicated in the transfer of pathologic processes involves the pharyngovertebral veins.[86] These vessels constitute a system that drains the superior posterolateral regions of the nasopharynx and coalesces into two to several veins that penetrate the anterior atlanto-occipital membrane to discharge into the venous complex surrounding the median and lateral atlantoaxial joints. Because posterior pharyngeal infections have been linked with the atlantoaxial rotatory subluxations characteristic of Grisel syndrome,[87] it is believed that the pharyngovertebral veins are instrumental in transporting infectious processes that may produce a hyperemic relaxation of the atlantoaxial ligaments. The existence of this venous system also explains the ease in transfer of superior pharyngeal metastatic processes to the upper cervical epidural veins.

Blood Supply of the Spinal Cord

Throughout the length of the spinal cord, a system of three longitudinal vessels receives blood from the irregularly located medullary branches of the segmental spinal arteries and distributes it to the substance of the cord. This system consists of the single median ventral anterior spinal artery and two smaller dorsolateral spinal arteries (Fig. 2.36).

Anterior Spinal Artery

Despite its great functional significance, the anterior spinal artery remains one of the more inaccurately described and inadequately understood blood vessels. Derived from the fusion of bilateral pairs of ascending and descending anastomotic branches of the original segmental arteries of the developing spinal cord,[88] this median ventral pial vessel supplies approximately 80% of the intrinsic spinal cord vasculature. It is usually depicted in texts as a single continuous artery of nearly uniform caliber that extends from the medulla oblongata to the conus. The anterior spinal artery is actually a longitudinal series of functionally independent vessels that may show wide luminal variations and anatomic discontinuities.[88-90]

Although the investigations of Crock and Yoshizawa[75] have tended to minimize the significance of predominant regional feeders, many functionally oriented reports have claimed that the cord has three major arterial domains along its vertical axis: (1) the cervicothoracic region (C1–T3), (2) the mid-thoracic region (T3–T8), and (3) the thoracolumbar (including sacral cord) region (T8-conus). The reports have also claimed that these areas have little anastomotic exchange between their junctions (Fig. 2.37).

Brewer and colleagues[89] and Lazorthes and associates[90] maintained that a series of human anterior spinal arteries consistently show interruptions, or critically narrow zones, in the mid-thoracic region, and these influence the potential collateral blood flow along the longitudinal axis of the cord. It is not only the observed size of the vessel that is of physiologic significance, however. The existence of a marked autoregulatory control of the intrinsic spinal cord blood flow has been independently shown in many mammalian species.[32,91] Microscopic investigation[92] of sections of the descending and ascending contributions of the arteria medullaris magna (artery of Adamkiewicz, also known as the arteria radicularis magna) to the anterior spinal artery showed that these arteries, in addition to their well-developed circumferential muscle of the tunica media, also possess a layer of predominantly longitudinal intimal musculature. Located between the internal elastic lamina and the endothelium, this layer ranges in thickness from one-fifth to one-half of the tunica media (Fig. 2.38).

In following a series of cranial to caudal sections of the thoracolumbar anterior spinal artery, it was noted that the intimal muscle layer did not extend into any of its branches. At the mouth of the central (sulcal) arteries, which are the largest anterior spinal artery derivatives, the intimal musculature stops abruptly, often forming a liplike projection over the opening of the branch vessel, but no intimal muscle fibers extend into the central arteries. A sphincter-like thickening of the central artery tunica media, seen at the ostium of the vessels, indicates that this muscle layer has a greater contractile influence at this point (see Fig. 2.38). The intimal musculature, in addition to enhancing the luminal control of the anterior spinal artery, also is involved in controlling the blood flow into the central arteries. Where the intimal layer shows the liplike projections, successive serial sections indicate that contraction of the longitudinally disposed intimal muscle fibers forms an ellipsoidal buttonhole-shaped orifice whose long axis is parallel to that of the fiber orientation. Such an arrangement permits exquisite muscular control of the blood flow from the anterior spinal artery to its central artery branches.

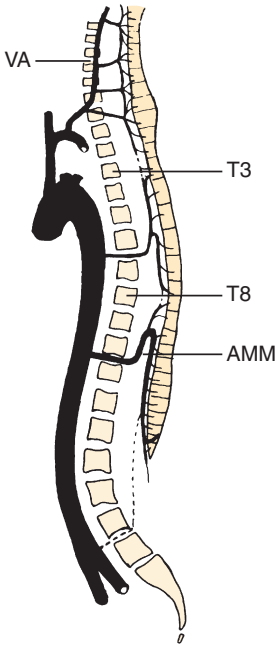

FIG. 2.37 Schema illustrating sources and relationships of medullary feeder arteries to the spine and the spinal cord. Anterior spinal artery (ASA) is shown to be formed by an anastomotic chain of ascending and descending branches of medullary feeders. Cervicothoracic, mid-thoracic, and thoracolumbar (includes sacral cord) regions are indicated, and their usual boundaries at vertebral levels T3 and T8 are shown. Medullary feeders range from 6 to 14, but the respective domains persist. *Dotted line* indicates frequent position of a smaller accessory medullary feeder to the thoracolumbar area. *AMM,* Arteria medullaris magna; *VA,* vertebral artery. (From Parke WW, Whalen JL, Bunger PC, et al. Intimal musculature of the lower anterior spinal artery. *Spine.* 1995;20:2074.)

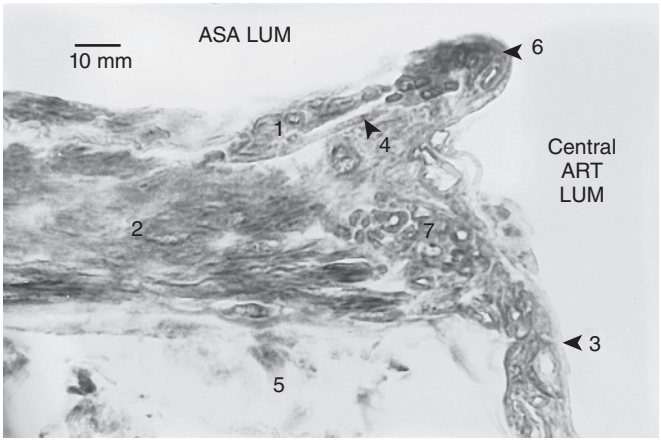

FIG. 2.38 High-power cross section of thoracolumbar anterior spinal artery (ASA) wall at junction with one side of a central artery. The intimal musculature (*1*) may extend as a liplike projection (*6*) over the central artery orifice. This muscle layer stops at this point and does not extend into branch vessels. A sphincter-like enlargement of the conventional circular muscle of the central artery (*7*) is indicated. Endothelium (*3*) and internal elastic lamina (*4*), tunica media (*2*), and adventitia-pia (*5*) are labeled. ART, artery; LUM, lumbar. (From Parke WW, Whalen JL, Bunger PC, et al: Intimal musculature of the lower anterior spinal artery. Spine 1995;20:2075.)

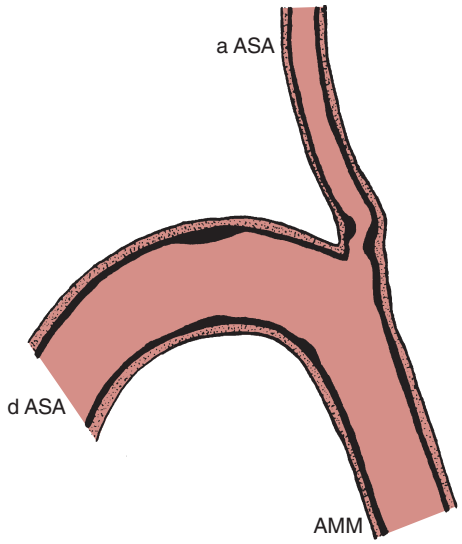

FIG. 2.39 Schema derived from sections of arteria medullaris magna (AMM)–anterior spinal artery (ASA) junction to show distribution of intimal musculature (*solid black*) in this region. Intimal cushions are shown guarding the orifice of the ascending ASA (a ASA) and a typical distribution is found in the arch of the descending ASA (d ASA). (From Parke WW, Whalen JL, Bunger PC, et al. Intimal musculature of the lower anterior spinal artery. *Spine.* 1995;20:2076.)

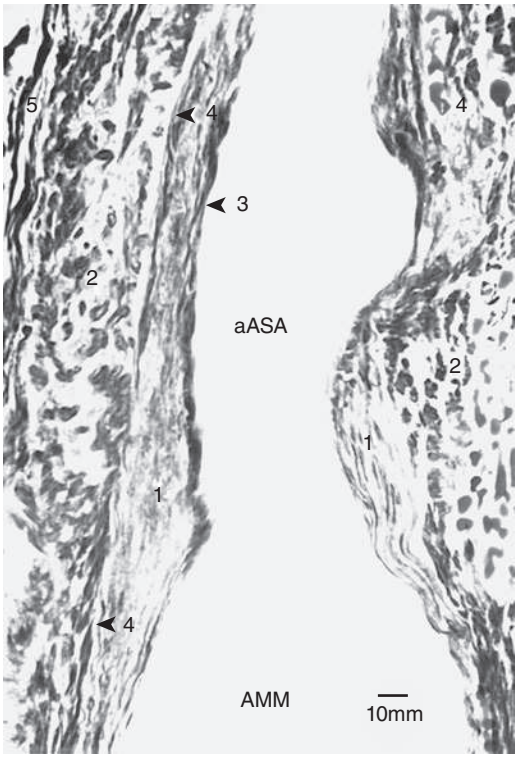

FIG. 2.40 Sagittal section through junction of arteria medullaris magna (AMM) arch and ascending anterior spinal artery (aASA) showing the intimal cushions guarding the aASA orifice (*1*). These may be reinforced by underlying enhancement of the circular fibers of the tunica media (*2*). Endothelium (*3*) and elastic lamina (*4*) are indicated. The longitudinal disposition of the intimal muscle fibers is apparent, particularly in the intimal cushion on the right side. The contraction of these muscular systems would dramatically alter the radius of the aASA lumen. *5,* Adventitia-pia. (From Parke WW, Whalen JL, Bunger PC, et al. Intimal musculature of the lower anterior spinal artery. *Spine.* 1995;20:2076.)

In addition to the fairly uniform layer of the intimal musculature throughout the walls of the examined sections of the thoracolumbar anterior spinal artery, serial sections cut through the arch-shaped junction of the arteria medullaris magna and the descending anterior spinal artery branches show that this intimal layer, in most cases, is organized into prominent intimal cushions. These muscular thickenings are erratically distributed along the lumen of the hairpin-shaped arterial arch and the initial segment of the ascending branch of the anterior spinal artery (Figs. 2.39 and 2.40). This latter location is of considerable interest because its prominent cushions, with reinforced thickenings of the underlying tunica media, could exert considerable influence over the quantity of blood flow between the thoracolumbar and mid-thoracic vascular domains. This intimal control system, when coupled with the intramedullary arteriovenous anastomoses (described in a subsequent section on intrinsic vascularity), provides an anatomic basis for the dramatic range of spinal cord blood flow autoregulation. The presence of the intimal cushions explains the often-noted failure of the arteria medullaris magna to supply adequately the mid-thoracic cord region above the arteria medullaris magna–anterior spinal artery junction during aortic cross clamping.

The ventral position of the anterior spinal artery and its nutritional importance may have consequence in spinal stenosis. Particularly in the lower cervical region, its compression by dorsal osteophytes and cartilaginous protrusions related to cervical disc degeneration may lead to the neurologically disastrous anterior spinal artery syndrome.[93] The medullary feeder arteries that supply the anterior spinal artery may arise from any spinal segmental artery. Studies by Dommissee[94] showed, however, that there are statistical preferences for certain segmental levels. There are usually three anterior medullary arteries for the cervical region, one or two for the thoracic region, and a conspicuous medullary vessel (the arteria medullaris magna) for the lumbosacral cord region. The levels of origin for all these vessels center around certain "average" locations in each region. The anterior spinal artery is usually of greatest caliber in the lumbosacral part of the cord, where it supplies the considerable tissue mass of the proximal cauda equina in addition to the lumbosacral cord intumescence.

The dorsolateral spinal arteries arise from the posterior inferior cerebellar vessels and are of lesser caliber and nutritional significance. They also are less likely to be longitudinally continuous and often present a more plexiform distribution over the dorsum of the cord. They have a greater frequency of smaller medullary sources.

The larger intradural spinal arteries are unusual in that, similar to the cerebral arteries, they have no significant vasa vasorum. In all other regions of the body, a vessel with an external diameter approaching 1 mm shows a fine vascular plexus (vasa vasorum) on its external surface that supplies nutrients to its outer layers of tissue. Because the cerebral and spinal vessels are bathed in the nutrient-rich cerebrospinal fluid, their external layers presumably derive metabolic exchange from this source.

Lateral Spinal Arteries of the Cervical Cord

The highest three to four segments of the cervical spinal cord receive blood from a unique pair of vessels, the lateral spinal arteries. Although, ontogenetically, these seem to be the most rostral expressions of the dorsolateral spinal arteries, they have a more extensive distribution and are without equivalents in other levels of the cord. They usually arise from the intradural parts of the vertebral arteries near the origins of the posterior inferior cerebellar arteries, or they may arise from the proximal sections of the posterior inferior cerebellar arteries themselves. Their typical course carries them anterior to the posterior roots of the cervical spinal nerves C1 to C4, dorsal to the denticulate ligaments, and parallel to the spinal components of the 11th cranial nerve. Their general distribution is to the dorsolateral and ventrolateral cord regions caudad to the olives.

Although these vessels were observed in the later 19th century, they were usually regarded as variants, and their functional significance was not appreciated. Lasjaunias and colleagues[95] compiled an extensive report on the variations and selective angiography of these important vessels.

Intrinsic Vascularity of the Spinal Cord

The tissues of the spinal cord are supplied by two systems of vessels that enter its substance. The first is a centripetal arrangement of arteries that supplies the superficial tracts of the ventral and lateral funiculi, all of the dorsal funiculus, and the extremities of the dorsal horns. They are radially penetrating branches of the vasa corona and the dorsolateral spinal arteries, which serve only a little more than one-fourth of the cord. The greater part of the cord and almost all of its gray matter is supplied by a second centrifugal system of vessels derived from the sulcal (or central) arteries.[96] These arteries are a repetitive series of branches derived from the dorsal aspect of the anterior spinal artery that penetrate the depths of the anterior median fissure. In the mid-sagittal plane, they form a close palisade of vessels that occur with a frequency of 3 to 8 arteries per 1 cm in the cervical region and 2 to 6 per 1 cm in the thoracic cord; they are densest in the lumbar region, where they number 5 to 12 per 1 cm of the anterior spinal artery. The average diameters of the sulcal arteries are greater in the cervical (0.21 mm) and lumbosacral (0.23 mm) regions than in the thoracic cord (0.14 mm).[97]

As these vessels approach the anterior commissure, most turn to either the right or the left and supply only the corresponding side of the cord.[14,73,98,99] This unilateral proclivity reflects their origins in the early embryonic stages when the anterior spinal arteries first condensed from a primitive plexus as a symmetrical pair of longitudinal vessels, each supplying its respective half of the cord. In subsequent development, these two vessels fused in the midline to form the definitive single median anterior spinal artery, but their sulcal branches retained their original unilateral affinities. Bilateral distributions occur in 9%, 7%, and 14% of the cervical, thoracic, and lumbar vessels.[97,100]

Although the sulcal arteries may give infrequent branches to the septomarginal white fibers as they extend into the median anterior fissure, their major distribution is derived after they enter the substance of the cord, just ventral to the anterior white commissure. Here the individual right and left arteries subdivide into dorsal and ventral branches. A group of ventral branches supplies the ventral horns and, through more radial extensions, provides vessels to Clarke column and the deeper fibers of the anterior and lateral funiculi. The smaller, more dorsal group of branches supplies the gray commissure and the ventral one-half to two-thirds of the dorsal horns. A few second-order or third-order branches form anastomotic arcades with their counterparts of adjacent sulcal artery territories. All these vessels provide the finer arterioles that eventually lead to the spinal capillary beds.

The greater metabolic requirements of the spinal gray matter, in contrast to the funicular tissue, are dramatically reflected in their relative capillary densities. Quantification of the microvascularity in the spinal cord has shown that the capillary density of the gray matter is four to five times as great as the white matter.[101] The capillary distribution within the gray matter is not homogeneous, however, and varies with the regional concentrations of the nuclei. The nuclei of the dorsal horn are fairly uniformly distributed. The ventral horn shows segmental nuclear clusters, which display distinct nerve cell groups.

As noted by Feeney and Watterson,[102] the capillary densities of the white and gray matter of the central nervous system are established at a level that is minimally requisite for the metabolic needs of the given tissue. This situation is in contrast to most other body tissues, which have a capillary "reserve" and normally function with only part of their capillary channels open, varying their intrinsic vascular resistance by dilation of the accessory channels. Nevertheless, despite the lack of this method of control, the spinal cord exhibits a remarkable range of blood flow autoregulation.[1,32,103] The intrinsic cord vasculature maintains a constant blood flow throughout a wide range of systemic blood pressure alterations, although each animal species has a definite upper and lower limit to the systemic blood pressure at which the regulation decompensates. Because transection of the upper cervical cord has no effect on this autoregulatory capacity, it may be assumed that this reflex is local and independent of autonomic nerve control.

Numerous third-order branches of the sulcal arteries communicate directly with veins through convoluted anastomoses. These vascular structures are located primarily in the area that divides the ventral two-thirds of the dorsal horn from the dorsal one-third and in the more central regions of the ventral horn. They show a paucity of contractile elements and instead exhibit an "epithelioid" type of media that seems capable of swelling and diminishing its thickness. Because this action could rapidly control the caliber of the anastomotic lumina in immediate response to local metabolic changes, these anastomotic convolutions may be the site of the reflex adjustment in the flow resistance of the spinal cord vasculature.[104]

Perhaps the most essential part of knowledge of the vascular supply of the spinal cord is awareness of the ranges of

individual variability. The numerous successful surgical cases in which the arteria medullaris magna has been inadvertently interrupted without producing a disastrous spinal cord ischemia give the impression that an adequate collateral vascularity may protect the cord in most individuals when a single major artery is compromised. In procedures involving the interruption of blood flow in numerous consecutive segmental branches of the aorta, such as aortic cross clamping for abdominal vascular surgery, the maintenance of adequate spinal cord blood flow, particularly in the thoracic area, seems to depend more on the regional competence of the anterior spinal artery than on the number of collateral sources to the cord. Spinal cord injury after cross clamping without adjunctive vascular support has been reported to range from 15% to 25%, depending on the series of cases reviewed.[105,106] Proximal-to-distal aortic shunting may alleviate the undesirable hypertension in the aortic distribution proximal to the first clamp and the hypotension in the segments distal to the second clamp. The work of Molina and colleagues[105] on dogs indicated, however, that the shunt capacity should provide more than 60% of the baseline descending aortic flow and have a diameter greater than one-half of the descending aorta to be effective.

Of particular significance was the study by Svensson and colleagues[107] on the blood flow in the baboon spinal cord and its implications in aortic cross clamping. This animal was chosen because its spinal vascularity is similar to humans in that its anterior spinal artery is a continuous vessel without the occasional interruptions noted in some quadrupeds. This study indicated that in baboons, as in humans, the caliber of the anterior spinal artery is often critically narrowed where the thoracic anterior spinal artery joins the lumbar segment of this vessel at their common junction with the arteria medullaris magna. The functional implication is that the shunting of the cross-clamped aorta may help maintain an adequate flow in the lumbosacral sections of the cord but is of little help to the supply of the lower sections of the thoracic cord, owing to the marked discrepancy that usually exists between the anterior spinal artery diameters above and below the junction of the arteria medullaris magna.

In accordance with the hemodynamic principles of Poiseuille's equation, the resistance to blood flow upward from the arteria medullaris magna junction was more than 50 times greater than the flow resistance downward into the lumbosacral anterior spinal artery in the baboon. Because a series of direct measurements showed that this discrepancy in the anterior spinal artery diameters was even greater in humans, Svensson and colleagues[107] concluded that even the lowest segments of the thoracic cord were dependent on a blood flow from the superior end of the thoracic anterior spinal artery despite the shunting.

Intrinsic Venous Drainage of the Spinal Cord

Compared with the arterial anatomy, the structural and functional aspects of the venous drainage of the spinal cord have been relatively neglected. In contrast to other organ systems in which the equivalent orders of veins and arteries tend to course in a common vascular bundle, the veins of the central nervous system are generally less numerous than the arteries, they are larger than their corresponding efferent vessels, the larger branches may not show a pattern concurrent with the arterial distribution, and they are not accompanied by lymphatics.

The internal substance of the dorsal half of the cord drains by a centrifugal arrangement of intrinsic vessels that are tributaries, by way of a venous vasa corona, to a large median dorsal longitudinal spinal vein; the ventral half sends tributaries to sulcal veins that empty into a large median ventral longitudinal vein that runs parallel to the anterior spinal artery. Both of these longitudinal vessels are circumferentially connected by a prominent venous vasa corona. This entire system drains into the epidural venous plexus by medullary (previously called *radicular*) veins that are as infrequent in their distribution as the medullary arteries.[108] The proximal sections of the spinal nerve roots drain centripetally into the vasa corona and longitudinal veins of the cord and then to the epidural system via the medullary veins.

Vascularization of the Spinal Nerve Roots

Although it has been generally recognized that much of the pain consequent to degenerative changes in the spinal motion segment is associated with compression or tension on the spinal nerve roots, the mechanisms that initiate the actual nerve discharge have remained obscure. Because experimental studies on peripheral nerves and observations on numerous cases of neurogenic claudication have suggested that much of the pain may have a neuroischemic basis, investigations were undertaken to determine the nature of the intrinsic vascularity of the spinal nerve root and its response to localized compression or tension. The nerve roots had long been regarded as part of the peripheral nervous system and were viewed as histologically and vascularly similar to peripheral nerves. Consequently, research on the latter was often uncritically extrapolated to apply to the nerve roots.

The very long roots of the lumbosacral spinal nerves seemed to be particularly vulnerable because their vascularity was initially believed to be supplied only from their distal ends without the access to the frequent collateral support that is characteristic of peripheral nerves. Because the nerve root fasciculi do not have a strong connective tissue support, it also seemed that the fine vascularity they possessed would be at risk from the repeated tension and relaxation resulting from the flexion and extension of the spine. Parke and colleagues[109] and Parke and Watanabe[110] showed by vascular injection that the roots receive their arterial supply from both ends (Fig. 2.41; see Fig. 2.36), however, a fact physiologically confirmed by Yamamoto.[111]

The existence of many redundant coils along the branches of the true radicular arteries ameliorates the stresses that would result from the interfascicular movements that accompany the repeated stretch and relaxation. A significant finding was the occurrence of numerous, relatively large arteriovenous anastomoses throughout the length of the root (Fig. 2.42).

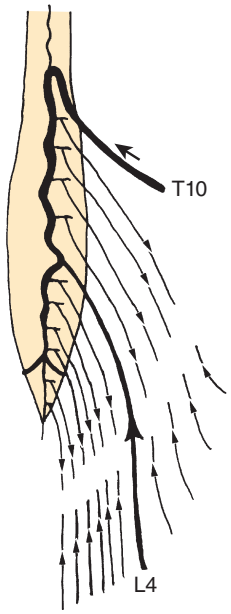

FIG. 2.41 Schema indicating directions of normal blood flow in cauda equina. The anterior spinal artery of the lumbosacral part of the cord is supplied by medullary arteries and supplies 75% at the cord substance and upper parts of the cauda equina via the proximal radicular arteries. This accounts for enlargement of the anterior spinal artery in the lumbosacral region.

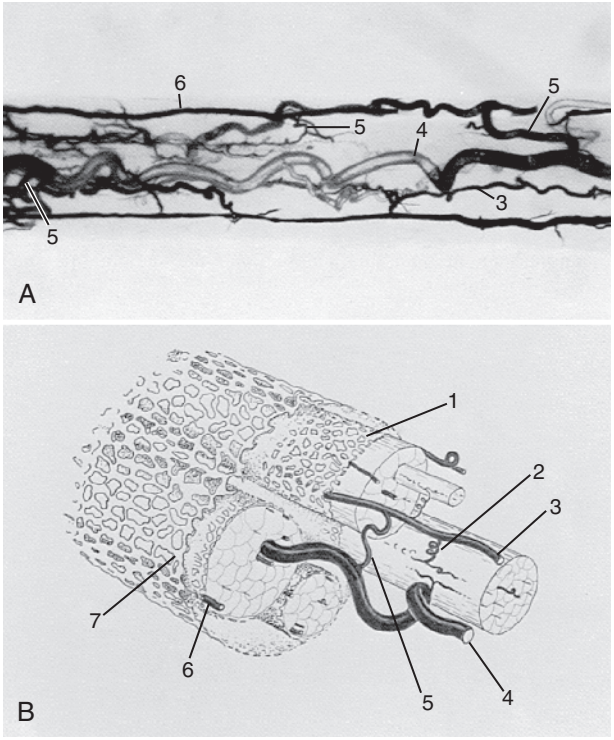

FIG. 2.42 (A) Low-power (×20) transillumination photomicrograph of midsection from part of L4 nerve root treated with hydrogen peroxide after vascular injection with latex–India ink but before clearing in a solution of tributyl-tricresyl phosphates. The peroxidases within the residual blood elements inflated the radicular veins (*4*) to provide a temporary contrast medium. Note the frequency of the large arteriovenous anastomoses (*5*) that permitted the latex–India ink to enter the veins. (B) Compilation showing structure of a typical lumbosacral nerve root derived from data obtained by injection studies and scanning electron microscopy (see Fig. 2.38). The gauzelike pia-arachnoid membranes permit the cerebrospinal fluid to percolate into nerve tissues and assist metabolic support. Numbers in (A) and (B) are common to equivalent structures. *1,* Fascicular pia. *2,* Interfascicular and intrafascicular arteries showing compensating coils to allow interfascicular movement. *3,* Longitudinal radicular artery. *4,* Large radicular vein (does not course with arteries). *5,* Arteriovenous anastomosis. *6,* Collateral radicular artery. *7,* Gauzelike pia-arachnoid that permits percolation of cerebrospinal fluid to assist in metabolic support.

These vascular cross connections apparently allow blood flow to be maintained in sections of the root above and below a point of compression. Of particular significance to root nutrition is the work of Rydevik and colleagues[111a] who, using isotopically labeled methylglucose, showed that approximately 50% of the root nutrition is derived from the ambient cerebrospinal fluid; this necessitates a gauzelike architecture of the radicular pia-arachnoid sheath (Fig. 2.43; see Fig. 2.42B).

A study by Watanabe and Parke[112,113] of chronically compressed roots indicated that the compressed segment is most likely metabolically deprived. It has been suggested that radicular pain is related to root ischemia because a reduction of oxygen intake in patients with neurogenic claudication exacerbates the symptoms.[114] The arterial side of the vasa radiculorum seems to be well compensated, however, and maintains a continuity despite severe chronic compression. Further study has indicated that the venous side of the radiculomedullary circulation is more vulnerable.[113] Because the roots are part of the central nervous system, the relationships of the arteries to the veins resemble those of the brain more than those of peripheral nerves. The radicular veins do not follow the arterial pattern. They are fewer in number and run a separate and usually deeper (more central) course. Being thin-walled, they are more liable to the spatial restrictions imposed by degenerative changes in the dimensions of the spinal canal and intervertebral foramina and show complete interruption in the chronically compressed root. The metabolically deprived, or inflamed, nerve root becomes hypersensitive to any mechanical deformation, and any additional insult to such a nerve may initiate ectopic impulses that produce pain.

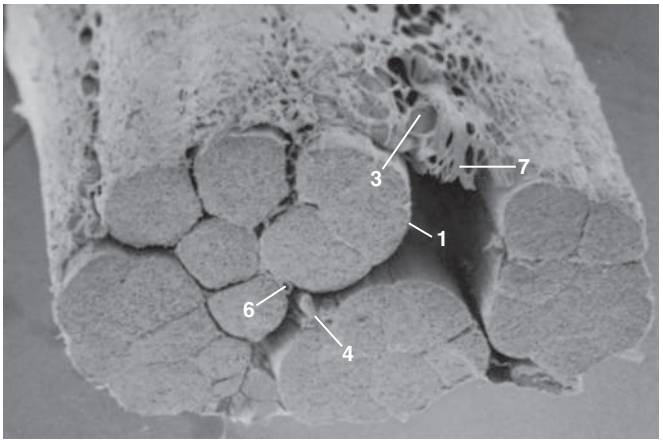

FIG. 2.43 Scanning electron photomicrograph of section of proximal part of L5 ventral nerve root. The gauzelike pia-arachnoid sheath is very evident. The numbers correspond to the structures labeled in Fig. 2.42.

Impedance of the radiculomedullary venous return can occur without topographically related venous constriction. The exacerbation of neurogenic pain in cases in which spinal stenosis has been associated with venous hypertension has been recorded by clinical investigators. LaBan[115] and LaBan and Wesolowski[116] noted that patients with diminished right-sided heart compliance and spinal stenosis may eventually exhibit neurogenic pain even in static or recumbent situations. They attributed this phenomenon to an increased external pressure on the already sensitized roots by the engorgement of the epidural venous sinuses (see Fig. 2.35), but the venous hypertension alone may be sufficient to impede the venous return from an already compromised radicular circulation. Madsen and Heros[117] showed that "arterialization" of spinal veins by abnormal arteriovenous shunts in the region of the conus medullaris exacerbates the neurogenic pain in patients with spinal stenosis. Their hypothesis suggested that a variable combination of increased mechanical constriction by dilated epidural veins and the direct increased resistance to the radicular circulation by the venous hypertension could contribute to the elicitation of pain. Aboulker and colleagues[118] also concluded that epidural venous hypertension alone may produce radicular symptoms or cord symptoms or both without adjunctive stenotic compression.

If the intrinsic circulation of the nerve root is impeded in either its arterial input or its venous outflow, the net effect seems to be the same: a neuroischemia of the compressed root segment that may enhance the generation of ectopic nerve impulses. A phenomenon that could be related to radicular venous stasis is the swelling of the disc-distorted nerve root that Takata and colleagues[119] showed in CT myelograms. This phenomenon is difficult to explain because extravasated fluids in the root tissues should have free access to the surrounding cerebrospinal fluid. Nevertheless, the fluid balance of the root tissues seems to be altered, particularly in the segment proximal to the level of the offending disc. The intricacies of the hemodynamic relationships responsible for this change remain unknown.

The role of the ubiquitous arteriovenous anastomosis in autoregulation of the intrinsic radicular vasculature also offers a fertile field for clinical investigations. Because these vascular shunts are mostly without contractile elements but seem instead to control their lumina by the thickening response of an epithelioid endothelium, they probably react to chemical changes in the blood within their lumina and can offer an immediate local reflex to alterations in the nerve root metabolism.

Functional Anatomy of the Spine

The biomechanics of the spine is a very complex and extensive subject. A comprehensive discussion is beyond the scope of this chapter, so the reader is directed to the work of White and Panjabi,[120] which is generally regarded as the major book in this field. Because an appreciation of the essential functional relationships of the spinal components does enhance an understanding of their anatomy, however, a brief overview follows.

The spine is capable of ventroflexion, extension, lateral flexion, and rotation. This remarkable universal mobility may seem at odds with the fact that its most essential function is to provide a firm support for the trunk and appendages. The apparent contradiction may be resolved when one realizes that the total ranges of motion are the result of a summation of limited movements permitted between the individual vertebrae and that the total length of the spine changes very little during its movements. The role of the musculature in the performance of the supportive functions cannot be minimized, as the disastrous scolioses that result from their unilateral loss in a few motor segment units may attest.

The degree and combination of the individual types of motion described earlier vary considerably in the different vertebral regions. Although all subaxial-presacral vertebrae are united in a tripod arrangement consisting of the intervertebral disc and the two zygapophyseal articulations, the relative size and shape of the former and the articular planes of the latter determine the range and types of motion that an individual set of intervertebral articulations contributes to the total mobility of the spine. In general, flexion is the most pronounced movement of the vertebral column as a whole. It requires an anterior compression of the intervertebral disc and a gliding separation of the articular facets, in which the inferior set of an individual vertebra tends to move upward and forward over the opposing superior set of the adjacent inferior vertebra. The movement is checked mainly by the posterior ligaments and epaxial muscles.

Extension tends to be a more limited motion, producing posterior compression of the disc, with the inferior articular process gliding posteriorly and downward over the superior set below. It is checked by the anterior longitudinal ligament and all ventral muscles that directly or indirectly flex the spine. Also, the laminae and spinous processes may sharply limit extension. Lateral flexion is accompanied by some degree of rotation. It involves a rocking of the bodies on their discs, with a sliding separation of the diarthroses on the convex side and an overriding of the diarthroses related to the concavity. The rotational component brings the anterior surface of the bodies toward the convexity of the flexure and the spinous processes toward its concavity. This phenomenon is well illustrated in a dried preparation of a scoliotic spine. Lateral flexion is checked by the intertransverse ligaments and the extensions of the ribs or their costal homologues.

Pure rotation is directly proportional to the relative thickness of the intervertebral disc and is mainly limited by the geometry of the planes of the diarthrodial surfaces. Although the architecture of the disc permits limited rotation between the bodies, it also serves to check this movement by its resistance to compression. The consecutive layers of the anulus fibrosus have their fibers arranged in an alternating helical fashion, and rotation in either direction can be accompanied only by increasing the angularity of the opposing fibers to the horizontal, which requires compression of the disc.

The entire vertebral column rotates approximately 90 degrees to either side of the sagittal plane, but most of this traversion is accomplished in the cervical and thoracic sections. It flexes nearly the same amount, using primarily the

cervical and thoracic regions. Approximately 90 degrees of extension is permitted by the cervical and lumbar regions, whereas lateral flexion with rotation is allowed to 60 degrees to both sides, again primarily by the cervical and lumbar areas.

Specific Regional Considerations

The atlanto-occipital joints mostly permit flexion and extension with a limited lateral action, all being checked by the suboccipital musculature and the atlanto-occipital ligaments. The atlantoaxial articulations allow only rotation, the pivoted joint being stabilized and checked by the alar ligaments and the ligaments forming the capsules of the atlantoaxial diarthroses.

One-half of the rotational mobility of the entire cervical region takes place between the atlas and the axis, and the remainder is distributed among the joints of the subaxial vertebrae. The atlanto-occipital joint accounts for approximately half of the cervical flexion. The remaining 50% is not evenly distributed among the cervical vertebrae but is greater in the upper section.

The subaxial part of the cervical region shows the ranges of motion that are the most free of all the presacral vertebrae. The discs are quite thick in relation to the heights of the vertebral bodies and contribute about one-fourth of the height of this part of the column. In addition, a sagittal section shows the middle part of the cervical disc to be lenticular, so that the anteroinferior lips of the bodies are more capable of sliding slightly forward and overriding one another. The range of spinal flexion is greatest in the cervical region, and although the posterior nuchal ligaments and muscles may tend to resist this motion, it is ultimately checked by the chin coming to rest on the chest.

The cervical spine is normally carried in a moderately extended position and shows a median variation of 91 degrees between extension and flexion. Extension is checked by the anterior longitudinal ligament and the combined resistances of the anterior cervical musculature, fascia, and visceral structures, all three of which may be traumatized in hyperextension injuries.

Cervical lateral flexion is quite limited by the articular pillars and the intertransverse ligaments, and most lateral motion involves considerable rotation. The nearly horizontal position of the planes of the cervical articular facets provides good supportive strength to the articular pillars but increases the lateral rigidity, so that hyperextension injuries may be more disastrous if the head is rotated at the time of impact from the rear.

The mobility of the thoracic region is also not uniform throughout its length. Although the upper segments resemble the cervical vertebrae with respect to the size of the bodies and the discs, the ribs attached to the sternum greatly impair the ranges of motion. The circumferential arc of the plane of the articular facets shows that rotation is the movement least restricted by these structures.

Flexion and extension become freer in the lower thoracic region, where the discs and vertebral bodies progressively increase in size and the more mobile and less restrictive they become. The last few thoracic vertebrae are transitional with respect to the surfaces of the articular facets. These begin to turn more toward the sagittal plane and tend to limit rotation and permit greater extension.

The articulations of the lumbar region permit ventroflexion, lateral flexion, and extension, but the facets of the synovial joints lie in a ventromedial to dorsolateral plane that virtually locks them against rotation. This lumbar nonrotatory rigidity is a feature shared with most mammals and achieves its greatest manifestation in certain quadrupeds in which the inferior articulation fits like a cylindric tenon into the semicircular mortise of the corresponding superior process of the vertebra below. It provides a gliding action that permits the neural arches to separate or approximate each other only during extension and flexion. The morphology of the joints can be well appreciated in an appropriate cut of loin chop or T-bone steak.

The synovial articulations at the lumbosacral junctions are unique. In contrast to the more superior lumbar joints, the facets of the inferior articulating processes of the fifth lumbar vertebra face forward and slightly downward, to engage the reciprocally corresponding articular processes of the sacrum. Because of the position of these joint surfaces, a certain amount of rotation should be possible between the fifth lumbar segment and the sacrum, but the presence of the strong iliolumbar ligaments quite likely restricts much motion of this type.

The most essential function of the synovial lumbosacral articulations involves their role as buttresses against the forward and downward displacement of the fifth lumbar vertebra in relation to the sacrum. When one considers that each region of the spine has its own characteristic curvature, the tracing of the vertical line indicating the center of gravity shows that it intersects the column through the bodies of the transitional vertebrae. The normal cervical lordosis places most of the cervical vertebrae anterior to the center of gravity, and the compensating thoracic kyphosis places the thoracic vertebrae posterior to the center of gravity. The lumbar lordosis brings the middle lumbar vertebrae anterior to the line. The transitional vertebrae between each region intersect the center of gravity and seem to be the most unstable regions of the spine; this is emphasized by the fact that disc problems and fractures most frequently occur in the transitional vertebrae.

Because the sacrovertebral angle produces the most abrupt change of direction in the column, and the center of gravity, which passes through the fifth lumbar body, falls anterior to the sacrum, there is a marked tendency for the thick, wedge-shaped fifth lumbar disc to give way to the shearing vector that the lumbosacral angularity produces. The resulting condition, spondylolisthesis, most frequently reveals a deficiency in the laminae (spondylolysis) that fails to anchor the fifth vertebral body to the sacrum and allows its forward displacement. There has been considerable discussion as to whether spondylolysis is congenital or acquired, but the spondylolisthesis seldom occurs without the laminar deficiencies as a preceding condition.

Biomechanics of the Intervertebral Disc

It is axiomatic in mechanical engineering that a well-designed machine automatically reveals its function through the analysis of its structure. There are few instances in biologic circumstances in which this statement is more applicable than in the case of the intervertebral disc. Even when the disc is simply divided with a knife and examined grossly, it is apparent that one is dealing with an organ that is remarkably constructed simultaneously to alleviate shock and transmit forces from every conceivable combination of vectors. This appreciation of the functional competency of the disc increases as its structure is analyzed at the finer levels of organization.

The internal composition of the disc has evolved to withstand great stresses through the liquid and elastic properties of nucleus and anulus acting in combination. The nucleus is distorted by compression forces, but being liquid it is in itself incompressible. It serves to receive primarily vertical forces from the vertebral bodies and redistribute them radially in a horizontal plane. It is the distortion of the anulus by the internal pressure of the nucleus that gives the disc its compressibility, and its resilience makes possible the recovery from pressure.

Were the nucleus pulposus simply a cavity filled with water, it would momentarily act in the same capacity, but the ability to maintain the appropriate quantity of fluid during the continual compression and recovery cycle would be lacking. This ability to absorb and retain relatively large amounts of water is the unique property of the living tissue of the nucleus.[121] The essential compound involved in this process is a protein-polysaccharide gel, which through a high imbibition pressure binds nearly nine times its volume of water. It is apparent that the hydrophilia is not a form of biochemical bonding because a quantity of water can be expressed from the nucleus by prolonged mechanical pressure. This accounts for the diurnal decrease in the total length of the spine and its recovery in the supine position at night.

The anulus must receive the ultimate effects of most forces transmitted from one vertebral body to another. Because the major loading of the intervertebral disc is in the form of vertical compression, it may seem paradoxical that the anulus is best constructed to resist tension, but the nucleus transforms the vertical thrust into a radial pressure that is resisted by the tensile properties of the lamellae. Although the basic plan of alternating bands of fibers is one of the obvious sources of the tensile strength of the anulus, this arrangement is not uniform with respect to the directions of the fibers or the degrees of resistance and resilience encountered throughout the anulus. The fibers generally become longer, and the angle of their spiral course becomes more horizontal near the circumference of the disc because it is here that the shearing stresses of vertebral torsions would be most effective. Experimental analysis has also shown that various parts of the anulus do not respond equally to the same degree of tension, and the discrepancies were related to the plane of section and the location of the sample.[122] The anulus proved to have the greatest resistance and the greatest recovery in horizontal sections of the peripheral lamellae, whereas vertical and more medial sections were more distensible.

Because the spine acts as a flexible boom to the guidewire actions of the erector spinae muscles, it is essentially the fulcrum of a lever system of the first class, in which the loading has a considerable mechanical advantage. Pure vector analysis has indicated that a theoretical pressure of approximately three-fourths of a ton could be applied to a disc when 100 lb is lifted by the hands,[21] but this is considerably in excess of the actual pressures achieved. Increased intrathoracic and intra-abdominal pressures alleviate much of the fulcrum compression of the discs by effectively counteracting the load of the anterior lever arm.

The actual pressure variations occurring with postural changes have been recorded by inserting transducers into the third lumbar disc.[123,124] This procedure indicated that the internal disc pressure increases from approximately 100 kg in a standing position with the spine erect to 150 kg when the trunk is bent forward and to 220 kg when a 70-kg man lifts a 50-kg weight. It was particularly revealing that the pressure showed a considerable increase when the equivalent maneuvers were repeated in a sitting position, and the weight lifting ultimately created a pressure of 300 kg on the third lumbar disc.

The disc is also "preloaded." The inherent tensions of the intervertebral ligaments and the anulus exert a pressure of about 15 kg because this weight is required to restore the original thickness of the disc after the ligaments have been divided.[110] From a comparative standpoint, this preloading probably offers increased stability to the spine as a functional flexible rod. One is almost induced unconsciously to use teleologic thinking in terms of the vertical thrust resistance when regarding the structure of the disc. In perspective, however, the intervertebral disc shows a consistent morphology in all mammals, yet humans are the only species that truly stand erect. Although analysis of muscular action would most likely show that all mammalian discs must dissipate and transfer axial thrusts, the preloading would enhance the "beam strength" that is obviously necessary in the vertebral column of quadrupeds.

CHAPTER 3

Skeletal Muscle: Architectural Design, Physiology, and Function

SECTION I

Samuel R. Ward
Anita Vasavada
Scott Delp
Richard L. Lieber

Spinal muscles generate movement of the spine and provide the stability needed to protect vital anatomic structures, in coordination with the rest of the neuromusculoskeletal system (vertebrae, tendons, ligaments, and the nervous system). For example, large movements of the head require appropriate muscle strength, vertebral geometry (e.g., facet joint orientation), ligament compliance, and neural control. Spinal muscles have been described as one of three subsystems (along with passive spinal column and neural control) that must work together to stabilize the spine.[1]

Spinal musculature dysfunction is hypothesized to be the cause of a variety of pathologic conditions, such as segmental instability, low back or neck pain, and degenerative disc syndromes. However, the mechanisms that relate muscle function (or dysfunction) to pathologic processes are unclear. Some factors that lead to pathologic processes may be elucidated by biomechanical analyses of spine kinematics along with the associated tissue strains and loads. Such analyses rely heavily on accurate knowledge of muscle forces, moment arms, and activation patterns to calculate loads and displacements, which is frequently unavailable for spinal muscles. Often, spinal muscles are ignored or overly simplified (e.g., modeled together as one muscle) because the anatomy of these muscles is considered too complex to represent realistically. However, the complex anatomy and architecture of spinal muscles profoundly influence their function; thus, this information must be incorporated into analyses in order to accurately predict the role of these muscles in spinal function and dysfunction.

In this chapter, an overview of skeletal muscle contractile properties is presented first. Then, a description of the important, and often neglected, principles of skeletal muscle architecture along with the ways that architecture determines muscle function are provided. In Chapter 4, specific information about the anatomy and architecture of the spinal musculature is provided, as well as information on the implications of spinal muscle anatomy and architecture for motor control, injury, and pain.

Cross-Bridge Cycle

The basic force-generating event in skeletal muscle is the cyclic formation of cross-bridges between the filamentous proteins actin and myosin. Most of our understanding of the mechanism of muscle contraction has come from excellent biochemical studies performed in the 1950s and the decades that followed.[2-4] It was during this period that methods for isolating specific muscle proteins were developed, together with methods for measuring their physicochemical and biochemical properties. In simple terms, biochemical experiments on muscle contractile proteins have shown that, during the cross-bridge cycle, actin (A) combines with myosin (M) and adenosine triphosphate (ATP) to produce force, adenosine diphosphate (ADP), and inorganic phosphate (P_i), which can be represented as a chemical reaction in this form:

$$A + M + ATP \rightarrow A + M + ADP + P_i + Force \qquad \text{(Eq. 1)}$$

It is obvious that if ATP is either not present or is rapidly depleted with the muscle cell, the number of A-M cross-bridges, and therefore force, will decrease. This is manifested in muscles as "fatigue." Importantly, many factors can cause ATP depletion and fatigue, which may predispose muscle tissue to injury.

Muscle Fiber Types

Overwhelming evidence indicates that skeletal muscle fibers are heterogeneous. In the early 1800s, it was observed that the gross appearance of different skeletal muscles ranged in color from pale white to deep red. In fact, one of the earliest classification schemes for muscle was based on color; thus, muscles were classified as "red" or "white" (Table 3.1). However, as experimental methods became more sophisticated, it became clear that numerous other differences existed between muscles. For example, certain muscles contract rapidly, whereas others contract more slowly; certain muscles maintain force for a

TABLE 3.1 Fiber Type Classification Schemes

Basis for Scheme	FIBER TYPE SPECTRUM			Reference
Metabolic	SO	FOG	FG	Peter et al., 1972[39]
Morphology and physiology	Slow red	Fast white	Fast white	Ranvier, 1873[40]
Z-line width	Red	Intermediate	White	Gauthier, 1969[41]
Histochemistry	III	II	I	Romanul, 1964[42]
Histochemistry	Type 1	Type 2A	Type 2B	Brooke and Kaiser, 1972[43]

Gene sequencing	Type 1	Types 2A and 2X	Type 2B	Schiaffino and Reggiani, 1993[46]

FG, fast glycolytic; FOG, fast oxidative glycolytic; SO, slow oxidative.

long period of time, whereas others fatigue rapidly; and certain muscles generate large forces, while others generate small forces. These functional properties led to descriptions of muscle as "fast twitch" or "slow twitch," and "fatigable" or "nonfatigable." In addition, with the advent of light microscopy and histochemistry, it became possible to classify individual fibers based on their appearance following a particular staining protocol. Unfortunately, many of these classification schemes did not correlate simply with muscle color. In fact, many of them did not correlate at all with one another. The main problem with fiber-type classification schemes is that the classified feature may correlate with one physiologic or biochemical property, but may have no relationship to others.

The current view of muscle fiber types is that skeletal-muscle fibers possess a wide spectrum of morphologic, contractile, and metabolic properties.[5] The appropriate view of any classification scheme, therefore, is that it is an artificial system superimposed on a continuum of properties for our convenience. Probably the most useful "fiber-typing" scheme is one that describes contractile speed and muscle oxidative capacity. There are a variety of ways to do this; several schemes are listed in Table 3.1. The most definitive method for typing human skeletal muscle (not necessary the most physiologic, but very consistent among labs) is to use the type of myosin heavy chain expressed in the fibers. One of the most convenient methods to type a muscle based on myosin heavy chains is to homogenize large-muscle biopsies and separate the myosin isoforms on protein gels.[6] Using this method, it is possible to identify the three fiber types in human muscle: types 1, 2A, and 2X (see Table 3.1). Although there are four human myosin heavy chain gene—type 1, type 2A, type 2X, and type 2B—only the former three are expressed.[7] This strange phenomenon can make it difficult to compare animal muscle studies with human muscle studies.

Fiber Type Distribution of Paraspinal Muscles

Since fiber types develop in response to functional demands, the fiber type of paraspinal and lumbar extensor muscles provides insight into their function and use patterns. It has been clearly shown that the paraspinal and lumbar extensor muscles are largely composed of type 1 and type 2A fibers. Thus, these muscles are predicted to be relatively slow contracting and fatigue resistant compared to most limb muscles. In fact, recent analysis of paraspinal muscles showed that multifidus, longissimus, and iliocostalis muscles comprised more than 60% type 1 muscle fibers[8]; this proportion is greater than many limb muscles, such as flexor digitorum profundus (35.5 ± 4.8%), triceps (42.4 ± 3.6%), brachioradialis (45.5 ± 6.4), or vastus lateralis (48.3 ± 9.5%), but approaching the values of other tonic, postural muscles such as soleus (88%).[9] Fiber-type distributions of different spinal muscles are described further in Chapter 4.

Muscle Injury

Injury to muscle fibers can occur as a result of trauma, disease, application of myotoxic agents (e.g., local anesthetics), inflammatory processes, or intense exercise. The degree to which muscle injury relates to low back pain or neck pain is unknown. However, muscle injury, and the pain that accompanies it, have been studied extensively. Skeletal-muscle injury and soreness frequently occur when a muscle is rapidly lengthened while it is activated. Active lengthening of muscle (also called eccentric contraction) has been used to study injuries in animals and humans for more than 30 years. Muscle pain accompanying eccentric exercise peaks 24 to 48 hours after the exercise bout. Several studies have reported that eccentric exercise results in a significant increase in serum creatine kinase levels 24 to 48 hours after the exercise bout[10,11] that may persist for 3 to 6 days, depending on the precise nature of the exercise. The appearance of creatine kinase in the serum is interpreted as a result of increased permeability, or breakdown of the muscle cell membrane surrounding the muscle cell.

Eccentric training of a specific muscle group prevents, or at least attenuates, the magnitude of muscle injury that occurs after eccentric exercise in that muscle group. However, general increased fitness does not prevent or reduce eccentric contraction-induced muscle injury.

Experimental studies of skeletal muscles directly subjected to eccentric exercise suggest that early mechanical events result in muscle injury.[12,13] For example, during cyclic eccentric exercise of the rabbit tibialis anterior, significant

biomechanical changes were observed in the first 5 to 7 minutes of exercise.[14] Other studies have revealed structural disruption of the cytoskeleton within the fibers during these early time periods,[15,16] which may provide further insights into the damage mechanism.

Animal and human studies have provided evidence for selective damage of fast-fiber types after eccentric exercise.[17-19] In human studies, this damage was generally confined to the type 2 muscle fibers; but in animal studies, damage has been further localized to the fastest of the fast-fiber subtypes. Because these are also the most highly fatigable muscle fibers,[20] it has been speculated that the high degree of fatigability of these fibers may predispose them to injury. In fact, several clinical studies have proposed that the fatigability of spinal muscles may be a predisposing factor to injury. However, it is difficult to test this idea directly because of the many other differences between these fibers and other fiber types. Further studies are required to elucidate the basis for fiber type–specific injury to skeletal muscle and to document the relationship between spinal muscle injury and back and neck pain.

Muscle Architecture

While muscle fiber types are much more widely studied and reported (probably due to the ease with which fiber-type data can be obtained), muscle functional properties are much more highly determined by muscle architecture—the number and arrangement of muscle fibers relative to the axis of force generation.[21–23] Whereas muscle fiber size (which is directly proportional to force generation) is relatively consistent among muscles of different sizes, architectural differences between muscles are much more variable and much more strongly affect function. Thus, muscle architecture is a primary determinant of muscle function, and understanding this structure–function relationship is of great practical importance not only in clarifying the physiologic basis for production of force and movement but also in providing a scientific rationale for surgery or rehabilitation. Muscle architectural studies also guide electrode placement for electromyographic measures of muscle activity, explain the mechanical basis of muscle injury during movement, and aid in the interpretation of histologic specimens obtained from muscle biopsies.

Basic Architectural Definitions

The various types of architectural arrangement are as numerous as the muscles themselves. For discussion purposes, however, we present three general classes of muscle-fiber architecture. Muscles composed of fibers that extend parallel to the muscle's force-generating axis are described as having a parallel or longitudinal architecture (Fig. 3.1A). Muscles with fibers that are oriented at a single angle relative to the force-generating axis are described as having unipennate architecture (Fig. 3.1B). The angle between the fiber and force-generating axis has been measured at resting length in different mammalian muscles and varies from about 0 to 30 degrees. It becomes obvious when performing muscle dissections that most muscles fall into the third and most general category,

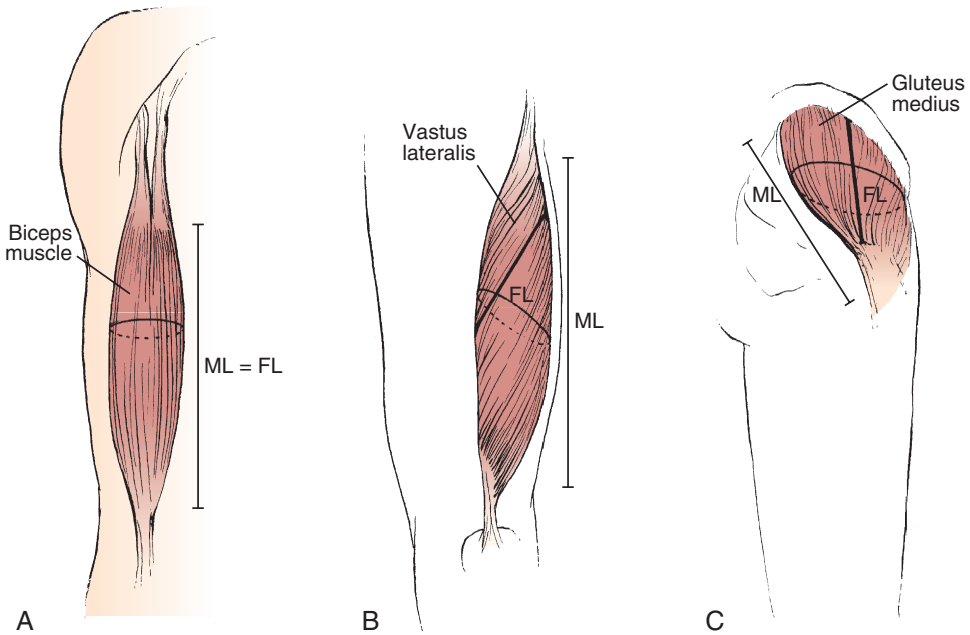

FIG. 3.1 Three general types of skeletal muscle architecture. (A) Longitudinal architecture in which muscle fibers run parallel to the muscle force-generating axis. A typical example is the biceps brachii. (B) Unipennate architecture in which muscle fibers run at a fixed angle relative to the muscle's force-generating axis. The vastus lateralis muscle is shown. (C) Multipennate architecture in which muscle fibers run at several angles relative to the muscle's force-generating axis. The gluteus medius muscle is shown. FL, fiber length; ML, muscle length.

multipennate muscles—muscles constructed of fibers that are oriented at several different angles relative to the axis of force generation (Fig. 3.1C). Obviously, these three designations are oversimplified, but they provide a vocabulary with which to describe muscle architecture. Because fibers may not be oriented along any of the classic anatomic axes, determination of muscle architecture is impossible from a single biopsy or even magnetic resonance imaging (MRI), computed tomography (CT), or ultrasonography, because these methods cannot account for the variations in fiber length and orientation that occur along the muscle length. Thus, other methods, which are described in some detail later, have been developed to characterize the architectural properties of skeletal muscle.

Experimental Determination of Skeletal Muscle Architecture

Quantitative studies of muscle architecture were pioneered by Gans and his colleagues,[23,24] who developed a precise methodology for defining muscle architecture based on microdissection of whole muscles. The parameters usually included in an architectural analysis are muscle length, fiber or fascicle length, pennation angle (i.e., the fiber angle relative to the axis of force generation), and physiologic cross-sectional area (PCSA). Typically, muscles are chemically fixed in formalin to maintain fiber integrity during dissection.

Pennation angle (θ) is measured by determining the average angle of the fibers relative to the axis of force generation. Usually only the pennation angle of fibers on the superficial muscle surface is measured, although pennation angles may vary from superficial to deep and also from proximal to distal. In fact, variation in pennation from superficial to deep fibers has been documented in several spinal muscles (see Chapter 4). Although more sophisticated methods could be developed for measurement of pennation angle (e.g., diffusion tensor imaging), it is doubtful they would provide a great deal more insight into muscle function because variations in pennation angle do not dramatically affect function.[23]

Muscle length is defined as "the distance from the origin of the most proximal muscle fibers to the insertion of the most distal fibers."[25] Fiber length represents the number of sarcomeres in series, and experimental evidence suggests that muscle fiber length is proportional to fiber contraction velocity.[24,26] Muscle length and fiber length are not always the same because there is a variable degree of "stagger" seen in muscle fibers as they arise from and insert onto tendon plates (see Fig. 3.1). Muscle fiber length can only be determined by microdissection of individual fibers from fixed tissues or by laborious identification of fibers by glycogen depletion followed by serial sections along the length of the muscle.[27] Unless investigators are explicit when they refer to muscle fiber length, they are probably referring to muscle fiber bundle length (also known as fascicle length) because it is extremely difficult to isolate intact fibers that run from origin to insertion, especially in mammalian tissue.[27,28] Experimental studies of mammalian muscle suggest that individual muscle fibers do not extend the entire muscle length and may not even extend the entire length of a fascicle.[27,28] Detailed studies of individual muscle fiber lengths have not been conducted in human spinal muscles, but studies in feline neck muscles illustrate that muscle fibers are often arranged in series, ending in tendinous inscriptions within the muscle or terminating intrafascicularly.[29,30] Although the terms fiber length and fascicle length are often used interchangeably, technically they are identical only if muscle fibers span the entire length of a fascicle. In muscle architecture studies, bundles consisting of 5 to 50 fibers are typically used to estimate fiber length, which may be reported as either fiber length or fascicle length.

The final and crucial experimental step required to perform architectural analysis of a whole muscle is to measure the sarcomere length within the isolated fibers. This is necessary to compensate for differences in muscle length that occur during fixation. In other words, to conclude that a muscle has "long fibers" one must ensure that it was not merely fixed in highly stretched position corresponding to a long sarcomere length. Similarly, muscles with "short fibers" must be further investigated to ensure that they were not simply fixed at a short sarcomere length. To permit such conclusions, fiber length measurements should be normalized to a constant sarcomere length. Fiber (or fascicle) lengths are usually normalized to the sarcomere length at which the sarcomere generates maximum force. This normalized fiber length is referred to as optimal fiber (or fascicle) length and provides a reference value that can be related back to the physiologic length if the relationship between muscle length and joint position is noted. Then, based on measured architectural parameters and joint properties, the relationship between sarcomere length and joint angle can be calculated. As an alternative to measurements in cadavers, sarcomere lengths can be measured in live humans using intraoperative laser diffraction[31] or less invasively with microendoscopy.[32,33] Because sarcomere length strongly influences muscle force generation, an understanding of the relationship between sarcomere length change and movement has been used in many studies to provide added understanding of muscle design.[31,34–37]

The physiologic cross-sectional area (PCSA) is the main architectural calculation. Theoretically, PCSA represents the sum of the cross-sectional areas of all the muscle fibers within the muscle, and thus it is the only architectural parameter that is directly proportional to the maximum tetanic tension generated by the muscle. The PCSA is almost never the same as the cross-sectional area of the muscle measured in any of the traditional anatomic planes, as would be obtained using a noninvasive imaging method such as MRI, CT, or ultrasonography. It is calculated as muscle volume divided by fiber length and has units of area. Because fibers may be oriented at a pennation angle relative to the axis of force generation, not all of the fiber tensile force is transmitted to the tendons. Specifically, if a muscle fiber is pulling with X units of force at a pennation angle θ relative to the muscle axis of force generation, only a component of muscle fiber force ($X \bullet \cos\theta$) will actually be transmitted along the muscle axis. Thus, the volume/length is often multiplied by cosine θ (pennation angle) to yield PCSA.

Mechanical Properties of Muscles With Different Architectures

As stated earlier, muscle force is proportional to PCSA and muscle velocity is proportional to fiber length. By stating that velocity is proportional to fiber length, it is implicit that the total excursion (active range) of a muscle is also proportional to fiber length. Thus, it is important to understand how these two architectural parameters, PCSA and fiber length, affect muscle function.

Comparison of Two Otherwise Identical Muscles With Different PCSAs

Suppose that two muscles have identical fiber lengths and pennation angles but one muscle has twice the mass (equivalent to saying that one muscle has twice the number of fibers, thus twice the PCSA). For the sake of simplicity, suppose that these two muscles have identical fiber-type distributions and that they generate the same force per unit area. The functional difference between these two muscles is shown in Fig. 3.2.

The muscle with twice the PCSA has an isometric length–tension curve with the same shape, but it is amplified upward by a factor of 2. Thus, the maximal tetanic tension (P_o) of the larger muscle will be twice that of the smaller muscle. Similarly, comparison of isotonic force–velocity curves indicates that the differences between muscles will simply be an upward shift in P_o for the larger muscle.

Comparison of Two Otherwise Identical Muscles With Different Fiber Lengths

For two muscles with identical PCSAs and pennation angles but different fiber lengths, the schematic in Fig. 3.3 demonstrates that the effect of increased fiber length is to increase muscle excursion and velocity. Peak force of the length–tension curves is identical between muscles, but the range of lengths over which the muscle generates active force is different. For the same reason that increased fiber length increases the active muscle range of the length–tension relationship, it also results in an increase in the muscle's maximum velocity (V_{max}).

Interplay of Muscle Architecture and Moment Arm

In addition to its architecture, the moment generated by a muscle is influenced by its moment arm. Moment arm, the

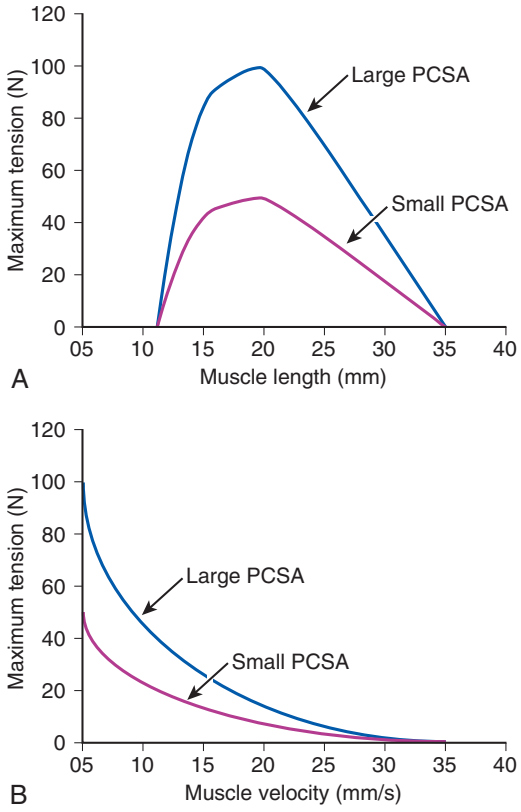

FIG. 3.2 Two muscles with different physiologic cross-sectional areas (PCSAs) but identical mass. (A) Comparison of isometric length–tension properties. (B) Comparison of isotonic force–velocity properties. The effect of increased PCSA with identical fiber length is to shift the absolute length–tension and force–velocity curves to higher values, but with retention of the same range and intrinsic shape.

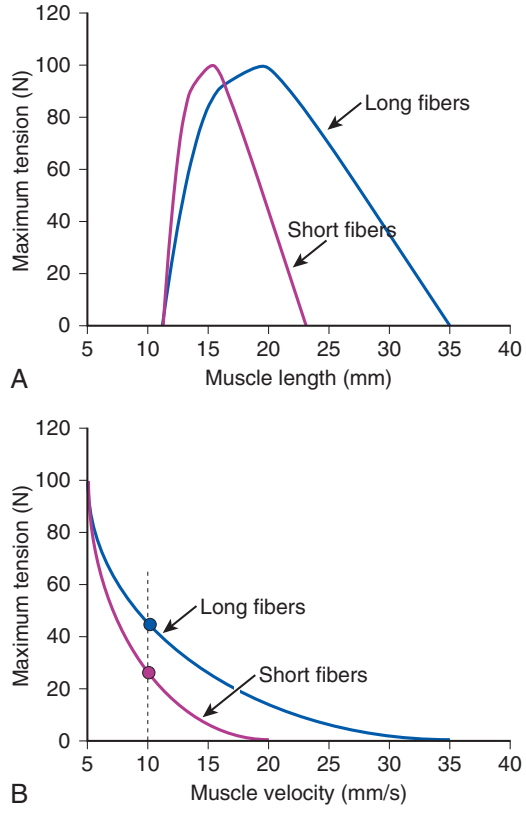

FIG. 3.3 Two muscles with different fiber lengths but identical physiologic cross-sectional areas. (A) Comparison of isometric length–tension properties. (B) Comparison of isotonic force–velocity properties. The effect of increased fiber length is to increase the absolute range of the length–tension curve and absolute velocity of the force–velocity curve, but with retention of the same peak force and intrinsic shape. The dotted vertical line in (B) demonstrates that, for an equivalent absolute velocity, the muscle with longer fibers will generate a greater force.

"mechanical advantage" of a muscle, is the distance from a muscle's line of action to the joint axis of rotation and is directly related to a muscle's change in length with joint rotation.[38] In other words, the amount of muscle fiber length change that occurs as a joint rotates—and, consequently, the range of joint angles over which the muscle develops active force—both depend on the muscle moment arm. This idea can be explained by comparing the situation in which two muscles with identical fiber lengths have different moment arms at a joint (Fig. 3.4). In the case in which the moment arm is greater, muscle fibers will change length much more for a given change in joint angle compared with a muscle with a shorter moment arm. As a result, the range of joint motion over which the muscle develops active force will be smaller for the muscle with the larger moment arm in spite of the fact that the muscular properties of both muscles are identical. The architectural design of a muscle and its placement in relation to skeletal geometry are both important determinants of its function. Although it is true that muscles with longer fibers can generate force over a greater range of lengths than muscles with shorter fibers (e.g., Fig. 3.3A), this does not necessarily indicate that muscles with longer fibers are associated with joints that have larger ranges of motion. Muscles that appear to be designed for speed based on their long fibers may not actually produce large joint velocities if they are placed in the skeleton with a very large moment arm, because joint excursion and joint angular velocity are inversely related to moment arm. A large moment arm results in a large joint moment, so that the muscle would be highly suited for torque production but at low angular velocities. Similarly, a muscle that appears to be designed for force production due to a large PCSA, if placed in a position with a very small moment arm, may actually produce high joint excursions or angular velocities. Differences between muscle–joint systems thus require complete analysis of both joint and muscular properties. These interrelated concepts of architecture and moment arm (gross anatomy) must be considered when examining the design and function of spinal muscles. This concept is fairly complex and it takes practice to become facile with such functional anatomic descriptions.

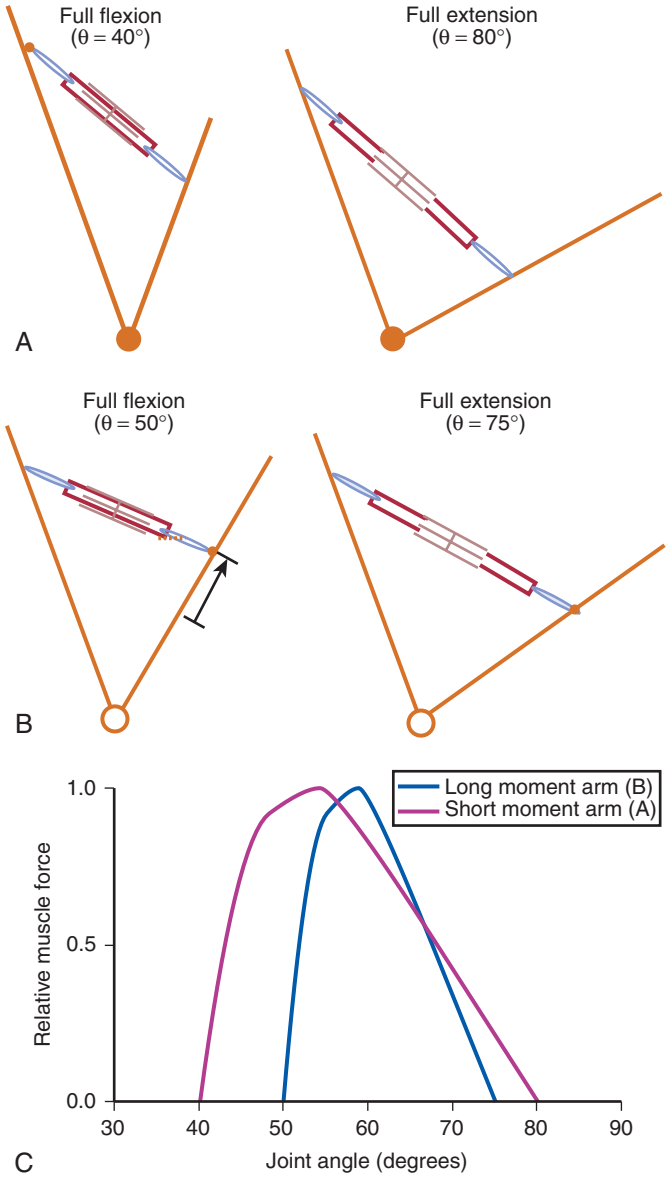

FIG. 3.4 Effect of changing moment arm on active range of motion (ROM). In this example, a schematic muscle (shown as a sarcomere in series with some tendon) is attached with two different moment arms. (A) 40 degrees range of motion for "normal" muscle (from 40 degrees to 80 degrees). (B) Moment arm increase results in a decrease in range of motion to 25 degrees muscle (from 50 degrees to 75 degrees). In (B), the active ROM is smaller since the moment arm is greater; therefore, more sarcomere length change occurs for a given angular rotation. (C) Comparison of force versus joint angle (ROM) for muscles with short or long moment arms.

Summary

In this chapter, the basic functional properties of muscle sarcomeres that generate force via the cross-bridge cycle were reviewed. Muscle fibers are heterogeneous, and descriptors of human muscle typically refer to types 1, 2A, and 2X, relating to the type of myosin heavy chain expressed in the fibers. Finally, the major anatomic property that predicts skeletal-muscle function is muscle architecture. This arrangement of muscle fibers and placement of the muscle in relation to skeletal geometry determines the moments generated at all joints—whether relatively simple, such as the elbow, or complex, such as intervertebral movement. Application of these concepts to the spine and spinal muscles is presented in more detail in Chapter 4.

CHAPTER 4

Spinal Musculature: Anatomy and Function

SECTION I

Anita Vasavada
Samuel R. Ward
Scott Delp
Richard L. Lieber

Anatomy and Architecture of Spinal Musculature

The architecture of spinal muscles is complex and dramatically different from the architecture of limb muscles. For example, instead of distinct tendinous attachments to bone, many spinal muscles have very little tendon at their ends, but have a complex arrangement of internal tendons and aponeuroses. Their attachments are generally broad, and many spinal muscles branch and have insertions at multiple vertebral levels. Some spinal muscles have short fascicles and high pennation, whereas others have long, parallel fascicles. All of these factors affect the force- and moment-generating capacity of muscles (as described in Chapter 3), which ultimately influences control of spinal movement and injury mechanisms.

Spinal muscles can be divided into intrinsic muscles, which connect vertebrae with each other or with the skull, and extrinsic muscles, which attach vertebrae to the limbs, shoulder girdle, ribcage, or pelvis. Embryologically, intrinsic muscles originate from the epimere and extrinsic muscles originate from the hypomere. Intrinsic muscles receive innervation from the dorsal rami of spinal nerves, whereas extrinsic muscles are innervated by the ventral rami of spinal nerves and generally have functions related more to the proximal portion of limbs or respiration.

Intrinsic Spinal Muscles in the Lumbar, Thoracic, or Cervical Spine

Intrinsic muscles of the spine are dominated by the erector spinae, a group of interdigitated muscles that span the entire length of the spine, from the sacrum and iliac crest to the skull. Another important group of muscles, the multifidus, are shorter and deeper, and are described in more detail later. In the thoracolumbar region, the erector spinae and multifidus muscles comprise the bulk of the spinal musculature. These two distinct functional units have large differences in innervation that probably result in significant functional differences,[1] although the detailed biomechanical function of these groups remains only partially elucidated.[2] Lying deep to the multifidus are even smaller muscles: the rotatores, interspinales, and intertransversarii. The cervical region is composed of other unique intrinsic muscles (described later).

The erector spinae are commonly considered to be composed of three muscles; from medial to lateral, they are the spinalis, longissimus, and iliocostalis. The anatomy and architecture of these muscles vary among different levels of the spine. Therefore, the words "lumborum," "thoracis," "cervicis," and/or "capitis" are often appended to the muscle name to describe the anatomy more accurately. Although there are varying definitions of the composition of the erector spinae, the study by MacIntosh and Bogduk[2] provides the most comprehensive descriptive anatomy of the lumbar erector spinae to date; Delp and colleagues[3] provided the first architectural measurements of these muscles. A description of the continuation of the erector spinae into the cervical region is discussed by Kamibayashi and Richmond.[4]

The spinalis muscle is the most medial division of the erector spinae. MacIntosh and Bogduk[2] describe the spinalis as mostly aponeurotic in the lumbar region, but Delp and colleagues[3] obtained architecture measurements from muscle fibers in the thoracic spinalis (Table 4.1). The spinalis is generally absent in the cervical region.

Caudad to rostrad, the longissimus consists of the longissimus thoracis, cervicis, and capitis. The longissimus thoracis is divided into lumbar and thoracic portions. The lumbar fascicles of the longissimus thoracis (longissimus thoracis pars lumborum) are composed of five bands that arise from the lumbar transverse processes and attach in a caudal fashion onto the iliac crest (Fig. 4.1A). Each band arising from vertebrae L1 to L4 is actually a small fusiform muscle that has an elongated and flattened caudal tendon of insertion. Bands from more rostral levels attach more medially on the iliac crest. The juxtaposition of these caudally located tendons forms the lumbar intermuscular aponeurosis. Fascicles of the thoracic component of longissimus thoracis (longissimus thoracis pars thoracis) arise from all thoracic transverse processes and most ribs, and attach to either lumbar spinous processes, the sacrum, or the ilium. These are long slender muscles with pronounced caudal tendons that juxtapose to

TABLE 4.1 Architectural Data of Rectus Abdominis and Lumbar Spine Muscles

Muscle	Musculotendon Length (cm)	Muscle Length (cm)	Fascicle Length (cm)	Pennation Angle (degrees)	Sarcomere Length (μm)	Optimal Fascicle Length (cm)	Muscle Fiber Mass (g)	PCSA (cm^2)
Rectus abdominis	35.9 (1.9)	34.3 (2.7)	28.3 (3.6)	0 (0)	2.83 (0.28)	28 (4.2)	92.5 (30.5)	2.6 (0.9)

Iliocostalis lumborum	43.8 (4.3)	33.1 (9)	12 (1.7)	13.8 (4.5)	2.37 (0.17)	14.2 (2.1)	60.9 (29.9)	4.1(1.9)
Multifidus	NA	NA	4.8 (1.7)	18.4 (4.2)	2.26 (0.18)	5.7 (1.8)	73 (12.4)	23.9 (8.4)

Values are mean (standard deviation).
NA, not applicable; PCSA, physiologic cross-sectional area.
Modified from Delp SL, Suryanarayanan S, Murray WM, et al. Architecture of the rectus abdominis, quadratus lumborum, and erector spine. *J Biomech* 2001;34:371–375; and Ward, SR, Kim CW, Eng CM, et al. Architectural analysis and intraoperative measurements demonstrate the unique design of the multifidus for lumbar spine stability. *J Bone Joint Surg Am.* 2009;91:176-185.

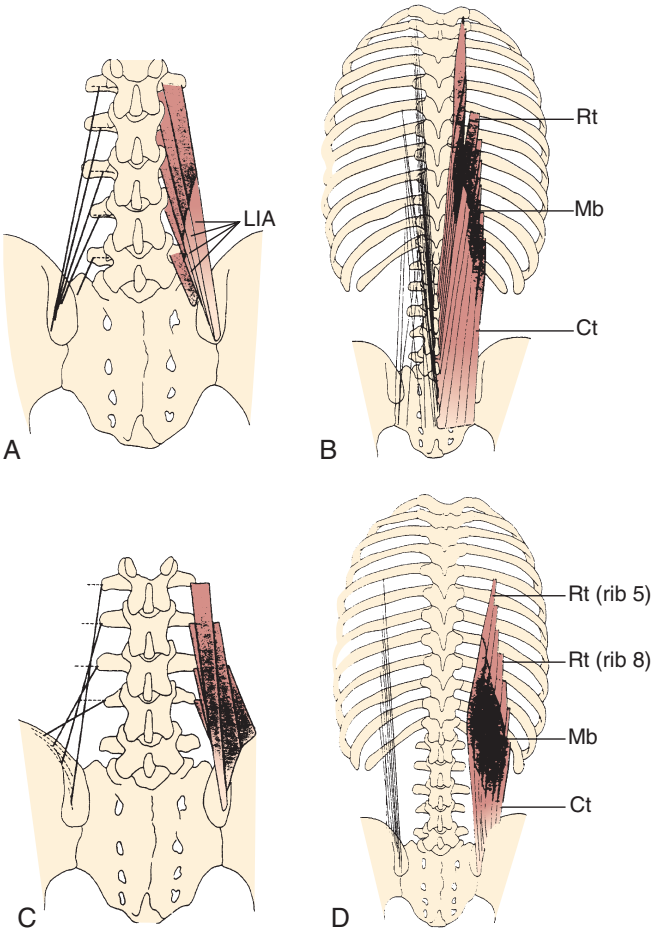

FIG. 4.1 Longissimus thoracis (medial division of erector spinae) schematic of (A) lumbar and (B) thoracic regions and iliocostalis lumborum (lateral division of erector spinae) schematic of (C) lumbar and (D) thoracic regions. Ct, caudal tendon; Mb, muscle belly; LIA, lumbar intermuscular aponeurosis; Rt, rostral tendon. (From Bogduk N. A reappraisal of the anatomy of the human lumbar erector spinae. *J Anat,* 1980;131:525-540; and MacIntosh JE, Bogduk N. The morphology of the lumbar erector spinae. *Spine.* 1987;12:658–668.)

form the strong erector spinae aponeurosis (see LIA and Ct in Fig. 4.1A–B), which bounds the lumbar paraspinal muscles dorsally. In the upper thoracic and cervical region, the longissimus cervicis connects transverse processes of thoracic and cervical vertebrae, whereas the longissimus capitis originates on transverse processes and inserts on the mastoid process of the skull (Fig. 4.2B).

The lumbar fascicles of the iliocostalis lumborum (iliocostalis lumborum pars lumborum) lie lateral to the longissimus thoracis muscles arising from the tip of the transverse processes of vertebrae L1 to L4 in the lumbar region, thus are composed of four small, broad bands (see Fig. 4.1C) that attach to the thoracolumbar fascia and the iliac crest. The thoracic fascicles of the iliocostalis lumborum (iliocostalis lumborum pars thoracis) arise from ribs and attach to the iliac spine and crest, forming the lateral part of the erector spinae aponeurosis. In contrast to the more medially located longissimus thoracis, the caudal tendons are less prominent, giving the iliocostalis lumborum a much more fleshy appearance. Caudad to rib 10, the iliocostalis lumborum and longissimus thoracis lie side by side, forming the erector spinae aponeurosis. Rostral to rib 9 or 10, the iliocostalis thoracis separates the iliocostalis lumborum and longissimus thoracis. In the upper thoracic and cervical region, the iliocostalis cervicis connects the ribs to the transverse processes of cervical vertebrae. MacIntosh and Bogduk measured muscle and tendon lengths in the thoracic portions of the longissimus thoracis and iliocostalis lumborum (Table 4.2).[2] Detailed architecture of the lumbar erector spinae, including muscle tendon and fascicle length, sarcomere lengths, and physiologic cross-sectional areas (PCSAs) have also been reported by Delp et al.[3] (see Table 4.1). They found that fascicle lengths were approximately 30% of muscle lengths in these muscles and that sarcomere lengths measured from cadavers in the supine position were generally shorter than the optimal length, which may imply that the erector spinae are capable of developing greater force in elongated positions (i.e., in flexion).[5] This muscle may thus be designed to restore spine extension from flexion. Although longissimus and iliocostalis may have different functions because of their medial-to-lateral anatomic locations, their fiber type distributions are similar, with approximately 60% type 1 fibers,[6] the slowest muscle fiber

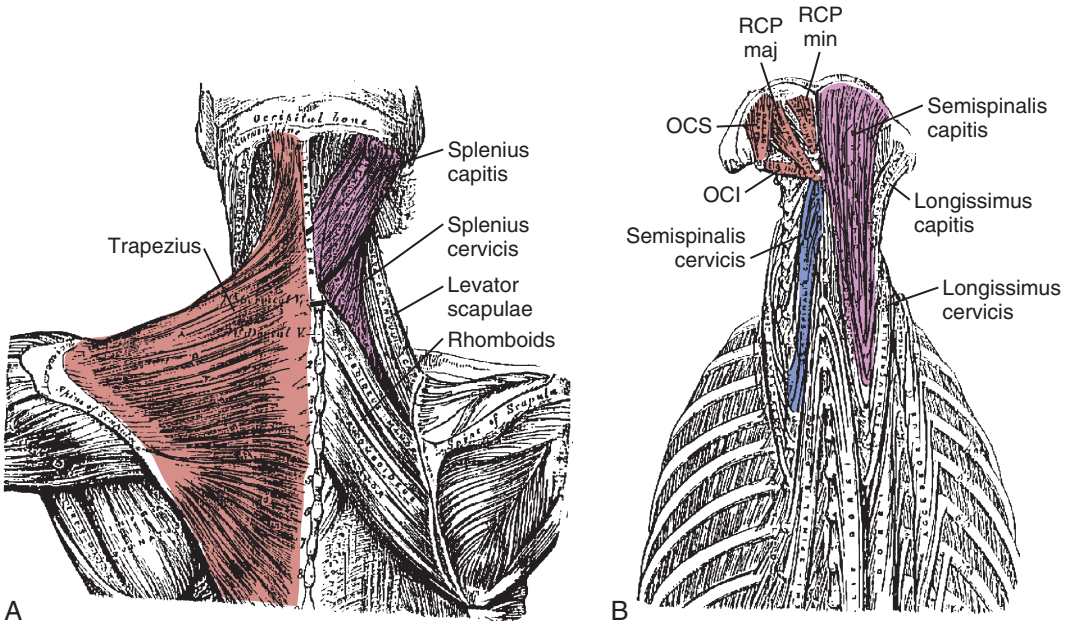

FIG. 4.2 Posterior view of neck muscles. (A) Left side shows the superficial muscle, the trapezius. Underneath the trapezius lie the splenius capitis, splenius cervicis, levator scapulae, and rhomboids. (B) Right side shows semispinalis capitis, longissimus capitis, and longissimus cervicis, which lie deep to splenius capitis. Left side shows semispinalis cervicis and the suboccipital muscles, which lie under semispinalis capitis. OCI, obliquus capitis inferior; OCS, obliquus capitis superior; RCP maj, rectus capitis posterior major; RCP min, rectus capitis posterior minor. TABLE 4.2 Muscle and Tendon Length Data of Lumbar Erector Spinae

Muscle	Muscle Belly Length (cm)	Rostral Tendon Length (cm)	Caudal Tendon Length (cm)
Longissimus thoracis pars thoracis	9-12	3-4	Up to 24
Iliocostalis lumborum pars thoracis	10-13	12-15	18-19

From MacIntosh JE, Bogduk N. The morphology of the lumbar erector spinae. *Spine.* 1987;12:658–668.

type. The detailed anatomy of the erector spinae provided by MacIntosh and Bogduk[2] also provides important information for electromyographic studies. Because thoracic fascicles of the longissimus thoracis and iliocostalis lumborum lie over the lumbar fascicles, electrodes placed at lumbar vertebral levels may not represent activity of fascicles directly attached to lumbar vertebrae.

The lumbar multifidus muscles consist of multiple separate bands arising from each vertebral spinous process and lamina, and inserting from two to four segments below the level of origin (Fig. 4.3B). The shortest fascicle of each muscle inserts onto the mammillary process of the vertebra located two segments caudad, whereas longer, more superficial fascicles insert sequentially onto subsequent vertebrae three or more segments lower (see Fig. 4.3). Thus, the shortest band of the multifidus arising from L1 inserts on L3; subsequent bands insert sequentially on L4, L5, and the sacrum. Multifidus muscles arising from lower lumbar vertebrae consist of fewer fascicles because the number of vertebrae caudad to the origin decreases. Of note is the fact that all multifidus muscles that arise from a given level are innervated by the medial branch

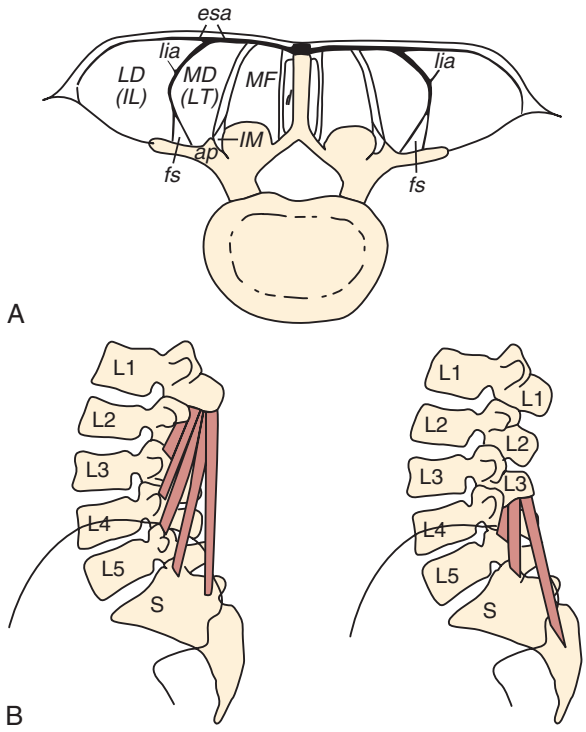

FIG. 4.3 Schematic arrangement of multifidus muscle in (A) cross-section and (B) longitudinal section. ap, accessory process; esa, erector spinae aponeurosis; fs, fat-filled space; I, interspinalis; IL, iliocostalis lumborum; IM, intertransversarii mediales; LD, lateral division; lia, lumbar intermuscular aponeurosis; MF, multifidus. (From Bogduk N. A reappraisal of the anatomy of the human lumbar erector spinae. *J Anat.* 1980;131:525–540.)

of the primary dorsal rami of the spinal nerve from a single segment (i.e., each band of multifidus muscle is innervated from a single dorsal ramus). This unisegmental innervation has implications for electromyography and diagnosis of zygapophyseal joint pain related to abnormal activity in multifidus. For instance, medial fibers of multifidus (i.e., those immediately lateral to a given spinous process) arise from the spinous process directly above, whereas those from higher levels will be more lateral, but all the fibers of the multifidus arising from a particular vertebra are innervated by the same nerve.[7]

In the cervical region, multifidus fascicles from the spinous processes and laminae of C2, C3, and C4 attach onto facet capsules of two adjacent vertebral articular processes from C4 to C7; fascicles from the spinous processes and laminae of C4 to C7 attach onto transverse processes of upper thoracic vertebrae.[8] The principal action of the multifidus is extension, but the multisegmental nature of the muscle as well as the complex three-dimensional orientation in the cranial-caudad and mediolateral directions renders this statement a gross oversimplification.[9] The multifidus is not necessarily a prime mover of the spine; rather, its function is likely to produce small vertebral stabilizations. Its fiber type distribution of approximately 60% type 1 fibers supports this postural role. In fact, similar fiber type distributions between multifidus and erector spinae muscles suggest similar functions for these two muscle groups.[6,10]

A recent study of the multifidus muscle revealed three major design factors that suit it well for stabilizing the lumbar spine.[5] First, the architecture of the multifidus is highly pennated, with fibers only extending about 20% of the length of the muscle. Thus, a large number of muscle fibers are packed into a small volume and, even though the multifidus has a smaller mass compared to several other lumbar extensors, it is predicted to create the greatest lumbar extension force by a factor of two (see Table 4.1). Second, direct mechanical testing of the multifidus muscle cells and extracellular connective tissue revealed that, while the multifidus fibers have the same mechanical properties as limb muscles, the fiber bundles, which include extracellular connective tissue, are about twice as stiff. Thus, the multifidus has a high passive elastic capacity that would suit it for passively resisting flexion of the lumbar spine. Third, the multifidus muscle sarcomere length, measured intraoperatively, is relatively short when the spine is extended, suggesting that the muscle gets stronger as it gets longer. In other words, as the spine flexes, multifidus force increases, suiting it to restore spine angles toward neutral or more extended positions.

Deep to the multifidus are smaller muscles that span one or two vertebral segments. The rotatores attach from caudal transverse processes to the base of rostral spines one or two segments away. Rotators are prominent in the thoracic region; although some authors claim that they exist in the lumbar region,[11,12] MacIntosh and Bogduk did not find any muscles deep to the lumbar multifidus.[7] Likewise, Anderson et al.[8] did not find rotatores in the cervical region. The interspinalis and intertransversarii (found in the lumbar and cervical regions) connect the spines and transverse processes, respectively, of adjacent vertebrae.

Intrinsic Spinal Muscles Specific to the Cervical Spine

Because of different functional demands in the cervical spine (e.g., large head movements), this region has additional intrinsic muscles. Kamibayashi and Richmond quantified neck muscle anatomy and architecture of the neck muscles (Table 4.3).[4]

Splenius Capitis and Cervicis

The splenius capitis originates at the spinous processes of the lower cervical and upper thoracic vertebrae and inserts on the skull near the mastoid process (see Fig. 4.2A). Contiguous, slightly deeper, and sometimes inseparable is the splenius cervicis, which originates on thoracic spinous processes and inserts on cervical transverse processes. Although both the splenius capitis and splenius cervicis function in extension, lateral bending, and axial rotation, the splenius capitis is oriented more obliquely than the splenius cervicis, providing more axial rotation capacity for movements of the skull relative to the vertebrae. The fascicle lengths of the splenius capitis and splenius cervicis are similar, but their muscle tendon lengths are not similar. This occurs because the splenius capitis has short aponeuroses, whereas the splenius cervicis has long aponeuroses (Fig. 4.4A).[4]

Semispinalis Capitis and Cervicis

The semispinalis capitis originates on the articular processes of the lower cervical vertebrae and transverse processes of the upper thoracic vertebrae, and inserts medially on the skull between the inferior and superior nuchal line (see Fig. 4.2B). The semispinalis capitis is characterized by complex patterns of internal tendon and tendinous inscriptions in the medial portion, whereas fascicles in the lateral portion are uninterrupted (see Fig. 4.4B).[4] The semispinalis cervicis (deep to the semispinalis capitis) originates on thoracic transverse processes and inserts on cervical spinous processes from C2 to C5, with the bulk of its mass inserting on C2.

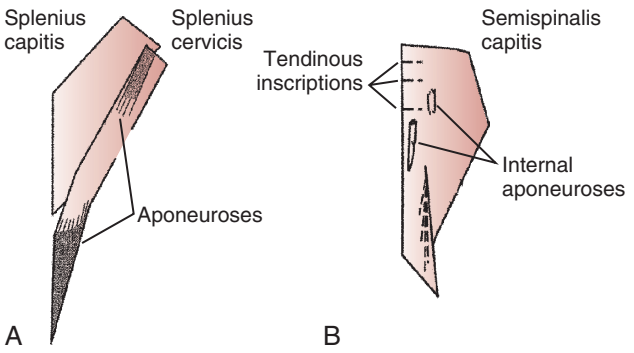

FIG. 4.4 Architecture of splenius capitis, splenius cervicis, and semispinalis capitis. (A) Splenius capitis and splenius cervicis. Note aponeuroses at both ends of splenius cervicis. (B) Semispinalis capitis. The medial portion is characterized by tendinous inscriptions and internal aponeuroses interrupting the fascicles. (Modified from Kamibayashi LK, Richmond FJR. Morphometry of human neck muscles. *Spine.* 1998;23:1314–1323.)

Longus Capitis and Colli

On the anterior side of the vertebral column, the longus capitis runs from the anterior surface of transverse processes to the baso-occiput (Fig. 4.5). Because it lies close to the vertebral bodies, it has only a small flexion moment arm; the superomedial orientation could provide ipsilateral rotation. Its counterpart, the longus colli, has a more complicated structure. Some fibers run vertically along the anterior vertebral bodies, other fibers run superolaterally from thoracic vertebral bodies to lower cervical transverse processes, and others run superomedially from transverse processes to the anterior vertebral bodies (see Fig. 4.5). Thus, although all parts of the longus colli have small flexion moment arms, the superomedial and superolateral portions would have ipsilateral and contralateral rotation moment arms, respectively. The longus capitis and colli are also characterized by an aponeurosis covering much of the superficial surface, from which fascicles have long tendons that attach to the vertebrae (Fig. 4.6).[4]

The longus capitis and longus colli were found to be composed of 50% type 1 fibers by number and 61% to 64% type 1 fibers by area.[13] Because of their small moment arms, their function is considered to be postural. The cross-sectional area of longus colli was found to be inversely correlated to cervical lordosis, suggesting a stabilizing function.[14]

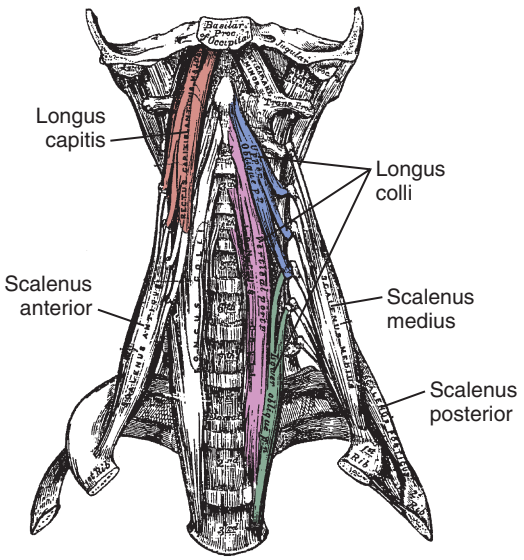

FIG. 4.5 Anterior view of deep neck muscles: longus capitis, longus colli, and scalenes. Note the three parts of longus colli: superior oblique, vertical, and inferior oblique. (Modified from Gray H. *Gray's Anatomy*. New York: Gramercy Books; 1977.)

Suboccipital Muscles

The suboccipital muscles span the region between C2 and the skull (see Fig. 4.2B). The rectus capitis posterior major and minor connect the spinous processes of C2 and C1, respectively, with the skull. The obliquus capitis superior is oriented in a superoinferior direction between the transverse process of C1 and the skull, and the obliquus capitis inferior runs primarily mediolaterally from the spinous process of C2 to the transverse process of C1. All four of these muscles can contribute to extension of the head with respect to the neck. In addition, the rectus capitis posterior major and the obliquus capitis inferior are oriented to produce ipsilateral rotation, and the lateral location of the obliquus capitis superior implies a lateral bending function. The obliquus capitis superior has an internal tendon on the deep surface that causes some fascicles to have large pennation angles.[4] On the ventral side, the rectus capitis anterior and rectus capitis lateralis are very small muscles that connect the skull to C1, presumably with (small) moment arms for flexion and lateral bending, respectively.

Extrinsic Muscles Linking Vertebrae to the Pelvis

The quadratus lumborum attaches from the iliolumbar ligament and iliac crest onto the 12th rib and transverse processes of L1 to L4. It assists in lateral bending of the lumbar spine. The proximal component of the quadratus lumborum (i.e., the set of fascicles running from the iliac crest to the 12th rib and L1) has a larger moment arm for lateral flexion and has longer fascicles than the distal component of the muscle. Electromyographic evidence shows that the quadratus lumborum has a dominant role in spine stabilization.[15]

The psoas major attaches from the anterior surface of the transverse processes, the sides of vertebral bodies, and intervertebral discs of all lumbar vertebrae. Together with the iliacus, which arises from the ilium, they form the iliopsoas, which inserts on the lesser trochanter of the femur and is a major flexor of the thigh and trunk. Fascicles of the psoas generally have the same length, regardless of their level of origin. Thus, because of their attachments to a common tendon, bundles from higher levels are more tendinous, whereas the bundle from L5 remains fleshy until it joins the common tendon.[16] The psoas is the largest muscle in cross-section at the lower levels of the lumbar spine.[17] Biomechanical analysis shows that the psoas has the potential to laterally flex the lumbar spine, generate compressive forces that would increase stability, and create large anterior shear forces at L5 to S1.[18] However, if psoas were designed for lumbar spine motions, one would expect an architectural design consisting of longer fascicles attaching to more rostral segments because they would undergo larger excursion. The uniform fascicle lengths suggest that the psoas may actually be designed to flex the hip[19]; electromyographic studies confirm that its primary function is hip flexion.[20]

Extrinsic Muscles Linking Vertebrae or Skull to the Shoulder Girdle or Rib Cage

On the anterior and lateral surface of the neck, the sternocleidomastoid originates from the sternum and medial clavicle to attach on the skull at the mastoid process and superior nuchal line of the occiput (Fig. 4.7). Kamibayashi and Richmond[4] divided this muscle into three subvolumes: sternomastoid, cleidomastoid, and cleido-occipital. The fascicles on the superficial surface (sternomastoid and cleido-occipital portions) lie in parallel. However, the cleidomastoid portion on the deep surface, which runs from the clavicle to mastoid process, increases the proportion of muscle fascicles exerting force on the mastoid process (Fig. 4.8).[4] Superficial inspection of muscle architecture can neglect the arrangement of these deep fascicles, which would decrease the estimated moment-generating capacity of the sternocleidomastoid in

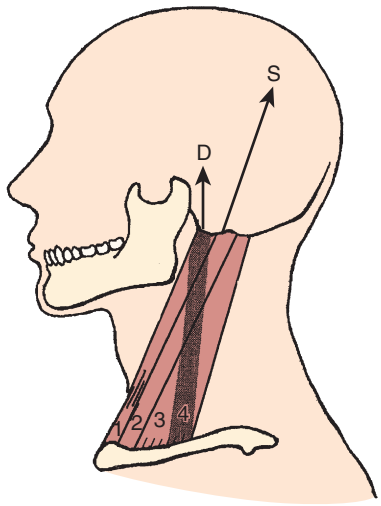

FIG. 4.8 Lines of action of sternocleidomastoid, including deep cleidomastoid portion. Arrows indicate differences in pulling direction of deep (D) and superficial (S) subvolumes. (Modified from Kamibayashi LK, Richmond FJR. Morphometry of human neck muscles. *Spine.* 1998;23:1314–1323.)

biomechanical models by more than 30%.[21] The sternocleidomastoid has moment arms for flexion, contralateral rotation, and lateral bending, and has been found to be active during movements in all three of these directions.

Also on the anterior surface of the neck, the infrahyoid muscles (sternohyoid, sternothyroid, thyrohyoid) link the hyoid bone, thyroid cartilage, and sternum, whereas the suprahyoid muscles (digastric, stylohyoid, mylohyoid, and geniohyoid) connect the hyoid bone to the mastoid process and mandible (see Fig. 4.7). The hyoid muscles are generally considered to maneuver the hyoid bone for deglutition and maintaining airway patency, but could potentially generate a neck flexion moment if the infrahyoid and suprahyoid muscles were activated in concert.

On the posterior surface of the neck, the trapezius is the most superficial muscle (see Fig. 4.2A). It can be divided into three segments: the rostral segment (also called clavotrapezius or trapezius pars descendens) runs from the lateral part of the clavicle to the occiput or ligamentum nuchae; the middle part (acromiotrapezius or pars transversa) runs nearly perpendicular to the midline at the lower cervical and upper thoracic levels from the lateral part of the scapular spine; and the caudal part (spinotrapezius or pars ascendens) attaches to spinous processes of T4 to T12 from the scapula. Its superficial position means that the trapezius has large moment arms for spine and head movements; however, its attachments to the scapula mean that shoulder movements also influence its function. Furthermore, the clavotrapezius (which attaches to the skull) has less than one-fifth of the mass of the acromiotrapezius,[4] indicating that the trapezius has less moment-generating potential for movements of the skull than generally believed.

Three other muscles connect the scapula to the cervical and thoracic vertebrae. The rhomboideus major and rhomboideus minor run from the medial border of the scapula to the midline at upper thoracic levels. Their major function is retraction of the scapula. The levator scapulae runs from the superior border of the scapula to the transverse processes of upper cervical vertebrae (see Fig. 4.2A). Like the trapezius, the functions of these muscles are related to movements of the shoulder.

The scalene muscles (scalenus anterior, medius, and posterior) run from the ribs to transverse processes of cervical vertebrae (see Fig. 4.5). Because of their lateral placement due to attachments to the ribs, the scalene muscles have substantial moment arms for cervical lateral bending; however, their main function is likely related to respiration. The scalene muscles were found to be composed of 52% to 72% type 1 fibers by number and 76% to 84% type 1 fibers by area. Although they are not postural muscles, the high percentage of type 1 fibers is likely related to their tonic function in respiration.[13] The serratus posterior superior and inferior also attach the vertebral column to the ribs. The serratus posterior superior arises from the lower part of ligamentum nuchae and the spines of the upper thoracic vertebrae, and attaches to ribs 2 to 5. The serratus posterior inferior originates from the spines of the lower thoracic and upper lumbar vertebrae, and attaches to ribs 9 to 12. These muscles function to elevate and depress the ribs, respectively.

The latissimus dorsi arises from the spinous processes of the lower six thoracic and upper two lumbar vertebrae, the thoracolumbar fascia, the iliac crest, and the lower ribs to insert on the humerus. The magnitudes of its potential force and moment on the lumbar spine and sacroiliac joint are small.[22] It is generally considered to move the arm, but if the upper limb were fixed, its activity could move the trunk (e.g., as in wheelchair transfers or crutch locomotion).

In summary, the spinal muscles are characterized by complex anatomy and architecture, and important biomechanical features are revealed when the architecture is studied in detail. However, the architecture of many spinal muscles, and its effects on function, remains to be determined.

Implications of Spinal Muscle Anatomy and Architecture for Motor Control

While the function of a muscle is dependent on muscle activity, neural control of a muscle is influenced by its architecture. Thus, architectural specialization of muscles means that the nervous system is not the only means available to modify muscular force and excursion. Although neural inputs can change muscle force, the effectiveness of neural input is altered by different muscle architectural features. In other words, nervous system commands are "interpreted" through the design of muscles to control posture and movement. Understanding both the biomechanics and neural control of spinal muscles, through models and experimental studies, is vital to understanding their role in pain and injury mechanisms.

Fascicle Length Changes With Posture

In the cervical spine, many extensor muscles undergo large length changes over the flexion–extension range of motion

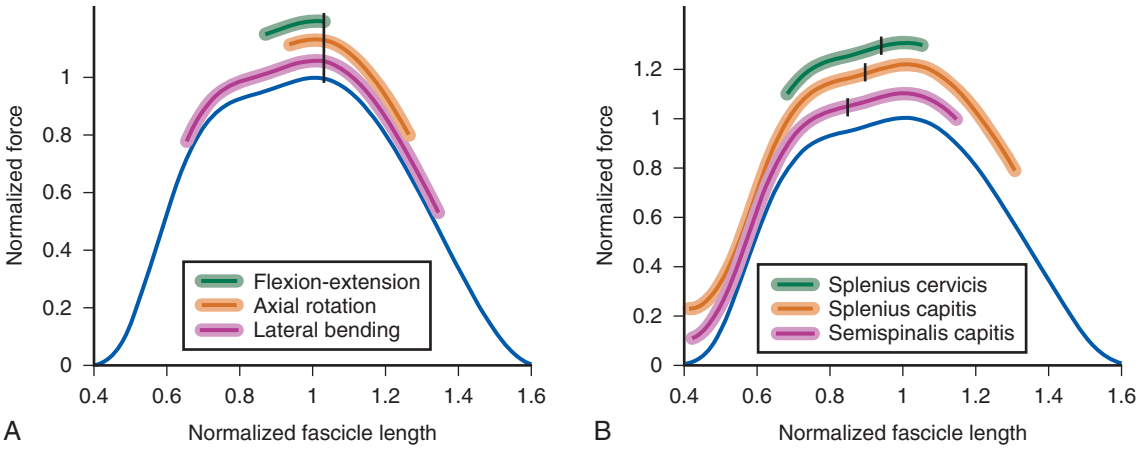

FIG. 4.9 Fascicle length excursions over the range of neck flexion–extension motion superimposed on a normalized muscle active force-length curve. (Modified from Vasavada A, Li S, Delp S. Influence of muscle morphometry and moment arms on the moment-generating capacity of human neck muscles. *Spine.* 1998;23:412–421.)

(ROM). A biomechanical model showed that the splenius capitis, semispinalis capitis, semispinalis cervicis, rectus capitis posterior major, and rectus capitis posterior minor all experience fascicle length changes greater than 70% of optimal length over the full ROM.[21] The change in fascicle length depends on both the optimal fascicle length of the muscle and the moment arm. For example, the splenius capitis and splenius cervicis have the same optimal fascicle length (see Table 4.3), but the splenius capitis has a much larger moment arm than the splenius cervicis. Thus, the splenius capitis undergoes larger fascicle length changes than the splenius cervicis over the same ROM (Fig. 4.9). On the other hand, the semispinalis capitis has shorter fascicle lengths but also a smaller moment arm than the splenius capitis. Thus, both the semispinalis capitis and splenius capitis experience similar large fascicle length excursions over the range of flexion–extension motion (see Fig. 4.9). In both muscles, fascicle lengths are extremely short in extended postures. This implies that the central nervous system must compensate for the associated decrease in force-generating potential by increasing activation or recruiting other extensors of the neck.

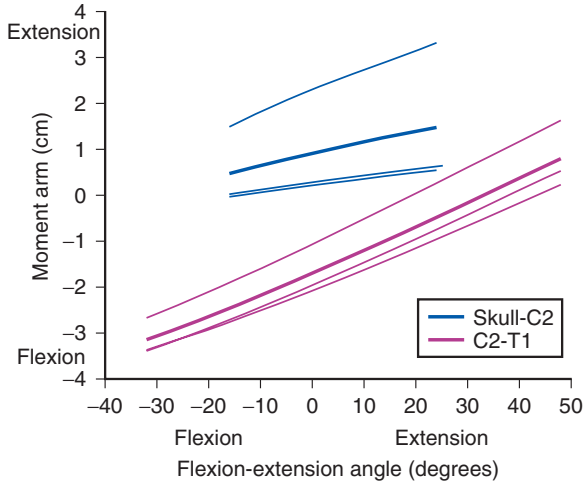

FIG. 4.10 Sternocleidomastoid flexion–extension moment arms. Light lines indicate individual subvolumes (sternomastoid, cleidomastoid, and cleido-occipital), and dark lines indicate a mass-weighted average. (Modified from Vasavada A, Li S, Delp S. Influence of muscle morphometry and moment arms on the moment-generating capacity of human neck muscles. *Spine.* 1998;23:412–421.)

Moment Arm Changes With Posture

Different parts of a muscle may have different moment arms, and the magnitude (and in some cases, direction) of these moment arms changes with posture. Furthermore, muscles that cross multiple joints (as most spinal muscles do) may have different mechanical functions at different joints. A biomechanical model of the neck muscles[21] demonstrated that the moment arm of sternocleidomastoid varies dramatically for flexion–extension movements (Fig. 4.10). For motions of the upper cervical joints, the cleido-occipital segment of the sternocleidomastoid actually has an extension moment arm that increases in extended postures (see Fig. 4.10); the other two subvolumes of sternocleidomastoid (which attach to the mastoid process) have very small moment arms. During flexion of the lower cervical joints, the flexion moment arm of the sternocleidomastoid increases. These results indicate that the function of sternocleidomastoid depends highly on posture and the joints about which movement occurs. Furthermore, the change in sternocleidomastoid flexion moment arm in the lower cervical region indicates a destabilizing effect, because it potentially increases the flexion moment-generating capacity of the muscle in flexed postures.

The same model[21] also showed that for axial rotation of the upper cervical region, many muscles have moment arms that vary by 2 to 3 cm but remain in the same direction throughout the ROM (e.g., sternocleidomastoid, splenius capitis; Fig. 4.11). For other muscles, the direction of moment arm changes with axial rotation. At the neutral position, the right rectus capitis posterior major has a right rotation moment arm; its magnitude

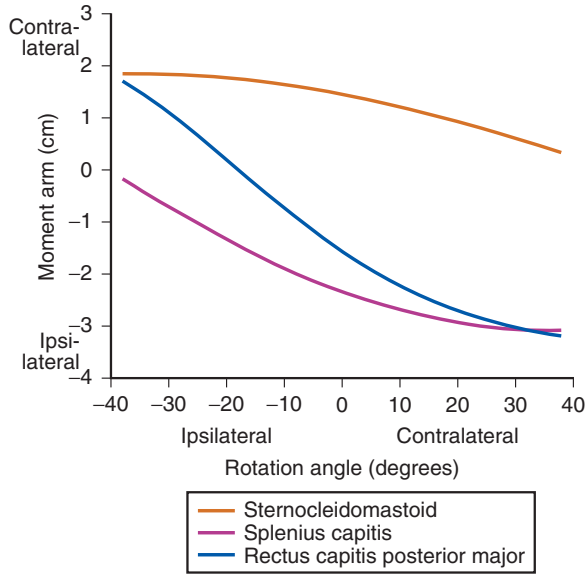

FIG. 4.11 Axial rotation moment arms for the upper cervical region. (Modified from Vasavada A, Li S, Delp S. Influence of muscle morphometry and moment arms on the moment-generating capacity of human neck muscles. *Spine*. 1998;23:412–421.)

increases in left rotated postures. However, when the head is rotated to the right, the moment arm decreases in magnitude and eventually changes to a left rotation moment arm. These results indicate that the rectus capitis posterior major has an axial rotation moment arm appropriate to restore the head to neutral posture from the most rotated head positions. The moment arms of other muscles, such as the semispinalis capitis and longissimus capitis, show the same pattern, although their moment arms are smaller. The implication of these findings is that the moment arm provides a "self-stabilizing" function to assist the central nervous system in maintaining neutrally rotated (i.e., eyes forward) head posture. This function is particularly relevant in the upper cervical region, because most axial rotation occurs between C1 and C2.

In the lumbar spine, posture also changes the mechanical function of erector spine muscles. McGill and associates[23] measured the fiber angles of longissimus thoracic and iliocostalis lumborum with the lumbar spine in neutral and fully flexed using high-resolution ultrasound. They found that flexion changes the line of action of these muscles, decreasing their capacity to resist anterior shear forces. This finding is important because anterior shear loads are related to the risk of back injury.[24]

Implications of Spinal Muscle Anatomy and Architecture for Injury and Pain

There are at least three ways in which spinal muscles may be implicated in mechanisms of injury and pain. First, the muscle itself may be injured from eccentric contraction, as described in Chapter 3. This may occur during an imposed movement (particularly one in which the kinematics are abnormal). Second, muscle forces may alter the load distribution within anatomic structures that have been clinically linked to pain. Third, muscle activity can alter spinal stiffness and kinematics, which would indirectly affect soft-tissue loads and strains. The relationship between muscles and injury can be elucidated by biomechanical models, the validity of which depends on accurate modeling of anatomy and architecture.

Muscle Injury Resulting From Eccentric Contraction

As noted in Chapter 3, rapid lengthening of muscle is an important mechanism of muscle injury. An example of potential muscle injury due to imposed lengthening occurs during whiplash. During the retraction phase of whiplash injury, when the head translates rearward with respect to the torso, the sternocleidomastoid muscle can experience lengthening strains of 5% to 10% while it is active.[25,26] During the rebound phase of whiplash injury, when the head translates forward with respect to the torso, the splenius capitis and semispinalis capitis muscles can experience lengthening strains of 10% to 20%. These predictions of muscle strains, based on a biomechanical model that incorporates muscle architecture,[21] are above thresholds for strain that causes injury to active-lengthening muscle.[27–29]

Muscles Altering Load Distribution in Other Anatomic Structures

Because muscles are oriented primarily vertically, their activation produces axial compression of the spine. The compressive loads on the discs and facet joints are a function of muscle force, moment arm, and activation. When the detailed anatomy of the lumbar erector spinae was included in a biomechanical model,[30] the predicted disc compression and shear loads were reduced compared with a lumped extensor "muscle equivalent" commonly used in many models. This study highlights the importance of creating an accurate representation of muscle anatomy in biomechanical models.

Compressive loads may severely alter tissue loads, particularly if abnormal vertebral kinematics occur. For example, the synovial fold of the facet joint may become impinged during the abnormal kinematics that occur during whiplash.[31] Muscles may also contribute to injury by directly loading passive structures. For instance, the cervical multifidus has direct attachments to facet capsular ligaments[8,32]; the combined loading from joint motion and muscle forces may lead to subcatastrophic injuries in facet capsular ligaments. These observations are important because the cervical facet joints and capsular ligaments have been clinically isolated as a source of neck pain.[33]

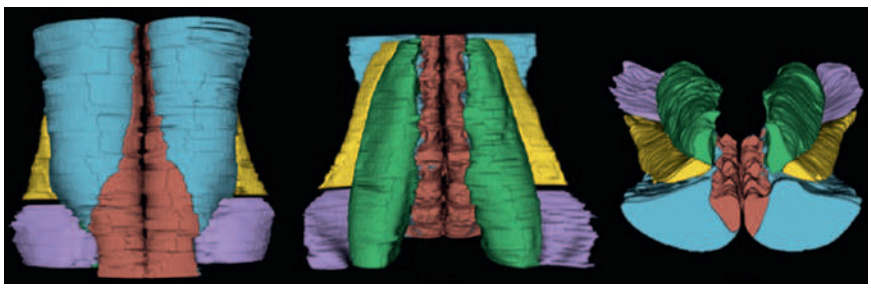
Muscle Effects on Spinal Stiffness and Stability

It has long been recognized that muscles are necessary for spinal stability. However, it is unclear which muscles contribute

most to spinal stability; this question has been addressed in several theoretical and experimental studies. Crisco and Panjabi[34] examined the role of gross muscle anatomy (e.g., the number of joints crossed by a muscle) in lateral stabilization of the lumbar spine using a mathematical model. They calculated minimal muscle stiffness necessary for spinal stability and found that muscles spanning only one vertebral body required the highest stiffness (i.e., activation) for stability, whereas those muscles that spanned the largest number of vertebrae were most efficient (required the least activation). Efficient stabilization (less muscle activation) is important because it implies lower disc loads. Electromyographically driven modeling by Cholewicki and McGill[35] suggested that large muscles may provide the bulk of stiffness to the spinal column, as suggested by Crisco and Panjabi,[34] but that the activity of short intrinsic muscles was also necessary to maintain stability. In fact, biomechanical models have shown that buckling (loss of stability) can occur from a temporary reduction in activation to one or more intersegmental muscles.[35] Presumably, small intrinsic muscles are better suited to stabilize displacements at a single joint with a minimum increase in joint loads at other levels. Similarly, Winters and associates used both computer and physical models of the cervical spine to demonstrate that activating only large, long muscles resulted in instability, especially around the upright posture.[36,37] The authors also concluded that activation of deep muscles was necessary for spinal stability. These types of analyses demonstrate the importance of both gross anatomy and architecture of spinal muscles on spinal stability. However, many important questions remain, such as the effect of muscle fatigue on spinal stability and the best muscle activation patterns for stability in the prevention and rehabilitation of low back and neck pain.

Muscle fatigue has been implicated in low back and neck pain[38]; the mechanism may be related to altered loads in other structures, decreased spinal stability, accumulation of metabolites, or involvement of peripheral and central mediation of pain. Patients with neck pain or cervical radiculopathy demonstrate altered neck muscle endurance and myoelectric evidence of fatigue.[39,40] In patients with pain, as well as healthy subjects, fatigue can lead to differences in neuromuscular control, including altered activation patterns or flexion–relaxation, which can increase the loads in passive tissues.[39,41] There is some evidence for fiber type transformations (from type 1 toward type 2) in patients with back or neck pain,[42,43] but other studies have found that spine musculoskeletal disorders are not related to a change in fiber type.[44,45] Fiber type studies in these muscles are extremely difficult due to their complex architectural design and limited ability to perform muscle biopsies.

Although the average architectural features of the major muscles in the lumbar spine have been documented (see earlier discussion and associated tables), there is an increasing need to generate patient-specific architectural data for diagnostic purposes, surgical planning, and musculoskeletal modeling. Recent advances in MRI and image processing allow these muscles to be rapidly visualized and quantified in three dimensions in an unprecedented fashion previously impossible with ultrasound, MRI, or CT scanning (Fig. 4.12). Additionally, these tools allow muscle tissue to be fractionated into contractile and fat compartments, which is extremely relevant clinically, as "muscle quality" appears to be an important feature in the lumbar spine and other joint systems subjected to chronic disease. As can be seen in Fig. 4.13, the fraction of muscle contained within "normal" muscle boundaries can be substantially lower than anticipated. Further, fatty infiltration is found in neck muscles in cases of whiplash injury with poor functional recovery[46] and the amount decreases with exercise[47]; disc injury is associated with increased adipose and connective tissue in lumbar multifidus, and a decrease in adipose tissue on biopsy was associated with positive outcome after surgery.[48] Last, in Chapter 3 we discussed the need for (and difficulty of) quantifying muscle fiber or fascicle lengths in individual patients. Magnetic resonance diffusion tensor imaging (MR-DTI) now allows fascicle length estimates on a subject-by-subject basis (Fig. 4.14). However, it is important to note that these are nonnormalized fascicle (not fiber) lengths; thus, they cannot be used to predict muscle excursion or velocity, nor can they be used to calculate PCSA. Future developments in methods to measure sarcomere length are required to make these normalizations. Nevertheless, these are emerging scientific tools that should be considered in clinical and scientific work as they are more rigorously validated.



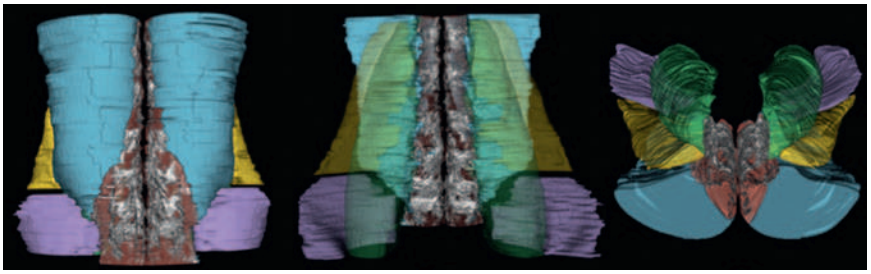


FIG. 4.12 Magnetic resonance imaging–based, patient-specific three-dimensional lumbar spine muscle volumes view from (A) posterior, (B) anterior, and (C) inferior. Multifidus *(red)*, erector spinae *(blue)*, quadratus lumborum *(yellow)*, and psoas *(green)* are easily visualized.

A B C

FIG. 4.13 Magnetic resonance imaging–based, patient-specific three-dimensional lumbar spine muscle volume fractions (muscles in colors and fat in white) view from (A) posterior, (B) anterior, and (C) inferior. Multifidus *(red)*, erector spinae *(blue)*, quadratus lumborum *(yellow)*, and psoas *(green)* are easily visualized and quantified.

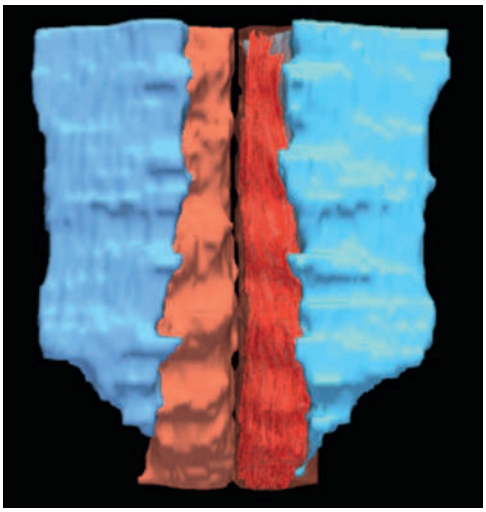

FIG. 4.14 Magnetic resonance diffusion tensor imaging (MR-DTI) can be used to generate tractography maps of individual muscles. Based on imaging resolution, these tracts likely represent muscle fascicles (or larger), but the diffusion properties themselves are heavily influenced by muscle fiber geometry. In this example, a posterior view of three-dimensional muscle volumes demonstrates bilateral erector spinae *(blue)* and multifidus muscles *(red)*. The right multifidus muscle has MR-DTI tractography results superimposed on the multifidus muscle volume depicting fascicle orientations and lengths.

Summary

Muscular architecture is an important, and often overlooked, determinant of muscle function. Because muscle architecture interacts with the skeletal and nervous systems in complex ways, all of these factors must be examined together to fully understand the biomechanical function of a muscle and its contribution to any pain or injury mechanisms. Detailed anatomic and architectural studies have yielded insights into spinal muscle functions, but the architecture of many spinal muscles remains to be examined. These data are necessary for accurate biomechanical models, which must be used in conjunction with experimental studies to elucidate the function of spinal muscles and their role in pathologic processes of the spine. This information can ultimately be used to develop improved prevention and rehabilitation strategies.

CHAPTER 5

The Intervertebral Disc: Normal, Aging, and Pathologic

SECTION I

Adam S. Olsen
James D. Kang
Nam Vo
Gwendolyn Sowa

The intervertebral disc is a structure interposed between the bodies of the vertebral column that acts as the shock absorber of the spine, transmitting compressive loads between bony segments. Its structure is generally fibrocartilaginous, consisting of several anatomic segments with distinct functional importance in both the native and pathologic spine. Degeneration of the disc is thought to be the leading cause of low back pain worldwide and is associated with multiple other conditions, such as spinal stenosis, herniated nucleus pulposus, and deformity.[1] Throughout the human life span, intervertebral discs undergo progressive but highly variable degeneration, often beginning in early life.[1,2]

This chapter discusses the basic structure of the intervertebral disc and surrounding tissues, followed by a review of the degenerative cascade leading to intervertebral disc degeneration (IDD) as well as clinical consequences. Despite the ubiquity of IDD and its association to low back pain, the exact mechanisms of discogenic low back pain IDD are not well defined. What has been established is that the process is multifactorial, involving a complex interaction of genetics, aging, mechanics, and environment biology.

Normal Disc

Disc Anatomy

The intervertebral disc is composed of three main structures: the cartilaginous endplates (CEP), the central nucleus pulposus (NP), and the peripherally located anulus fibrosus (AF) (Fig. 5.1).

Cartilaginous Endplates

The endplates are cartilaginous structures that serve as the superior and inferior margins of the intervertebral disc. In early life, the endplates are analogous to epiphyseal plates elsewhere in the body, and serve as the growth centers of the intervertebral bodies.[3] Similar to epiphyses elsewhere, the hyaline cartilage of the endplate initially occupies a significant portion of the disc. As aging occurs, this cartilage layer thins, and by adulthood consists of about a 1-mm-thick layer of avascular tissue composed of rounded chondrocytes and type II collagen.[4] Cartilaginous endplates (along with surrounding subchondral bone) do undergo some degree of elastic deformation during loading, but their contribution to the shock-absorptive properties of the disc is minimal. Instead, the endplates functionally allow force transmission along the vertebral axis via the discs and act as semipermeable barriers for nutrient and waste exchange.

Nucleus Pulposus

The nucleus lies between adjacent endplates and forms the gel-like core of the disc. The nucleus consists of a proteoglycan and water matrix held together by an irregular network of collagen type II and elastin fibers. Proteoglycans have numerous highly anionic glycosaminoglycan (GAG) side chains (i.e., chondroitin sulfate and keratan sulfate), which attract countercations and allow the NP to imbibe water. This composition is similar to articular cartilage, and the ability of the matrix to imbibe and release water in relation to applied stresses allows the disc to cushion against compressive loads. The primary proteoglycan is aggrecan; the high concentration of this hydrophilic molecule provides the osmotic properties needed to resist compression.[5]

Cells in the NP are initially notochordal, but their numbers decline after birth and eventually become undetectable at about age 4 to 10 years in humans.[6] The NP is gradually replaced during growth by smaller and rounded cells resembling the chondrocytes of articular cartilage.[7] These chondrocyte-like cells synthesize mostly proteoglycans and collagen type II in response to changes in hydrostatic pressure. These cells are also able to survive in the hypoxic environment of the intervertebral disc and contain inducible hypoxia-responsive transcription factors.[8] The NP functions as a shock absorber, acting in essence as a pressurized, deformable sphere that dissipates compressive forces to the AF and the adjacent vertebral bodies. As compressive forces on the spine increase, hydrostatic pressure within the nucleus pushes outward from its center in all directions.

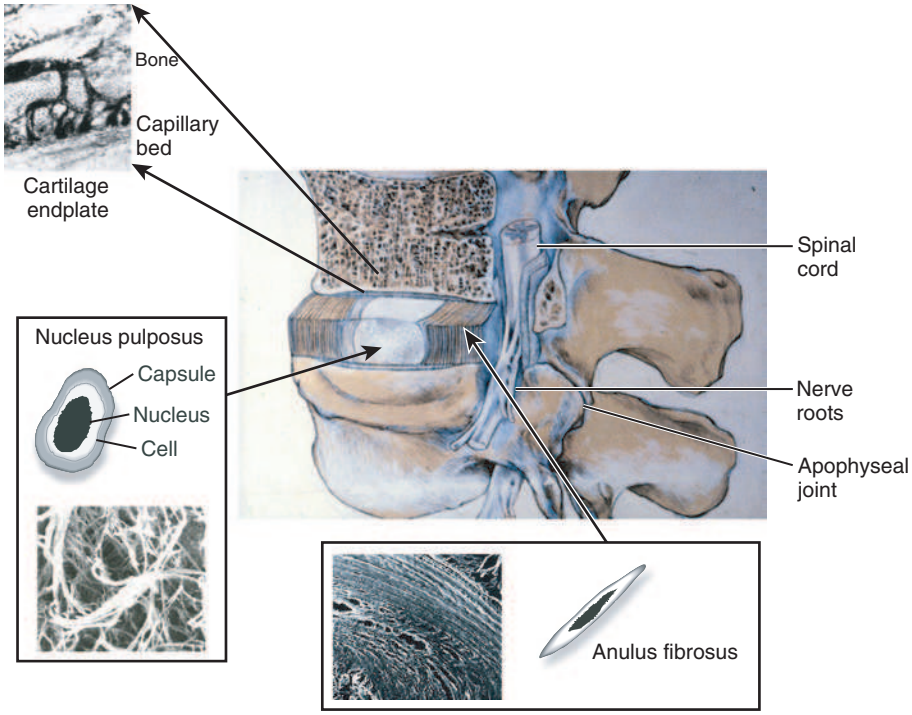

FIG. 5.1 The intervertebral disc is a pivotal part of the spinal column; its properties influence behavior of adjacent tissues. There is great variation in matrix organization, composition, and cell morphology and activity in different regions of the disc.

Anulus Fibrosus

The AF surrounds the NP and is composed of approximately 20 concentric rings (lamellae) of highly organized collagen fibers, primarily collagen type I. The collagen fibers are oriented approximately 60 degrees to the vertical axis of the spine and run parallel within each lamella but perpendicular between adjacent lamellae, allowing for maximal tensile strength.[9] Individual lamellae are connected to one another by radially oriented elastin fibers, which account for approximately 2% of the anulus' dry weight. A network of bridging tissues that span multiple lamellae, containing both elastic and vascular elements, has also been described.[10] Fibers of the outer anulus attach to the periphery of the vertebral bodies, whereas inner fibers pass from one endplate to another. Cells in the anulus are found between lamellae, arranged in parallel to the collagen fibers. Outer anulus cells are thin, elongated, and phenotypically similar to fibroblasts, whereas cells of the innermost anulus are more spheroid, similar to articular chondrocytes.[1,11] The anulus contains the NP and maintains its pressurization under compressive loads. The tensile properties of the anulus allow the nucleus to recover its original shape and position when the compressive load is reduced.

Blood Supply, Nutrition, and Innervation

Blood Supply

In early fetal life, vascular channels traverse the endplates, but they diminish in size starting at birth until complete disappearance by approximately 5 years of age. In adults, the blood supply of the disc arises from two capillary plexuses. One plexus penetrates 1 to 2 mm into the outer anulus, supplying only the periphery of the anulus. The other capillary plexus begins in the vertebral body and penetrates the subchondral bone (see Fig. 5.1), terminating in capillary loops at the bone-cartilage junction.[12] The density of this capillary network varies in location across the endplate, being greatest in the center and lowest at the periphery. Although blood flow to the disc is minimal, it may not be entirely passive as muscarinic receptors have been identified on the disc periphery, which may influence perfusion.[13] Cells in the center of the human adult lumbar NP are 8 mm from the nearest blood source, making the disc one of the largest avascular structures in the body.

Nutrition

The limited vascularity of the intervertebral disc has important physiologic implications—mainly that nutrition depends almost entirely on diffusion (Fig. 5.2).[14–16] The nutritional environment of the cells varies throughout the disc because of its size and architectural makeup, with cells in the NP being 6 to 8 mm from the nearest blood vessel. Small molecules necessary to maintain cellular function (i.e., glucose and oxygen) readily leave vertebral capillaries and diffuse across the thin cartilaginous endplate and the outermost layers of the anulus into the disc extracellular matrix (ECM). Concentration gradients of glucose, oxygen, and other nutrients and metabolites exist across the disc, regulated by the rates of nutrient supply and consumption as well as the net negative charge of the NP produced by high proteoglycan concentration. The low

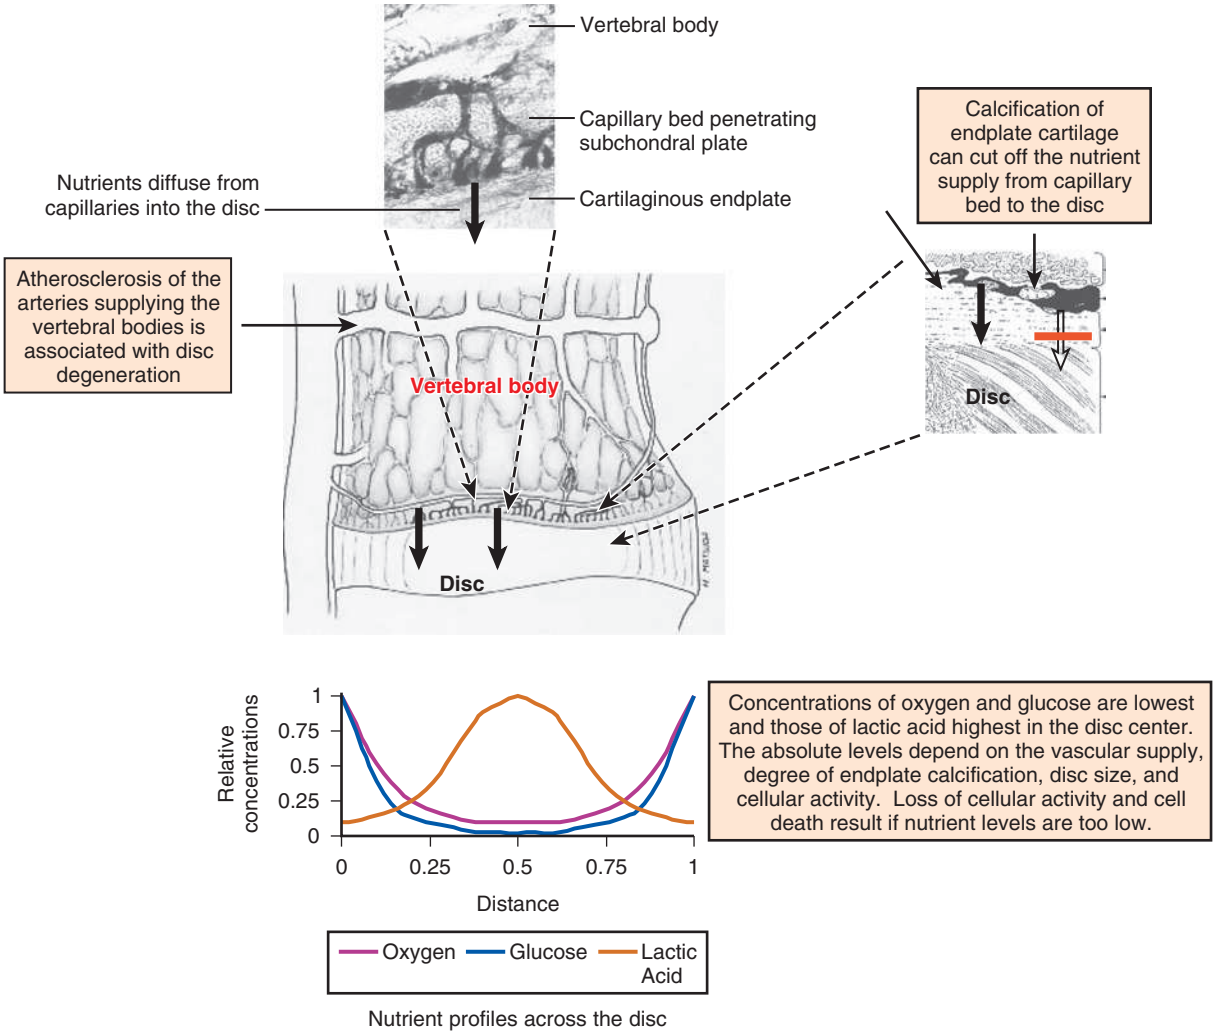

FIG. 5.2 Schematic view of routes for nutrient transport into avascular disc and resulting nutrient profiles. The diagram also shows possible regions of disturbance. (Modified from Crock HV, Goldwasser M, Yoshizawa H. Vascular anatomy related to the intervertebral disc. In: Ghosh P, ed. *Biology of the Intervertebral Disc*. Boca Raton, FL: CRC Press; 1991:109–133.)

oxygen tension in the nucleus leads to anaerobic metabolism (i.e., glycolysis), resulting in a high concentration of lactic acid and a lower pH in the nucleus compared with the periphery of the disc.[16] Metabolic byproducts, such as lactic acid, diffuse from the disc in the opposite direction of glucose entry.

Innervation

Under normal conditions, only the outer 1 to 2 mm of the AF is innervated in nondegenerated human discs; the majority of these fibers are sympathetic perivascular nerves. A small number of mechanoreceptors are also reported in the outer several AF lamellae, likely providing some level of proprioceptive feedback.[17] The sources of this innervation are variable, but include plexuses contained in both the anterior longitudinal and posterior longitudinal ligaments; these nerves have been found to contain various substances, such as neuropeptide Y, substance P, acetylcholinesterase, and others.[18] The remainder of the anulus and nucleus are uniquely avascular and lacking neurons under normal, nondegenerated conditions. Several studies have described further nerve ingrowth into degenerated lumbar discs, however, which is discussed later in this chapter.

Disc Composition

The function of the intervertebral disc depends greatly on the properties of its ECM. The ECM provides the biomechanical properties and acts to regulate the extracellular fluid composition and the rate at which nutrients and metabolites are exchanged. The ECM consists of a complex network of macromolecules whose composition varies in different regions of the disc (Fig. 5.3).[4,19] ECM macromolecules are synthesized and maintained by a small population of cells (~9000 cells/mm^3 in the anulus and ~5000 cells/mm^3 in the nucleus) occupying less than 1% of the disc volume.[4] Disc cells also produce a complex array of cytokines, growth factors, and proteases to maintain equilibrium between the rates of synthesis and degradation of ECM components.[20,21]

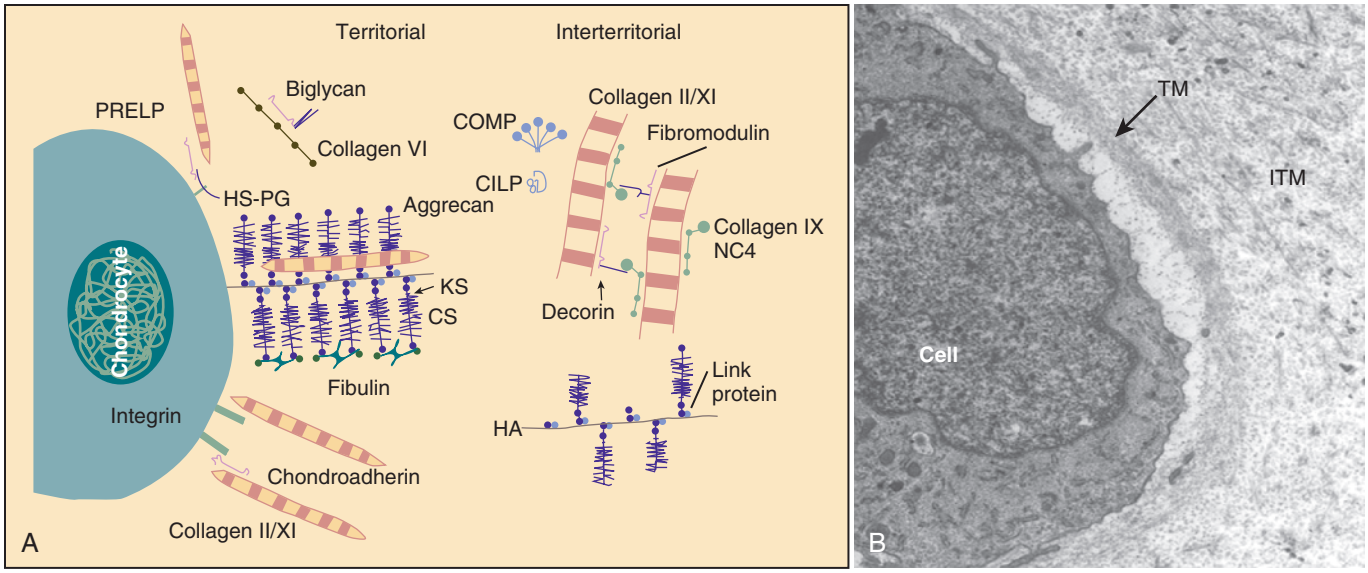

FIG. 5.3 (A) Schematic view of different matrix macromolecules, their interactions with the cell and with other matrix molecules, and their distribution within the territorial matrix (TM) and interterritorial matrix (ITM). (B) Transmission electron micrograph of section through disc cell and its surrounding matrix. TM and ITM not only have different molecular compositions, but also a different morphology. COMP, cartilage oligomeric matrix protein; CILP, cartilage intermediate layer protein; CS, chondroitin sulfate; HA, hyaluronan; HS-PG, heparan sulfate-proteoglycan; KS, keratan sulfate; NC4, N-terminal noncollagenous domain 4; PRELP, proline/arginine-rich end leucine-rich repeat protein. (A, Modified from Heinegard D, Aspberg A, Morgelin M, et al. Extracellular matrix of cartilage. Section for Connective Tissue Biology, University of Lund, 2003. Available at http://www.cmb.lu.se/ctb.)

Water

The major component by weight of the intervertebral disc is water; its concentration is regulated by the abundance of proteoglycan aggregates in the disc. The concentration of water varies with age, location within the disc, and body position.[22] The NP is most highly hydrated, and the water concentration can be as high as 90% in an infant, declining to approximately 80% in nondegenerated young adult discs.[23] The water content of the anulus is lower than the nucleus, declining to 65% in the outer anulus in adult discs.

Water content varies with load, leading to diurnal changes in disc hydration.[24] During the diurnal cycle, 25% of the disc's water can be lost and regained in young lumbar discs.[25] Some water is expelled from the disc during the day because of the increased forces of body weight and muscle contractions; it is reimbibed at night when the compressive forces are removed. This diurnal cycle results in changes in disc height and affects the disc's mechanical properties.

Macromolecules

Collagen is one major macromolecular component of the disc. The collagen content of the disc is highest in the outer anulus, and the dry weight decreases significantly in the nucleus of adult discs.[26] The concentration of collagen type I is highest in the outer anulus and decreases going toward the nucleus.[26] Collagen type II follows the opposite gradient, with the highest concentration located in the nucleus. Along with collagen types I and II, the ECM contains many other minor collagens, including types III, V, VI, IX, and XI.

The other major macromolecule of the disc is aggrecan,[27] which consists of a protein core with approximately 100 anionic GAG side chains. Many aggrecan molecules covalently attach to hyaluronan chains, forming large aggregates. These aggregates are trapped by the surrounding collagen network, imparting a net negative charge to the ECM. The interstitial water contains an excess of cations, which is directly related to the concentration of negative charge (i.e., GAG concentration). The high concentration of cations imparts a high osmotic pressure in the nucleus. Changes in proteoglycan concentration and GAG concentration lead to changes in osmotic pressure, affecting the ability of the disc to maintain hydration and turgor when loaded.[27]

In addition to collagens and aggrecan, the disc contains lower concentrations of numerous other macromolecules,[14] including elastin, the smaller proteoglycans decorin and fibromodulin, cartilage oligomeric matrix protein, and cartilage intermediate layer protein. These molecules function either structurally or biomechanically and are important for normal disc function.

Intervertebral Disc Degeneration

Degeneration

IDD is defined as an aberrant, cell-mediated response to progressive damage, with combined structural failure and accelerated or advanced signs of aging. These proposed definitions also suggest that structurally intact discs with accelerated

age-related changes be classified as *early degenerative discs,* whereas the term *degenerative disc disease* should be applied if the disc is also painful.[28]

Although the exact mechanism of disc degeneration has not been determined, it is known to involve a complex interaction of factors, including ECM macromolecule changes, decreased water content, altered enzyme activity, decreased endplate permeability, impaired metabolite transport, structural failure, and cell senescence and death. These biologic and biomechanical factors cause extensive histomorphologic changes of the disc, leading to disorganization of the anulus, solidification of the nucleus, and thinning and calcification of the cartilaginous endplates. Recently, it has also been suggested that several general types of degeneration may exist—namely, endplate driven and anulus driven—that potentially affect different areas of the spine at different ages.[29]

Matrix Macromolecule Changes

The most physiologically important changes of disc degeneration start in the nucleus.[23] Early changes include increased proteolytic degradation of aggrecan and other aggregating proteoglycans coupled with an increased concentration of nonaggregating proteoglycans. The accumulation of degraded proteoglycans further impairs diffusion of nutrients and oxygen through the disc. A change in the proportions of the GAGs chondroitan sulfate, heparan sulfate, and keratan sulfate also occurs, with increasing amounts of heparan sulfate and keratan sulfate as degeneration progresses. These changes diminish the hydroscopic properties of the ECM further, resulting in decreased water content and decreased ability to imbibe water. Loss of proteoglycans and hydration leads to decreased swelling pressure[27] and loss of disc height. The changes result in altered responses to applied biomechanical loads, ultimately leading to the structural features of degeneration.

Intervertebral disc degeneration also results in disorganization and destruction of the collagen network.[30] As the overall proteoglycan and water content decreases, there is a corresponding increase in collagen content. Collagen type I replaces collagen type II in the inner anulus and nucleus, and there is a tendency for collagen type I fibrils throughout the disc to become coarser. The highly organized collagen fiber arrangements of the anulus are also disrupted, and collagen and elastin networks become more disorganized. When the collagen network has been damaged, disc biomechanics are markedly altered, and the potential for structural damage increases.

Increased levels of proinflammatory cytokines lead to increased production of proteinases, causing breakdown of collagens such as types VI, IX, and X. Collagen type IX is degraded in the pericellular microenvironment, allowing for local alteration of this microenvironment during degeneration. With disc degeneration, collagen type IX decreases similarly to collagen type II, implying advanced stages of degeneration and fibrosis of the nucleus. The synthesis of collagen type VI, a matrix protein with relatively low cross-linking, increases as degeneration progresses and functions to hold proliferating cells together.

The overall ECM content in the nucleus is a well-controlled equilibrium between degradative and synthetic pathways involving numerous proteins. In disc degeneration, there is an imbalance between degradative and synthetic pathways whereby the latter overtake the former with a predominance of catabolic enzyme activity. Proteinases of the matrix metalloproteinase (MMP) and "a disintegrin and metalloproteinase with thrombospondin motifs" (ADAMTS) families cleave proteoglycans, collagens, and other macromolecules and have been implicated in the breakdown of the ECM.[31] The degradative enzymes MMP-3 and MMP-13 (also known as stromelysin-1 and collagenase 3, respectively) have been found at increased levels in degenerated human discs.

The regulation of MMP and ADAMTS production and ECM macromolecule production is achieved by numerous cytokines and growth factors. Of particular importance in disc ECM homeostasis are members of the interleukin (IL) family (catabolism) and transforming growth factor-β (anabolism) superfamily.[32,33] Mediators of inflammation such as nitric oxide and prostaglandin E_2 and the cytokines IL-1 and IL-6 are found at increased levels in degenerated discs.[32–34] The synthetic capabilities of nucleus cells are unable to sustain appropriate levels of aggrecan and collagen production in the face of this increased catabolism, which contributes to further degeneration of the disc.

Cellular Changes

It has long been recognized that there is a gradual progressive loss of cells during disc degeneration,[35] leading to further loss of the ECM due to synthesis deficiency. An increasing body of literature has shown that apoptosis, or programmed cell death, and cellular senescence may be responsible for many of the features of degeneration.[36–38] More recent literature has also shown an increase in lacunae containing cell clusters,[39,40] possibly causing an overall increased number of cells at the site of injury. This increased cell proliferation may be an attempt to offset the progressive destruction and loss of the ECM. One reason for increased cellularity may be the focal increase in nutrient supply owing to the ingrowth of blood vessels in degenerating discs, as discussed elsewhere in this chapter.

Cell clusters have been discovered in areas adjacent to the newly formed blood vessels within degenerated discs. Cells in these areas have access to nutrient supply and growth factors, and undergo proliferation. The cellular changes in degenerated discs resemble osteoarthritis, in which remodeling of the pericellular microenvironment with chondrocyte proliferation and cluster formation have also been found. Ultimately, cellular attempts at repair become ineffective as disc degeneration progresses due to the abnormal local mechanical environment of the cells.

Structural Changes

As disc hydration decreases, the distinction between anulus and nucleus becomes less defined and disc height decreases (Fig. 5.4).[41] In later stages, gross tissue changes become

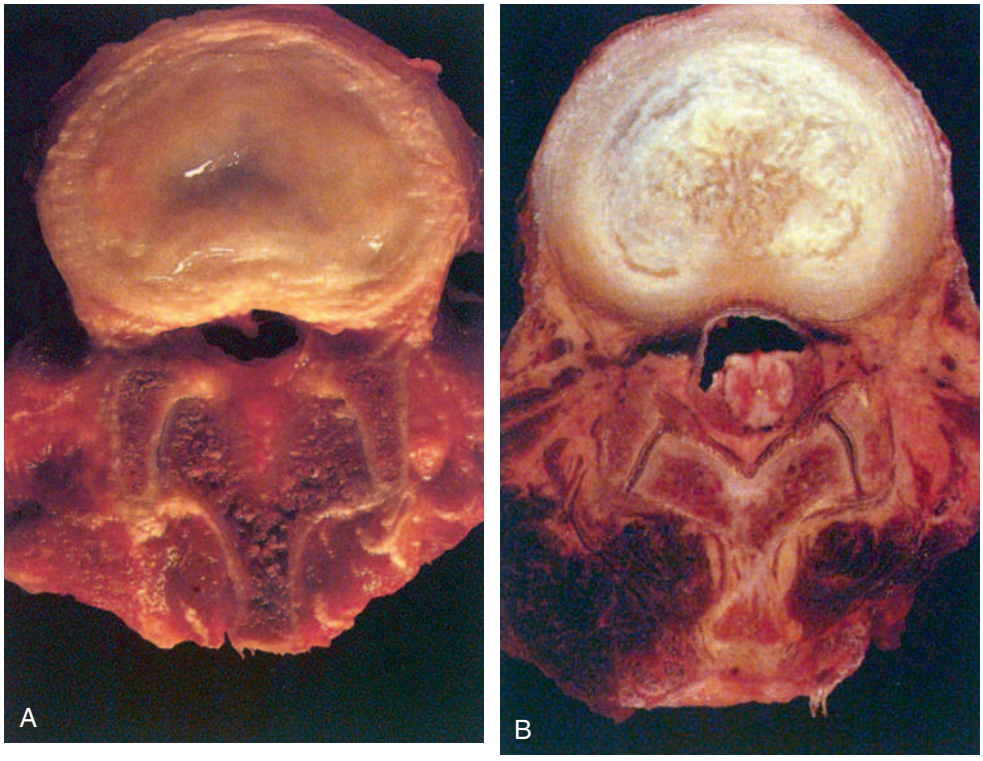

FIG. 5.4 Transverse sections of lumbar discs and apophyseal joints showing decrease in nucleus hydration, loss of demarcation between anulus and nucleus with age, and appearance of circumferential fissures by the third decade. (A) Adolescent. (B) At age 28 years. (Courtesy Bullough PG, Vigorita VJ. *Bullough's and Vigorita's Atlas of Orthopaedic Pathology*. Baltimore, MD: University Park Press–Gower Medical Publishing; 1995.)

increasingly apparent, including loss of lamellae organization, fissuring of the anulus,[42] and discoloration and solidification of the nucleus.[35,43] Radial and circumferential annular tears are often evident, sometimes extending to the disc periphery.[42] These changes are accompanied by ingrowth of nerves and blood vessels into the disc, as well as deposition of granulation tissue and calcification within the endplates. Endplate sclerosis is thought to impede nutrient transport to the disc by occluding both nutrient channels and blood vessels. These structural changes ultimately lead to altered, abnormal biomechanical properties of the disc. Damage to one area of the disc increases load bearing by adjacent tissues, making it more likely for damage to spread throughout the disc eventually. While a healthy intervertebral disc equalizes pressure within it, the decreased shock-absorbing capacity of the decompressed nucleus leads to high compressive stresses in the anulus.[44] Other gross morphologic changes of degeneration include disc bulging, disc space narrowing, endplate irregularities, and osteophyte formation.

Neovascularization and Sensory Nerve Innervation

As stated previously, the disc is largely avascular in adults with blood vessels normally restricted to only the outermost layers of the anulus. Likewise, only the outer 1 to 2 mm of the anulus is innervated in the normal human disc. The ingrowth of blood vessels and sensory nerves is an important feature of degenerated discs and seems to be associated with pain.[45] Ingrowth of capillaries may be facilitated by the loss of hydrostatic pressure in the inner regions of the disc, which would normally collapse small vessels. These newly formed microvessels release neurotrophic growth factors, such as nerve growth factor, allowing the ingrowth of small, nonmyelinated nerve fibers.[46–48] It has been hypothesized that discogenic pain arises because these nociceptive nerve fibers grow into areas of the disc that previously had no neurons.

Etiology of Intervertebral Disc Degeneration

Multiple risk factors have been hypothesized as the underlying cause, including aging, genetic predisposition, mechanical overload, and numerous environmental factors. Biomechanical studies have shown that excessive mechanical loading causes disruption of disc structure, including endplate defects, fissures, bulging, disc prolapse, and annular collapse.[49] Further experiments have confirmed that structural damage precipitates a cascade of cell-mediated responses, leading to further damage. Although mechanical loading may precipitate degeneration, the most important cause may be age-related biologic processes that impair the healing response and/or weaken the disc before structural damage. However, recent studies have shown that low-impact, cyclic loading increases trans-endplate nutrient diffusion in both healthy and degenerated discs, suggesting a complex interaction of host and environmental factors.[50] The combined effects of aging, unfavorable genetics, altered nutrition and metabolite transport, and excessive or repetitive loading all have been implicated in contributing to the process of degeneration.

Aging

The incidence of intervertebral disc degeneration increases with age and is most common in the lumbar spine.[51,52] Human intervertebral discs undergo very early aging and degeneration, resulting in histomorphologic and functional changes (Fig. 5.5).[41] Endplate permeability and vascular supply decrease throughout growth and aging, leading to altered metabolite transport.[41] Proteoglycans begin to fragment during childhood, and the overall proteoglycan content decreases with age, especially in the nucleus. There is a corresponding increase in collagen content, with collagen type I fibers replacing collagen type II fibers in the inner anulus and nucleus. In addition, reduced matrix turnover in older discs enables collagen fibrils to become increasingly cross-linked,[53] leading to retention of damaged fibers and reduced tissue strength. Synthesis of ECM components decreases steadily throughout life, which is partly attributable to decreased cell density, although synthesis rates per cell also decrease.

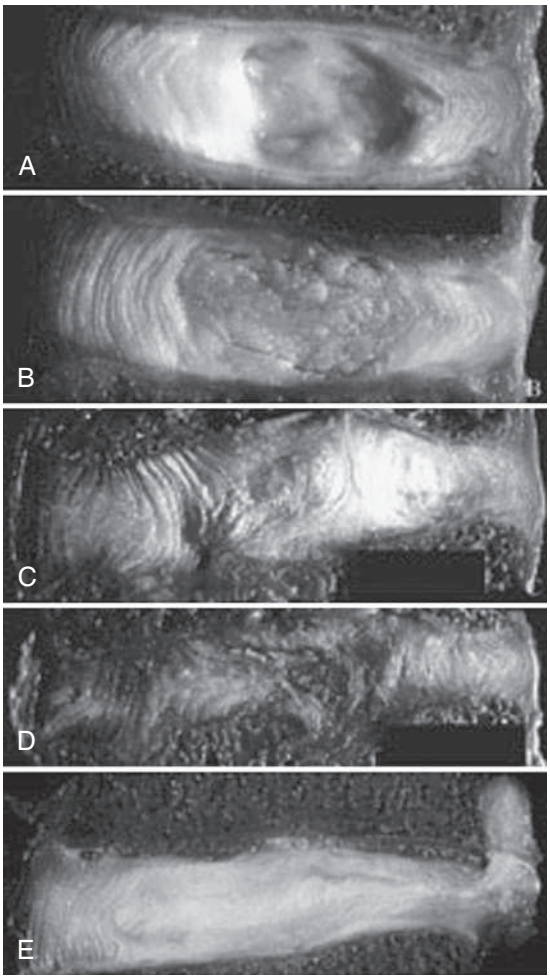

FIG. 5.5 Cadaveric lumbar intervertebral discs sectioned in midsagittal plane (anterior on left). (A) Young disc (35-year-old man). (B) Mature disc (47-year-old man). (C) Disrupted young disc (31-year-old man). Note endplate damage and inward collapse of inner anulus. (D) Severely disrupted young disc (31-year-old man). Note collapse of disc height. (E) Disc induced to prolapse in the laboratory (40-year-old man). Some nucleus pulposus has herniated through radial fissure in posterior anulus (right). (From Adams MA, Bogduk N, Burton K, et al. *The Biomechanics of Back Pain*. Edinburgh: Churchill Livingstone; 2002.)

In infants, the nucleus contains approximately 90% water and appears translucent.[23] The disc dehydrates slowly with aging, with water content of the nucleus declining to around 80% in young adults.[41] The nucleus also accumulates yellow pigmentation and becomes less distinguishable from the surrounding anulus.[23,41] As the disc water content decreases, the nucleus becomes smaller and decompressed, often condensing into several fibrous lumps. Dehydration of the nucleus leads to altered biomechanical properties of the disc, forcing the anulus to act as a fibrous solid to resist compression directly. The proteoglycan content of the anulus also decreases with aging, and the anulus becomes stiffer and weaker, resisting compressive loads in a haphazard manner.

Aging also causes progressive changes in disc nutrient supply and ECM composition. These changes decrease tissue strength and alter cell metabolism.[54] The alterations of proteoglycans and GAGs, decreased hydration, and changes in collagen distribution and cross-linking make the disc physically more vulnerable to injury. Age-related alteration to the vascular supply to the disc has been hypothesized as a primary initiator of age-dependent IDD. However, experimental endplate damage leads to degeneration[35] despite enhanced metabolite transport into the disc, suggesting that structural damage more strongly influences the degenerative process. Inadequate nutrition likely predisposes the disc to degeneration by compromising its ability to respond to increased loading or injury.

Genetic Predisposition

Genetic predisposition has been suggested as the greatest risk factor for disc degeneration, accounting for approximately 50% to 70% of the variability in identical twin studies.[55–57] Individual gene polymorphisms associated with disc degeneration include aggrecan,[57] cartilage intermediate layer protein,[57] collagen type IX,[58,59] MMP-3,[60] and vitamin D receptor.[61,62] The products of these genes alter the ECM composition, decrease tissue strength, impair regenerative capability, and undoubtedly influence disc cell function. There has also been recent attention to the roles of microRNA molecules, 18-22 nucleotide posttranslational regulatory elements, in intervertebral disc generation, but their roles have yet to be established.[62] Age-related disc degeneration develops after many decades, however, and preferentially affects the lumbar spine. Since unfavorable genetic predisposition is present throughout the life span, this suggests that genetic inheritance and polymorphic variations in susceptibility genes predispose the disc toward degeneration, but further insults such as excessive loading, structural damage, and other aging changes are necessary to trigger the cascade of degenerative events.

Nutrition

The failure of nutrient supply is hypothesized to be a primary cause of disc degeneration.[63] In vitro studies demonstrate that the metabolic activity of disc cells is sensitive to extracellular oxygen and pH, with matrix synthesis rates decreasing at acidic pH and low oxygen concentrations.[64,65] A decrease in glucose supply or altered pH could negatively affect the ability

of disc cells to synthesize and maintain the ECM, ultimately leading to disc degeneration.

A relationship between loss of cell viability and a decrease in nutrient transport in scoliotic discs has been found,[66] and there is evidence that nutrient transport is affected in disc degeneration in vivo.[67,68] Likewise, the transport of solutes from bone to disc was significantly lower in degenerated discs compared with normal discs as measured by in vitro studies.[63] Other factors affecting the blood supply to the vertebral body that may lead to an increased incidence of disc degeneration include atherosclerosis,[69,70] sickle cell anemia, caisson disease (decompression sickness), and Gaucher disease. In addition, calcification of the cartilaginous endplates can cause decreased nutritional supply even if the blood supply remains undisturbed, as seen in scoliotic discs.[63,71] All of this evidence supports the hypothesis that a decrease in nutrient supply ultimately leads to degeneration of the disc.

Environmental Factors

Environmental risk factors hypothesized to influence disc degeneration include heavy or repetitive mechanical loading (i.e., occupational physical loading and whole-body vibration),[56,72] obesity, and cigarette smoking.[73] Heavy physical loading, particularly related to occupation, was previously suspected to be a major risk factor for degeneration and commonly viewed as a "wear and tear" phenomenon. However, results of identical twin studies on physical loading specific to occupation or sport suggest that repetitive physical loading plays a relatively minor role in disc degeneration.[72]

Obesity has often been implicated as a risk factor for degeneration, but epidemiologic studies have reported mixed findings. More recently, obesity was found to be a risk factor for marked reduction of the NP magnetic resonance imaging (MRI) signal intensity of lumbar discs. The mechanism by which obesity contributes to degeneration is thought to be a combination of mechanical and systemic factors. Some authors suggest that atherosclerosis and cardiovascular disease associated with obesity parallel atherosclerosis of the spinal vessels, with decreased blood and nutrient supply leading to increased risk of degeneration.

The only chemical exposure associated with disc degeneration is cigarette smoking, which explains only 2% of the variance in lumbar disc MRI changes between identical twins with highly discordant lifetime exposures. In other studies of monozygotic twins in whom the mean of co-twin discordance was less, no significant association between disc degeneration and cigarette smoking was found. Cigarette smoke is presumed to alter blood flow to disc capillaries and nutrient transport, possibly as a result of the presence of muscarinic receptors in blood vessels of the vertebral endplate.[74]

Facet Joints, Ligaments, and Vertebral Bodies

No discussion of intervertebral disc degeneration would be complete without consideration of the other elements of the spine. Degeneration of the spine has an impact not only on the disc, but also the surrounding structures, such as the facet joints, ligaments, and vertebral bodies. Degenerative changes are thought to occur simultaneously or close in time in each of these components, altering the ability of the spine to respond to normal physiologic loads. In addition, degeneration of the surrounding nondisc structures may cause pain and reduced mobility of the spine.

Facet Joints

Degeneration of the facet joints resembles osteoarthritic changes occurring at other synovial joints, starting with synovitis and progressing to articular cartilage loss, capsular redundancy, and eventually degenerative spondylolisthesis. Hypertrophic osteophytes at the joint margins and periarticular fibrosis can also result in reduced mobility and pain at the facet joint. Osteoarthritis of the facet joints parallels degenerative changes of the disc, possibly resulting from abnormal loading and narrowing of the disc in the early stages of degeneration.[75]

Ligaments

The anterior longitudinal ligament and posterior longitudinal ligament contribute to the overall stability of the spine. The strong anterior longitudinal ligament buttresses the anulus anteriorly, whereas the posterior longitudinal ligament offers only weak reinforcement to the posterior anulus. Information regarding degenerative changes of these ligaments is minimal, but the anterior longitudinal ligament and the posterior longitudinal ligament become more redundant as disc height decreases, and ossification occurs in later stages. These changes may contribute to pain and reduced mobility of the spine.

Vertebral Bodies

Osteoarthritic changes of the vertebral body are also associated with intervertebral disc degeneration.[76] The cartilaginous endplates are normally the weakest structure under compressive loads, and thinning and calcification with aging further compromise endplate strength. The endplates accumulate trabecular microdamage and undergo remodeling in response to altered loads, and the nucleus bulges into the vertebral body as degeneration progresses. Endplate damage decompresses the nucleus further, and loss of disc height transfers forces onto the anulus, causing it to bulge into the nucleus.[49,76] The nucleus may eventually herniate through a damaged endplate; subsequent calcification of the herniated nucleus is called a Schmorl node. The loss of disc height and annular laxity leads to formation of osteophytes at the vertebral body margins, decreased separation of the posterior neural arches, and eventual bony ankylosis (Fig. 5.6).

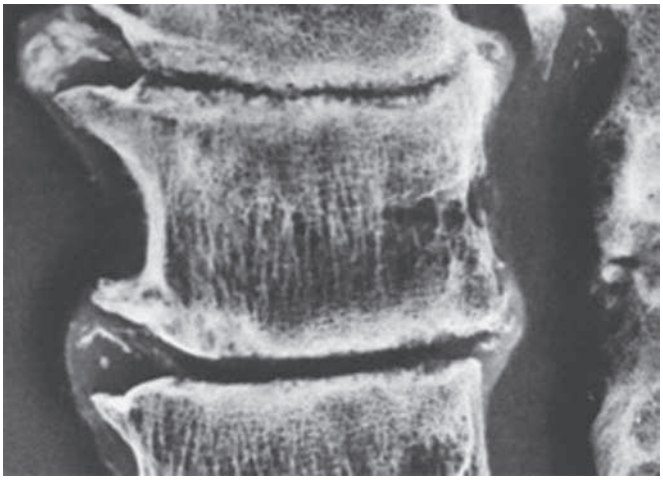

FIG. 5.6 Radiograph of old cadaveric lumbar spine (anterior on left). Radiograph depicts how severe disc narrowing can be associated with vertebral osteophytes, sclerosis of vertebral endplates, and selective loss of horizontal trabeculae from the vertebral body. CHAPTER 6

Biomechanics of the Spinal Motion Segment

William S. Marras
Prasath Mageswaran
Safdar N. Khan
Ehud Mendel

In biomechanics, information from the biologic sciences and engineering mechanics is integrated for the purpose of analyzing and quantifying the function of and forces occurring on tissue under various conditions. With an understanding of the natural behavior mechanics of the spinal motion segment, it can be possible to better understand the limitations of the system and the conditions under which tissue damage occurs and subsequent pain would be likely. Biomechanical assessments provide a quantitative means by which to accomplish this goal.

From a biomechanical standpoint, the spine accomplishes three major functions.[1] First, the spine provides a structure by which loads can be transmitted through the body. Second, the spine permits motion in multidimensional space. Third, the spine provides a structure to protect elements of the nervous system (spinal cord). To appreciate the ability of the spine to accomplish these functions, we need to understand the natural movements of the spine and its ability to withstand forces or loads that are transmitted through its structure.

With these goals in mind, this chapter (1) considers the physical characteristics of the spinal tissues that could influence function, (2) assesses the motion characteristics (kinematics) of the different portions of the spine, and (3) summarizes the ability of the spine to withstand forces that it is supporting (load tolerance). Collectively, this chapter shows, from a biomechanical perspective, how the spine functions and how it breaks down. Box 6.1 is a glossary of terms to facilitate better understanding of the content of this chapter.

Assessing the Biomechanics of the Spinal Motion Segment

Ideally, it would be desirable to measure directly the forces imposed on the various tissues within the spine. With current technology, invasive measures would be required, however, to understand the loading imposed on the various spinal tissues. Such invasive measures would disrupt the tissues of interest and would most likely alter the very factors that one is attempting to measure. Direct biomechanical measurements of the spine in vivo are rare and currently difficult in humans. Much of the biomechanical information about the human spinal motion segment is based on in vitro studies. This information must be considered with caution because the properties of the spine derived from cadaveric studies are understood to be different in many respects from those of a live individual.

An alternative to direct measurement of spine tissue loading is the prediction of tissue loads based on in silico or biomechanical models. A biomechanical model is a conceptual representation and prediction of how the forces within the biomechanical system interact ultimately to impose force on a particular tissue of interest. Biomechanical analyses assume that the body behaves according to the laws of newtonian mechanics that must govern the distribution of forces within the musculoskeletal system. The object of interest in spinal biomechanics is a precise quantitative assessment of the movement behavior and mechanical loading occurring within the tissue of the musculoskeletal system. Biomechanical modeling permits estimation of the direction and magnitude of forces acting on the spinal motion segment and allows estimation of when natural motion tolerances have been exceeded and when damage or degeneration would be expected to occur. Biomechanical assessments help one understand potential pathways of low back disorders and can potentially help surgeons understand how contemplated surgical interventions might affect the health of the spine.

Ultimately, biomechanical assessments are intended to determine how much loading of the tissues within the spinal motion segment is too much loading. This high degree of precision and quantification is the characteristic that distinguishes biomechanical analyses from other types of analyses.

Physical Charcteristics of the Spine Structures

The spine is composed of four types of vertebrae classified according to their regional location along the spinal column—cervical, thoracic, lumbar, and sacral. There are 7 cervical vertebrae, 12 thoracic vertebrae, and 5 lumbar vertebrae. In addition, the sacrum consists of five immobile— or

BOX 6.1 Glossary

Acceleration. The rate of change of velocity. In body angular motion, defined in degrees per second.

Acute trauma. Load applied to a structure with enough force to result in damage in one application.

Axis of rotation. The point about which two vertebrae move relative to one another.

Bending. Load applied to a structure at a point where it is not directly supported, causing it to deform.

Biomechanical model. A theoretical representation of how forces behave and interact in a biomechanical system.

Cortical bone. Compact bone forming a protective outer shell for a bone. It has high resistance to bending and torsion, and provides strength where bending would be undesirable.

Cancellous bone. Inner portion of bone containing a spongy matrix. Forms the interior scaffolding of the structure and helps maintain bone shape during force application.

Central coordinate system. A reference system that defines the positions and motions of the body in space.

Compression. Force that pushes together the materials of a structure.

Contact pressure. The force per unit area distributed over a contact area.

Coupling. Movements in which one motion is accompanied by the motion in a different plane.

Cumulative trauma. Repetitive load applied to a structure that weakens the structure and results in damage.

Degree of freedom. The number of directions and motions in which a body is able to move.

Dynamics. The study of forces applied to a structure in motion.

Force. An action that changes the state of rest or motion of a body.

Kinematics. The study of the motion of a structure that considers position, velocity, and acceleration without taking into account the force that produces the motion.

Kinetics. The study of the relationship between the force acting on a body and the change in motion produced

Load. The application of force or moment (torque) to a structure.

Loading cycle. The number of repetitions of a load application.

Local coordinate system. A reference system that defines the positions and motions of vertebrae relative to one another.

Microfracture. Small cracks in a structure.

Moment. A force applied about an axis. A force multiplied by a distance. Also known as *torque*.

Neutral zone. The amount of displacement between the neutral position of the vertebrae and point at which resistance to physiologic motion is experienced.

Pressure. Force per unit area.

Range of motion. The two points that define the extremes of physiologic motion.

Rotations. Movement about a point, as when bending.

Shear. A force applied parallel to the surface upon which it acts.

Stability. The ability of a system to respond to a perturbation and reestablish a state of equilibrium.

Statics. The study of forces occurring within a structure when they are not in motion.

Strain. The change in unit length or angle of a material that is subjected to load.

Stress. A measure of the intensity of force represented in force per unit area.

Tolerance. The point at which a structure can no longer resist a load without suffering damage.

Torsion. A twisting load applied about the long axis of a structure.

Translations. Straight line movements in any direction.

Velocity. The rate of change of position. In angular body motion, defined in degrees per second.

"fused"—vertebrae, and the coccyx (often referred to as the tailbone) is a fusion of four coccygeal vertebrae at the base of the spine. Each vertebra is referenced according to a nomenclature system in which the spine region (e.g., cervical, thoracic) is followed by a numbering system that refers to the vertical position of the vertebral body along the spine (beginning with the vertebra closest to the head) (e.g., first cervical vertebra, or C1). Disc levels are referenced relative to the vertebral levels surrounding the disc. The lowest lumbar vertebra (fifth lumbar vertebra, or L5) is adjacent to the first sacral vertebra (S1), and the disc between these vertebrae is referred to as L5–S1.

The shape of the vertebrae changes from level to level in the spine. The vertebral body shape and the orientation of the posterior elements change. In particular, the orientation of the bony structures that compose the posterior elements change in their shapes and contact angles. These subtle changes permit or restrict motions in different directions along the human spine.

Several physiologic curves are also characteristic of the upright spine (Fig. 6.1A). The curves within the cervical and lumbar regions of the spine are referred to as *cervical lordosis* and *lumbar lordosis,* whereas the thoracic and sacral curves are referred to as *thoracic kyphosis* and *sacral kyphosis* because these curves bow in the opposite direction of the lordotic curves. These curves work collectively to accommodate pelvic orientation under different conditions. When sitting, the pelvis rotates backward and the lumbar curve flattens. When the pelvis is rotated forward, the lumbar curve is accentuated. Collectively, the spinal curves balance each other and form a stable system that maintains the center of gravity in a balanced state. However, this normal balance can change with age and a number of other factors such as degeneration, osteoporosis, and trauma.

The "building blocks" of the spine are the spinal motion segments (Fig. 6.1B), also known as the *functional spinal unit*. This unit consists of two vertebrae and the disc in between them. This unit represents the central focus of biomechanical functioning and clinical assessment. This chapter explores the spinal motion segment from a biomechanical perspective with the intent of understanding the significance of features that may influence status.

Support Structures

The spine is constructed of a series of vertebral bones that are stacked on one another to form the spinal column that runs from the pelvis to the head. A vertebral bone, or vertebra, is shown in Fig. 6.2. The large, round portion of the bone is the vertebral body, which is the major load-bearing structure of the spinal column. The outer portion of this bone is composed of a thin, yet very strong, layer of cortical bone. Cortical bone, also known as *compact bone,* forms a protective outer shell, has a high resistance to bending and torsion, and provides strength in situations in which bending would be undesirable. The inner portion of the bone consists of a spongy matrix of

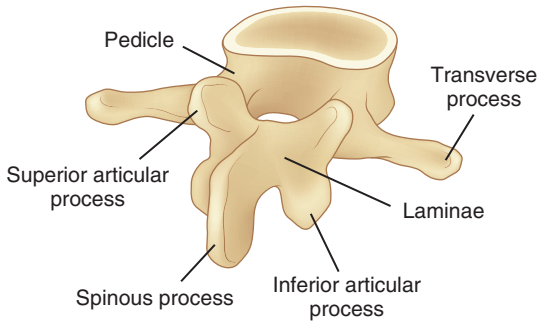

FIG. 6.2 Lumbar vertebra and its posterior elements. (Modified from Marras WS. *The Working Back: A Systems View.* Hoboken, NJ: John Wiley & Sons; 2008.)

cancellous bone. This type of bone is less dense and more elastic than cortical bone. Cancellous bone forms the interior scaffolding of the structure and helps the bone to maintain its shape despite compressive forces. This structure is composed of bundles of short and parallel strands of bone fused together.

The bony structures that constitute the posterior elements form a protective channel, or tunnel, for the spinal cord and nerves (see Fig. 6.1B). The biomechanical role of the posterior elements is to control the position of the vertebral bodies. These elements provide attachment points for muscles to control the position of the vertebra and supply lever arms to provide the system with mechanical advantage. In addition, these structures control motion and provide mechanical "stops" to prevent excessive movement of the vertebral body. A significant portion of the mechanical load is borne by the posterior elements, relieving the disc of excessive loading.

As shown in Fig. 6.2, toward the top of the posterior surface of each vertebra are pedicles. The pedicles provide a robust support structure (a type of pillar) to transmit force between the posterior elements and the vertebral body. Projecting out from each pedicle are the lamina structures that come together at the midline of the body and form a neural arch. This arch is a strong structure that provides protection to the spinal cord in the form of a channel (vertebral foramen).

Emanating out from the junction of the two laminae at the midline of the body is a bony protrusion called the *spinous process*. Projecting laterally on each side of the structure at the junction of the pedicle and the laminae is another bony structure called the *transverse process*. These processes provide muscle attachment surfaces and mechanical advantage for control of the spinal column.

Two sets of articulating surfaces are also present in the posterior elements. Projecting out from each of the cephalic lateral corners of the lamina is a bony extension called the *superior articular process*. A portion of this surface is covered by articular cartilage. Emanating from the caudal lateral corner of the lamina on each side are the *inferior articular processes*. The superior articular process from the lower vertebra interacts with the inferior articular process of the vertebra above it to form a synovial joint known as the *zygapophyseal joint*. This joint is also referred to as the *facet joint*. The inclination of the facet joint changes from the cervical spine to the thoracic spine to the lumbar spine. This joint is defined as a plane surface in the cervical and thoracic joints, but becomes

a curved surface in the lumbar spine. In the lumbar spine, the inferior facets are convex, whereas the superior facets have a concave shape. In addition, the angle of these surfaces relative to the sagittal plane changes (increases) as one moves down the lumbar spine. The differences in orientation of these facet joints restrict movement in different planes of motion. They serve an important function in that they permit certain motions and limit other motions of the spine. They can be thought of as the guidance system of the spine.

Collectively, the posterior elements can provide a significant load path for the forces running through the spinal column. Approximately one-third of a spinal load is carried through the posterior elements in the upright posture. The nature of the load transmission can be altered when spine degeneration occurs by altering the vector of force and magnitude of force transmitted through these posterior elements. This load path can be disengaged, however, when the spine is in a flexed posture, and the load can be entirely passed through the disc.

Disc

The vertebral bodies are connected by discs that serve several biomechanical purposes. First, the discs act as shock absorbers between the vertebrae, absorbing a portion of the mechanical forces transmitted through the spine. Second, they can transmit a portion of the mechanical load between vertebrae. Third, the discs are able to permit and govern motion between the vertebral bodies. Functionally, the discs are intended to provide a separation between consecutive vertebrae. This separation provides space between vertebrae so that the vertebral bodies can independently change their orientation and execute bending movements. With this arrangement, a pliable and deformable spinal structure is possible.

The disc consists of two distinct portions, each of which is associated with a distinct mechanical function. The outer portion of the disc, called the *anulus fibrosus* (AF), consists of alternating layers of fibers that are oriented at a 60- to 65-degree angle relative to the vertical. The AF consists of about 10 to 20 concentric, circumferential sheets of collagen called *lamellae* that are nestled together around the periphery of the disc (Fig. 6.3). The lamellae are stiff and can withstand significant compression loading. Given the collagenous nature of these lamellae, they are pliable and can also permit bending of the spinal column. If the structure were to buckle, however, it would lose its stiffness and would be unable to support compression. The second portion of the disc—the nucleus pulposus (NP)—is designed to overcome this potential problem.

Within the AF is a gelatinous core, the just-mentioned nucleus pulposus (see Fig. 6.3). When compressed, this core expands radially and places the AF in tension, providing stiffness. The integrity of the system changes throughout the day. The disc absorbs water while one is recumbent, which makes the system stiffer than when one is upright. Conversely, when one is upright, water is squeezed out of the disc, and the structure becomes more lax.

Finally, the endplate is located at the intersection of the disc and the vertebral body. The endplates are composed of cartilage and cover the superior and inferior portions of the

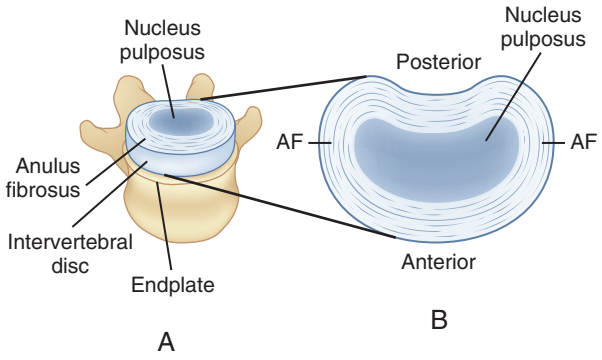

FIG. 6.3 (A) Disc, vertebral endplate, and vertebral body. (B) Construction of intervertebral disc. AF, anulus fibrosus. (Modified from Marras WS. *The Working Back: A Systems View*. disc. These structures bind the disc fibers to the vertebral bones and play a significant role in disc nutritional transport.

Spinal Ligaments

The spinal ligaments play a significant role from a biomechanical standpoint. Ligaments are most effective in supporting loads in the direction in which their fibers run. They support loads under tension and can buckle under compression. These structures can store energy and act much like a rubber band in that they can provide resistance to loads by developing tension.

The ligaments play three roles in biomechanics. First, they permit motion and help orient the vertebrae without muscle recruitment. Second, ligaments protect the spinal cord by restricting spinal motion segment movement to within specific ranges. Third, they absorb energy and protect the spinal cord during rapid motions.

The spinal ligaments are shown in Fig. 6.4. The arrangement of these structures provides support for the spine in different dimensions of loading. Because support is offered in

the different directions of motion, these structures provide stability when the spinal system is intact.

Coordinate System and Force/Movement Definitions

A biomechanical assessment of the spine is concerned with the analysis of movements and forces developing within the spine as it is exposed to activities of daily living (ADLs) and other work or environmental conditions. Movements or motions are compared with the natural limits of movement, and forces imposed on a tissue (also called *tissue loading*) are compared with tissue tolerances (magnitude of load at which damage occurs). To describe movement and force transmission through tissue accurately, it is necessary to describe precisely direction of movement and direction and magnitude of the force application on the tissue. Direction is defined relative to a coordinate system or reference frame. The central (global) coordinate system of the body is shown in Fig. 6.5. The origin or center of this coordinate system is located at the base of the spine. Fig. 6.5 describes the coordinate system (used in this chapter) as a traditional three-dimensional cartesian coordinate system with three mutually perpendicular axes oriented with a vertical z axis. Some references have adopted the International Society of Biomechanics (ISB) coordinate convention, in which the y axis is defined as the vertical axis.

All movements of the spine are described relative to the origin of the central coordinate system. Flexion and extension are typically described in the sagittal plane, lateral bending occurs in the coronal plane, and twisting occurs along the horizontal or transverse plane. Most activities are combinations of movements in these planes.

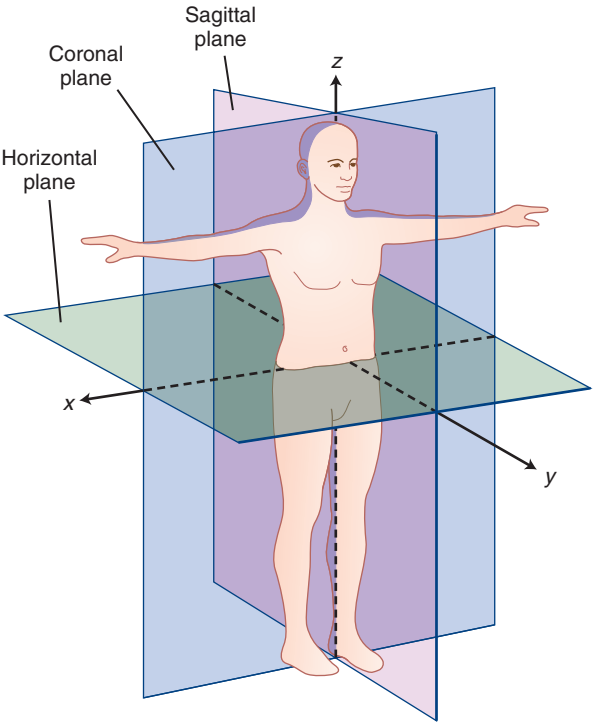

FIG. 6.5 Central or global coordinate system for the body.

Within the spinal motion segment or functional spinal unit, a local coordinate system can also be defined. The convention that defines this local coordinate system is shown in Fig. 6.6. Movement of the spinal motion segments is defined relative to the subjacent vertebrae. Movements of the motion segment can be either translations (indicating straight line movements in any direction) or rotations (indicating movement around a point, as when bending).

Fig. 6.6 indicates that forces and moments (torques) can develop along each dimension of the reference frame. Forces along the z dimension are either compression or tension depending on whether they compress the spinal motions segment or pull on the tissues. These are typically the forces of concern when lifting an object in the sagittal plane. Two types of shear forces are also of concern when evaluating the biomechanics of the spine. Anteroposterior shear force describes the forward or backward force in the y axis that can result from pushing or pulling activities. The lateral shear forces refer to the sideways forces acting along the x axis and represent the forces that develop in the spinal motion segment when pushing an object to the side of the body.

Compression of the disc causes pressure within the NP in all directions; this pressure places the AF under tension. As shown in Fig. 6.7, the nucleus pressure can lead to deformation near the center of the endplate with this form of loading.

Fig. 6.8 illustrates how shear, torsion, and tension influence the fibers of the anulus. Shear forces tense the fibers in the direction of movement and relax the fibers in the opposite direction. Similarly, torsion or twisting tenses the fibers that are lengthened by the movement and relaxes the remaining fibers. This differential of force among the fibers is believed to result in tissue damage. Finally, lengthening of the spine places the fibers under tension. This action increases the force on all the fibers regardless of their orientation.

Bending moments refer to forces acting around an axis, as seen in Fig. 6.6. The curved arrows in this figure show the direction in which moments act around a spinal segment. A bending moment can be defined around the x axis, resulting in a movement in the sagittal plane (forward bending moment), or it can be defined around the y axis, indicating a sideways or lateral bend. In either of these situations, the moment or torque around the central axis defines the loading of the segment. Twisting of the spine can result when forces are applied around the z axis of the spine. This situation results in what is typically referred to as a *torsional moment*.

The forces and moments can be defined around each vertebra along the spine, resulting in a very large number of forces and moments and numerous degrees of freedom. For practical purposes, the forces and moment are typically defined in most situations around one particular vertebra or disc (e.g., L5–S1) depending on the purpose of the study.

Movements between vertebral bodies can also be coupled. Coupling refers to the motion relationship of one vertebra around an axis relative to another vertebra around a different axis. In other words, coupling refers to the motion in different planes that occurs simultaneously. The spine can bend forward and twist at the same time—this is a coupled motion.

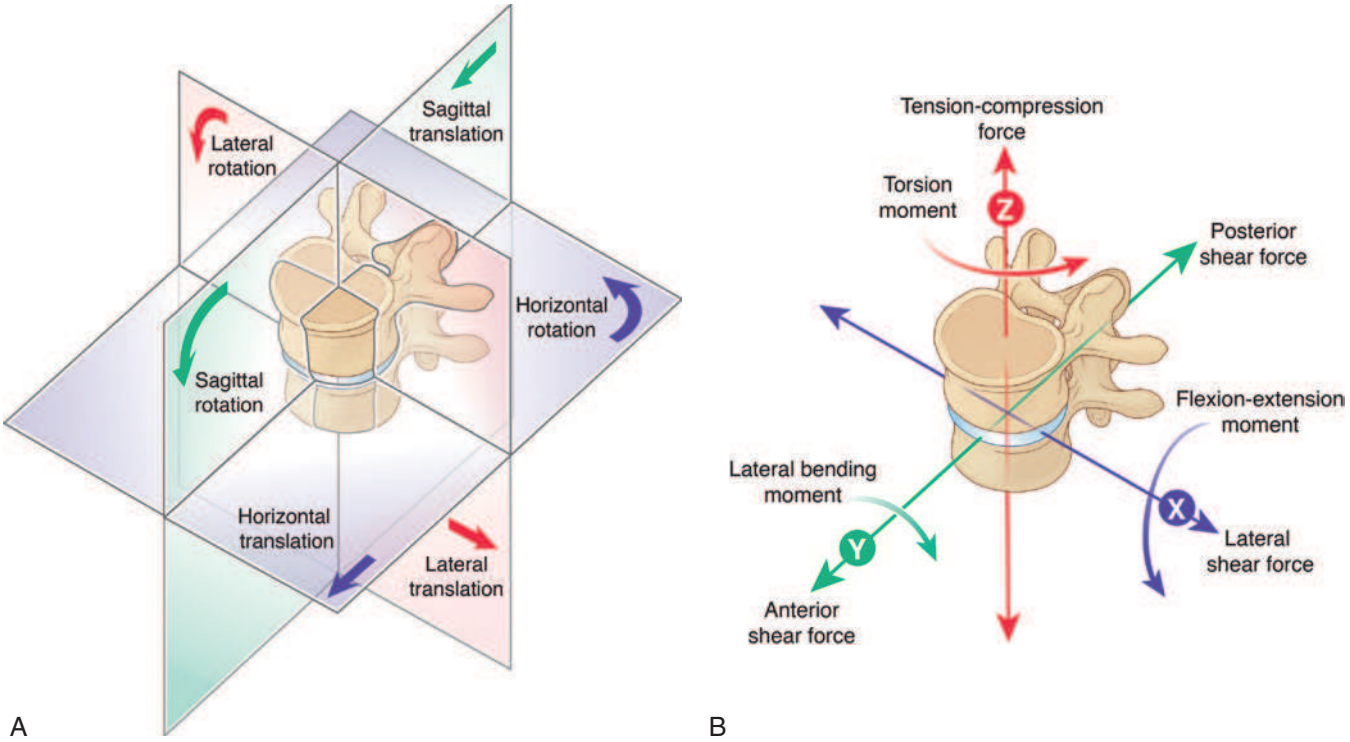

FIG. 6.6 (A) Spinal motion segment planes and directions of motion and (B) biomechanical coordinate system and direction of forces and moments. Motions and forces are described relative to this coordinate system. (Reproduced with permission from Bogduk N. *Clinical Anatomy of the Lumbar Spine and Sacrum*. 4th ed. Edinburgh: Elsevier, 2005.)

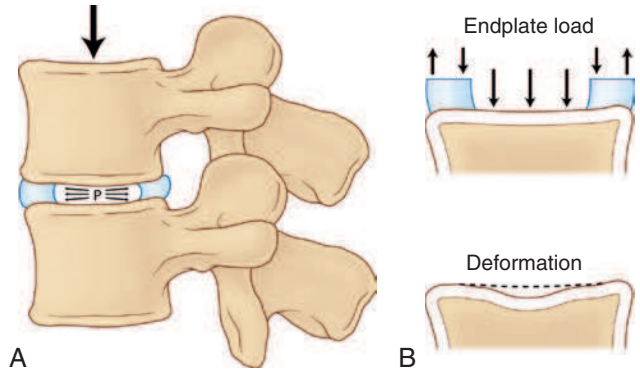

FIG. 6.7 (A) Compression of disc leading to increased pressure in the disc nucleus. (B) Increased nucleus pressure causes endplate loading and deformation. (From White AA III, Panjabi MM. *Clinical Biomechanics of the Spine*, ed 2. Philadelphia: JB Lippincott; 1990.)

The amount of displacement between the neutral position of the vertebra and the point at which resistance to physiologic motion is experienced is referred to as a *neutral zone*.[2] Neutral zones can be defined for translational and rotational movements. The neutral zone can be described for each of 6 degrees of freedom.

Tissue Load Characteristics

The forces represented in Fig. 6.6 define the direction of load application and the magnitude of the force. The nature and temporal characteristics of the loading situation also define the probability that the load application will result in tissue damage. It is believed that tissue damage can result from several different "types" of trauma to the tissue. Each type of trauma is believed to be associated with very different tolerance levels. First, acute trauma is the most familiar type of loading. *Acute trauma* refers to a single application of force that exceeds the tolerance level of the tissue. This would be the case if a large load was imposed on the spinal motion segment and a rupture of the disc occurred. In this case, the magnitude of the force applied in a particular direction would far exceed the tissue strength of the disc, resulting in a rupture.

Another well-recognized mechanism of tissue disruption involves repeated cumulative loading of the tissues. With *cumulative trauma*, moderate repetitive loads are applied to the tissues; this repeated loading is believed to weaken the structure so that the tolerance of the tissue is reduced. Although moderate loading can cause the tissues to strengthen and adapt to load, repetitive loading without proper rest (adaptation) time can cause degeneration of the tissues. Repetitive application of force to a structure is believed to cause microtrauma, which weakens the structure and leads to failure at lower levels than would be expected with an acute trauma to the tissue.

A third type of biomechanical trauma (instability) has received much attention in the literature.[3–8] Stability is the ability of a system to respond to a perturbation and reestablish a state of equilibrium.[2] *Instability* of the spine refers to the abnormal displacement of the spine under physiologic loading.

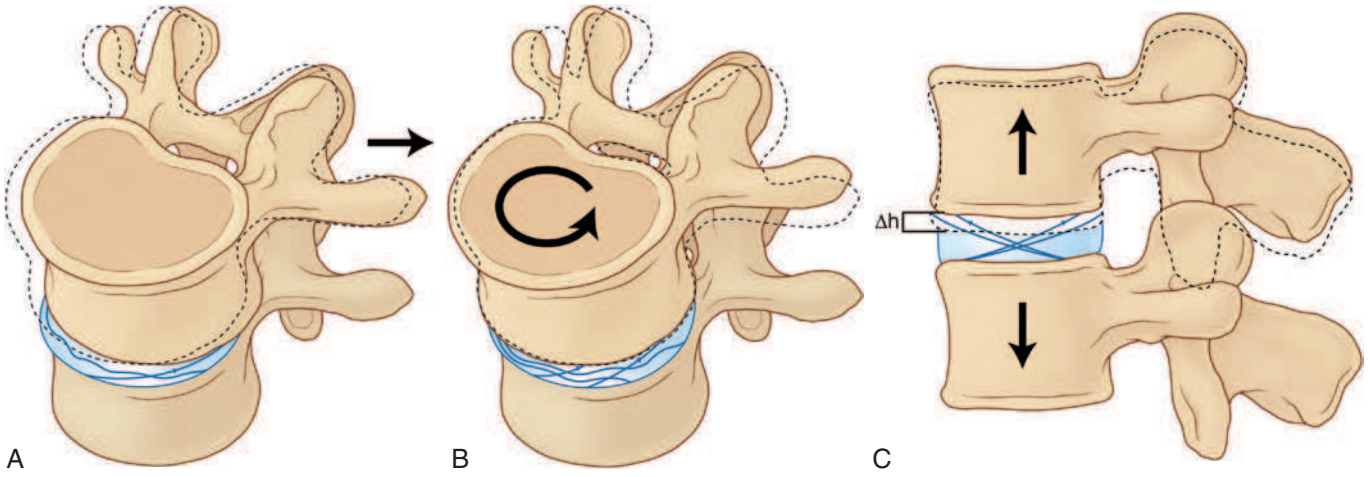

FIG. 6.8 The effects of shear (A), torsion (B), and tension (C) on the fibers of the anulus fibrosus. (From Adams MA, Bogduk N, Burton AK, et al. *The Biomechanics of Back Pain*, ed 2. Edinburgh: Elsevier; 2013.)

The abnormal displacement can occur in translation or rotation, but most likely would be some combination of these two types of motions. These abnormal motions are often small in magnitude, but the displacement may be enough to stimulate pain in sensitive tissue. Stability is significant because it is often the initiator of tissue damage when the system is out of alignment or when the musculoskeletal system overcompensates for a perturbation.[2] When the supporting musculature cannot offer adequate stability to a joint (owing to improper muscle recruitment, fatigue, structure laxity, or weakness), the structure may move abnormally and result in sudden and unexpected force applications on a tissue. This type of trauma is similar to the acute trauma pathway but is initiated by a miscalculation of the muscle recruitment pattern. Instability can also be secondary to trauma, developing over time in cases of degeneration and cancer.

Mechanical Degeneration: Tissues at Risk

Many tissues in the spinal motion segment can be influenced by structure loading. These tissues include bones, discs, ligaments, tendons, and nerves. Tissue loading can result in a disruption of tissue integrity. Bones can be cracked or broken, disc endplates can sustain microfractures, the disc can bulge or rupture, muscle can experience fiber tears, and blood flow to the tissues can be disrupted. All of these events are believed to be capable of initiating a sequence or cascade of events leading to back pain. The tolerance of many of these structures within the spine is reviewed in detail in this chapter.

Clinicians are beginning to understand that low back disorders can occur before tissue damage. Biochemical studies have shown that these types of tissue insults can result in an upregulation of proinflammatory cytokines. This upregulation may result in tissue inflammation at much lower levels of load than would occur under normal conditions. This inflammation makes nociceptive tissues more sensitive to pain and may initiate back pain.[9]

Much attention in spine biomechanics and clinical care has been focused on the intervertebral disc because disc disruption has been associated with pain. Over the past several decades, clinicians have also begun to understand how spine loading can initiate the degeneration process within the disc. To appreciate this process, the system behavior of the disc, vertebral body, and endplate must be considered in response to cumulative trauma. The disc receives no direct blood supply for nourishment. It relies heavily on nutrient flow and diffusion from surrounding vascularized tissue for disc viability. The nourishment is transported from the vertebral body through the endplate to the disc. The endplate is very thin (about 1 mm thick) and facilitates nutrient transport to the disc.

When endplate loading exceeds its tolerance limit, microfractures can occur in the structure. Microfracture of the endplate itself usually does not initiate pain because few pain receptors reside within the disc and endplate. Repeated microfracture of this vertebral endplate can lead to the formation of scar tissue and calcification, which can interfere with nutrient flow to the disc fibers. Because scar tissue is thicker and denser than endplate tissue, the scar tissue interferes with nutrient delivery to the disc. This reduced nutrient flow can lead to atrophy and weakening of the disc fibers and disc degeneration. Because the disc has relatively few nociceptors except at the outer layers, this degenerative process is usually not noticed by the individual until the disc is weakened to the point at which bulging or rupture occurs, and surrounding tissues that are rich in nociceptors are stimulated. Fig. 6.9 illustrates this sequence of events that are believed to lead to disc degeneration and potential tissue damage, such as herniation.[9]

The literature also provides some evidence that excessive motion within the spinal segment can lead to degeneration. Excessive motion at a joint is believed to increase the cumulative trauma on the spinal structures and potentially initiate either tissue degeneration or an upregulation of proinflammatory cytokines. This has become apparent in studies that have examined the degeneration of segments adjacent to spinal fusions.[10] If two spinal levels are fused, trunk motion usually results in exacerbated movement, especially at the facet joints within spinal levels adjacent to the fusion. One study noted

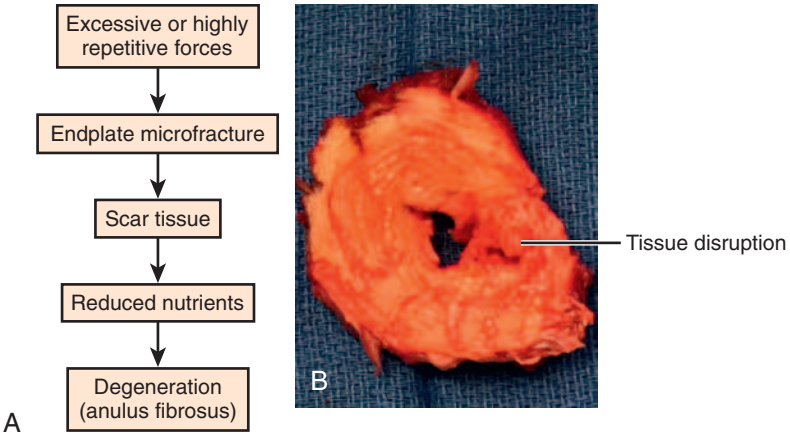

FIG. 6.9 (A) Sequence of events associated with cumulative or repeated trauma leading to disc degeneration. (B) Herniated disc showing disruptions to the anulus fibrosus. (B, Courtesy Ehud Mendel.)

hypertrophic degenerative arthritis of the facet joints in motion segments adjacent to a fusion typically following a symptom-free period (8.5 years, on average).[10] Another study found significant evidence of degeneration at levels adjacent to a fusion with the rate of symptomatic degeneration at the adjacent segment warranting either decompression or arthrodesis to be 16.4% at 5 years after fusion and 36.1% at 10 years after the surgery.[11] In addition, more recent studies examining artificial discs have reported facet arthrosis.[12] Facet load forces have been shown to depend on artificial disc placement and the subsequent load transferred to the facets.[13]

The application of damaging compressive forces on the vertebral body can result in several different types of failures of vertebrae. The failure characteristics have been described in the literature[14] and are shown graphically in Fig. 6.10. This figure indicates that seven types of failures are typically seen as a result of compression. These consist of stellate fracture, step fracture, intrusion fracture (with Schmorl's nodes), depression of the endplate, Y-shaped fracture, edge fracture, and transverse fracture.

Many of these fractures suggest weakness of the endplate. This weakness is a result of the thinness of the endplate necessary for nutrient transport to the disc. These fractures are believed to result from the NP of the adjacent disc bulging into the vertebra.[15] Clinically, vertebral body fractures that occur purely from axial compression are classified as type A based on the AOSpine classification system.[16] Fig. 6.11 shows four common subtypes of type A fractures.

In Vitro Spine Biomechanics

Motion Characteristics (Kinematics) of the Spinal Motion Segments

The typical ranges of motion (ROMs) associated with cervical, thoracic, and lumbar motion segments have been well described in the literature[4] and are summarized in Table 6.1. A graphic estimate of spinal segment ROM associated with the entire spine is presented in Fig. 6.12.[2] Table 6.1 shows the vast differences in motion capacity for the various vertebrae as a function of the spine region and the vertebral level. Each region of the spine allows or limits motion in a particular motion direction compared with other regions of the spine. This information shows that, in the sagittal plane, the most ROM occurs in the cervical spine followed by the lumbar spine. Laterally directed motions, although much smaller in magnitude than motions in the sagittal plane, occur freely in the cervical spine, with much less movement available in the thoracic and lumbar spine. Finally, very little axial rotation is possible in the lumbar spine, with most motion occurring in the thoracic vertebrae except for C1–C2.

Collectively, the body of work described in Table 6.1 and Fig. 6.12 represents the summary of expected movement characteristics derived in vitro. To the extent that in vitro characteristics are indicative of in vivo characteristics, they can provide a baseline for movement expectations for the various vertebrae along the spinal column.

It is also possible that abnormal movement of the motion segment can indicate disc damage. Studies have also shown that tears in the AF change the movement characteristics of the motion segments. Specifically, tears in the anulus increase the amount of motion in the motion segment when torque is applied to the segment.[17]

Axis of Rotation

To understand and describe better how motion occurs among vertebrae, an axis (or center) of rotation is often defined. When bones move relative to one another in a single plane, there is a point around which the object rotates. If a hypothetical line is extended from the constant point within a vertebra, the point at which these two lines meet when the vertebra moves between two different positions is called the *instantaneous axis of rotation*. This concept can be extended to three-dimensional space; however, identifying the axis of rotation becomes more complex. Understanding of the axis of rotation helps one understand how kinematics are altered because of degeneration or surgical intervention. Identification of this point also has implications for how forces are transmitted through the spine.

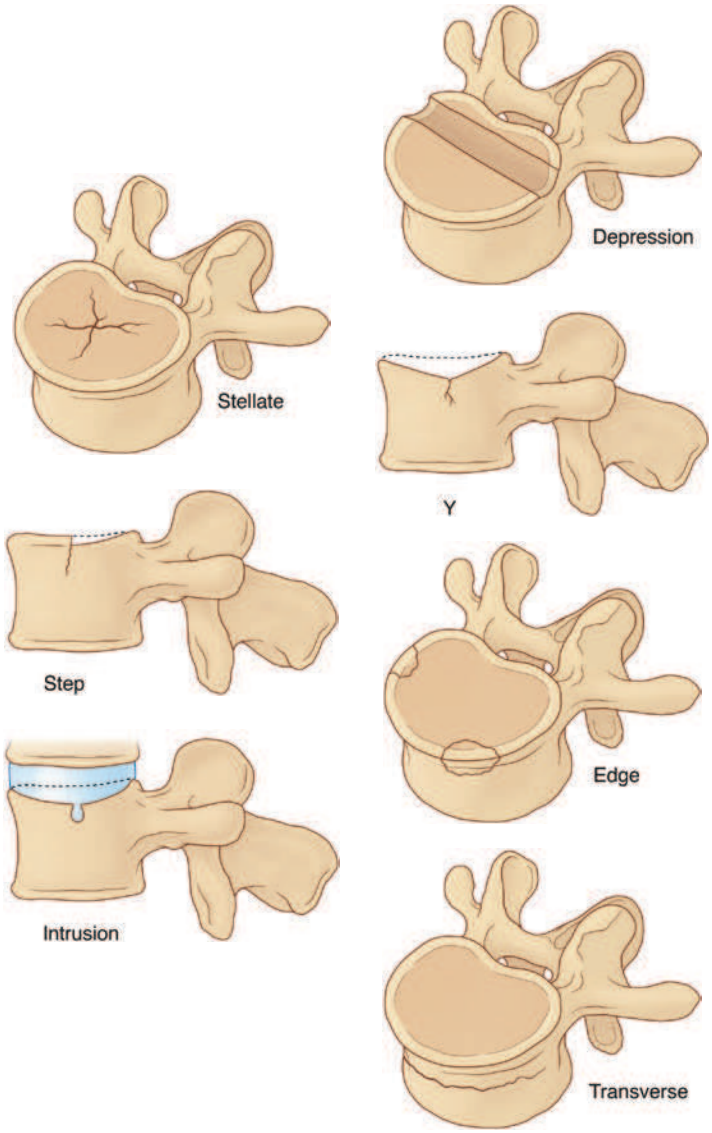

FIG. 6.10 Seven types of fractures identified by Brinkmann and colleagues.[14] (From Adams MA, Bogduk N, Burton AK, et al. *The Biomechanics of Back Pain*, ed 2. Edinburgh: Elsevier; 2013.)

Relative movement of a vertebra can be divided into translational movement (sliding motions) and rotational movement. During physiologic movements, the components of compression force and bending moment acting on the spine vary, along with the translational and bending movements. This action results in a varying axis of rotation position. The axis of rotation is defined as a "locus," or path, that the axis of rotation takes.[18]

During sagittal and frontal plane motions, the axis of rotation in the cervical spine is believed to be located in the anterior portion of the subjacent vertebra.[2] Coupling also occurs with cervical motions, however. In the thoracic spine, loads applied during flexion and extension motions result in an axis of rotation located at the inferior endplate of the lower vertebra. This axis of rotation moves farther down the vertebra when posterior shear force occurs during extension motions.[2] During flexion and extension motions, the axis of rotation occurs in the superior endplate of the inferior vertebra of the spinal motion segment.

During sagittal plane bending, the axis of rotation varies according to whether forward or backward bending is occurring. Because much of the flexion and extension in the sagittal plane occurs in the lumbar spine, much of the interest in the axis of rotation has also been focused on the lumbar spine. The superior vertebra translates anteriorly and posteriorly relative to the inferior vertebra as the vertebral body rotates around the nucleus. After degeneration of the disc, the axis of rotation can change dramatically,[19] resulting in marked changes in spine loading. Under these degenerative conditions, the axis of rotation has been reported to migrate toward the zygapophyseal joint during extension motions.[20] During flexion, the axis of rotation seems to move and is dependent on coupling patterns during the flexion movement.

During lateral motions, the axis of rotation in the lumbar spine lies at the opposite side of the disc from the direction of motion. In other words, when bending to the right, the left side of the disc is where the axis of rotation is located.[2]

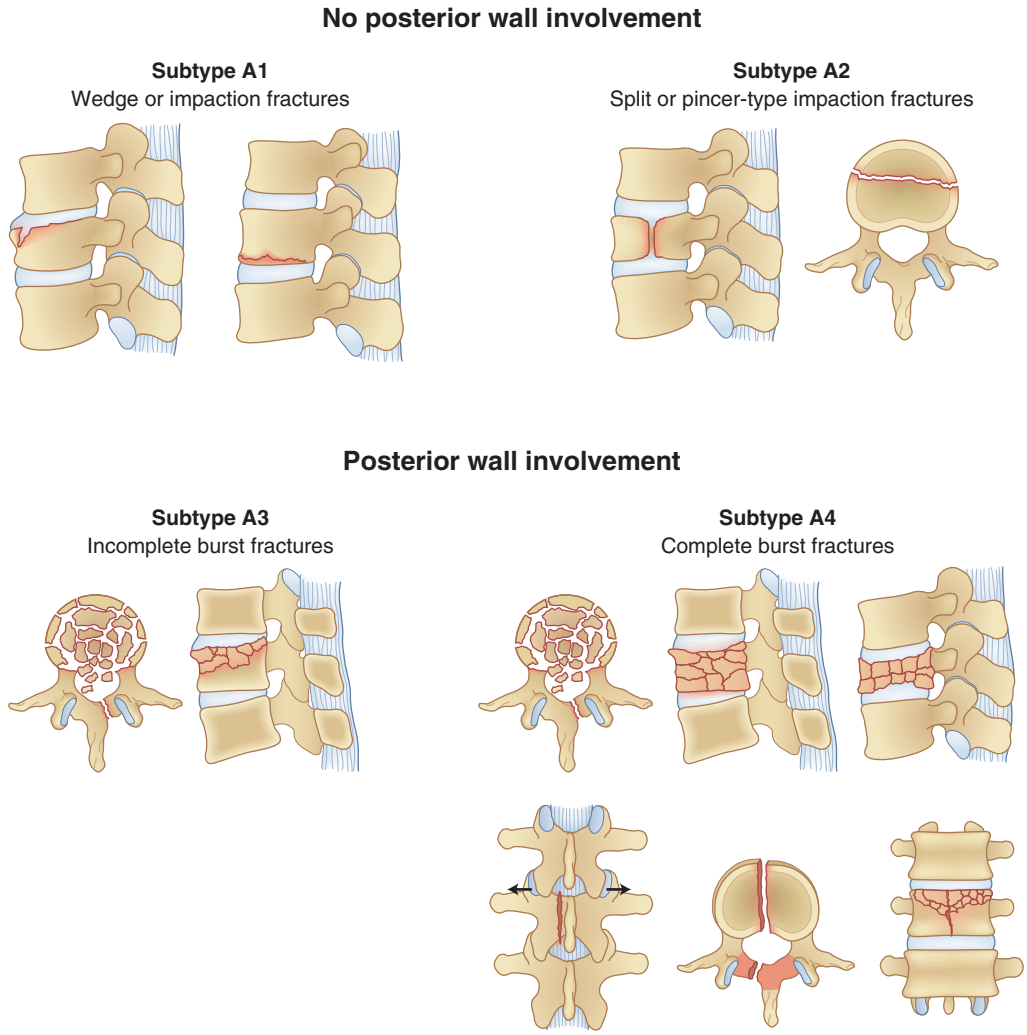

FIG. 6.11 Type A compression fractures based on the AOSpine Classification. (From Reinhold M, Audige L, Schnake KJ, et al. AO spine injury classification system: a revision proposal for the thoracic and lumbar spine. *Eur Spine J*. 2013;22[10]:2184-2201.)

The axis of rotation for axial (torsion) movements has been difficult to locate. This axis of rotation is believed to lie within the posterior AF when exposed to torque.[21] Even small axial motion can create compression at one facet surface and tension at the opposite facet surface.[5] With disc degeneration, the axis of rotation becomes far less apparent, however, in the lumbar spine.[4] Under degenerative conditions, the locus of the axis of rotation has been reported to be significantly spread out over an extended area.[21]

Collectively, the literature has described the locations of the axis of rotation for various "normal" motions. It is apparent, however, that these axes change dramatically with degeneration, and should be factored in when considering load bearing through the spine and motion profiles.

Motion Coupling

A significant amount of coupling has been observed along the spinal column. Coupling is a function of the geometric characteristics of specific vertebrae, limitations in tissue properties of the disc and ligaments, and spine curvature. Movements are considered coupled when one motion is accompanied by motion in a different plane.[2] The motion in the primary, or intended, plane of movement is referred to as the *main motion*; the accompanying motions are referred to as *coupled motions*.

Because coupling can have profound implications on the transmission of forces through the spine, it is important that the nature of coupling in the different regions of the spine be understood. From a clinical perspective, coupling is important in understanding the impact of various pathologies, such as scoliosis and different types of spine trauma. In addition, an appreciation for coupling is important for understanding the impact of surgical interventions, such as the impact of fusion.

Coupling is most common in the cervical and lumbar spine, but can also occur in the thoracic spine. Coupling in the cervical and lumbar spine involves axial rotation coupled with lateral bending. Lumbar motion can involve cross-coupling in all three rotation directions. Motions in the lumbar spine are rarely unaccompanied by coupled movements. Coupled motions of the lumbar spine vary as a function of the spine level and a function of spine posture.[2]

Coupling patterns within the spine differ depending on the region of the spine. The cervical spine exhibits a striking degree of coupling in that lateral bending of the head is

accompanied by significant amounts of cervical rotation. This is evident by observing the position of the spinous processes as lateral bending occurs. When lateral bend to the left occurs, the spinous processes point to the right; when lateral bending to the right occurs, the spinous processes go to the left. It is generally thought that the angle of incline of the facet joints in the sagittal plane increases from the head toward the lower spine.[2] Generally, the average ratio of the coupled lateral bending compared with axial rotation is 0.51.[22]

The coupling of lateral bending and spine rotation can also occur in the thoracic spine. As with the cervical spine, lateral bending is coupled with axial rotation in such a way that the spinous process moves toward the convexity of the lateral curve. The vertebrae in the upper portion of the thoracic spine have motions that are strongly coupled, but not to the same degree as in the cervical spine. In the middle segments of the thoracic spine, the coupling motions are far less apparent. Coupled motions in this portion of the thoracic spine are inconsistent and can result in rotations opposite of those in the upper thoracic spine. Coupling patterns in the lower portion of the thoracic spine are weak. Although the patterns of coupling between axial rotation and lateral bending have been described in the literature, most likely owing to a desire to understand scoliosis, Panjabi and colleagues[23] have shown that coupling can occur in all 6 degrees of freedom.

Coupling patterns in the lumbar spine seem to differ from those of the cervical and thoracic spine. The most dominant coupling pattern of the lumbar spine seems to be lateral bending coupled with axial rotation (Table 6.2).[24] In this case, the spinous process moves in the same direction as lateral bending. This is exactly opposite to the pattern in the cervical and upper thoracic spine. One group of researchers[25] reported, however, that coupling at L5–S1 occurs in a fashion similar to that of the lower cervical spine and opposite to that of the rest of the lumbar spine.

In vivo studies of the lumbar spine have shown the importance of muscular involvement in determining coupling patterns of the lumbar spine.[25] In vitro studies have reported that lateral bending motion was coupled with flexion motions between L1 and L3, whereas in vivo studies reported that lateral motions are coupled with extension movements in these vertebrae. In addition, biomechanical analyses have shown that coupling in the lumbar spine can be influenced by posture of the spine.[25,26] One would expect that muscle control can also play an important role in coupling patterns.

Neutral Zone Limits

As discussed earlier, the neutral zone is important for understanding when tissues first experience resistance to movement. Low intersegmental resistance to motion can be an indication of biomechanical problems. The neutral zones for the different planes of motion have been extensively described by Panjabi and colleagues.[27–29] Table 6.3 shows estimates for the neutral

TABLE 6.3 Average Neutral Zone (Degrees of Motion) for Different Spinal Motion Segments in Different Motion Planes

Vertebral Segments	Flexion-Extension	Lateral Bending	Axial Rotation
C0–C1	1.1	1.6	1.5
C1–C2	3.2	1.2	29.6
C3–C6	4.9	4	3.8

zones for rotary motions as a function of the plane of motion and the spine level.[2] For the most part, the neutral zone is limited in range except for certain vertebrae in certain axes of rotation. From a clinical perspective, one must be sensitive to the fact that normal and abnormal neutral zones can be very different for different vertebrae.

A large neutral zone can be an indication of several biomechanical factors. First, the neutral zone has been observed to increase with age.[30] Second, a larger-than-expected neutral zone can indicate injury to the tissue.[31] Third, some clinicians contend that low resistance to movement is an indication of clinical instability.[32] There are several reasons to consider carefully the range of movement within the neutral zone.

Load Tolerance of the Spinal Motion Segments

The precise tolerance characteristics of human spinal tissues—such as muscles, ligaments, tendons, and bones—loaded under various conditions have been difficult to establish. Structure tolerances have been observed to vary greatly even under similar loading conditions because of their dependence on many factors, such as strain rate (rate of loading), age of the structure, frequency of loading, physiologic influences, heredity, conditioning, and other unknown factors. In addition, it has been impossible to measure these tolerances under in vivo conditions. Many of the estimates of tissue tolerance have been derived from various animal or theoretical constructs.

Tolerance data limits have been derived primarily from cadaveric tissue. The obvious compromise in this approach is that in vitro tissue when tested does not have the ability to adapt or recover (and potentially increase tolerance) as does a live human. The material properties of cadaveric tissue vary depending on the manner in which the specimen was prepared for testing. At least one study suggests that living tissue failure might occur at magnitudes below those observed in cadaveric specimens.[33]

Muscle and Tendon Strain

Muscle has the lowest tolerance among the tissues of the spine. The ultimate strength of a muscle has been estimated at 32 MPa.[34] Muscle often ruptures before a (healthy) tendon.[35] Tendon stress has been estimated to be between 60 MPa and 100 MPa.[34,35] There seems to be a safety margin between the muscle failure point and the failure point of the tendon by a factor of about twofold[35] to threefold.[34]

Ligament and Bone Tolerance

Ultimate ligament stress has been estimated at approximately 20 MPa. The ultimate stress of bone has been found to depend on the direction of loading. Bone tolerance can range from 51 MPa in transverse tension to 190 MPa in longitudinal compression.

A temporal component to ligament recovery has also been reported. One study found that ligaments required extended periods to regain structural integrity. During the recovery period, compensatory muscle activities have been observed.[36–43] Recovery time has been observed to be several times the loading duration.

Because the spinal ligaments often are the structure that protects the spinal system, it is important to appreciate the failure limits of the various spinal ligaments; these are shown in Table 6.4. Note that the load tolerance of these ligaments and the deformation characteristics of the ligaments vary markedly according to the region of the spine and the specific ligament involved. Generally, the lower the level of the spinal ligament, the greater is the tolerance of the ligament. There are notable exceptions to this trend, however. Spinal ligaments are viscoelastic and can increase their length under load. They can be responsible for an increase in the neutral zone; excessive movement can also initiate muscle activities intended to regain stability.[36,44]

Contact Force Tolerance

Contemporary logic suggests that pain secondary to biomechanical loading of the spine may result from direct stimulation to the facet joints, pressure on the anulus, or pressure on the longitudinal ligaments.[9] At these sites, inflammatory responses and analgesic responses are thought to be involved in the development of pressure and pain. It is much more difficult to specify load tolerance thresholds for contact pressures because the body's individual responses to the imposed loads collectively define the pressure imposed on the spinal structure. The tolerance limits for these structures has not been well defined at this time.

Tolerance of Specific Spine Structures

The general structure tolerance, or failure, limits in response to loading of the lumbar spine have been well investigated. Table 6.5 provides a summary of these tolerances reported as a function of the nature of the loading for the spinal motion segment structures and the disc and vertebral body structures.[18]

Compression

The compression dimension of spine tolerance has been widely examined. Of all the structures in the spinal motion

segment, the endplate is considered to be the "weak point of the system," or the structure with the lowest tolerance to force. Compression failure limits are a function of age, with older endplates failing at lower levels of force, and a function of gender, with female tolerances lower than male tolerances.[45,46] Fig. 6.13 shows a summary of the compression strength for much of the spine. The magnitude of force required for endplate tissue failure follows a normal distribution that ranges from 2000 to greater than 14,000 N. When compression forces increase on a spinal motion segment, the first signs of damage usually occur at the endplate or the trabeculae that support the endplate. The endplate must be a thin structure to serve its nutrition transport function. Because it is thin, it is also a very weak structure, however, and subject to early failure when load is applied.

Failure is believed to be initiated by the NP of the adjacent disc. This nucleus causes the endplate to bulge and compromise the vertebral body. The superior endplate is damaged more often than the lower endplate. In some cases, it is possible for a portion of the NP to make its way vertically through a herniation of the endplate into the bone.[18] This herniation can calcify and form a Schmorl node. Endplate fractures are difficult to detect via routine radiographs; however, magnetic resonance imaging (MRI) can indicate biologic (modic) changes that are characteristic of vertical displacement of the NP.[18]

When the endplate experiences excessive compressive load, the endplate can bulge into the vertebral body, increasing the volume available to the nucleus. This decompression of the nucleus means that it cannot resist compression well, and more of the load is borne by the AF. The anulus can become unstable and the lamellae can become compressed, and cannot be supported any longer by the nucleus. It is believed that this form of disc loading can result in internal derangement of the disc and potentially reverse bulging of the inner lamellae.

TABLE 6.5 Tolerance of Lumbar Motion Segment and Disc Structures as a Function Load and Motion Characteristics

	Failure Site	Average Tolerance
Motion Segments		
Compression	Endplate	5.2 (±1.8) kN all specimens 6.1 (±1.8) kN men (20–50 y)
Shear	Neural arch	2 kN
Flexion	Posterior ligaments	73 (±18) N-m with compressive load of 0.5–1 kN
Extension	Neural arch	26–45 N-m
Torsion	Neural arch	25–88 N-m
Flexion and compression	Disc or vertebra	5.4 kN
Disc Plus Vertebral Bodies		
Shear	Anulus	0.5 kN
Flexion	Posterior anulus	33(±13 N-m)
Torsion	Anulus	10–31 N-m

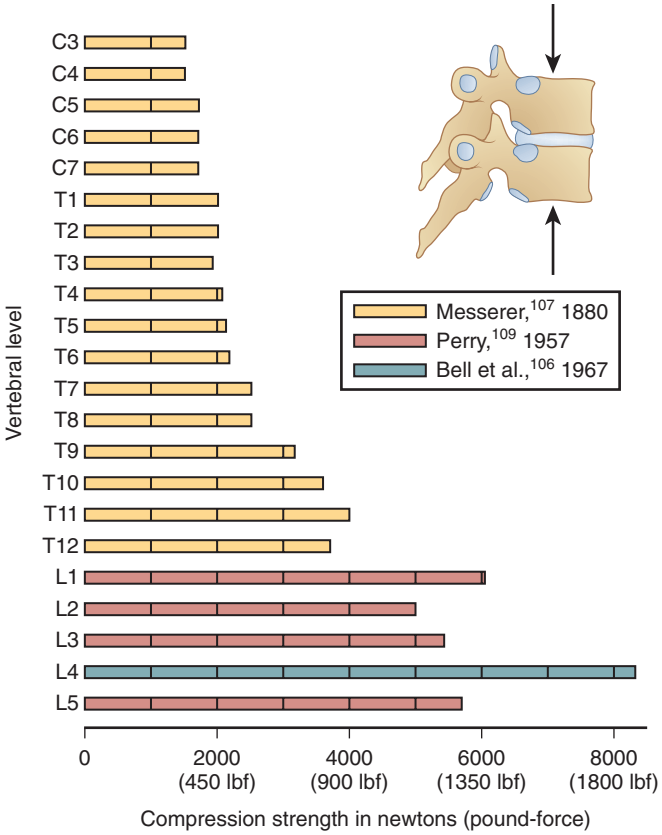

FIG. 6.13 Estimates of vertebral compression tolerance (strength) under slow load rates for the various vertebrae from C3 to L5.[106–108] (From White AA III, Panjabi MM. *Clinical Biomechanics of the Spine*, ed 2. Philadelphia: JB Lippincott; 1990.)

As noted earlier, endplate tolerance seems to be a function of gender and age.[45,46] Tolerance estimates based on a review of the literature are shown in Fig. 6.14. Although great variability is evident, women generally have lower compression tolerance by an average of almost 2 kN compared with men. In addition, tolerance reduces significantly with age. Age influences

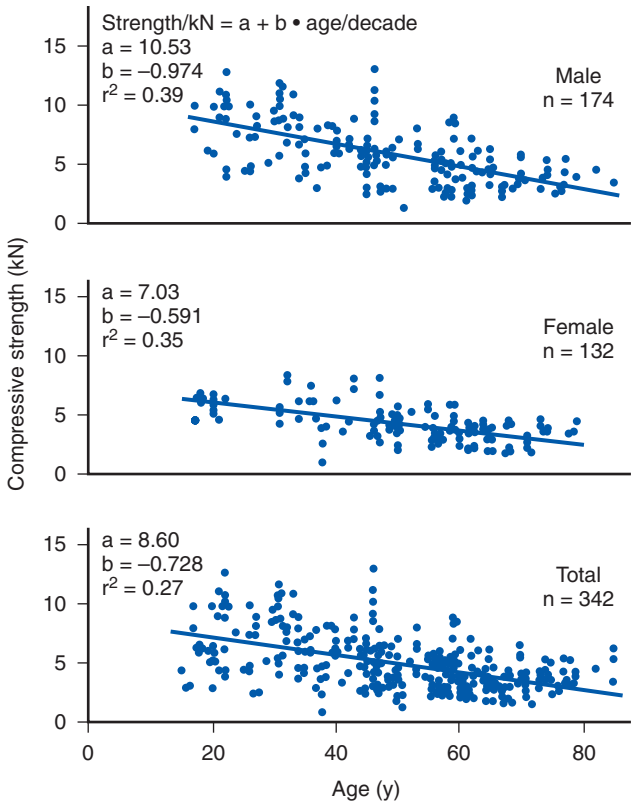

FIG. 6.14 Strength tolerance to static lumbar compression derived from the literature as a function of age and gender. (From Jager M, Luttmann A, Laurig W. Lumbar load during one-hand bricklaying. *Int J Indust Ergo.* 1991;8:261–277.)

endplate tolerance differently between men and women, however. The decrease in tolerance with age is nearly two times greater for men compared with women.[45,46] In addition, the strength of the vertebrae is nearly 0.8 kN lower than that of the disc.[46] Finally, strength increases as one moves down the lumbar spine by approximately 0.3 kN per lumbar level.[47]

Repetitive loading also seems to influence the tolerance to load of the motion segment. Fig. 6.15 shows how the number of load repetitions and the relative magnitude of the load collectively have a dramatic impact on probability of failure of the segment. As can be seen in this figure, when the relative load becomes greater, the chances of failure increase the risk significantly when the number of loading cycles increases.[48] Studies have also shown that, as the flexion angle increases, the number of cycles required for failure is dramatically reduced.[47,49]

Shear

The disc fibers and intervertebral ligaments are inadequately oriented to resist shear forces. Shear causes the disc to creep during repetitive loading.[50] Under many situations, the neural arch resists shear force, however. The articular process resists on average 2 kN of load before failure; however, this can range from 0.6 kN to 2.8 kN.[51] The specific point of load application can also greatly affect tolerance of the neural arch to shear. Fig. 6.16 shows how differing methods of shear force application can result in dramatically different neural arch load tolerances.[52,53]

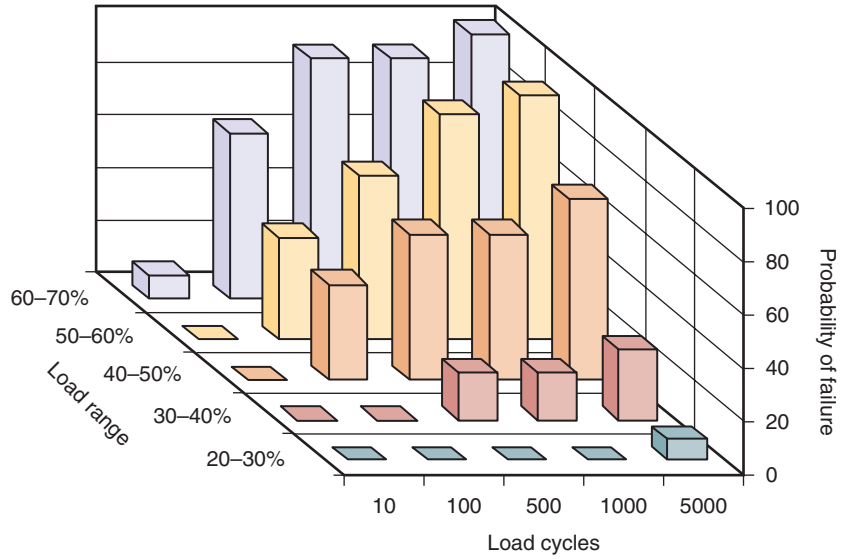

FIG. 6.15 Probability of vertebrae failure as a function of load magnitude and number of cycles of loading.[48] (Modified from Marras WS. *The Working Back: A Systems View*. Hoboken, NJ: John Wiley & Sons; 2008.)

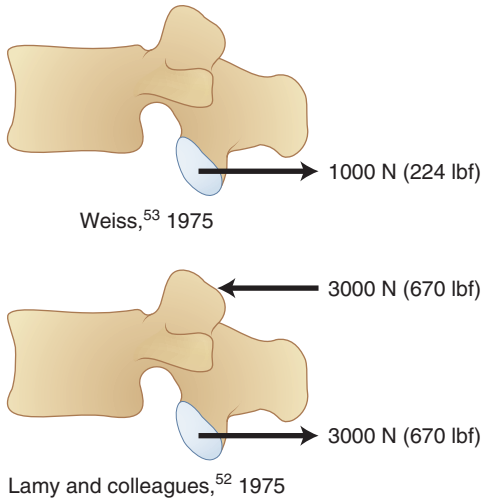

FIG. 6.16 Force tolerance of neural arch varies greatly as a function of shear force application method.[22,53] (From White AA III, Panjabi MM. *Clinical Biomechanics of the Spine*, ed 2. Philadelphia: JB Lippincott; 1990.)

Repetitive shear loading can also reduce the tolerance to 380 N.[51] Some authors have concluded that the limit at which shear begins to increase risk is 750 to 1000 N,[54–56] although this is also known to vary according to load rate.[57,58] In addition, studies have reported failure occurring at the pars under these conditions. Fig. 6.17 shows a summary of results of ultimate shear strength of human cadaveric lumbar spines obtained from in vitro studies.[59] Gallagher and Marras conducted a Weibull analysis on shear failure data of human cadaveric lumbar spines and recommended a maximum permissible shear limit of 1000 N for occasional exposure to shear loading (≤100 loadings/day) during occupational tasks. However, for activities resulting in more frequent shear loadings (100–1000 loadings/day), they recommended a shear limit of 700 N.[59]

Torsion

The motion segments offer little resistance to small angles of axial rotation. Torsion is first resisted by collagen fibers in the anulus that simply stretch slightly.[18,60] With further axial motion, the articular surfaces make contact at one of the zygapophyseal joints, and motion is limited to 1 or 2 degrees.[21] This ROM increases, however, with greater disc degeneration.[61–63] Under typical loading conditions (involving torsion and compression), the loads imposed on the spine are shared by several structures. At the limit of the natural range of movement, 30% to 70% of the applied torque is resisted by the zygapophyseal joint as a compressive load, 20% to 50% is resisted by the disc, and less than 15% is resisted by all of the intervertebral ligaments, collectively.[18,21]

The lower limit for initiation of damage owing to torque application seems to begin at about 10 to 30 N-m.[21] Many clinicians believe that damage owing to torsional movements occurs at the zygapophyseal joint before damage occurs to the discs.[18]

Flexion and Extension

Significant repositioning of the spine results when flexion and extension of the spine occurs. Different structures are responsible for resisting force, and the tolerance of the spine can change. During extension of the spine, 60% to 70% of the applied load is resisted by the neural arch. Studies have reported damage resulting from 3 to 8 degrees of extension under bending moments of 28 to 45 N-m.[64,65] Resistance to extension is offered by the disc and the anterior longitudinal ligament.[18] Of particular concern is the risk of the anulus bulging into the vertebral canal and compromising canal space.

It is hypothesized that the zygapophyseal joint would be the structure damaged first owing to extension. However, it is also believed that the interspinous ligament may be at risk because it would be compressed by opposing spinous processes. Rapid load rates, possibly resulting from athletic endeavors, are also thought potentially to increase risk.

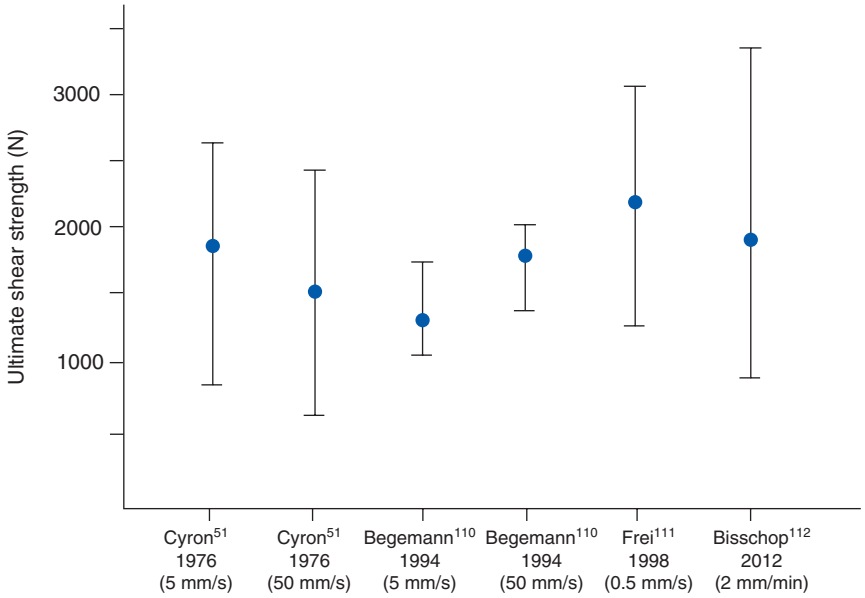

FIG. 6.17 Summary of in vitro studies measuring the ultimate shear stress of human lumbar segments (error bars represent the range of shear tolerance values). (From Gallagher S, Marras WS. Tolerance of the lumbar spine to shear: a review and recommended exposure limits. *Clin Biomech [Bristol, Avon]*. 2012;27[10]:973-978.)

Flexion can lead to injury when imposed moments reach 50 to 80 N-m.[66–68] Damage occurs when the spinal motion segment reaches 5 to 9 degrees per motion segment in the upper lumbar spine and 10 to 16 degrees per segment in the lower lumbar spine. The first structures to sustain damage are the interspinous and supraspinous ligaments.[68] During complex motions involving flexion and lateral bending, the capsular ligaments can also be compromised. The final tissue to fail is the outer posterior AF. In isolation (without the ligaments), the disc can fail when flexed at 18 degrees with an application of 15 to 50 N-m of load.[69] As with most structures, load rate also plays a role in tolerance. Resistance to flexion can increase by more than 10% when rapid motions (10 seconds) are compared with slow motions (1 second).[70] Static postures seem to reduce resistance to bending by very large amounts, probably owing to the interrelationship between the ligamentous system and muscular control.[38]

Lateral Motion

Less has been reported about the tolerance associated with lateral bending moment exposure. Some studies have reported that a lateral bending moment of 10 N-m results in 4 to 6 degrees of lateral bending in the lumbar spine, with most of the resistance occurring at the disc.[62,71] If the disc experiences degeneration, the ROM is greatly reduced to 3 to 4 degrees, however, practically eliminating the neutral zone.[62]

In Vivo Spine Biomechanics

Overview

Our fundamental knowledge of spine biomechanics has been primarily gained through in vitro studies on animal and human cadaveric models in laboratories. However, the value of these biomechanical results increases significantly only when it can be directly correlated to clinical outcomes.[72,73] Intuitively and experientially, we know that there are several limitations associated with in vitro studies—such as specimen integrity, lack of complex neuromuscular control, and proprioceptive and nociceptive inputs—that all play a significant role in producing the natural, graceful, and efficient motion of the spine. Of particular clinical significance is the understanding of pain-modulated motion, which is an in vivo phenomenon. Several studies have explored this complex phenomenon in symptomatic individuals with low back disorders and found significant modifications to their kinematics due to underlying pathology and pain when compared to asymptomatic individuals.[74–76] Unfortunately, current in vitro testing methods are unable to replicate pain-modulated kinematics, estimate pain, or determine the impact of altered kinematics due to pain avoidance on the overall mechanical response of the spine and potential injury risk or damage. This creates a substantial impetus for improving our understanding of the mechanical behavior of the spine under in vivo conditions and developing strategies to better translate biomechanical parameters from benchtop to bedside.

To address these limitations, over the past 15 years, several researchers have developed tools to enhance our understanding of in vivo spine biomechanics using advanced medical imaging, motion-capture systems, and efficient numerical techniques to help provide clinically measurable biomechanical metrics. These tools have the potential to help determine accurate in vivo spinal motions in three-dimensional (3D) load exposures, provide insights into mechanisms of spinal injury and pathology, and facilitate overall assessment of treatment outcomes, design of novel spinal implants, and improve current prevention and rehabilitation strategies. The following sections highlight key areas of research on in vivo spine biomechanics.

Quantitative Assessment of in Vivo Spinal Motion

Overall Spine Kinematics (Extrinsic Measurements)

To appreciate the differences involved in spine impairment, it is important to understand the normal motion or kinematics of the spine. It has been observed that people with low back pain move more slowly.[74,75,77] Motion reduction is assumed to be a result of the "guarding" that occurs in an attempt to minimize the stimulation of pain-producing nociceptors. Abnormal coupling of movement has also been shown to be associated with low back pain.[76]

Spine kinematic profiles associated with asymptomatic individuals and people with low back pain have been reported in the literature at least for the lumbar spine. Fig. 6.18 summarizes how trunk ROM, velocity, and acceleration change as a function of low back pain in the sagittal, lateral, and transverse planes of the body. There seem to be no differences in ROM between the low back pain group and the asymptomatic group. Significant differences are apparent, however, when trunk velocity and acceleration are considered. This seems to be the case in all motion planes of the body. More recent studies have shown that kinematic ability can be used to document the extent of a low back disorder.[74,77] These differences in velocity and acceleration are believed to be a result of protective "guarding" employed by patients with low back pain through the excessive coactive recruitment of the trunk muscles. This coactivity is believed to slow the motions of the torso. The use of objective quantitative biomechanical metrics to augment traditional subjective measures such as pain questionnaires or Oswestry Disability Index (ODI) may provide new insights during clinical evaluation and potentially improve overall treatment outcomes.

Spine Kinematics (Intrinsic Measurements)

Several studies have investigated noninvasive techniques to quantify normal in vivo spinal kinematics to aid in the clinical diagnosis of spinal impairments and instability.[27,78–81] A majority of these studies relied on static planar radiographs to assess in vivo spinal ROM.[27,82] Fig. 6.19 illustrates the estimated normal movement characteristics of the lumbar spine measured in living subjects. This figure indicates significantly different normal movements, particularly in flexion-extension, between in vivo and in vitro observations.[18,27] Fig. 6.20 highlights this difference between the in vitro and in vivo observations in the sagittal plane.[27]

There is a general overestimation of extension movement range in vitro and a general underestimation of flexion range in vitro. In addition, significant differences can be seen between levels between the two states. It should be noted that the measurements from these studies were from static

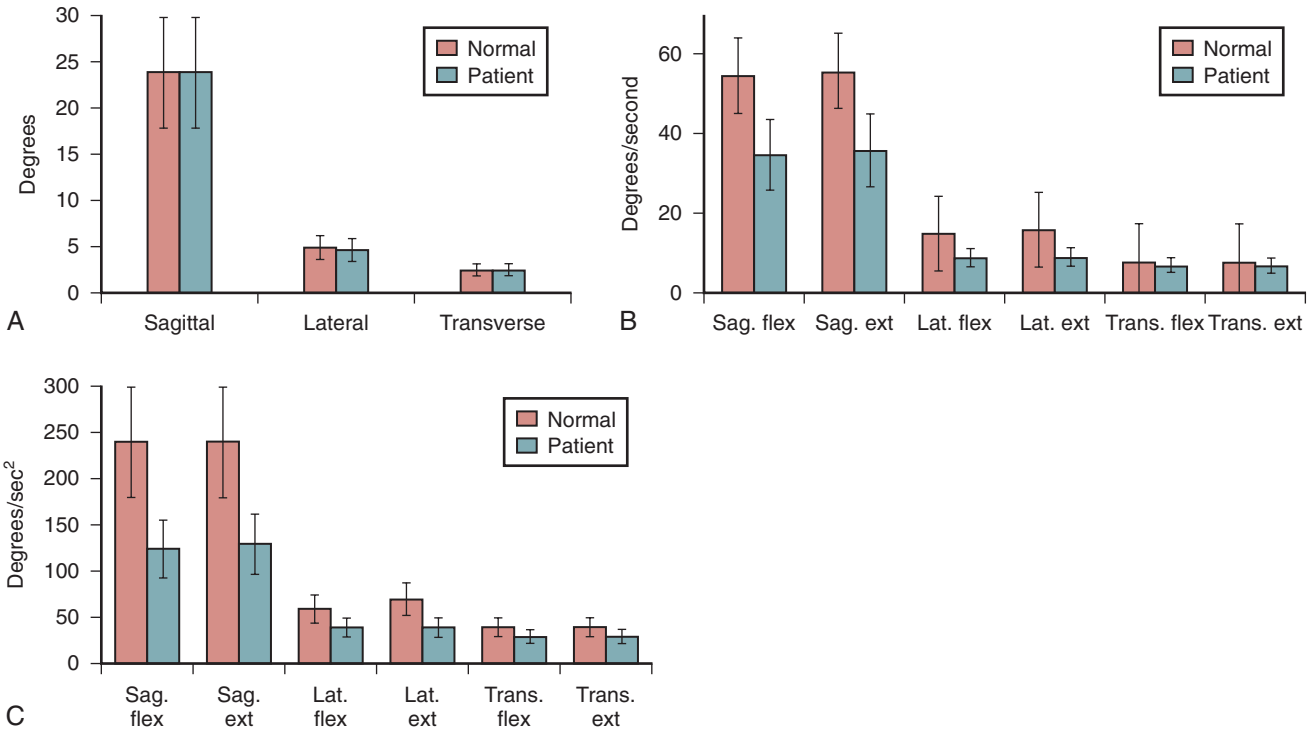

FIG. 6.18 (A) Spine range of motion characteristics (mean and standard deviation [SD]) associated with asymptomatic patients versus patients with low back pain in sagittal, lateral, and transverse planes of the body. (B) Spine velocity characteristics (mean and SD) associated with asymptomatic patients versus patients with low back pain in sagittal, lateral, and transverse planes of the body. (C) Spine acceleration characteristics (mean and SD) associated with asymptomatic patients versus patients with low back pain in sagittal, lateral, and transverse planes of the body.

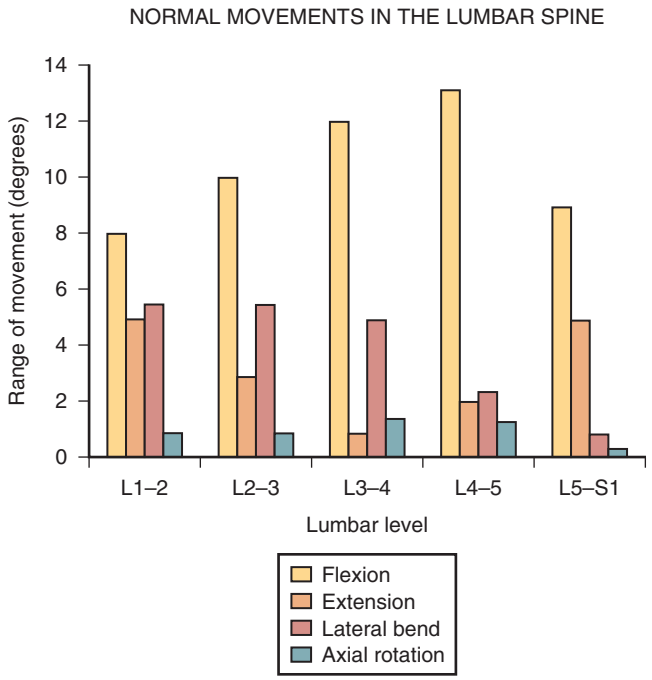

FIG. 6.19 Ranges of motion in lumbar spine during flexion, extension, lateral bending, and rotation.[25,27] (From Adams MA, Bogduk N, Burton AK, et al. *The Biomechanics of Back Pain*, ed 2. Edinburgh: Elsevier; 2013.)

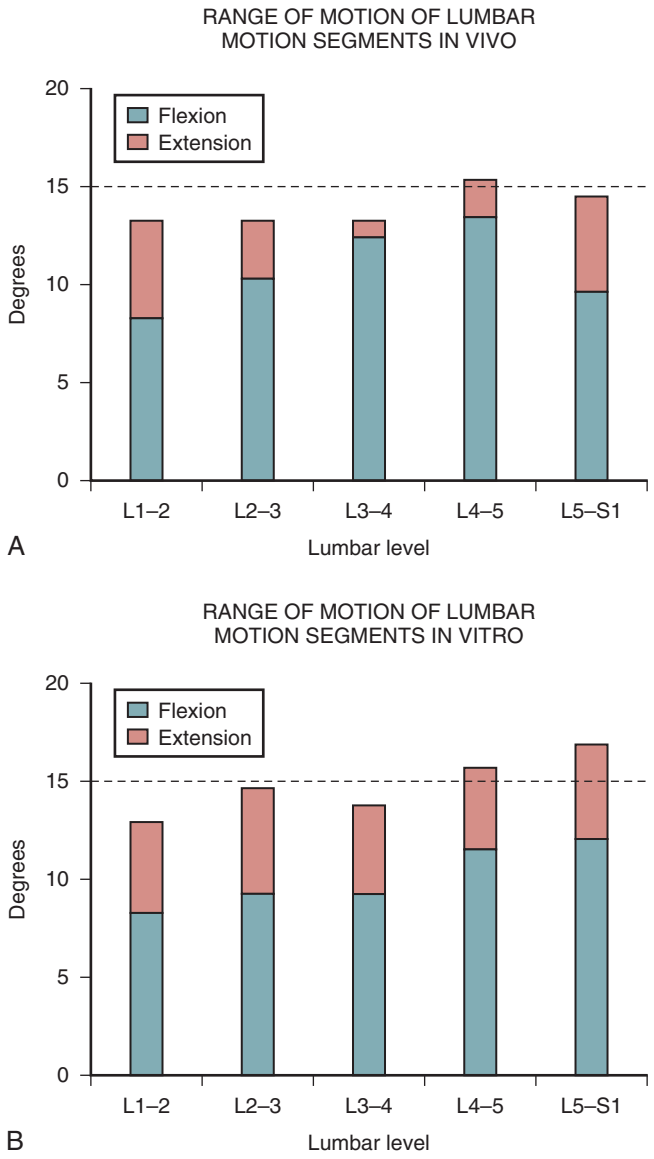

FIG. 6.20 Range of flexion and extension motion in lumbar spine measured (A) in vivo and (B) in vitro.[18,27] (From Adams MA, Bogduk N, Burton AK, et al. *The Biomechanics of Back Pain,* ed 2. Edinburgh: Elsevier; 2013.)

two-dimensional (2D) positions; thus, there are several inherent limitations with these measurements, such as kinematic differences between static and dynamic motions, inaccuracies in measurements using radiographs, and inability to measure multiplanar motion.[83–85]

Recent advances in imaging technologies have helped to address the limitations of static 2D measurements and have facilitated 3D dynamic motions of the spine to be measured in vivo with high accuracy and precision using a system of synchronized biplanar radiographs.[78–81] 3D person-specific spine models developed from computed tomography or MRI can be directly matched to the biplane radiographs, and segmental kinematics can be determined in real time. Using this technique, one study reported that, for healthy subjects, the upper vertebrae in the lumbar spine had larger ROMs than the lower vertebrae during functional flexion-extension. However, during lateral bending, the lower vertebrae showed higher motion than the upper vertebrae. They also found no significant difference between levels during axial rotation motion.[80] A subsequent study on patients with degenerative disc disease (DDD) found significant differences in spinal kinematics between patients and healthy controls, especially at L3–L4. They found that L3–L4 showed the largest ROM in patients in all planes of motion.[81] Fig. 6.21 shows the results of in vivo spinal rotations during dynamic functional motion of patients with DDD and healthy controls.

Adjacent-level degeneration is a common occurrence clinically following a fusion surgery; however, its etiology is unclear and controversial. Several in vitro studies have shown that there is a significant increase in adjacent-level kinematics following fusion; however, the findings of these studies are based on assumptions and testing protocols that are not necessarily true under in vivo conditions.[86] A group investigating in vivo segmental kinematics using dynamic biplanar radiography recently showed that cervical spine patients followed 1 year postoperatively after a fusion surgery at C5–C6 showed no increase in adjacent-level motions, contrary to the findings of in vitro studies.[78,79] Rather, they observed that, during flexion-extension, a redistribution of adjacent-level motion occurred with more extension motion, less flexion occurring at segments rostral to the fusion, and more posterior translations rostral and caudal to the fusion. These differences in motion may be attributed to iatrogenic factors such as alteration in neutral sagittal alignment and disruption of the anterior longitudinal ligament during fusion.[79] It appears also that, under in vivo conditions, overall ROM of the entire spine actually decreases after fusion.[87]

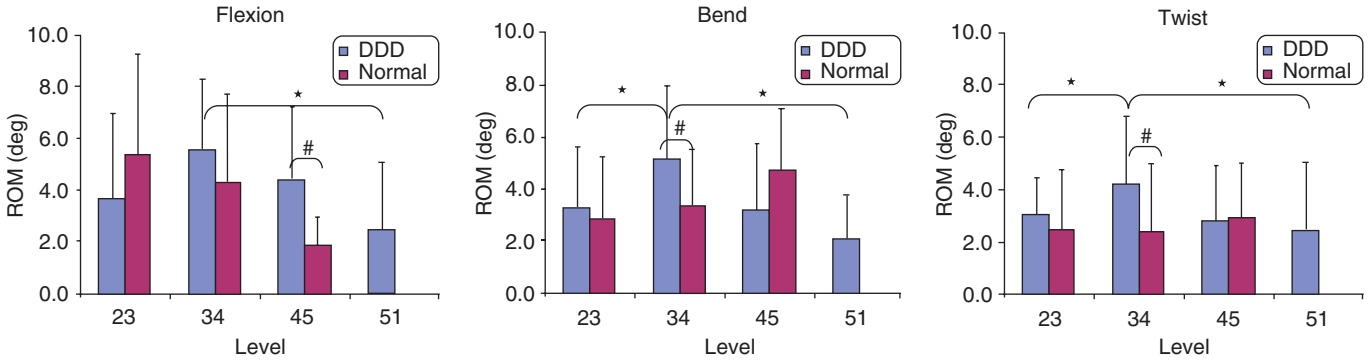

FIG. 6.21 Range of motion (ROM) of vertebral levels of patients with degenerative disc disease (DDD) and normal healthy controls. *Significant difference within group; #Significant difference between normal healthy controls and patients. (From Passias PG, Wang S. Kozanek M, et al. Segmental lumbar rotation in patients with discogenic low back pain during functional weight-bearing activities. *J Bone Joint Surg Am*. 2011;93[1]:29-37.)

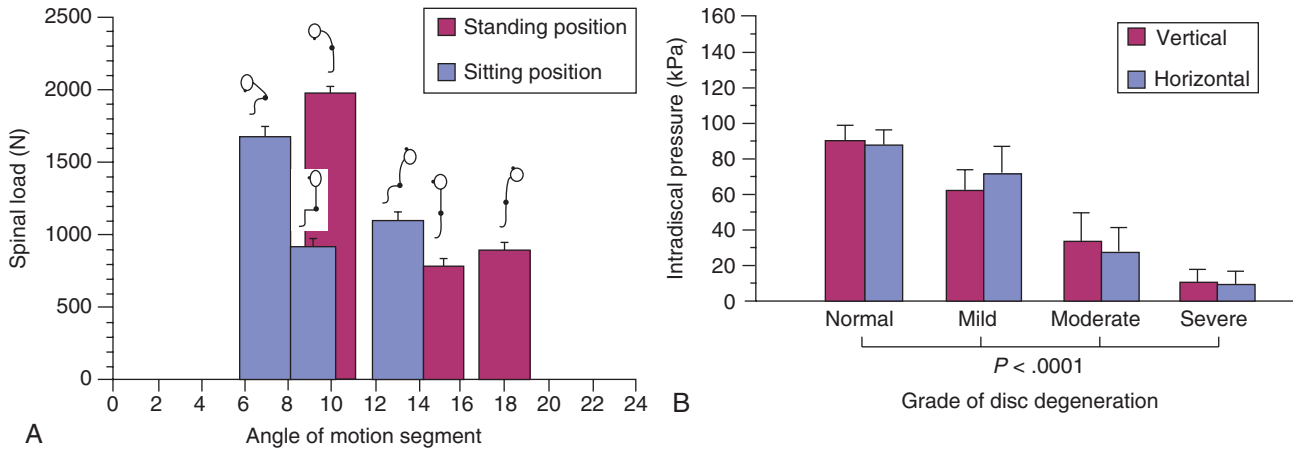

FIG. 6.22 (A) In vivo intradiscal pressure at different postures. (B) Intradiscal pressure variation with progression of disc degeneration. (From Sato K, Kikuchi S, Yonezawa T. In vivo intradiscal pressure measurement in healthy individuals and in patients with ongoing back problems. *Spine*. 1999;24[23]:2468-2474.)

Quantitative Assessment of in Vivo Spinal Loading

Accurate in vivo measurement of internal spinal loads requires placement of a measuring device or sensor invasively into the region of interest. This would not only pose ethical concerns, but there is potential risk associated with the implantation of load sensors in living subjects. Due to these factors, there are only a few documented studies that have investigated in vivo spinal loads. The earliest attempt at quantifying in vivo compressive loads was conducted by Nachemson in 1964, who measured intradiscal pressures using a needle-mounted pressure gauge.[88,89] Similar attempts were made again by two other groups in 1999.[90,91] The results from these studies can be summarized as follows: the lowest compressive loads were seen when lying down (144–250 N), standing upright showed loads of 500 to 800 N, and sitting erect was 700 to 996 N.[88–91] These studies also showed that both forward and backward bending caused an increase in spinal loads. Fig. 6.22A shows intradiscal pressures measured in vivo from different postures. One of these studies also compared intradiscal pressure (horizontal and vertical pressures based on orientation of pressure gauge) with respect to progression of disc degeneration, and found a significant reduction in pressure with grade of degeneration. Fig. 6.22B shows reduction in intradiscal pressure with disc degeneration.[91]

Rohlmann and colleagues implanted telemeterized vertebral body replacements (VBRs) on five patients with L1 or L3 compression fractures and measured the spinal loads in their anterior spinal column. Using this setup, they investigated the effect of locomotion on spinal loads and found that walking caused significantly higher loads than standing.[92] They also found that ascending stairs caused higher loads than descending (Fig. 6.23).

They also conducted a longitudinal study and observed 10 everyday activities that caused significant increases in spinal loads.[93] Fig. 6.24 shows 10 activities that caused the highest increase in spinal loads (compression and shear forces) for five patients. They observed large individual variations in loads for the various activities.

In Silico Modeling in the Spine

The structural architecture of the human spine exhibits a hierarchical organization spanning from the whole system level (macroscale), to the organ, tissue, and cellular levels

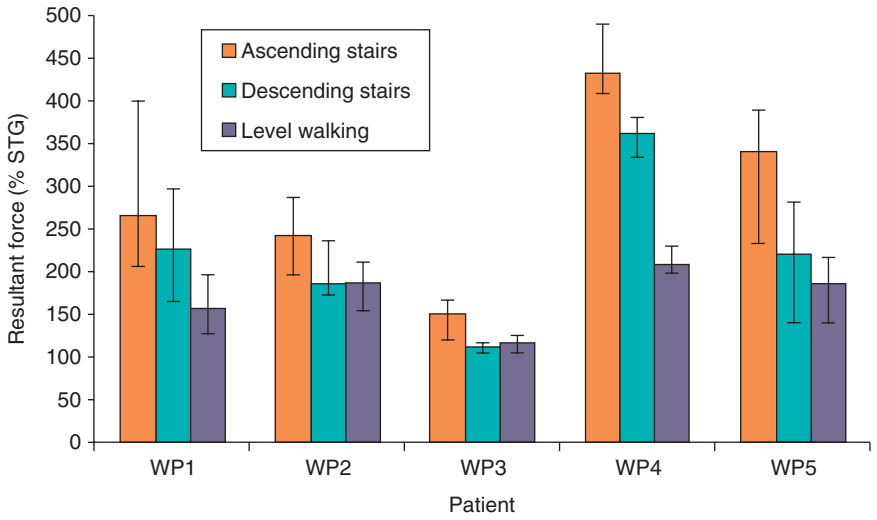

FIG. 6.23 Comparison of peak resultant forces while ascending stairs, descending stairs, and level walking normalized to standing.[92] STG, percentage relative to standing. (From Rohlmann A, Pohl D, Bender A, et al. Activities of everyday life with high spinal loads. *PloS One*. 2014;9[5].)

(microscale). Within this complex organization, there is a network of biologic and mechanical interactions between the different levels that dictates overall biomechanical responses of the spine. Unfortunately, it is extremely difficult to obtain biomechanical parameters, such as internal stress and strain distributions, especially at lower spatial scales (cellular). This knowledge would improve our understanding of the complex micromechanical environments in relation to normal structure–function relationships as well as the underlying mechanisms behind structural and functional breakdown due to disease.

In silico models, more commonly known as computational or biomechanical models, are seeing an increased utilization in spine-related research for investigating complex mechanobiologic phenomena. These models provide a viable and practical alternative to relate the physical and material characteristics of the spine to its mechanical function. Using advanced numerical and imaging techniques, detailed anatomic and material representations of each hierarchical level (macroscale to microscale) can be developed and used for biomechanical evaluations.[94,95] This multiscale approach enables whole body level simulations of spinal kinematics to be used to predict spinal loads within each segment, and then quantify tissue- and cellular-level stresses and strains. These models have the flexibility of precisely controlling a variety of parameters, then observing the effects of these changes on the biomechanical response of the modeled structures. They provide a unique platform to complement in vitro and in vivo experimental techniques.[96–100]

Within the spine, there are several areas of application for in silico models; for instance, mechanical loads are believed to play a major role in the initiation of degenerative changes in the disc. However, the underlying mechanisms by which onset of damage occurs is not well understood.[18,101,102] It is not clear how whole body level mechanical loads translate to deformations at the cellular levels that lead to localized damage and the onset of a degenerative cascade. Using in silico models, we can now begin to explore these complex mechanical relationships across spatial and temporal scales. It also paves the way for the exploration of various other mechanobiologic scenarios, such as age-related degeneration, effect of endplate microfractures, nutrient transport, and tissue remodeling and repair. This whole systems approach to predict the impact of spinal loads on the mechanical behavior of the spine would provide invaluable information for the development of appropriate preventive and therapeutic strategies against back injury.

Clinically, in silico models demonstrate a great potential to aid clinicians in the management of complex spinal ailments. Patient-specific computational models can be developed for use in presurgical planning and evaluation, and an optimized therapy can be implemented for the patient. These models can also be used for conducting comparative analysis of spinal implants.[99,100,103,104] In essence, an in silico model can serve as a valuable, cost-effective tool for the modification of existing implants or the design of new spinal implants aimed at stabilizing and/or preserving motion. Spinal stability following a surgical intervention on an individual can be simulated and evaluated, providing the clinician with valuable insight and quantifiable metrics to help guide the decision-making process prior to actual implementation of desired course of treatment. Knapik and colleagues investigated the biomechanical consequences of a total artificial disc replacement (TDR) at L5–S1 under various simulated dynamic loading conditions obtained from real-life task performance, such as forward bending and lifting of different weights (9.5 and 19 kg).[105] Fig. 6.25 shows mechanical stress distribution following a TDR.[105] Their study found a significant increase in spinal loads between intact and TDR at insertion level (Fig. 6.26). They also found that motion increased in all three planes (sagittal, lateral, and twisting) at insertion level. Fig. 6.27 shows sagittal motion across lumbar levels as a function of intact, TDR, and external loading. Their model was able to effectively show in detail the biomechanical trade-offs with TDR specific to that subject's spine under realistic loading conditions.

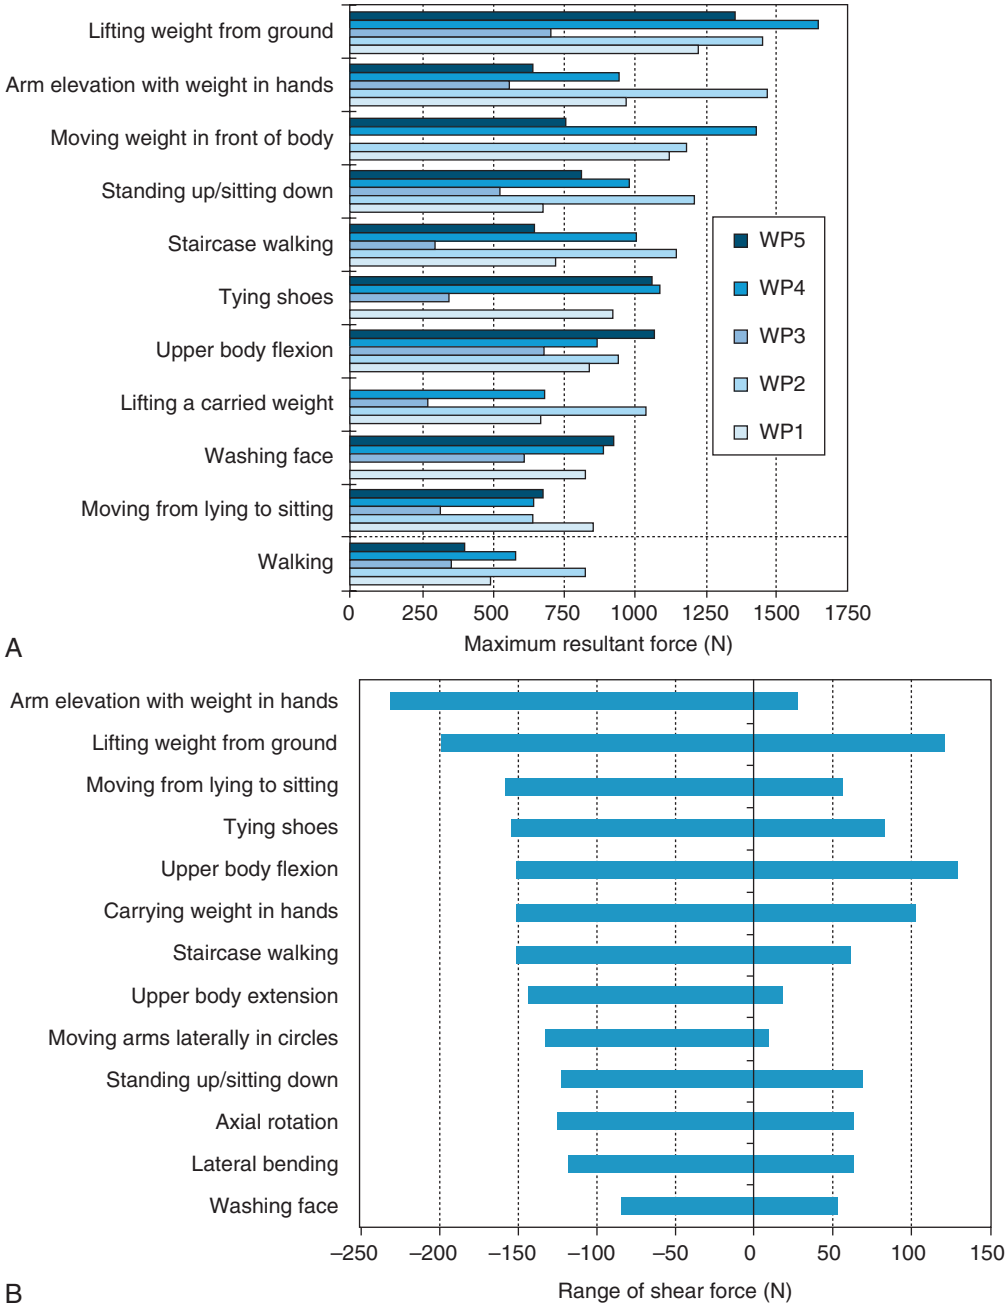

FIG. 6.24 (A) Ten activities with highest compressive forces. (B) Anterior (positive) and posterior (negative) shear forces for the 10 activities.[93] WP, patient label. (From Rohlmann A, Dreischarf M, Zander T, et al. Loads on a vertebral body replacement during locomotion measured in vivo. *Gait Posture.* 2014;39[2]:750-755.)

The System

As can be seen through this review, the spine performs several important functions: it transmits force, allows motion, and protects the spinal cord. Although these functions have been considered independently here, it is important to develop an appreciation for the systematic nature of these spine functions. Although these functions have been described independently, they interact in such a way that the inability to perform one of these functions can also affect the ability to perform other functions.

If the disc becomes compromised in its mechanical integrity, and disc space is reduced, it can alter the load transmission between vertebrae. With less disc space, more of the load may be transmitted through the posterior elements; this repeated loading may change the biochemical behavior of the system. This change may result in an upregulation of proinflammatory biochemical activity and increased pain transmission. Similarly, reduced disc space height may alter the motion characteristics of the spinal motion segments. With less disc space, the stability of the joint can be compromised, and the contact points of the posterior elements can be altered.

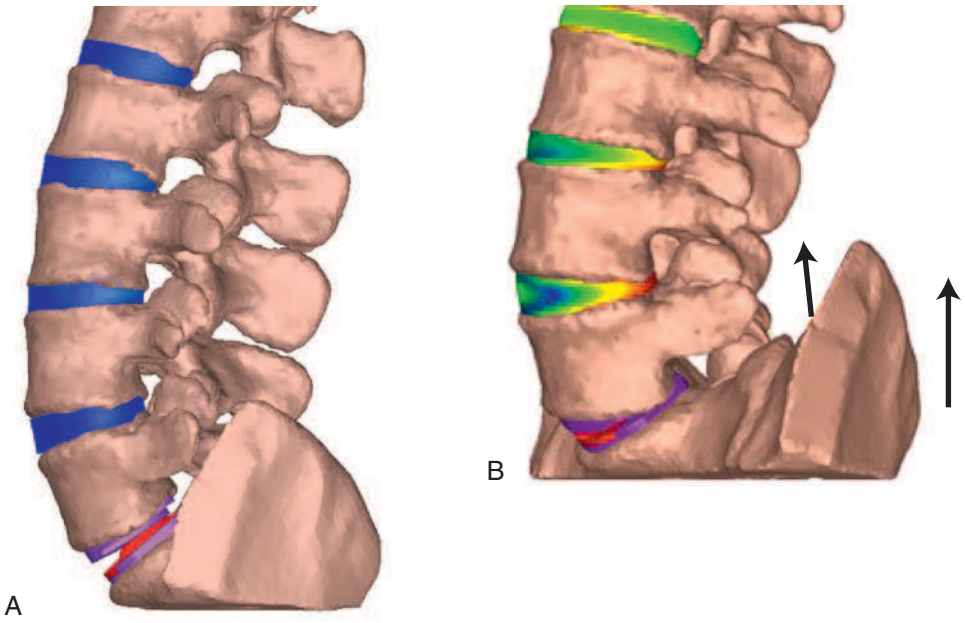

FIG. 6.25 (A) Sagittal view of computational model and (B) stress distributions following total artificial disc placement at L5–S1. (From Knapik GG, Mendel E, Marras WS. Use of a personalized hybrid biomechanical model to assess change in lumbar spine function with a TDR compared to an intact spine. *Eur Spine J.* 2012;21[suppl 5]:S641-S652.)

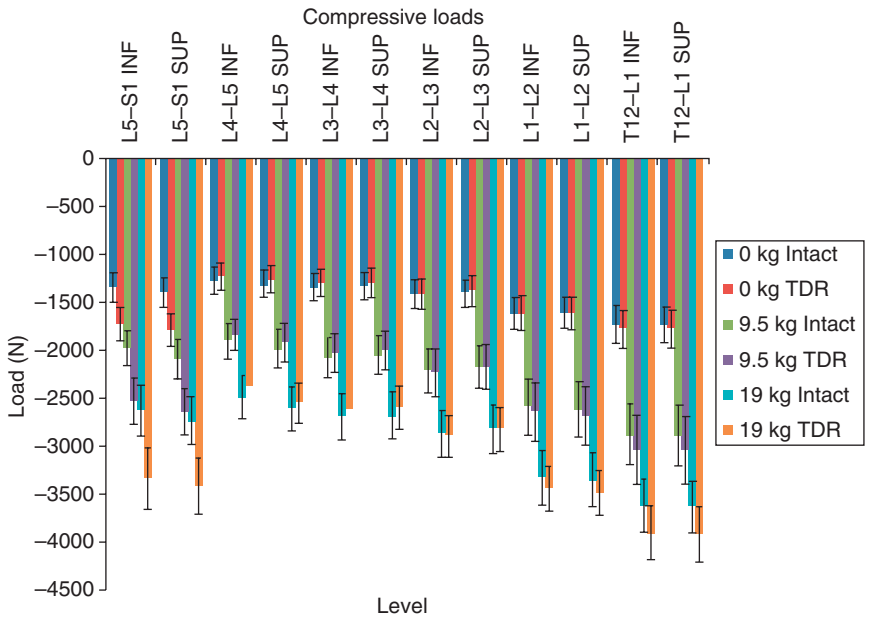

FIG. 6.26 Average of the peak compression loads on the lumbar spine endplates as a function of intact spine versus total artificial disc replacement (TDR) spine and external loading condition (bending while unloaded 0 kg, lifting 9.5 kg, lifting 19 kg). INF, inferior; SUP, superior. (From Knapik GG, Mendel E, Marras WS. Use of a personalized hybrid biomechanical model to assess change in lumbar spine function with a TDR compared to an intact spine. *Eur Spine J.* 2012;21[suppl 5]:S641-S652.)

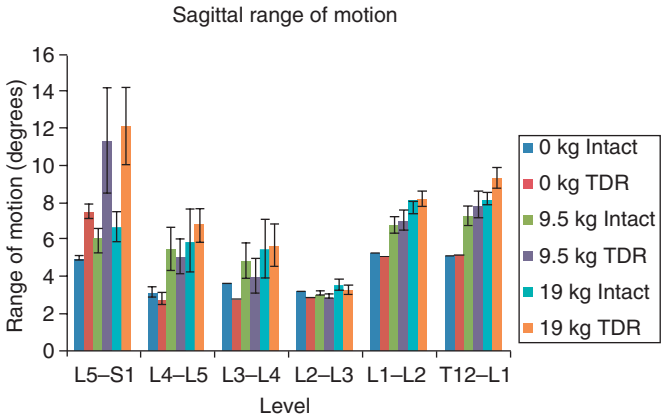

FIG. 6.27 Mean sagittal plane range of motion at each lumbar level as a function of intact spine versus total artificial disc replacement (TDR) spine and external loading condition (bending while unloaded 0 kg, lifting 9.5 kg, lifting 19 kg). (From Knapik GG, Mendel E, Marras WS. Use of a personalized hybrid biomechanical model to assess change in lumbar spine function with a TDR compared to an intact spine. *Eur Spine J*. 2012;21[suppl 5]:S641-S652.)

This alteration could change the kinematic signature of the spine.

Finally, a narrowed disc space could compromise the protection of the nerve root because there is less space for the nerve root to pass through the intervertebral foramen. A compromise of the disc could lead to load transmission irregularities, instability, motion restrictions, and a compromise of the nerve root. This is just one example of how interrelated the components of the spine are from a biomechanical perspective.

As can be seen from this discussion, biomechanics of the spine not only can influence the various dimensions of the biomechanical system, but it also can influence the biochemical behavior of the system. Because biomechanical considerations provide an understanding of the forces that are generated on the system, some authors are beginning to consider the spine as a mechanobiologic system.

Summary

By nature, the spine is a complex structure that provides protection for the spinal cord and a structure to support loads in numerous postures and positions. In addition, the healthy spine limits physiologic movement to conditions that protect the structures of the spine. With trauma and degeneration, the spine loses its ability to achieve these functions adequately.

Biomechanics provides a means to characterize and assess the status of the spine quantitatively and precisely. Quantification provides a rationale for one to determine "how much is too much" exposure to the physical conditions that might damage the spinal system. This chapter has systematically summarized and characterized the capacity of the spinal motion segments in terms of kinematic capacity and load tolerance.

The spinal structures themselves are physiologically unique, and have evolved in such a manner that their functions are unique. Although this chapter has examined the capacity of the individual motion segments, this evaluation should make it clear that the spine is truly a system of components that act collectively and interactively to achieve the functions of motion and load support. The kinematic and load support capacities of the motion segment vary significantly as a function of spinal level, direction of motion, direction of load application, and temporal exposure characteristics.

Although presented as basic information, this information should be considered the fundamental scientific foundation for understanding how the spine functions, how disorders and pain might occur in the spine, how exposure to ADLs and occupational conditions might affect the spine status, and what functions need to be restored clinically. Biomechanical features and function change throughout life. Aging alone alters the biomechanical properties of the spine. It has also been well established, however, that various exposures can greatly accelerate the degenerative process and the biomechanical functioning of the spine.

As knowledge of the spine increases, it is clear that a biomechanical foundation is essential for prevention and treatment of spinal disorders. A better understanding of spine function can be achieved through a better quantification of physical attributes, yielding improved sensitivity and specificity of functional understanding and interventions.

CHAPTER 7

Nerve Root Pain in Disc Herniation and Spinal Stenosis

SECTION I

Robert R. Myers
Björn Rydevik
Kjell Olmarker
Shinichi Kikuchi

The clinical symptoms associated with lumbar disc herniation and spinal stenosis are attributed to pathophysiologic changes in spinal nerve roots. Recent research has defined the basic pathophysiologic events at the tissue, cellular, or subcellular levels in relationship to the pathogenesis of sciatica and nerve root pain. This chapter reviews the current knowledge about these mechanisms and discusses these mechanisms in relation to the clinical features of lumbar disc herniation and spinal stenosis.

Nerve root pain is typically radiating in nature and usually related to a specific nerve root or adjacent roots. It is associated with pathologic changes and nerve dysfunction and may be present in motor and sensory modalities, producing motor weakness and sensory disturbances. These changes are tightly linked through mechanisms that are discussed in this chapter.

Two specific mechanisms at the "tissue level" may be defined: (1) mechanical deformation of the nerve roots and (2) biologic or biochemical activity of the disc tissue causing neuroinflammation of nerve roots.

Mechanical Effects on Nerve Roots

Enclosed by the vertebral bones, the spinal nerve roots are relatively well protected from external trauma, although somewhat more susceptible to injury than peripheral nerves. In 1934, Mixter and Barr[1] described that intervertebral discs can rupture and cause mechanical compression of the nerve roots, leading to sciatica. However, there has been moderate research interest in the past regarding nerve root compression. Gelfan and Tarlov[2] in 1956 and Sharpless[3] in 1975 performed some initial experiments on the effects of compression on nerve impulse conduction and showed that nerve roots were more susceptible to compression than peripheral nerves. Interest in nerve root pathophysiology has increased more recently, and numerous studies are reviewed here.

In 1991, a model was presented that allowed for experimental, graded compression of cauda equina nerve roots at known pressure levels.[4] In this model, the cauda equina of pigs was compressed by an inflatable balloon fixed to the spine (Fig. 7.1). The cauda equina could also be observed through the translucent balloon. This model made it possible to study the flow in the intrinsic nerve root blood vessels at various pressure levels.[5] The average occlusion pressure for the arterioles was found to be slightly below and directly related to the systolic blood pressure. The blood flow in the capillary networks was intimately dependent on the blood flow of the adjacent venules. This finding corroborates the assumption that venular stasis may induce capillary stasis and changes in the microcirculation of the nerve tissue, which has been suggested as one mechanism in carpal tunnel syndrome.[6] The mean occlusion pressures for the venules showed large variations; however, a pressure of 5 to 10 mm Hg was found to be sufficient for inducing venular occlusion.

Because the nutrition of the nerve root is affected by ischemia, a compression-induced impairment of the vasculature may be one mechanism for nerve root dysfunction. The nerve roots also have a considerable nutritional supply via diffusion from the cerebrospinal fluid.[7] To assess the compression-induced effects on the total contribution to the nerve roots, an experiment was performed in which ^{3}H-labeled methylglucose was allowed to be transported to the nerve tissue in the compressed segment via the blood vessels and via the cerebrospinal fluid diffusion after systemic injection.[8] The results showed that no compensatory mechanism from cerebrospinal fluid diffusion could be expected at low pressure levels. On the contrary, 10 mm Hg compression was sufficient to induce a 20% to 30% reduction of the transport of methylglucose to the nerve roots.

It is known from experimental studies on peripheral nerves that compression may also induce an increase in vascular permeability, leading to intraneural edema formation.[9] Such edema may increase the endoneurial fluid pressure, which impairs the endoneurial capillary blood flow and nutrition of the nerve roots.[10] Because the edema usually persists for some time after the removal of a compressive agent, edema may negatively affect the nerve root for a longer period than the compression itself. The presence of intraneural edema is also

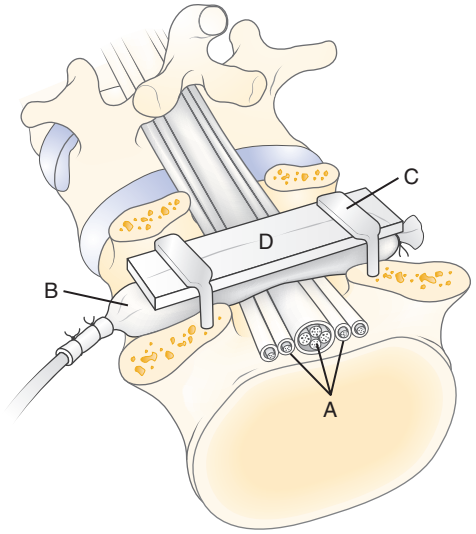

FIG. 7.1 Schematic of an experimental nerve root compression model. Cauda equina *(A)* is compressed by an inflatable balloon *(B)* that is fixed to the spine by two L-shaped pins *(C)* and Plexiglas plate *(D)*. (From Olmarker K, Holm S, Rosenqvist A-L, et al. Experimental nerve root compression: a model of acute, graded compression of the porcine cauda equina and an analysis of neural and vascular anatomy. *Spine [Phila Pa 1976]*. 1991;16:61-69.)

related to subsequent formation of intraneural fibrosis,[11] a neuroinflammatory response that is seen in some patients with nerve compression disorders.

Nerve root compression directly affects nerve conduction.[12,13] Our data show that the sensory fibers are slightly more susceptible to compression than the motor fibers.[13,14]

One factor that has not been fully recognized in compression trauma of nerve tissue is the onset rate of the compression. The onset rate (i.e., the time from compression start until full compression) may vary clinically from fractions of seconds in traumatic conditions to months or years in association with degenerative processes.

A rapid-onset rate of less than 1 second has been found to induce more pronounced pathophysiologic dysfunction. For the rapid-onset compression, which is likely to be more closely related to spine trauma or disc herniation than to spinal stenosis, it has been seen that a pressure of 600 mm Hg maintained only for 1 second is sufficient to induce a gradual impairment of nerve conduction during the 2 hours studied after the compression was ended.[15] In the case of spinal stenosis, the rate may be a great deal slower, and pain or nerve dysfunction may not be seen until after considerable ischemic injury.

Chronic Experimental Nerve Root Compression

To mimic various clinical situations, compression must be applied for long periods. In clinical syndromes with nerve root compression, the onset time may be quite slow and the duration may be quite long. A gradual development of degenerative changes that induce spinal stenosis leads to an onset time that can be many years. It is difficult to mimic such a situation in an experimental model. Chronic models should induce a controlled compression with a slow-onset time that is easily reproducible.

Delamarter and colleagues[16] introduced a model on the dog cauda equina in which they applied a constricting plastic band that was left in place for various times. The band was tightened around the thecal sac to induce a 25%, 50%, or 75% reduction of the cross-sectional area. The data indicated that structural and functional changes were proportional to the degree of constriction.

To induce a slower onset and more controlled compression, Cornefjord and colleagues[17] used a constrictor to compress the nerve roots in the pig. The constrictor consisted of an outer metal shell that on the inside was covered with a material called *ameroid* that expands when in contact with fluids. Because of the metal shell, the ameroid expands inward with a maximum of expansion after 2 weeks, resulting in a compression of a nerve root placed in the central opening of the constrictor. Compression of the first sacral nerve root in the pig resulted in a significant reduction of nerve conduction velocity and axonal injuries.[17] It has also been found that there is an increase in substance P in the nerve root and the dorsal root ganglion after such compression.[18] Substance P is a neurotransmitter that is related to pain transmission.

One important aspect in clinical nerve root compression conditions is that the compression level is probably unstable and varies as the result of changes in posture and movements.[19,20] In 1995, Konno and colleagues[21] introduced a model in which the pressure could be changed after some time of initial chronic compression. An inflatable balloon was introduced under the lamina of the seventh lumbar vertebra in the dog. By inflating the balloon at a known pressure slowly over 1 hour with a viscous substance that would harden in the balloon, compression of the cauda equina could be induced with a known initial pressure level. The compression was verified by myelography. Because the balloon under the lamina was composed of a twin set of balloons, the second balloon component could be connected to a compressed air device and could be used to add compression to the already chronically compressed cauda equina.

Acute nerve root compression experiments have established critical pressure levels for interference with various physiologic parameters in the spinal nerve roots. Studies on chronic compression may provide knowledge that would be more applicable to the clinical situation.

Spinal Stenosis: Experimental-Clinical Correlation

Patients with double or multiple levels of spinal stenosis may have more pronounced symptoms than patients with stenosis only at one level.[22] The mechanism for the difference between single and double compression may not simply be based on the fact that the nerve impulses have to pass more than one compression zone at double-level compression. There may also be a mechanism based on the local vascular anatomy of the nerve roots. In contrast to peripheral nerves, there are no regional nutritive arteries from surrounding structures to the intraneural vascular system in spinal nerve roots.[23–25] Compression at two levels might induce a nutritionally impaired region between the two compression sites. In this way the segment affected by the compression would be widened. Data

from a study on the nutritional transport to the nerve tissue in double-level compression showed that there is a reduction of this transport to the uncompressed nerve segment located between the two compression balloons that was similar to the reduction within the two compression sites.[26] Thus, there is experimental evidence that the nutrition to the nerve segment located between two compression sites in nerve roots is severely impaired, although this nerve segment itself is uncompressed.

If nerve compression is of an extremely low onset rate, as in spinal stenosis, there may be an adaptation of the nerve tissue to the applied pressure. In cadaveric experiments, Schönström and colleagues[27] found that when a hose clamp was tightened around a human cadaveric cauda equina specimen there was a critical cross-sectional area of the dural sac when the first signs of pressure increase among nerve roots were recorded by a catheter placed in the compression zone. This cross-sectional area was approximately 75 mm^2, which was also found to correlate with a corresponding measurement on computed tomography (CT) in patients with spinal stenosis.[28] When the hose clamp was tightened further, the pressure increased. Owing to creep phenomena in the nerve tissue, the pressure decreased with time, however. When the pressure did not normalize within 10 minutes, the "sustained size" was registered and was found to be in the range of 45 to 50 mm^2.[27] This study indicates that even in acute compression there is an adaptation of the nerve tissue to the applied pressure. From a longer perspective, this probably means that the nerve may also be reorganized in its microstructural elements, which would result in a nerve with a smaller diameter. Under such circumstances, with gradually decreasing nerve diameter, the pressure acting on the nerve would be reduced to some degree.

There is a correlation between the experimental animal observations regarding critical pressures for functional and nutritional changes in nerve roots under compression and the measurements of pressure levels among nerve roots in human cadaveric lumbar spines after experimental constriction of the dural sac.

Epidural pressure measurements have been performed, evaluating the relationship between epidural pressure and posture.[20] It was found that the local epidural pressure at the stenotic level was low in lying and sitting postures and high in standing postures. Pressure was increased with extension but decreased with flexion of the spine. The highest epidural pressure, 117 mm Hg, was found in standing with extension. Measurements have also been reported regarding changes in epidural pressure during walking in patients with lumbar spinal stenosis.[29] The pressure changed during walking with a wave pattern of increasing and decreasing changes. Such observations correlate with the previously mentioned experimental observations regarding intermittent cauda equina compression.[19]

Mechanical Nerve Root Deformation and Pain

Some experimental observations indicate that mechanical nerve root deformation per se may induce impulses that cause pain. Howe and colleagues[30] found that mechanical stimulation of nerve roots or peripheral nerves resulted in nerve impulses of short duration and that these impulses were prolonged if the nerve tissue had been exposed to mechanical irritation by a chromic gut ligature for 2 to 4 weeks. Corresponding results were obtained in an in vitro system using rabbit nerve roots.[31] In this setup, it was also evident that the dorsal root ganglion was more susceptible to mechanical stimulation than the nerve roots. The dorsal root ganglion has elicited special interest in this regard, and an increase in the level of neurotransmitters related to pain transmission has been found in the dorsal root ganglion in response to whole-body vibration of rabbits.[32] A similar increase has been seen in the dorsal root ganglion and nerve root after local constriction of the same nerve root.[18] In vivo models of pain behavior have shown that mechanical nerve deformation superimposed on inflammation is painful, whereas either factor alone might not cause severe pain.[31–34] The magnitude of nerve root compression pressure (measured intraoperatively) correlates with neurologic deficit but not with degree of straight-leg raising test.

Neuropathologic Changes and Pain

There is considerable research evidence regarding the relationship of pain to neuropathologic changes.[35] Much of what is known has been studied in relationship to mechanical and inflammatory injury of the sciatic nerve in the rat. Entrapment of a peripheral nerve produces pathologic change in proportion to the degree of compression and its duration,[36] as is known to be the case for nerve root compression. In an electron microscopic study,[36] minor degrees of nerve compression were associated with ischemic injury to Schwann cells, resulting in their necrosis and in demyelination. Severe nerve compression was associated with injury to the axon, resulting in wallerian degeneration.

Subsequent experiments established the relationship of pain to these forms of neuropathologic change.[37] These studies established that mild levels of ischemia producing demyelination were generally not painful, whereas severe ischemia-producing wallerian degeneration resulted in hyperalgesia. The pathology of the chronic constriction injury model of neuropathic pain is based on this relationship and the added insult of inflammation caused by the chromic gut ligatures used to compress the nerve.[38] It is now recognized that the cytokine-driven processes of wallerian degeneration are the dominant neuropathologic factors linking nerve injury and pain[37,39,40] and that the degree and extent of wallerian degeneration relate directly to the magnitude and duration of hyperalgesia.[41]

Biologic and Biochemical Effects on Nerve Roots

The clinical picture of sciatica with a characteristic distribution of pain and nerve dysfunction in the absence of herniated disc material at radiologic examination and at surgery has indicated that mechanical nerve root compression may not be

the only factor that is responsible for sciatic pain. In 1984 it was suggested that the disc tissue per se may have some injurious properties.[42] It was later confirmed experimentally that local epidural application of autologous nucleus pulposus in the absence of mechanical deformation induces significant changes in structure and function of the adjacent nerve roots.[43]

Biologic Effects of Nucleus Pulposus

In 1993, Olmarker and colleagues[43] published a study that showed that autologous nucleus pulposus can induce a reduction in nerve conduction velocity and light microscopic structural changes in a pig cauda equina model of nerve root injury. These axonal changes had a focal distribution, however, and the quantity of injured axons was too low to be responsible for the significant neurophysiologic dysfunction observed. A follow-up study of areas of the nerve roots exposed to nucleus pulposus that appeared to be normal by light microscopy revealed that there were significant injuries of Schwann cells with vacuolization and disintegration of Schmidt-Lanterman incisures (Fig. 7.2).[44] Schmidt-Lanterman incisures are essential for the normal exchange of ions between the axon and the surrounding tissues. An injury to this structure would be likely to interfere with the normal impulse conduction properties of the axons, although these models' changes may not fully explain the neurophysiologic dysfunction observed.

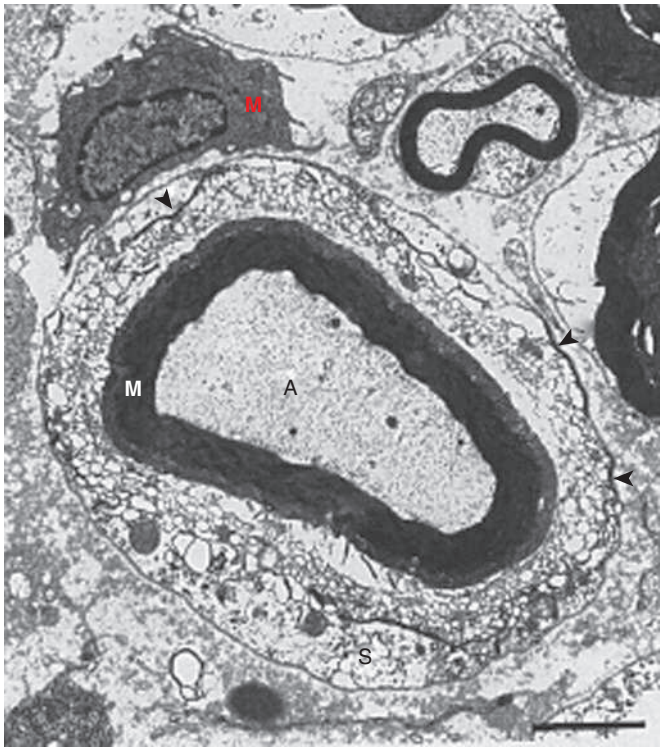

FIG. 7.2 Seven days after application of nucleus pulposus. Myelinated nerve fiber with prominent vesicular swelling of Schmidt-Lanterman incisure. Note mononuclear cell (*red M*) in close contact with nerve fiber. *Arrowheads* indicate myelin sheath layers outside Schmidt-Lanterman incisure. *A,* well-preserved axon; *white M,* myelin sheath; *S,* outer Schwann cell cytoplasm. (*Bar* = 2.5 μm.) (From Olmarker K, Nordborg C, Larsson K, et al. Ultrastructural changes in spinal nerve roots induced by autologous nucleus pulposus. *Spine [Phila Pa 1976].* 1996;21:411-414.)

The pathophysiologic potential of the nucleus pulposus was emphasized further in an experiment using a dog model in which it was seen that a surgical incision of the anulus fibrosus, with minimal leakage of nucleus pulposus, was enough to induce significant changes in structure and function of the adjacent nerve root.[45] It has also been seen that epidural application of the autologous nucleus pulposus within 2 hours induces an intraneural edema[46,47] that leads to a reduction of the intraneural blood flow.[47] Histologic changes of the nerve roots are present after 3 hours,[48] and a subsequent reduction of the nerve conduction velocity starts 3 to 24 hours after application.[43,48] The nucleus pulposus may also interfere with the nutrition to the intraspinal nerve tissue. After application to the dorsal root ganglion, it was found that the intraneural blood flow was dramatically decreased and that there was a simultaneous increase of the tissue fluid pressure.[47]

Methylprednisolone reduces the pathophysiologic events of the nucleus pulposus–induced nerve root injury if given within 24 hours. To establish if the presence of autologous nucleus pulposus could initiate a leukotactic response from the surrounding tissues, a study was initiated that assessed the potential inflammatogenic properties of the nucleus pulposus.[49] Autologous nucleus pulposus and autologous retroperitoneal fat were placed in separate perforated titanium chambers and placed subcutaneously, together with a sham chamber, in the pig. The number of leukocytes was assessed 7 days later for the chambers. The nucleus pulposus–containing chambers had a number of leukocytes that exceeded the two others by 150%. In another experiment, autologous nucleus pulposus and muscle were placed in Gore-Tex tubes subcutaneously in rabbits.[50] After 2 weeks, there was an accumulation of macrophages and T-helper and T-suppresser cells in the tube with nucleus pulposus that persisted the full observation time of 4 weeks.

Kawakami and colleagues[51] showed that neuropathic pain in an experimental setting seems to be mediated by infiltrating leukocytes, a finding consistent with the previous observations of neuroimmunologic inflammatory changes and pain.[52] In rats made leukopenic by using nitrogen mustard, the pain response was absent after application of nucleus pulposus, whereas normal rats with nucleus pulposus application displayed a pathologic response to stimulation. The same group also showed that inhibition of cyclooxygenase-2 might reduce nucleus pulposus–induced pain behavior.[53] Taken together, these data further support the impression that autologous nucleus pulposus may elicit inflammatory reactions when outside the intervertebral disc space and that such reactions may not be restricted to resorption of the herniated tissue but also may be intimately involved in the pathophysiology of sciatica.

Nucleus Pulposus and Sciatic Pain

Pain is much more difficult to assess than nerve conduction in controlled experimental studies. The available literature indicates that pain may be induced by both mechanical factors and nucleus pulposus–mediated factors. The role of the nucleus pulposus in this context is interesting in view of

patients with obvious symptoms of disc herniation but with no visible herniation at radiologic examination or surgery.[54,55] The potential of nucleus pulposus material to induce pain has also been indicated in clinical studies that showed that non-contained herniations (the nucleus pulposus was in contact with the epidural space) were much more painful and had a more pronounced straight-leg raising test result than contained herniations.[56-58]

Studies on rats using pain behavior assessment indicated that the nucleus pulposus is involved in pain production. Pain behavior in this context refers to response thresholds to thermal and mechanical stimulation. The role of the various anatomic components of the nerve root complex for the production of spinal pain was further elucidated by Cavanaugh and colleagues[31] and Weinstein and colleagues.[32] Other studies[33] suggest a dose-response relationship between pain behavior and the amount of nucleus pulposus material in the epidural space. The combination of nucleus pulposus herniation and mechanical injury produces pain.[33] This observation is consistent with the neuropathologic understanding of pain and the consequences of combined mechanical and inflammatory injury to nerve fibers that are superimposed to increase the number of fibers injured and the corresponding increase in proinflammatory cytokines.[40,41]

These experimental studies on pain behavior suggest that the presence of nucleus pulposus has sensitized the nerve tissue. Minor compression of peripheral nerves is not painful, and touching of a normal nerve root during local anesthesia is not painful.[59] Touching of a nerve root exposed to a disc herniation often reproduces the sciatic pain, however.[59] Although the combination of a mechanical component and the presence of nucleus pulposus seems to be a prerequisite to produce changes in the in vivo situation, more recent neurophysiologic studies have shown that the mere application of nucleus pulposus may induce increased neuronal pain transmission.[60]

The spinal dura mater is known to contain nerve endings, and stimulation of the dura has been suggested as a mechanism for sciatic pain.[42,59,61,62] Irritation or stimulation of the dura as one important factor for sciatica is an interesting theory that could explain many clinical features. One may assume that the dura is segmentally innervated, the sensory nerves travel in a caudal-lateral direction, and the dura is drained to the corresponding nerve root by the nerve of Luschka.[63] Stimulation of the dura at a point where dorsolateral disc herniations appear (*1* in Fig. 7.3) might be recorded by the corresponding nerve root. At this location, the irritation may spread medially to the contralateral segment, producing bilateral symptoms, or laterally, producing symptoms from levels above. Similarly, a lateral disc herniation (*2* in Fig. 7.3) could produce symptoms in the lower level.

If the pain of the straight-leg raising test is the result of dura irritation owing to friction to the herniated mass, one may consider the phenomenon of crossed straight-leg raising to be based on simultaneous stimulation of the contralateral dura. Such a "radiculitis" or "local meningitis" probably could be regarded as similar to peritonitis. When there is peritonitis, there is usually a reflectory muscle contraction present over the affected area. An analogue for this local meningitis could be the reflectory ipsilateral contraction of the spinal muscles, producing the "sciatic scoliosis" or lateral bending of the spine at the level of herniation.

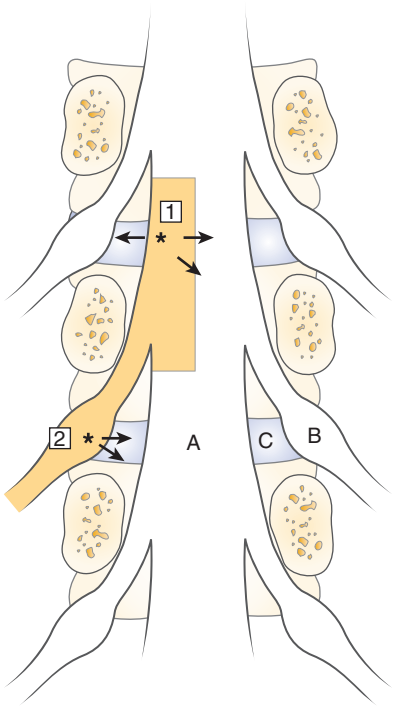

FIG. 7.3 Suggested area of innervation by one recurrent sinuvertebral nerve (nerve of Luschka). Disc herniation at location 1 may be recorded by the same nerve and by the nearby innervation areas, laterally and contralaterally, as indicated by *arrows*. At location 2, lateral disc herniation of disc one level below may affect same nerve root but also root one level below, located medial to this root, as indicated by *arrows*. *A,* Thecal sac; *B,* dorsal root ganglion; *C,* intervertebral disc. (From Olmarker K. The experimental basis of sciatica. *J Orthop Sci.* 1996;1:230-242.)

Other Consequences of Herniated Nucleus Pulposus

Histologic observations have indicated that nerve root changes caused by nucleus pulposus are focal and mainly found in the center of the nerve roots, resembling a mononeuritis simplex that is induced by nerve infarction secondary to embolism of the intraneural vessels.[43,44] Particularly in view of the work of Jayson and colleagues[64,65] indicating an impairment of the venous outflow from the nerve roots owing to periradicular vascular changes, one must consider vascular impairment as one factor.

The inflammatory components of nucleus pulposus may be involved in vascular and rheologic phenomena, such as coagulation, and may be involved in nerve root vascular embolism. It has been observed that the presence of nucleus pulposus may induce thrombus formation in microvessels.[49] Inflammatory mediators may also exert a direct effect on the myelin sheaths, as indicated by an electron microscopic study of nerve roots exposed to autologous nucleus pulposus in the pig.[44] There were significant injuries of Schwann cells with vacuolization and disintegration of Schmidt-Lanterman incisures, which closely resembles the injury pattern of inflammatory

nerve disease.[66,67] As previously described, epidural application of nucleus pulposus induces an increase of the vascular permeability and a subsequent reduction of the blood flow in the adjacent nerve roots, which suggests vascular impairment as being of pathophysiologic importance.

It has also been suggested that because the nucleus pulposus is avascular and "hidden" from the systemic circulation, a presentation of the nucleus pulposus could result in an autoimmune reaction directed to antigens present in the nucleus pulposus and that bioactive substances from this reaction may injure the nerve tissue.[68-75] The work of Li and colleagues[76] has demonstrated that there are autoimmune reactions not only to the disc but also to components from the nerve tissue that are released as the result of injury, such as basic myelin proteins. Another study also assessed the presence of immune complexes in herniated disc tissue obtained at surgery as an indicator of immunoactivation.[77] Immunoglobulin G (IgG) was found in close relation to the disc cells in herniated disc material. No IgG was found, however, in the residual disc that was evacuated at the time of surgery. No immune complexes were found in control disc material obtained at spine surgery for other causes than pain.

Chemical Components of Nucleus Pulposus

The nucleus pulposus is composed mainly of proteoglycans, collagen, and cells.[78,79] The proteoglycan component has gained the most attention and has been suggested to have a direct irritating effect on nerve tissue.[74,80,81] Neither the collagen nor the cells have previously been suggested to be of pathophysiologic importance. More recent studies of the cells of the nucleus pulposus have shown, however, that these cells are capable of producing metalloproteinases such as collagenase or gelatinase and interleukin (IL)-6 and prostaglandin E_2 and do so spontaneously in culture.

Substances such as IgG, hydrogen ions, nitric oxide, and phospholipase A_2 have also been suggested to be responsible for the pathophysiologic reactions.[74,82-86] Another substance produced by the disc cells that has similar pathophysiologic effects as nucleus pulposus is tumor necrosis factor (TNF)-α.[87]

Cytokines as Mediators of Nerve Dysfunction and Pain

TNF is known to be a regulatory proinflammatory cytokine that has specific biologic effects and the ability to upregulate and act synergistically with other cytokines such as IL-1β and IL-6.[88-90] Immediately after nerve injury, TNF is released and upregulated by Schwann cells at the site of nerve injury[91]; this is followed by release and upregulation of TNF in many other endoneurial cells, including endothelial cells, fibroblasts, and mast cells. This local production of TNF is the stimulus that results in macrophage attraction to the injury site,[39] which contributes massively to the concentration of proinflammatory cytokines in the injured tissue. Several studies have shown that blocking TNF production or delaying the invasion of macrophages to the site of nerve injury results in reduced or delayed neuropathologic change and reduced hyperalgesia.[52,92]

TNF is known to induce axonal and myelin injury similar to that observed after nucleus pulposus application,[93-99] intravascular coagulation,[100-102] and increased vascular permeability.[102] TNF is also known to be neurotoxic[96,98,103,104] and to induce painful behavioral changes[93,105] and ectopic nerve activity when applied locally.[94,104] TNF is sequestered in a membrane-bound form and is activated after shedding by certain enzymes. Matrix metalloproteinases (MMPs) are particularly important in this regard. MMP-9 and MMP-2 are upregulated immediately after a nerve injury.[106] MMPs process the inactive, membrane-bound form of TNF and its receptors to the biologically active form and are directly associated with breakdown of the blood-brain and blood-nerve barriers. MMP-9 and TNF receptors are also retrogradely transported from the site of nerve injury to the corresponding dorsal root ganglion and spinal cord,[107] where they may have a direct role in gene regulation. This may relate to the observation that cell membranes of disc cells are sufficient to mediate the nucleus pulposus–induced effects.

TNF induces activation of endothelial adhesion molecules such as intercellular and vascular cell adhesion molecules, adhering circulating immune cells to the vessel walls (Fig. 7.4).[88,108,109] As a consequence of the TNF-induced increased vascular permeability, these cells migrate into the endoneurial space where the axons are located. The cells release their content of TNF and other cytokines, which may induce accumulation of ion channels locally in the axonal membranes.[110-112] The channels may allow for an increased passage of sodium and potassium, which may result in spontaneous discharges and in discharges of ectopic impulses after mechanical stimulation. TNF by itself can cause spontaneous electrical activity in A-delta and C nociceptors.[104] Such discharges, whether they come from a pain fiber or a nerve fiber transmitting other sensory information, are interpreted as pain by the brain.

Previous studies have also indicated that local application of nucleus pulposus may disintegrate the myelin sheath[42,43]; this is also a known effect of TNF.[113] This injury could also contribute to the formation of ectopic impulses and to the sensitization to mechanical stimulus. Experimental and clinical studies have shown that nerve root compression and disc herniation can induce increased concentrations of neurofilament in the cerebrospinal fluid.[114,115] Increased levels of serum antibodies against one or more nervous system–associated glycosphingolipids have been shown in patients with sciatica and disc herniation, indicating a possible autoimmune response.[116]

More recent work regarding molecular events in the pathophysiology of neuropathic pain has suggested a potential role of TNF for inducing allodynia.[94,117,118] TNF may mediate the formation of allodynia in the dorsal root ganglion and at the spinal cord level because of its local upregulation, which occurs via a positive feedback loop caused by TNF itself. This cycle seems to be broken by a direct effect of TNF on the upregulation of antiinflammatory cytokines such as IL-10, which eventually leads to a reduction of TNF and the physiologic balance of proinflammatory and antiinflammatory cytokines. Such regulation seems to be induced by mechanical

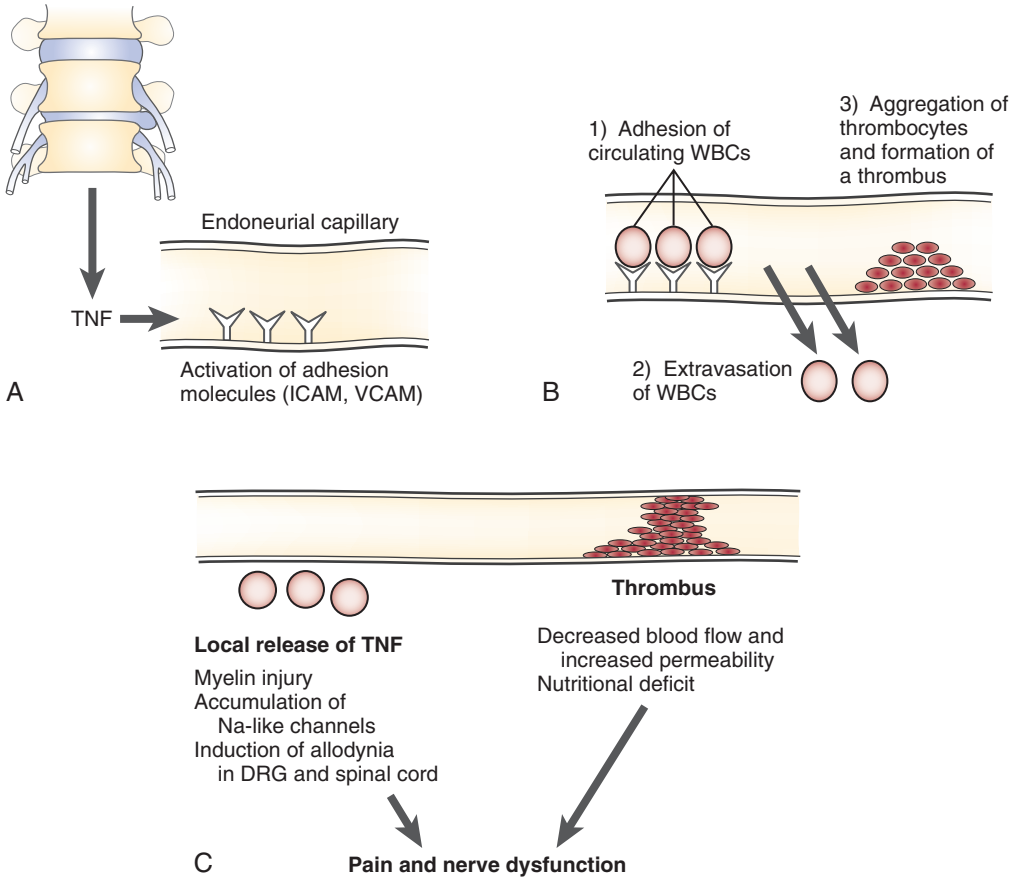

FIG. 7.4 Suggested mechanism of action for tumor necrosis factor (TNF). (A) TNF from cells of herniated nucleus pulposus enters endoneurial capillaries and activates endothelial adhesion molecules. (B) Circulating white blood cells (WBCs) adhere to vessel walls (*1*) and extravasate from capillaries out among axons owing to TNF-induced increase in vascular permeability (*2*). TNF also induces accumulation of thrombocytes that form intravascular thrombus (*3*). (C) There is local release of TNF from extravasated WBCs among axons that induce myelin injury, accumulation of sodium channels, and allodynia in the dorsal root ganglion (DRG) and at the spinal cord level. Thrombus, together with edema owing to increased permeability, induces nutritional deficit in the nerve root. Local effects of TNF and nutritional deficit may induce pain and nerve dysfunction. CAM, cell adhesion molecule; VCAM, vascular cell adhesion molecule. (From Olmarker K, Myers R, Kikuchi S, et al. Pathophysiology of nerve root pain in disc herniation and spinal stenosis. In: Herkowitz H, Dvorak J, Bell G, et al, eds. *The Lumbar Spine.* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2004:11-30.)

injury to peripheral parts of the axons and by a direct effect of TNF exposure and further enhances the impression that TNF may be an important mediator of neuropathic pain. TNF is a potent activator of cells; because it is retrogradely transported from the site of nerve injury to the dorsal root ganglion and spinal cord, it may be this proinflammatory stimulus that activates central glia and neurons.[107]

Apart from directly affecting the endoneurially located axons, TNF may also indirectly interfere with the axons by compromising the nutritional transport. TNF can induce intravascular coagulation after local application[119]; this reduces the local blood flow in the intraneural capillaries.[54]

TNF was found in disc cells and there is evidence that elevated levels of TNF and its receptor, TNFR1. In herniated lumbar discs correlated with the chronicity of postoperative sciatic pain.[120] Specific TNF inhibitors, such as a monoclonal antibody to TNF (infliximab) and a soluble TNF receptor (etanercept) can inhibit pathophysiologic dysfunction. It has been shown that infliximab may attenuate immunoreactivity of brain-derived neurotrophic factor and may prevent neurologic and histologic changes in dorsal root ganglion in rats after experimental disc herniation.[121] More recent studies reinforce the potential utility of cytokine inhibition in treating the inflammatory hyperalgesia induced by nucleus pulposus[122] and spinal nerve injury.[123]

Application of certain cytokines to intraspinal nerves may also increase the somatosensory neural response.[124] Discharges from wide-dynamic-range neurons after stimulation of a receptor field of a dorsal root ganglion exposed to nucleus pulposus increased significantly after application. This increase may be related to the sensitization of the sensory system caused by proinflammatory cytokines and the production of low-grade spontaneous electrophysiologic activity in nociceptors by TNF,[104] which by itself is an important factor that contributes to sensitization. Administering an antibody specific for TNF efficiently inhibited this effect. An in vivo study assessing changes in spontaneous behavior clearly showed that changes induced by the combined action of mechanical deformation

and disc incision were markedly inhibited by intraperitoneal injection of a monoclonal antibody specific for TNF.[55]

TNF seems to be an important mediator for the observed effects on nerve function and for pain induced by local application of nucleus pulposus. Additional support for this hypothesis comes from previous work that showed that blockade of TNF upregulation in macrophages by thalidomide[92] and downregulation of TNF by IL-10 administration reduced the magnitude and duration of hyperalgesia after nerve injury. Because cytokine interactions are complex, other cytokines such as IL-1β and IL-6 may be involved as well. Because these cytokines are induced by TNF, as well as inducing TNF, their role is complex.

The possible role of brain-derived neurotrophic factor in nerve root pathophysiology and experimental disc herniation has been analyzed.[125] The appearance and distribution of macrophages and TNF in the dorsal root ganglion of rats after experimental disc herniation and the relationship between nerve growth factor and pain behavioral changes have been described.[126] It has also been shown that disc-related cytokines can inhibit axonal outgrowth from dorsal root ganglion cells in vitro.[127]

Clinical Use of Cytokine Inhibitors for Treatment of Sciatica

On the basis of the experimental findings that TNF may mimic nucleus pulposus–induced nerve dysfunction and pain, pilot clinical trials regarding the possible use of TNF inhibition for the treatment of sciatica were initiated. Karppinen and colleagues[128] administered a monoclonal antibody specific for TNF (infliximab [Remicade]) to 10 volunteers waiting for surgery for radiologically verified disc herniations with severe sciatica. In this open-label study, infliximab reduced pain assessed by visual analog scale by 50% at 1 hour after infusion. After 2 weeks, 60% of the patients were pain free. At 3 months after the single infusion, 90% were pain free. No adverse drug reactions were noted, and no patients required surgery. A 1-year follow-up[129] of the 10 patients treated with infliximab showed that the beneficial effect of a single infusion of 3 mg/kg of infliximab for disc herniation–induced sciatica was sustained in most patients. The authors also noted that infliximab did not seem to interfere with spontaneous resorption of disc herniations.

Genevay and colleagues[130] administered a TNF inhibitor in the form of a soluble TNF receptor (etanercept [Enbrel]) by three subcutaneous injections to 10 patients with severe sciatica. The patients had a 70% reduction of leg pain assessed by visual analog scale 10 days after starting the treatment. At 6 weeks, the reduction was 83%. The results were statistically significantly better than for 10 patients treated with three intravenous injections of methylprednisolone.

In one randomized study published by Cohen and colleagues,[131] treatment of sciatica by local epidural injections of the TNF inhibitor etanercept was effective. The investigators randomly assigned 24 patients with subacute radiculopathy into three groups each consisting of eight patients. The patients in each group received either 2, 4, or 6 mg on two occasions, and two of the eight patients were saline controls. All etanercept-treated patients had significant improvement 1 month after treatment compared with saline-treated patients regarding leg and back pain. The effects persisted 6 months after treatment in all but one patient. The authors concluded that "etanercept holds promise as a treatment for lumbosacral radiculopathy."[131] Genevay and colleagues[132] published the results of a multicenter, double-blind, placebo-controlled trial on the use of the TNF inhibitor adalimumab (Humira) subcutaneously injected in 31 patients with severe, acute sciatica caused by disc herniation. Two injections were given 7 days apart; 30 control patients received placebo injections in the same manner. The results showed that there was a significantly more favorable evolution of leg pain in the adalimumab group than in the placebo group, but the effect size was relatively small. There were twice as many patients in the adalimumab group who fulfilled the criteria for "responders," and there were significantly fewer surgical discectomies in this group compared with the placebo-treated controls.

The issue of anti-TNF therapy for human sciatica remains complex. In spite of encouraging basic science studies in experimental animals, its efficacy and utility in humans remains unsettled.[133] While there continues to be reports of positive results in animals and humans,[134] a second multicenter, randomized trial by Cohen et al.[135] of 84 adults with lumbosacral radiculopathy revealed only a short-term relief for some of their patients. Issues of experimental design and placebo effects complicate the interpretation of the results. Indeed, this point is emphasized by Williams et al.,[119] who performed a systematic review and meta-analysis of biologic treatments targeting TNF-α for sciatica and concluded that there was insufficient evidence to recommend these agents when treating sciatica. They concluded, however, that additional studies are warranted.

Taken together, these observations indicate a potential clinical effect of TNF inhibition in the treatment of sciatica. It is unconfirmed although provocative that early treatment with TNF inhibition seems superior to late antiinflammatory treatment by nonsteroidal antiinflammatory drugs, methylprednisolone, or even morphine in many patients. We suggest that it is more efficient to target the responsible mediators of neuropathic pain early and directly before additional dysfunction occurs than to treat a patient with conventional antiinflammatory drugs after the neuropathic pain state has fully developed. Sciatica has a neuropathic pain component, and nonspecific antiinflammatory medication and morphine are less efficient in such conditions. Further studies must be undertaken, however, before any definite conclusions regarding the efficacy of anti-TNF therapy for the treatment of sciatica may be drawn.

Summary

The pathophysiology of sciatica is complex, with numerous substances and mechanisms acting at various levels of the neural axis. These mechanisms have attracted attention of basic scientists, and numerous studies looking into

neuroimmunologic events have provided important insights into the pathophysiologic mechanisms of the human disease state. The intervertebral disc has certain biologic effects that contribute directly to these pathophysiologic processes. Epidural application of nucleus pulposus induces structural and functional changes that relate closely to sciatica. The nucleus pulposus also sensitizes nerve roots, producing a painful condition. These experimental observations correlate with the clinical impression that preoperative touching of nerve roots that have been exposed to disc herniation under local anesthesia reproduces the sciatic pain and that surgical removal of the mechanical compression of the nerve root often relieves symptoms.

The biologic substance of importance in the pathogenesis of painful radiculopathy seems clearly at this stage of understanding to be TNF-α. The activation and upregulation of this ubiquitous proinflammatory cytokine produces acute pain and neuropathologic changes associated with chronic pain states. TNF stimulates fibroblast scar formation in a vicious cycle whereby the local presence of TNF stimulates other cells to upregulate this cytokine. Initiation of this cycle by the leakage of TNF from herniated nucleus pulposus produces a cascade of tissue injury, scar formation, and local pain. Superimposition of mechanical injury to the nerve root in this environment exacerbates the neural immune insult, causing macrophage-mediated wallerian degeneration with significant increases in TNF concentrations. We suggest that these combined events explain the problem of sciatica. Although the pathophysiology of sciatica is far more complex than one might first suspect, future research is certain to reveal substances and mechanisms of importance to the induction of symptoms in sciatica, and such research would provide a basis for improved diagnosis and treatment of this common disorder.

CHAPTER 8

Basic Concepts in Genetics and Intervertebral Disc Degeneration and Scoliosis

Jason Pui Yin Cheung
Kenneth M.C. Cheung

Introduction to Genetics

Genetics has a growing role in the field of clinical medicine. Genes are the fundamental make-up of any organism; thus, understanding what genes and environmental factors contribute to certain disease traits/phenotypes are of interest. By identifying the mutations in the genes that lead to disease, focused management such as early detection, targeted therapies, or even disease prevention can be developed.

With genome sequencing and public access to the electronically compiled genome data, the Human Genome Project allows scientists to identify genes of interest at particular locations in the genome. This can allow researchers to use a certain DNA sequence of a particular gene as an initial reference sequence to carry out mutation screening and permit rapid identification of genetic markers within or adjacent to genes of interest. This database of DNA reference sequences can also help design primers that bind to a certain sequence of the genome. The available data allow studies regarding expression patterns in different tissues and sequence variations between subjects such as single nucleotide polymorphisms (SNPs).

Many genetic disorders have already been identified and stored in the Online Mendelian Inheritance in Man (OMIM) database. The pattern of how genetic information is passed through subsequent generations is based on the Mendelian laws of inheritance. Using modern technology, potential genetic variants that predispose to disease can be determined. For spine surgeons, disc degeneration and scoliosis are two of the most sought after conditions in terms of genetic background. Both conditions are likely influenced by multiple genes and various environmental factors. This chapter aims to provide clinicians with a basic concept of genetics with regard to the terminology and principles, with a specific focus on disc degeneration and scoliosis. Readers may be able to equip themselves with a general understanding and thereby the ability to follow novel literature regarding advances in genetics.

Chromosomes and DNA

Before discussing genetics and how to determine genetic variations, concepts of chromosomes, DNA, and polymorphisms need to be understood. Any single human genome is comprised of 22 pairs of homologous chromosomes with an additional pair of sex chromosomes inherited from parents. A full set of chromosomes is also known as diploid and a half set is known as haploid. Chromosomes are made up of DNA, which is a nucleic acid that carries genetic material. DNA contains a super-phosphate with nitrogenous bases. The nitrogenous bases include base pairs of adenine (A) and guanine (G)—purines—and cytosine (C) and thymine (T)—pyrimidines. Each molecule of DNA is comprised of two nucleotide chains that are coiled in a clockwise fashion to form the double helix. These chains have two ends, called the 5′ and 3′ ends, and the two nucleotide chains run in opposite directions, either from 5′ to 3′ or from 3′ to 5′. Base pairings in these chains are obligatory A:T and G:C.

The main function of these nucleic acids is coding protein synthesis. The basic architecture of proteins is comprised of amino acids, and the order of sequence in which amino acids are encoded judge the way the resulting protein is formed and functions. These proteins are encoded by DNA, and therefore by its gene. DNA is double stranded, whereas ribonucleic acid (RNA) is single stranded. In addition to this difference, uracil (U) replaces T in RNA sequences. Exons are sequences of DNA that contain coding information, whereas introns are noncoding sequences. DNA is used as a template to create RNA in a process known as transcription. As any set of three base pairs form the codes for an amino acid, the transcribed messenger RNA (mRNA) encodes the information for a certain protein with a specific amino acid sequence that is imprinted by a certain gene. Through the transcription process, the DNA strands separate and act as the template for the enzyme RNA polymerase II to synthesize nucleotides in the opposite direction of the DNA template (5′ to 3′ matched to 3′ to 5′). This process will include all introns and exons. Despite being a noncoding region, introns have regulatory functions during transcription. Introns are eventually removed after splicing; the remaining exons form mature mRNA.

The next stage in protein synthesis is known as translation, which occurs in the cell cytoplasm. The mRNA attaches to a ribosome; each ribosome moves along the mRNA to form a matching transfer RNA (tRNA), which will contribute its specific amino acid to a growing protein chain until it reaches a stop codon. Proteins are important for normal

bodily functions, as they regulate different mechanisms both intracellularly and extracellularly.

Genetic Variations

Despite having pairs of chromosomes, there are variations in sequencing that distinguish between chromosomes. Variants on the same location of paired chromosomes are known as alleles. They may be homozygous, meaning the same, or heterozygous, meaning different. Small variations can exist in individual nucleotides. Larger variations include microsatellites, deletions, insertions, and copy number variations (CNVs). All variations can cause significant alteration of the protein structure, thus gene expression and possibly disease manifestation. However, these genetic variants can be manipulated into a genetic marker for identifying their location on the DNA sequence. These markers are important for studying the causative relationship between a genetic variant and an inherited disease.

SNPs are particularly of interest, as they are commonly used for genetic analysis. They are also commonly found throughout the genome, comprising up to 90% of the genetic variants. They are 1-base pair (bp) substitutions of DNA sequences that can occur anywhere in the genome. On average, a SNP may be observed in every set of 300 nucleotides; thus, there are approximately 10 million SNPs found in the entire human genome.

Microsatellites or variable number of tandem repeats refer to repeating short nucleotide sequences. Due to the variable number of repeats in different chromosomes, it is a useful marker for identifying different people. Deletion or insertion of one or more base changes may lead to significant changes in DNA sequences, thus causing missing or extra amino acids in any protein chain. A complete change in protein sequence may result from more than 3 bp of sequence addition or loss. These usually cause serious genetic diseases. CNV refers to large structural variations in DNA sequences. The "copy number" refers to the number of duplications that occur. CNV involves duplications of large segments of a certain chromosome that alters one or more genes. Inversions may also occur as a result of reversal in a segment of chromosome, which may cause complex genetic diseases.

Mutations and Polymorphisms

Mutations result from permanent damages to DNA or replication errors. The effects are variable: from fatal to only mildly detrimental. If fatal, these mutations will not be inherited, thus are very rarely found in the population. For mild cases, individuals are likely to reproduce and encourage the mutation to be inherited, leading to an increase in prevalence in the general population. Rare variants are more commonly researched, as they are more likely to have positive findings in genetic research and usually are associated with more clinically relevant diseases. They are defined as variants with a minor allele frequency (MAF) of less than 1%. Polymorphisms are defined as MAF greater than 1%; among these, MAF greater than 5% are common variants and those from 1% to 5% are low-frequency variants. Polymorphisms rarely cause significant external effects despite changes in the gene sequence.

Terminology and Types of Disease

Genotype is the definition of the status of two alleles or actual denotation of the genetic data. In contrast, *phenotype* is the observable expression of the subjects' traits. Differences in genotypes contributed by polymorphisms lead to phenotypical variations between individuals. Expression can exist at the molecular level in the form of protein expression or can be more clinically notable, such as height differences and symptoms. As the clinical expression of the disease relies heavily on the genotype, being able to phenotype a disease carefully is very important for any genetic analysis. Not all genotypical differences may manifest clinically, however, as this relies on penetrance. Incomplete penetrance may not result in disease, as the genotype is not fully expressed clinically. These cases are considered to be complex genetic disorders in which environmental factors must interact with the susceptibility genes before developing disease. Many orthopedic conditions—such as osteoarthritis, disc degeneration, and even scoliosis—are types of complex genetic disorders. This is in contrast to Mendelian diseases, which are simpler but rarer forms of disease caused by single gene mutations.[1,2] Usually, these are severe diseases, such as osteogenesis imperfecta. Mendelian diseases are usually predictable in inheritance patterns.

For complex disorders, meticulous qualitative and quantitative phenotyping is important to classify disease severity.[3] For example, in disc degeneration, most phenotyping relies on magnetic resonance imaging (MRI) which is used to assess the disc's hydration status, any bulging discs or herniation, and Schmorl's nodes or endplate irregularities. Qualitatively, whether there is disc degeneration is evaluated. However, quantitative evaluation is more important in these complex disorders, as the phenotype may alter in severity and over time, such as with the degenerative process. On the MRI, Schneiderman's and Pfirrmann's grading describe the signal intensity of the nucleus pulposus on T2-weighted MRI. Schneiderman's grading describes the signal intensity of the nucleus pulposus by four grades (grade 0 indicating a normal disc and grade 3 indicating hypointensity with disc space narrowing).[4] Pfirrmann's classification evaluates the homogeneity of disc structure, signal intensity, distinction of nucleus pulposus and anulus fibrosus, and disc height by five grades (grade 0 indicating a homogeneous disc structure, hyperintense signal, and normal disc height with grade 5 indicating inhomogeneous disc structure, hypointense signal, loss of distinction between nucleus pulposus and anulus fibrosus, and collapsed disc space).[5]

Gene Mapping

Gene mapping must be performed prior to claiming that a disease is caused by a certain gene. Accurate mapping helps us understand the etiology and pathogenesis, and identifies genes that may be manipulated into targeted therapies. The method for gene mapping works differently for Mendelian versus complex diseases. In Mendelian diseases, due to the

rarity of the contributing gene variations, most are identified by studying affected families. Family genetics allow visualization of the mode of inheritance, and can help locate the position of the genetic variant. Although there are limitations in this analysis because family members are exposed to similar environmental factors and may mask some real genetic factors, examining monozygotic (identical) twins may help analysis for purely genetic disorders since they should both have disease. However, if both monozygotic and dizygotic (nonidentical) twins both have similar disease rate (concordance rate), then it is likely that shared environmental factors are the major factor instead. In complex genetic diseases, there is contribution from multiple genes; with their complex interactions with the environment, special mapping designs are required. For family-based designs, linkage analysis will be used. For population-based designs, association analysis or biologically relevant candidate gene analysis are used.

Linkage Analysis

Preferably, linkage analysis has the greatest yield with large families and multiple affected members. Genotyping for microsatellite markers is performed to locate disease genes that are nearby (Fig. 8.1). The premise of linkage analysis is that recombination is less likely to occur between the disease gene and the designated genetic marker since their positions are nearby, allowing "linkage" of the disease gene with the marker. In other words, affected members of the same family are likely to pass on this region of the genome with the disease gene. If sufficient microsatellite markers are available to cover the whole genome, linkage analysis can help locate the diseased gene even if it is unknown at the outset. However, this is dependent on the distance between the disease gene and marker. With a large distance, it is likely that recombination may have occurred in between. Thus, the rate of recombination can help calculate the distance between the diseased gene and marker used. In general, a 1% recombination rate (θ) is represented as 1 centimorgan (cM) apart or approximately 1 million bp distance.[6,7]

One of the main tests used is the parametric linkage analysis, in which the test hypothesis (true linkage of the diseased gene to the marker) is tested against the null hypothesis (no linkage). Sequential recombination rates are performed to compare the likelihood of either hypothesis. This is known as likelihood ratio or odds. Using a logarithm to base 10 of this ratio, the logarithm of odds (LOD) score can be calculated. The highest LOD score represents the likely distance between the disease gene and marker.[8] LOD is an important parameter to decide whether a finding is significant or not; a score of 3.3 is required to achieve genome-wide significance.[9] This LOD score can be strengthened by combining results from different studies with the same disease model.

With linkage analysis, prior knowledge of the position of the disease gene is unnecessary since it can be determined by linkage with microsatellite markers. Thus, it is most useful in diseases in which only a small number of genes are involved. The main limitation is its inability to detect common alleles without a strong influence on the disease. Therefore, in common conditions with multiple gene and environmental contributions, such as disc degeneration, association studies are preferred.

Association Studies

Population-based gene association studies aim to identify alleles associated with a single trait across the population. Although it is similar to linkage analysis, in that it identifies a disease gene in subjects with a common ancestry (population based instead of family based), it assumes that the "linkage" distance between the marker and disease gene of interest is extremely close so that recombination over generations would not affect its position. Thus, positive association represents that a particular disease gene is overexpressed in diseased individuals as well as underexpressed in normal subjects.

Association studies can be classified as either direct or indirect.[10] Direct association studies target the variants that have functional effects, which leads to disease. Although successful identification of a predisposing allele shows powerful association, the chance of positive identification is low. In indirect association studies, the association between the marker and disease gene is targeted. This association relies on the concept of linkage disequilibrium (LD), that is, because

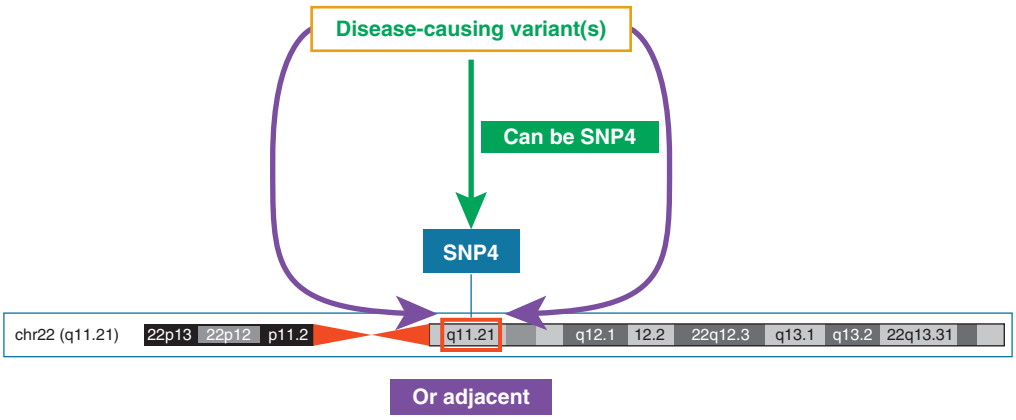

FIG. 8.1 SNP4 is the disease-causing variant. In linkage analysis, markers nearby (or adjacent in this figure) to the disease variant can be easily picked up, as recombination is unlikely to have occurred in between.

markers are near the disease gene, they are associated and thus lead to higher frequency of disease than expected. Identifying this marker will suggest that a disease-causing variant is nearby, helping to narrow down the search for the disease gene.

Association studies can be conducted via a candidate-gene or genome-wide association type of approach. Candidate-gene approaches utilize possible disease genes that are previously identified or are in relation to the disease pathway and directly screen the individuals for these disease genes using markers, which are usually selected SNPs. Genome-wide association studies (Fig. 8.2) adopt a similar principle as candidate-gene studies, but, rather than testing for possible single genes, a SNP mapping of the entire genome is performed. All possible SNPs are tested for association with the disease by comparing the frequencies of occurrence between cases and controls. Conventionally, the threshold for genomewide significance is 5×10^{-8}. Technological advancements with the addition of DNA genechips allow for this scale of study.[11] The cost and time spent to perform these studies are now much more reasonable.

Newer Technologies

With the advancement in sequencing technologies,[12] whole human genome or whole exon (1%–2% of the human genome)

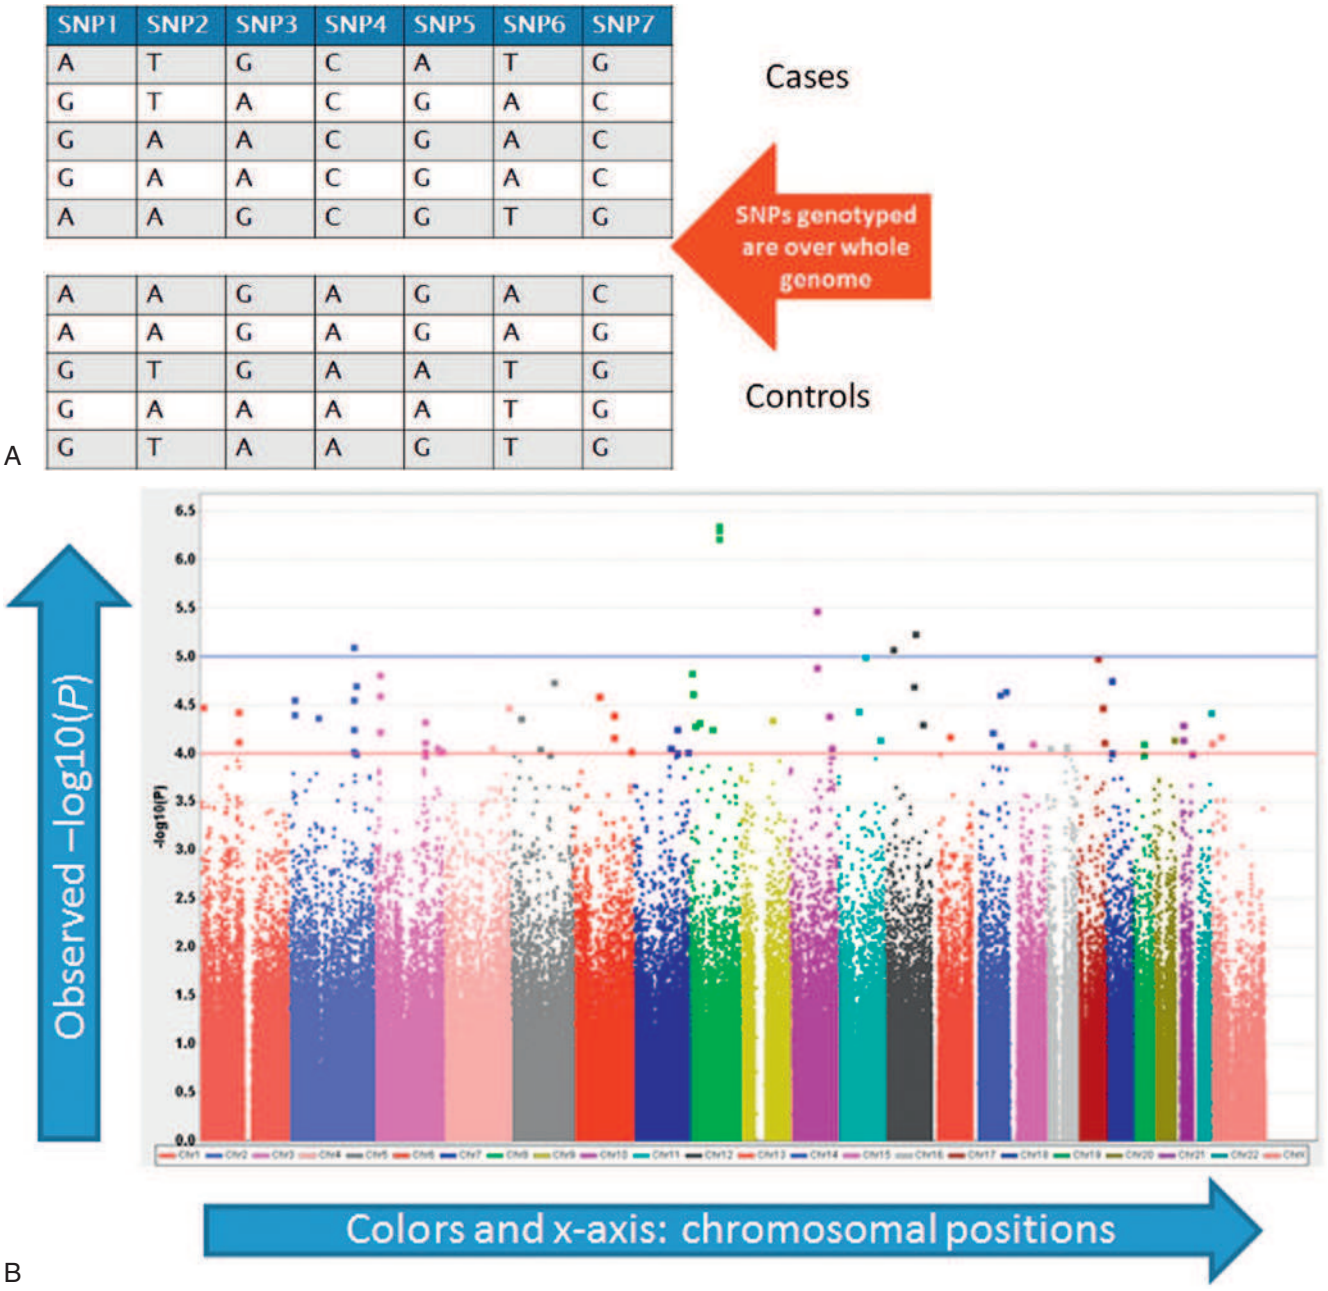

FIG. 8.2 (A) Genome-wide association studies pick up all single nucleotide polymorphisms (SNPs) between cases and controls. (B) Manhattan plots are used to define which SNPs are significant by logarithm to base 10 of the observed *P* value.

sequencing is becoming more affordable and feasible. This allows assessing of all DNA variations in the genome, such as CNVs instead of only SNPs or microsatellites. Exome sequencing is used for sequencing the protein-coding genes in a genome. Thus, only the DNA that encodes for proteins is sequenced. This technique is a simpler approach to rare variants. Since diseases are caused by these rare variants, targeting the protein coding sequence usually has a high yield for identifying the causative variants. Because of this, an understanding of the clinical implication of the disease and the protein sequence that is defective is required. This is in contrast to whole-genome sequencing, which determines the entire DNA sequence of an individual's genome. More than 95% of the genome is thus genotyped, allowing information on the individual's genetic susceptibility to diseases to be generated. Despite its wide coverage and reduced cost with technological advancements, it is still comparably the most expensive sequencing technique.

Interpretation of Results

Using association studies, possible significant results may be generated in the form of direct or indirect association or false-positive results. Direct association indicates that the genotyped polymorphisms are the true causal genetic variant leading to disease. Indirect association indicates that the polymorphisms are in LD with the true variant. A false-positive result is usually due to population stratification, suggesting that differences in allele frequency exist between subpopulations of the subject population, indicating that these individuals are of a different ancestry.

As with all statistical analysis, genetic testing to determine whether variants are associated with disease susceptibility requires certain *P* values. The null hypothesis with regard to *P* value is the possibility of no association in genotype distribution between cases and controls. Similarly, this hypothesis of no association is rejected with a $P < .05$. Special tests may be adopted in candidate-gene or genome-wide association studies since all variants undergo study. Increased false-positive rates exist with increased hypothesis testing. Bonferroni correction is one of the most common approaches[13] in these studies. The corrected statistical significance level is 1/n times what is expected from only one variant testing. Therefore, the significance threshold is 0.05 divided by the number of markers under testing.

Disc Degeneration Genetics

There has been a gradual shift in understanding of disc degeneration from purely a reaction to aging and prolonged mechanical load to a more complex interaction between genetics (Table 8.1) and environmental factors.[14] Earlier studies suggest contributions of age, gender, occupation, cigarette smoking, and increased height and weight.[15] Using familial studies, several genetic variants have suggested this relationship, as young patients may also develop disc degeneration.[16,17] In addition, a familial link can be generated due to similarities (26%–72%) found between identical twin pairs.[18] With analysis of monozygotic twins, up to 61% of the genetic variance can be explained by familial aggregation with only limited (16%) contribution by age and mechanical loading.[19] Subsequent twin studies suggest that 74% of disc degeneration is heritable after adjustment for age, body weight and height, smoking, occupation, and degree of physical exercise.[20]

As compared to spine deformity, in which the phenotype is clear, disc degeneration is overall more subjective for diagnosis (Fig. 8.3). There is a wide range of symptoms, severity, and presentations, with particularly complex MRI features including loss of nucleus pulposus signal intensity, disc herniation and bulging, endplate irregularities and Schmorl's nodes, osteophyte formation, and disc space narrowing, Modic changes, and high-intensity zones. Some very young individuals may develop severe disc degeneration, while some of the elderly may have normal discs. Clinical presentation is especially variable as not all individuals with "black" discs develop back pain.

Despite evidence of heritability suggested by studies of twins, limited validation studies exist for the identified common variants. Considering the substantial population with disc degeneration, causality is still unclear with many unknown common variants still requiring identification. Most of the current studies focus around candidate-gene analysis with common SNPs. However, there is an increasing interest in rare variants due to their role in complex diseases.

Via linkage study, a novel susceptible variant in carbohydrate sulfotransferase 3 (*CHST3*) is found to be associated with early-onset disc degeneration.[21] This is accomplished by genotyping candidate regions on chromosomes 1, 5, 8, 10, and 20. A follow-up epigenetics study detected a reduction in expression of *CHST3* mRNA in intervertebral disc cells of individuals carrying the A allele of the SNP rs4148941. By understanding the biologic pathways leading to the disc degeneration phenotype, probable candidate genes can be used to identify possible disease variants. The extracellular matrix is an integral part of the disc architecture; thus, genes encoding structural proteins including collagen and aggrecan are good candidate genes to analyze with regard to disc degeneration.

The vitamin-D receptor (*VDR*) has been most commonly replicated in different population cohorts, thus is the most robust of all associated genes under study. A Finnish twin study[22] first identified *TaqI* and *FokI* polymorphisms manifesting as reduced signal intensity of the disc on MRI. *TaqI* has been replicated in a Japanese cohort[23] and a Chinese population-based study.[24] The next stage of functional validation has yet to be performed, however. The expression of this variant is likely extracellular matrix alterations.[25]

The gene *ACAN* encodes aggrecan, which is responsible for maintaining disc hydration as it is the major proteoglycan contributing to the cartilage and nucleus pulposus structure of the intervertebral disc. Variable number tandem repeats in *ACAN* is associated with disc degeneration in a young Japanese cohort,[26] which has been replicated in the Han Chinese,[27] Korean,[28] and Turkish[29] populations. A greater risk of symptoms has been observed in smokers (odds ratio [OR]

TABLE 8.1 Genetic Variants for Disc Degeneration

Gene	Protein	Cohort/Study Population Size (N)	Variant	Reference

= 4.5), suggesting further interactions with environmental factors.

Collagen is another structural protein that has been commonly studied. Type XI collagen encoded by *COL11A1* (SNP: rs1676486; T-allele) has been suggested in a Japanese study to be associated with disc herniation and sciatica due to destabilizing mRNA.[30] Trp2 allele is a rare mutation of *COL9A2* (type IX collagen) and is suggested to be a disease-causing mutation in a Finnish family linkage study.[31] This association is replicated in the Chinese population, in which its frequency is even higher.[32] Trp3 is another variant suggested to be causative in a Finnish population,[33] but is not replicated in the Chinese[32] or Southern European[34] cohorts. *COL1A1* and *COL1A2* are two genes encoding collagen type I, and a SNP (rs1800012) is identified to be associated with disc degeneration.[35] However, no large-scale study has replicated these results.

Other degeneration phenotypes, such as osteoarthritis, may have similar variants as disc degeneration. For example, associations with the gene *ASPN* (Asporin) have been observed in Asian cohorts.[3] Asporin is an extracellular matrix protein that contributes to knee osteoarthritis. Growth differentiation factor (*GDF5*) is also a commonly used candidate gene for osteoarthritis[36] as it is important for joint formation,[37] but has also been shown to lead to disc degeneration. A SNP (rs143383) is related to disc space narrowing and osteophyte formation.[38] In a meta-analysis with regard to rs143383, a significant association can be detected among women for this phenotype.[38]

Matrix metalloproteinases (MMPs) are important proteins that are expressed in intervertebral discs. Thus, MMPs have increased enzymatic activity and increased expression in degenerated disc cells.[39] *MMP1*, *MMP2*, *MMP3*, and *MMP9* have been linked to disc degeneration. In a cohort of Southern Chinese subjects, the significance of the *MMP1* variant is found only in subjects older than 40 years.[40] A significant SNP located at the promoter region of *MMP2* is associated with severe disc degeneration.[41] Polymorphisms of *MMP3* may lead to the onset and progression of disc degeneration.[42] Finally, for *MMP9*, a SNP at the promoter region may also be associated with disc degeneration.[43] All of these findings are in Asian cohorts and have yet to be replicated in other ethnicities.

Thrombospondin-2 genes (*THBS2*) have also been studied in Japanese cohorts as possible candidate genes. A significant

FIG. 8.3 Importance and variations in phenotypes observed in disc degeneration. The left T2-weighted magnetic resonance image (MRI) shows a relatively normal phenotype with signal intensity of the nucleus pulposus. The center MRI shows multiple discs with loss of signal intensity and disc height, bulging and high-intensity zone anteriorly at L4–L5. The right MRI shows discs with normal signal intensities but multiple endplate irregularities and Schmorl's nodes.

SNP (rs9406328) has been proposed[44] to be related to regulation of *MMP* expression in the disc. The combined effects of *THBS2* and *MMP9* variants amounts to an OR of 3.3 for disc degeneration.[44]

Sickle tail (*SKT*) gene polymorphisms have been analyzed in a Japanese cohort.[45] Here, a significant SNP (rs16924573) observed has been replicated in the Finnish population.[46] The risk of lost signal intensity at the nucleus pulposus and the *SKT* SNP has been established (OR = 0.27 [95% CI, 0.07–0.96], $P = .024$).[46] However, further functional studies of this relationship are required.

A recent large-scale (4600 subjects) genome-wide association study of a Northern European cohort suggests that the SNP (rs926849) of the *PARK2* gene ($P = 2.8 \times 10^{-8}$) is also associated with disc degeneration.[47] Polymorphisms have also been found for *CILP* (rs2073711) and *IL6* (rs1800795 and rs1800797) genes via association study.[46]

From the summary of genetic studies with regard to lumbar disc degeneration, many genes have been reported, but just a few have been replicated with different cohorts and ethnicities. A systematic review of disc degeneration association studies[14] suggests that most of the reported studies have only a weak level of evidence. It is thus likely that cross-cohort validations are required in subsequent studies to raise the significance of reported results.

Scoliosis Genetics

Early-Onset Scoliosis and Congenital Scoliosis

Early-onset scoliosis (EOS), according to the Scoliosis Research Society, is a lateral curvature of the spine that is diagnosed before the age of 10. Thus, any diagnoses can fall under this category including neuromuscular, syndromic, congenital, and idiopathic scoliosis. With regard to idiopathic scoliosis, both infantile (ages 0–3 years) and juvenile (ages 4–10 years) idiopathic scoliosis are considered EOS. Due to the variable presentations of EOS, little evidence is available in regard to their inheritance. For idiopathic scoliosis, subjects that are younger commonly are boys as compared to older age groups, in which girls are more commonly affected.[48] Older-onset scoliosis, in particular, has a higher incidence among relatives.

The occurrence of congenital scoliosis is usually sporadic, with an incidence of 0.5 to 1 per 1000 live births.[49,50] Its etiology is likely to be multifactorial, with contributions from both genetic and environmental factors. Vertebral anomalies may arise from the fetal development with mothers exposed to environmental factors such as hypoxia, hyperthermia, carbon monoxide, and alcohol exposure.[51] Gestational hypoxia, in particular, has been shown to potentiate abnormal fibroblast

ICSG, International Consortium for Scoliosis Genetics.

growth factor (FGF) signaling in mice, which thus develop congenital scoliosis.[52]

The phenotype of congenital scoliosis includes vertebral and rib malformation caused by failure of segmentation or formation in utero. Overall, the genetic understanding (Table 8.2) of this condition is still limited, with only a few significant association studies performed. Complex interactions between the signaling pathways such as *FGF*, *Wnt*, and *Notch*, occur in the embryo to form vertebral bodies from somites.[53] Various notch pathway genes. including *MESP2*,[54] *LFNG*,[55] and *HES7*,[56] have been identified to trigger normal somite segmentation and vertebral development in mice. Any mutation in these genes alters the pathway of vertebral development and may lead to anomalies. The association is more complex in humans due to the less predictable vertebral and rib malformations. Several gene variants of the *Notch* pathway have been identified in spondylocostal dysostosis[57] and Alagille syndrome.[58,59] However, the actual gene and protein mechanisms responsible for the phenotype representation are still unknown; thus, these mutations may not be the sole contributory element. Via animal studies, several human candidate genes from the *Wnt*, *FGF*, and *Notch* signaling pathways have been identified.[49,60] *PAX1*, *DLL3*, and *TBX6* are candidate genes that have been studied using association analysis.[61–65] One study on Han Chinese subjects comparing patients with congenital scoliosis with normal spines yielded two SNPs of the *TBX6* gene (rs2289292 and rs3809624) to be in strong LD (LOD = 57.48), suggesting that these rare variants play important roles in the development of congenital scoliosis.[62]

Adolescent Idiopathic Scoliosis

As compared to EOS, adolescent idiopathic scoliosis (AIS) involves patients older than 10 years of age. AIS usually involves girls and with right-sided thoracic involvement instead of the opposite in early-onset idiopathic scoliosis. It is the most common pediatric spinal deformity, affecting 2% to 3% of children.[66] There is an adequate sampling for genetic studies (Table 8.3) as shown by more research in this area as compared to EOS. Original twin studies supported a genetic etiology in AIS.[48,67] Within AIS families, the disease characteristic may differ and may not affect every generation.

Similar to other spinal deformities, it is a complex trait that likely involves more than one gene.

In a further assessment of AIS family history, one study found that 97% of AIS patients have familial origins.[68] The genes that contribute to AIS are likely to exist with different types of expression and penetrance, which explains why some subjects have more florid phenotypes than others despite sharing a similar gene pool. This suggests that only up to 30% male and 50% female carriers of the disease variant develop more pronounced scoliosis.[69]

Based on family studies, linkage analysis and association studies are conducted to identify the disease susceptibility genes. Previous reviews on familial AIS genetics have been published[70,71] with identification of significant linkage regions specifically located on chromosomes 6, 10, and 18. Large family genetics showed the highest LOD score on chromosome 18.[72] This prompted further study into AIS families, which found a plethora of susceptibility areas in the genome that might give rise to scoliosis. Some found linkage areas with a LOD score of 3.63 on chromosome 19p13.3.[73] This region was verified in a subset of families with probands having Cobb angles of 30 degrees or greater.[74] Others reported the X chromosome with a maximum LOD score of 1.69[75] and specifically kyphoscoliosis to be associated with linkage at chromosomes 5 and 13.[76] Other positive findings were observed with marker D17S799 (LOD 3.20) in a three-generation Italian family,[77] and linkage at marker D9S2157 of chromosome 9q (LOD 3.64) and at marker AAT095 of chromosome 17q (LOD 4.08) in the British population.[78]

Overlap of genes associated with congenital abnormalities is also observed in AIS subjects. The *CHD7* gene has been found to be associated with CHARGE syndrome during gene mapping.[79] The *CHD7* gene is known to be expressed in undifferentiated neuroepithelium and in neural crest mesenchymal cells. It is found in the dorsal root ganglia, cranial nerves, auditory area, pituitary area, nasal tissues, and neural retina near the end of the first trimester. Gao et al.[80] identified an A to G SNP in intron 2 of the *CHD7* gene that disrupted a transcription factor binding site associated with late-onset idiopathic scoliosis. Resequencing of the *CHD7* gene verified potential functional polymorphisms that may disrupt this transcription factor binding site, suggesting an etiologic overlap between CHARGE syndrome and idiopathic scoliosis.[80]

Using genome-wide association studies, several genes have been identified as potential susceptibility genes. An allele of a microsatellite marker in the *MATN1* gene is overtransmitted from parents to affected probands, suggesting a link to familial idiopathic scoliosis.[81] Using a chicken pinealectomy model, melatonin deficiency is observed as a possible disease mechanism for AIS. The melatonin receptor 1B (*MTNR1B*) has also been identified as a possible candidate gene in a study on Chinese AIS subjects.[82] A "C-C" genotype with a promoter SNP (rs4753426) significantly increases the risk of AIS (OR, 1.29). These results, however, are not verified in Japanese and Hungarian cohorts.[83,84] The *Xbal* polymorphism of the gene encoding the estrogen receptor has been linked to curve severity.[85] Although this association is observed in a Chinese dataset,[86] this has not been replicated in other studies.[87]

Several contributing variants have been detected by linkage analysis. However, detecting disease genes related to AIS remains limited. Complex genetic disorders such as AIS are expected to be associated with multiple gene variants with only moderate effects of each. In view of this, linkage analysis may be limited in detection of all genes, and association studies may have better success.[88] In addition to larger sample sizes to obtain significant findings, identified disease genes require verification in other populations and ethnicities.

Using genome-wide association studies, several recent findings are worth mentioning. The SNPs (rs10510181) near the *CHL1* gene[89] and (rs11190870) near the *LBX1* gene[90] have been identified and replicated in the Chinese population.[91,92] Several Asian and non-Asian cohorts have also verified rs11190870 in a meta-analysis and yielded P values of 1.22×10^{-43} for both genders and 2.94×10^{-48} for females.[93] This is the first susceptibility locus for AIS that is replicated in several populations. A third significant SNP (rs6570507) has also been detected in a Japanese population to exist in the *GPR126* (encoding G protein–coupled receptor 126) gene, which has been replicated in Chinese and European cohorts.[94] These SNPs are suggested to have ORs of 1.2 to 1.4 for AIS susceptibility. These association studies are now the go-to method for identifying gene variants; further studies are expected to be generated in a similar manner.

Conclusions and the Future

This chapter is an introduction into the field of genetics. It acts as a basic guideline for clinicians to understand the genetic jargon and available evidence with regard to genetic susceptibility genes identified for disc degeneration and scoliosis. Numerous genetic studies have been carried out to locate susceptibility genes responsible for development of lumbar disc degeneration and scoliosis. As both are complex diseases, studies have identified multiple gene interactions as well as different risk patterns according to exposure to environmental factors such as aging and smoking for disc degeneration. With increasing demand and interest for higher-level genetic studies, the advancement of genotyping and sequencing technologies have followed suit, with the more complex and stronger association studies and exome-sequencing methods.

Due to these advances, better understanding of complex disorders is possible.[95] However, there are still significant limitations in our current understanding. Very few of the susceptible genes are replicated, and many of their functions are unknown. Before functional studies can be performed by testing gene knockout in animal models, larger sample sizes with cross-validation of different cohorts are necessary to have a more accurate evaluation of possible genetic variants to avoid testing incorrect and false-positive polymorphisms. Thus, multicenter and multiethnic genetic studies with international collaborations are inevitable to produce results of higher significance. To ensure standardization among research groups, phenotypes should be defined properly with good reliability of assessment. In addition to the study phenotypes, gene–gene and gene–environmental interactions must be

assessed and accounted for during analysis. This is a necessary process for all complex genetic diseases.

9 CHAPTER Twin Studies: Elucidating Genetic and Environmental Influences

Michele C. Battié
Jaakko Kaprio

For the latter half of the 20th century, problems with back pain and degenerative conditions were thought to be primarily a result of excessive loading and the cumulative effects of physical demands on the back. Thus, injury and "wear-and-tear" models were commonly used to explain degenerative conditions and back pain.[1] Accordingly, prevention focused on ergonomic interventions, education in proper lifting and other strategies aimed at decreasing daily loading of the spine, particularly through workplace safety and health initiatives.[2] However, over the past few decades, a dramatic shift has occurred away from this view such that degenerative conditions, such as disc degeneration and lumbar spinal stenosis, are now thought to be substantially driven by genetic factors.[3,4] While environmental factors are also important, exposure to heavy materials handling and other physical demands that were once believed to be the primary risk factors appear to have relatively modest effects overall. Twin studies have been major contributors to this shift in how common degenerative spinal conditions are viewed.

This chapter briefly reviews some of the highlights of what has been learned about common degenerative conditions through twin studies. Many examples come from the Twin Spine Study, a research program spanning more than 2 decades utilizing the Finnish Twin Cohort,[3] and projects utilizing the TwinsUK registry,[5] which have been long-standing contributors in the area. Chapter 8 focuses specifically on genotypes suspected of influencing risk of various common spinal disorders and the biologic mechanisms through which they may act. This chapter concentrates on the contribution of twin studies to elucidating overall genetic versus environmental influences.

Twin Studies

Many traits, conditions, and diseases run in families; therefore, family history is often assessed in the work-up of a patient. However, families share not only genes but also many aspects of the environment (here defined very broadly as all nongenetic influences, be they physical, chemical or microbiologic agents, lifestyle factors, or psychosocial influences). These nongenetic environmental influences are more important during the time that family members share a common household, that is, during childhood and adolescence, but these influences can be maintained either socially or even through epigenetic mechanisms. If we study nuclear families (parents and children), we can observe familial aggregation but cannot be confident in ascribing where it arises from—is it common genes, shared exposures and experiences, or both? Naturally, there may be opportunities to conduct experiments (in animal models) or even interventions/field trials in humans to resolve this, but for many putative causes of disease, such experimentation is not possible logistically or ethically.

One approach to provide more insight into the relative role of genetics versus environment is the study of twins. Two types of twinning exist. First, monozygotic (MZ; early division of the zygote into two individuals) twins share the same genomic sequence and hence are genetically identical, thus often called identical twins. However, external influences act in them in utero and postnatally; thus, they can be and are to some degree phenotypically different from one another. Dizygotic (DZ) twinning arises from the release and fertilization of two eggs. DZ twins are genetically full siblings and often called nonidentical, or fraternal, twins. Both twinning types result in a twin pregnancy with birth of the two individuals at the same time.

For more than 100 years, the realization of two types of twins has led to comparison of the similarity of MZ versus DZ twins to provide information about the contribution of genetic factors. If MZ and DZ twin pairs are overall more similar than two individuals chosen at random from the same population, this result, like those from other types of family studies, is evidence for familial aggregation and familial influences on the trait being studied. If there is no difference in the average similarity of MZ versus DZ cotwins, this speaks to primarily nongenetic family influences giving rise to familial resemblance and suggests the absence of genetic influences. If there are genetic influences, then MZ twins would be expected to resemble each other for the trait in question more than DZ twins, as MZ twins share the same genomic sequence and DZ twins share only 50% of their segregating genes, on average.

For a trait that is due to multiple genes, each of quite small effect, the similarity of MZ twins is expected to be twice that

of DZ twins. If assessed as correlations, the expected genetic correlation of MZ pairs is unity (1) and that of DZ twins is 0.5. This has been found to be the case for multiple traits, a prime example of this being height. Such effects are additive across all contributing loci and each risk allele contributes equally in both heterozygotes (i.e., carrying one risk allele) and homozygotes (carrying two risk alleles having twice the effect size compared to heterozygotes). This source of variation in the phenotype is known as additive genetic variance (A). Extensive reviews of twin study designs and modeling approaches are available elsewhere.[6,7]

Genetic effects may also be due to dominance, that is, the sum of all nonlinear effects of alleles at a locus, in which the heterozygote phenotype value deviates from the midvalue predicted from the two homozygotes. The genetic correlation reflecting dominance effects is unity in MZ but only 0.25 in DZ pairs; this gives rise to genetic variance due to dominance (D). Finally, there may be gene-gene interactions or epistasis affecting phenotypes.

Nongenetic variance in a trait is divided into that shared by the twin siblings, that is, those experiences and exposures that make them similar, termed environmental effects in common (C) and those that are not shared; that is, unique to each twin (E). These are distinguished by whether the effects of the experiences and exposures are shared and have equal effects on both twins, not by the actual environmental factor. Thus, if both twins exercise extensively and that has effects on back pain, for example, that will create common (C) effects on back pain, but if only one twin does so, this will result in a contribution to unique environmental effects (E).

Based on these expectations, it is possible to model data from MZ and DZ twin pairs, to derive estimates of the relative contribution of genetics, and thus estimate the heritability of a trait. The latter is defined as the proportion of total variance for a trait accounted for by genetic factors, typically additive (A), but sometimes the overall genetic variance A+D. Of note is that A effects are transmitted from one generation to the next, but D effects are not. The current statistical approaches to modeling permit evaluation of which models best account for the observed variance in a trait, providing the best statistical fit. Thus, we can evaluate which of several models fits the data when a single trait is looked at. The simplest model is unique environment only (E), thus rejecting all evidence for familial effects. As measurement error and random effects are part of E, E is included in all more complex models. An AE model would specify that the pattern of twin similarity in MZ and DZ models fits a polygenic additive model, with no shared environmental effects (C) and no genetic effects due to dominance (D). Alternative models CE, ACE, and ADE can also be specified and tested. By comparing the fit of two models, such as ACE and AE, one can decide whether shared environment (C) effects are statistically compelling. The broad sense heritability or overall genetic influences from both A and D will be primarily reported from the so-called "classic twin studies" included in this chapter.

The statistical models and software to run such models have developed greatly in the past 30 years. At present, many types of multivariate and longitudinal models based on twin data are possible. Multivariate models permit answering questions about the degree of shared genetic or environmental effects across related traits. Such an example is our analysis of the genetic correlation of back pain and MRI-assessed disc degeneration.[8] Likewise, the longitudinal stability and change of genetic effects can be assessed. In other words, are the same genetic effects present in disc degeneration when assessed 10 years later, as the participants have aged? While genes do not change in structure over time, their expression and activity do, resulting in possible novel genetic effects as people develop and age. Finally, these models permit assessment of gene-environment interactions, asking whether a known exposure modifies the impact of genetic variation. An example is the well-replicated finding that physical activity buffers the impact of genes on obesity; among sedentary persons, genes account for a much larger fraction of variance in body mass index (BMI) than among physically active persons. This observation from twin studies[9] has now been extensively corroborated using measured genotypes associated with BMI.[9a] These designs have not yet been extensively used in back pain studies.

All of the aforementioned models target primarily the estimation of familial aggregation and the contribution of genetic and shared environmental effects. There is a massive twin literature on this topic summarized in a recent review article.[10] Nearly all studied traits have some degree of genetic influence.

When studying the association of a putative risk factor or exposure on an outcome, such as back pain, the association may be causal, that is, implying that reducing the risk factor would lead to a reduction in back pain. Alternatively, it can be due to confounding. Measurement of known confounders and adjustment for them in statistical models has been the standard approach in observational epidemiology, be they cohort or case-control studies. However, not all confounders are known or measureable. Genetic factors underlying back pain, as shown by the studies in this chapter, may be shared with genetic effects on the risk factor. Thus, the association of smoking with disc degeneration may be causal (and there are plausible biologic explanations for that) or it may be accounted for by confounders, known and unknown. As smoking itself is, in part, heritable and genes for various aspects of smoking behavior have been identified,[11] there is potential for confounding due to shared genes.

Study designs that adjust for genetic variation made possible by the study of twins are exposure-discordant and matched case-control designs to study nongenetic effects. As MZ twins share the same genomic sequence, all differences between the twins arise from nongenetic causes. If we can identify twin pairs in which one smokes and the other does not (exposure discordant), then a test of the causal hypothesis of the association between smoking and back pain would be to study back pain in a sufficiently large number of such pairs discordant for smoking. If the MZ cotwins who are smokers have significantly more back pain than their cotwins who do not smoke, strong evidence would be provided to support a causal hypothesis. The design controls for genetic background and for sex and age effects as well as the exposures that both

twins have shared (such as numerous childhood and adolescent exposures from their common childhood home). Matched case-control designs have also been used for the study of environmental influences on back pain, selecting pairs in which one cotwin has back pain and the other is "pain free."

Critical Importance of Phenotype

It is the observable trait (e.g., lumbar spinal stenosis, disc narrowing, and chronic low back pain), referred to as the phenotype, that we are trying to better understand through whatever genetic or other research is being conducted. Thus, a clear, well-conceptualized case definition is critical, yet often neglected. Inadequate phenotype definitions or descriptions can lead to an incorrect interpretation of results and inability to replicate findings. This problem became very apparent when a simple literature search was performed to identify gene association studies of "disc disease."[29] Definitions of phenotypes under the rubric of "lumbar disc disease" varied greatly, ranging from "discogenic sciatica" with severe, unilateral pain radiating from the back to below the knee to a loss of disc signal observed on magnetic resonance imaging (MRI) regardless of back pain history. Phenotypes of "degenerative disc disease" also lacked consistency in the underlying concept, varying from observations of disc signal loss, narrowing or bulging irrespective of history of back symptoms, to a diagnosis of degenerative disc disease for chronic low back pain for which spine surgery was planned.[29] Such widely varying, disparate phenotype definitions reveal underdeveloped clinical concepts (e.g., degenerative disc disease) that are the root of much miscommunication and misunderstanding. This problem is receiving long overdue attention; there are several international groups currently working toward consensus of broad underlying concepts and associated phenotype definitions of prevalent spinal conditions to create a common language to move the field forward. Furthermore, agreement on phenotype definitions would greatly facilitate the search for associated gene variants, as very large subject samples are needed, typically requiring meta-analyses across studies to confidently identify associated genes.

Phenotype measurement accuracy and precision are also important in all studies, including twin studies, as inaccurate measurements dilute or mask true associations. A couple of examples of this come from twin studies. For example, with respect to smoking, when nicotine intake was of interest and the associated phenotype was defined as the reported number of cigarettes smoked per day, the most strongly associated single nucleotide polymorphism within a cluster of three nicotinic acetylcholine receptor genes accounted for only 1% of the variance in nicotine intake. However, the variance explained by the single nucleotide polymorphism increased nearly fivefold when the phenotype was defined using cotinine, a more accurate biomarker of nicotine intake.[12] Some discrepant findings related to the heritability of disc degeneration, as indicated by disc signal loss on MRI, may have their roots in a similar problem. When defined by a four-point qualitative score, disc signal loss was not found to be heritable in a classic twin study of English and Australian women.[13] However, when using a more precise quantitative, continuous MRI measure of disc signal, disc desiccation was found to be substantially heritable (30%–54%) in a classic twin study of Finnish men.[14]

Genetic Versus Environmental Influences on Lumbar Degenerative and Pathoanatomic Findings

Disc Degeneration

High suspicions of substantial genetic influences are often raised when traits are observed to be much more similar within family members than would be expected by chance. Such was the case for disc degeneration. While there had been a number of previous case reports documenting high degrees of similarity in disc degeneration within family members, it was two studies of independent samples of Finnish male monozygotic twins in 1995, one with 20 pairs and the other 116 pairs, which provided strong evidence of familial aggregation suggesting that disc degeneration may be much more genetically determined than previously thought (Fig. 9.1).[15] Not only were the lumbar spines of the cotwins morphologically similar, as might have been expected, they were also similar in terms of the degree, type, and location of qualitatively assessed degenerative findings (e.g., disc signal loss, narrowing, and bulging) on MRI. The suspicion that the similarities observed may have been largely due to genetic influences rather than shared environmental influences was heightened as exposures to the main suspected environmental risk factors explained very little of the variance in disc degeneration or the high degree of cotwin similarities.

Later, *heritability,* or the proportion of population variance in a trait or disease accounted for by interindividual genetic variation, was estimated for various disc degeneration phenotypes using a classic twin study design and genetic influences were confirmed to be high. In a classic twin study involving primarily English and Australian women (326 twin pairs) reported in 1999, Sambrook et al. found that approximately 75% of the variance in disc degeneration—defined as a summary score of disc signal loss, bulging, disc narrowing, and osteophyte formation—was explained by genetic influences.[13] A later study of a sample of 300 pairs of monozygotic and dizygotic adult male Finnish twins investigated genetic influences on disc signal, bulging, and narrowing and found less dramatic but substantial heritability estimates of 29% to 54% depending on the particular phenotype.[14]

Findings from the latter study also included multivariate analyses to examine shared genetic influences between traits. The findings suggested that disc signal, bulging, and narrowing have primarily shared genetic influences, with lumbar disc bulging and narrowing nearly fully sharing their genetic influences (genetic correlations >0.90). However, degenerative findings at upper and lower lumbar levels have important independent genetic effects. Thus, it may be wise to consider lumbar level when defining phenotypes for gene mapping of

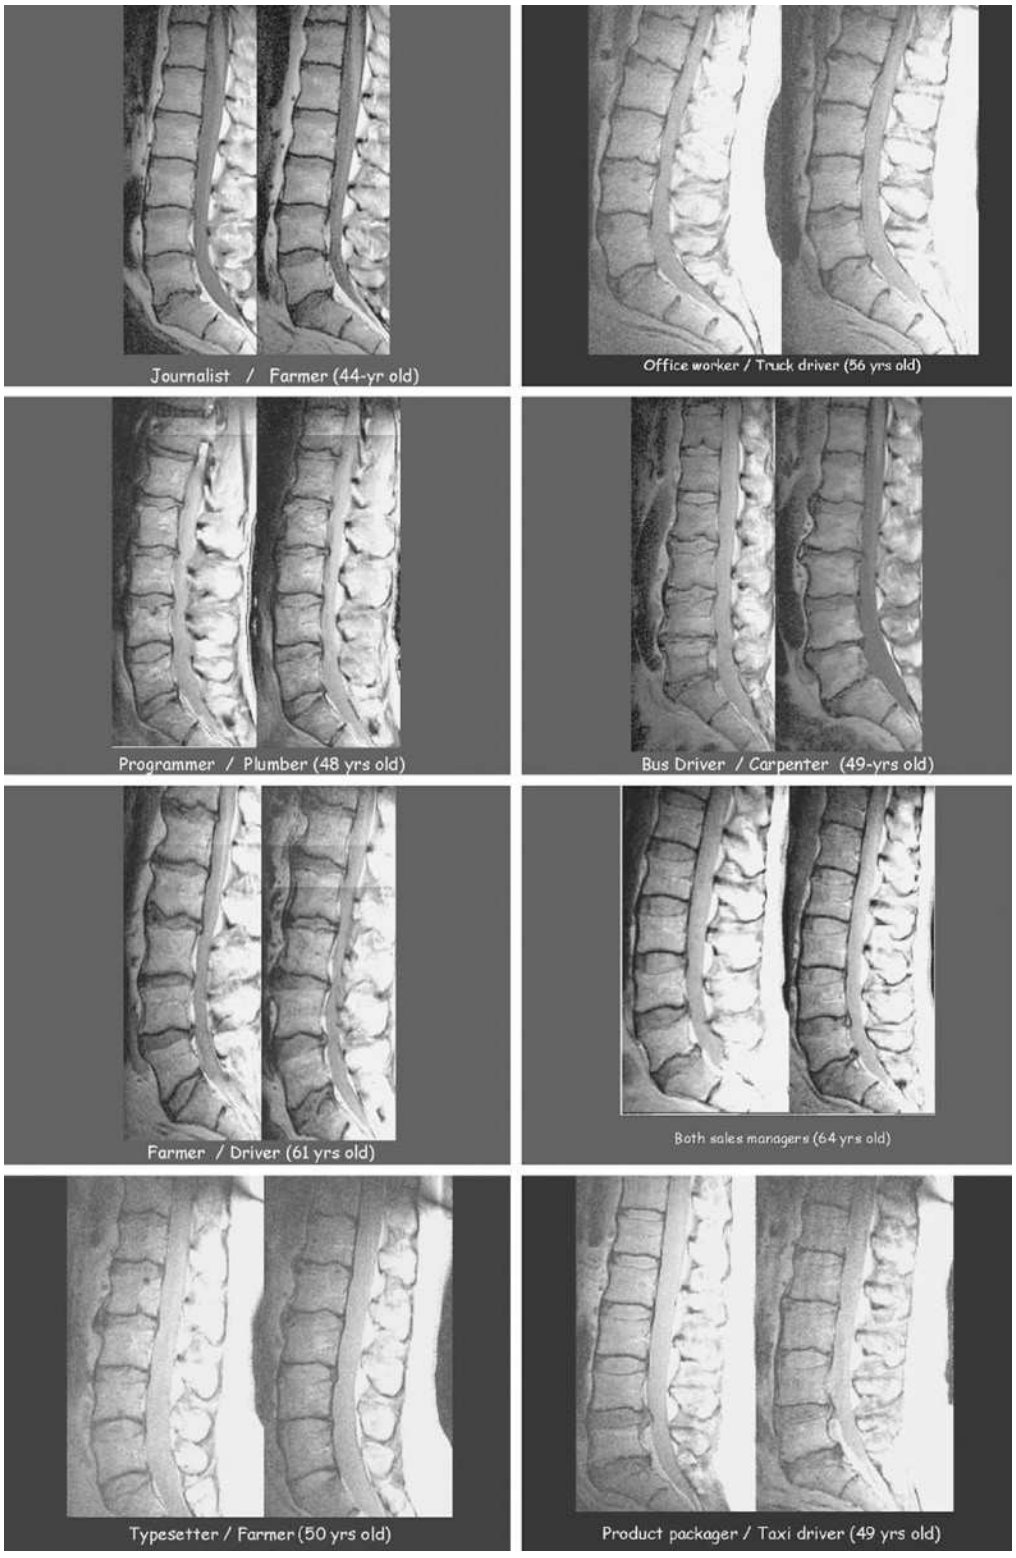

FIG. 9.1 A high degree of similarities in disc degeneration and endplate defects or irregularities was noted between twin siblings, often despite high discordance in lifetime occupational loading histories. (From Battié MC, Videman T, Kaprio J, et al. The Twin Spine Study: contributions to a changing view of disc degeneration. *Spine J.* 2009;9(1):47–59.)

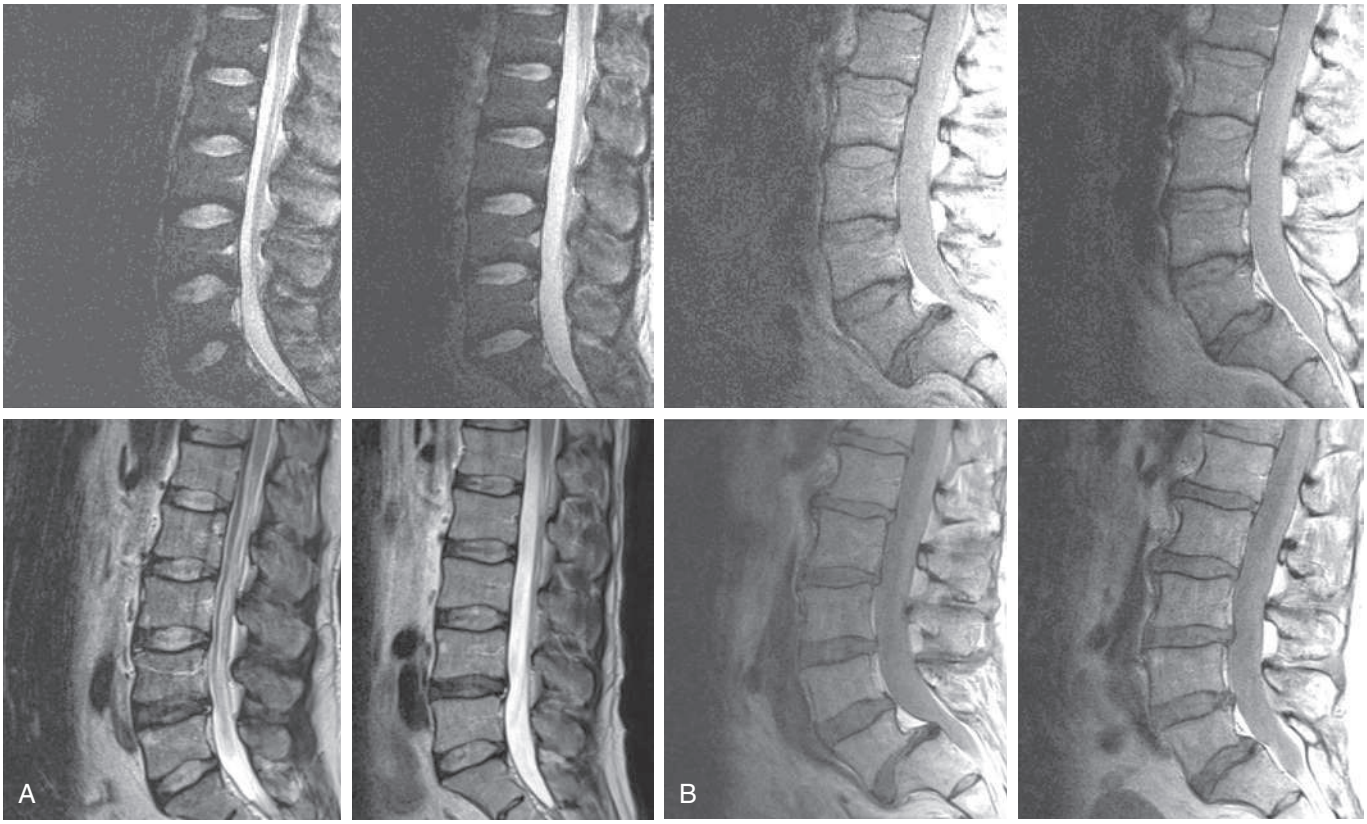

FIG. 9.2 (A) *Top,* Images from a pair of 51-year-old male monozygotic twins from the Twin Spine Study; *bottom,* images of the same pair 15 years later. (B) *Top,* Images from a pair of 36-year-old male monozygotic twins; *bottom*, images of the same pair 15 years later.

disc degeneration and related pathology or, at least, to consider upper and lower lumbar levels separately.[14]

Not surprisingly, as disc degeneration is substantially genetically determined when studied in cross-sectional studies, the rate or progression of degenerative findings (disc signal loss, bulging) assessed longitudinally has also demonstrated familial aggregation and genetic influences (Fig. 9.2).[16–18] Yet, it is interesting that familial aggregation explained 56% of the variance in progression of disc narrowing in 75 MZ male twin pairs,[16] whereas no heritability was found for the progression of disc narrowing in a classic twin study of 234 pairs of primarily female MZ and DZ twins.[18] The contrasting findings are curious, as it seems unlikely that the high degree of familial aggregation for disc narrowing found in the male MZ twins would be entirely explained by shared environmental influences. While heritability of progression is notable, the identification of stark variations in the development of degenerative and pathoanatomic findings between MZ cotwins may offer unique opportunities for exploration of possible environmental and behavioral influences.

When considering overall genetic influences, it should be kept in mind that heritability of a trait in a population is not necessarily static. For example, if important influential environmental and behavioral exposures change over time and explain more or less of the population variance in a trait, all else being equal, there will be inverse variations in the heritability of the trait. In addition, heritability of a trait may vary by gender and age. For example, findings from the previously mentioned twin study of disc degeneration progression in women suggested that genetic influences on progression of disc bulging were only clear under the age of 50 years.[18] While heritability is an important concept related to the overall magnitude of genetic versus environmental influences on a trait at the population level, it must be recognized that there is a highly complex interplay between genetic and environmental factors, as seen in epigenetics and gene expression, for example.

Beyond heritability estimates, classic twin studies with multivariate analyses have allowed the examination of shared genetic influences between phenotypes to test hypotheses regarding shared etiologies or possible pathways of genetic influences on clinical phenotypes. For example, a couple of studies have investigated disc degeneration as one pathway through which genes may influence back pain reporting.[19,20] Both studies identified shared genetic influences between disc degeneration and back pain phenotypes. In one study, significant genetic correlations were observed for disc degeneration (narrowing) and hospitalization due to back problems, duration of worst back pain episode, and presence of disabling back pain over the prior year, but only a minority of the genetic variance of the pain phenotypes examined was explained by genetic influences in common with disc degeneration.[20] Both studies found that while disc degeneration may be one pathway through which genes influence back pain

phenotypes, it would appear to account for only a small portion of genetic influences on back pain problems at the population level.

The role of disc degeneration in lumbar range of motion and lordosis has also been investigated in twin studies using multivariate analyses. Findings from the Finnish Twin Spine Study (300 male pairs) suggested that lumbar flexion was predominantly influenced by genetic factors (64%) and extension to a lesser extent (39%).[20] Following an earlier observation of an association between lesser lumbar range of motion and greater disc degeneration after adjusting for age,[21] correlations between the genetic components of the phenotypes were examined. The genetic correlations of lumbar extension and the disc degeneration phenotypes of disc bulging and disc narrowing demonstrated shared genetic influences ($r = -0.38$ to -0.43, respectively).[20] Thus, one pathway through which genetic influences appear to affect lumbar extension is through degenerative changes of the spinal motion segment as seen through disc bulging and narrowing, which explained approximately one-fifth of the genetic influences on lumbar extension.

Lumbar lordosis has also been shown to be largely genetically determined in a classic twin study of women from the TwinsUK registry, with a heritability estimate of 59% based on 123 twin pairs. While multivariate analyses were not conducted to look specifically at shared genetic influences between lordosis and disc degeneration, more disc degeneration—as indicated by a summary score of disc signal, bulging, narrowing, and anterior osteophytes—was found to be strongly associated with less lordosis.[22]

Modic Changes

Modic changes are signal variations at the endplate extending into the vertebral body as seen on MRI,[23] which have been associated with disc degeneration and back pain.[24,25] Modic changes are classified into three types. Type 1 is thought to reflect edema and is demonstrated by decreased signal on T1-weighted MR images and increased signal on T2-weighted images; type 2, fatty degeneration demonstrated by increased signal on both T1- and T2-weighted images; and type 3, endplate sclerosis with decreased signal on both T1- and T2-weighted images.

A twin study of mostly women from the TwinsUK registry suggests that Modic changes are primarily environmentally determined, with overall genetic influences on their presence estimated at 30%. However, as only T2-weighted images were available in the study, the presence of type 1 and type 2 Modic changes could not be differentiated.[24] Given that Modic changes are associated with disc degeneration, it could be informative to investigate shared genetic and other influences to gain insights into the causal pathways and mechanisms of these phenotypes.

The TwinsUK registry study also found that when both Modic changes and a summary disc degeneration variable—including disc signal, narrowing, and osteophytes—was considered in multivariable analysis, only disc degeneration remained in the model explaining "having ever experienced back pain disability lasting more than one day."[24] Yet our preliminary analyses utilizing the Twin Spine Study cohort as a population-based sample of Finnish men suggest that while correlated, both disc degeneration and Modic changes have modest independent contributions to explaining back pain depending on the back pain phenotype. More research is needed to understand the relationships of Modic changes, disc degeneration, and back pain, with careful attention given to the particular case definitions or phenotypes of each.

Schmorl's Nodes and Endplate Defects

Endplate defects have attracted attention recently as another possible condition or pathology underlying back pain. There appear to be several distinct endplate lesion or defect types, which vary in their association with back pain.[26,27] From visual inspection of the osseous endplates of a large cadaveric study, defects were categorized by Wang et al. as Schmorl's nodes, fractures, erosions, and calcification.[26,27] Unfortunately, challenges in adequately visualizing the endplate on MRI and other clinical imaging modalities create difficulties in both detecting and characterizing endplate defects, but this will likely improve as imaging technologies continue to develop. Presently, given prior and current limitations, endplate defects visualized on MRI are often lumped into the category of Schmorl's nodes.

In another study using the TwinsUK data from over 250 twin pairs, Schmorl's nodes were found to be common in middle-aged women and highly genetic, as indicated by a heritability estimate of 70%.[28] Furthermore, the endplate defects labeled as Schmorl's nodes were associated with disc degeneration and back pain. However, in multivariable analyses, once disc degeneration was in the model, no independent association of Schmorl's nodes with the back pain phenotype remained. Thus, the association of the endplate defects with back pain appeared to be through their association with disc degeneration. A clearer understanding of the interrelationship of endplate defects, disc degeneration, and back pain may require improved imaging and careful attention to the specific definitions of the imaging and pain phenotypes.

Lumbar Spinal Stenosis

Lumbar spinal stenosis is an increasingly common clinical syndrome responsible for chronic pain and disability in older adults. It is considered to be primarily a degenerative condition, but through an investigation of 299 twin pairs in the Finnish Twin Spine study, the pathoanatomic component was found to be *highly* genetic.[29] The heritability of lumbar spinal stenosis was estimated at 67% when assessed from the clinical perspective of an experienced spine surgeon using a standard qualitative rating scheme for MRI. When dural sac cross-sectional area was measured quantitatively across lumbar levels at the narrowest point at each disc, the heritability estimate was even higher (81%).

In the sample of Finnish male twins, spinal stenosis as measured at the narrowest point of the spinal canal at the disc level was explained from the best-fitting model by additive

and dominance genetic influences as well as unique environmental effects, whereas the mean anteroposterior diameter of the bony canal, as measured along the length of the vertebral body, had a particularly strong dominance genetic component, suggesting an influence of one or more major genes or important gene–gene interactions. If this is truly the case and is not due to chance fluctuation, there may be implications for the search for influential genes with substantial effects. However, even with a relatively large sample of 598 twins, the study was underpowered to definitively distinguish additive and dominance genetic effects simultaneously.

Disc degeneration as measured through disc bulging and stature as a measure of bone size and development were investigated as possible pathways through which genes may be influencing spinal stenosis. Remarkably, additive genetic influences on dural sac cross-sectional area (measured at the disc level) were fully shared with those of disc bulging, while dominance genetic influences were completely independent. This suggests the presence of a set of gene variants with effects that are additive to each other and usually small and another set of gene variants with specific effects that tend to interact with each other, creating larger effects. Consistent with earlier research (other than on achrondroplasia) revealing low correlations of bony lumbar vertebral canal size and vertebral body size or stature, skeletal size or development as depicted through standing height had no genetic association with dural sac cross-sectional area.[29]

Another interesting finding from the Finnish twin study was that the heritability across lumbar levels differed depending on the particular stenosis phenotype used. The genetic contribution to the variance in qualitatively assessed lumbar spinal stenosis differed significantly by lumbar level, being less at the lower than upper lumbar levels. Yet, heritability estimates were similarly high across all lumbar levels for dural sac cross-sectional area measured quantitatively. This difference in heritability by spinal level between the surgeon's qualitative assessments and the quantitative measurements suggest that the spine surgeon's assessments may be taking other factors into account in determining stenosis beyond dural sac cross-sectional area, which are more affected by environmental influences in the lower than upper lumbar levels.

While a narrow canal, either central or foraminal, is an essential aspect of the clinical diagnosis of spinal stenosis, findings on imaging are generally poorly correlated with symptoms and disability. Thus, it cannot be assumed that the heritability estimates for the pathoanatomic aspects of spinal stenosis will generalize to the clinical syndrome. Furthermore, there are likely to be mediators (e.g., neurovascular or inflammatory factors) that cause symptoms to manifest in the presence of a narrow canal, which may have their own sets of genetic and environmental influences.

Genetic Versus Environmental Influences on Back Pain

Back pain phenotypes, while very important, present many research challenges. Among them are the subjective nature of reported back pain, measuring symptoms that are often transient and of varying intensity when present, and inaccurate recall. Furthermore, there are no universally accepted case definitions for back pain that have been consistently used across twin and other studies, making it difficult to compare study results and conduct meta-analyses.

Despite the challenges, there have been approximately a dozen twin studies of the heritability of back pain, defined in a variety of ways, coming primarily from developed countries of Northern Europe and Scandinavia.[19,20,30–37] Several years ago Nielsen et al.[38] conducted a review of twin studies of pain, which investigated back and neck pain separately from other pain conditions. While they found widely varying heritability estimates ranging from 0% to 68%, when studies of children and the elderly were excluded, estimates were less disparate in the remaining studies of adults. The related meta-analysis of back pain studies yielded an overall heritability estimate of 34% (95% confidence interval, 30–39%). There was also a tendency noted for greater heritability for case definitions involving more severe back pain problems.[20,34]

In the aforementioned review, widespread pain and the diagnosis of fibromyalgia, which often includes back pain, had a somewhat higher heritability estimate of around 50% based on available studies.[38] Concordant with a higher genetic influence on widespread pain compared to single-site musculoskeletal pain, a Swedish twin study found a higher heritability estimate for concurrent back and neck pain (60%) than for either when present alone (24–30%).[35] However, there have been conflicting findings. Heritability estimates for neck, thoracic, and lumbar pain experienced separately or altogether were similar (32–39%) in a large sample (>15,000) of Danish twins, with lower estimates for various combinations of pain affecting any two spinal regions.[32]

Pain comorbidity is common in cases of back pain problems and raises questions about shared genetic or environmental influences, which can be investigated through twin studies. A few studies from the TwinsUK registry have investigated shared genetic influences between back pain and pain at other musculoskeletal sites and chronic widespread pain.[37,39] Both studies, using different analytic approaches, supported substantial shared genetic influences between the pain phenotypes. The authors reported that 39% of the variance in chronic widespread pain and 70% of the variance in low back pain interfering with daily activities due to genetic influences was attributable to shared genetic effects and that roughly 40% and 67% of the residual variation was caused by shared environmental influences affecting both pain syndromes.[39] Moderate to high genetic correlations for pain in different spinal regions (neck, thoracic, and lumbar) have also been found in a large Danish twin study (>15,000).[32] The possibility of largely shared influential gene variants, as well as environmental factors, between back pain and musculoskeletal pain at various body sites and chronic widespread pain has important implications. Such findings may point to systemic pain mediators (e.g., inflammatory and neurologic) or differences in pain processing, rather than purely local factors (e.g., disc degeneration) driving pain, which could inform the search for important causal factors and mechanisms that are

needed to develop more effective preventive and therapeutic interventions.

Specific Environmental and Behavioral Influences on Disc Degeneration and Back Pain

Exposure-Discordant Twin Studies of Disc Degeneration

When twin studies were first used in the early 1990s to study the etiology of common spinal conditions, the main suspected risk factors for disc degeneration, pathology, and so-called degenerative disc disease were heavy physical loading (typically occupational), exposure to motorized vehicles and associated whole-body vibration, and cigarette smoking. Effects of height, weight, and genetics were unclear.[40] However, there was much conflicting evidence and uncertainty related to whether or not these factors did indeed affect the disc, as there were concerns about inadequate control of potentially confounding factors in the available epidemiologic literature. This motivated a series of studies using exposure-discordant MZ twins selected from the Finnish Twin Cohort to examine each of the suspected factors.[3] As discussed earlier in this chapter, well-designed, exposure-discordant MZ twin studies provide an exceptionally high degree of control of confounding factors, particularly since genetic influences on disc degeneration are substantial.

The first study of this type related to spinal conditions was of the effects of long-term cigarette smoking on disc degeneration (disc signal, bulging, and narrowing).[41] Findings from the study of 20 MZ twin pairs with an average smoking discordance of 32 pack-years revealed greater disc degeneration in smokers as compared to their nonsmoking cotwins. Also, the difference was present across spinal levels, supporting a mechanism acting systemically. While degeneration was clearly higher in smoking than nonsmoking cotwins (mean, 18%), smoking only explained 2% of the variance in disc degeneration in the study sample. In addition to providing evidence of smoking effects, the study demonstrated the efficiency of the exposure-discordant twin study design in investigating environmental and behavioral influences on spinal conditions of multifactorial etiology.

Subsequently, the same design has been used to study the effects of driving and associated whole-body vibration,[42] heavy physical workload,[3] excessive body weight,[43] recalled trauma or injury to the back,[44] and various types of exercise on disc degeneration in men.[45] The studies of heavy physical loading were remarkable in that despite extreme, long-term contrasts in physical workload between cotwins, related differences between cotwins in disc degeneration (e.g., signal, bulging, narrowing) were modest or equivocal. This was also the case for cotwins who had maintained highly discordant body weight[43] or were discordant in recalled history of back trauma or injury.[44] In 12 twin pairs, in which cotwins had an average contrast of 2300 versus 200 hours of weightlifting exercise, there was only slightly more degeneration seen in the mid- to lower thoracic region in the weightlifters as compared to their MZ cotwins. A difference was not observed in the lumbar region.[45] These findings suggest that routinely performed heavy occupational and leisure physical activities have a relatively minor effect on disc degeneration. Finally, our study of 45 pairs of MZ twins grossly discordant for exposure to driving and associated whole-body vibration revealed no tendency for greater disc degeneration in the drivers, even when considering a range of phenotypes of lumbar degeneration.[42] Collectively, the studies provided strong evidence raising doubts about whether the main previously suspected environmental risk factors were really important causative factors in disc degeneration.

Cohort and Matched Case-Control Studies of Back Pain

There have been several exposure-discordant twin studies of various back pain phenotypes embedded in larger twin cohort studies of back pain, such as an investigation of incident low back pain in 1387 elderly Danes, including 86 pairs that were discordant for occasional strenuous activity at baseline.[46] The more active elderly twins had significantly lower risk of developing low back pain of both shorter and longer duration over the following 2 years. We will likely see many more twin studies of back pain using similar combined study designs, as in just the past year combined cohort and case-control designs have been reported investigating the effects of educational attainment,[47] obesity and body fat distribution,[48] and depression.[49]

Summary

Twin studies have been major contributors to the shift away from the long-standing injury or wear-and-tear model of degenerative spinal conditions, in which exposure to heavy occupational and other physical loading factors were viewed as the major determinants. Following consistent evidence from so-called "classic" twin studies, it is now recognized that spinal function, degenerative conditions, pathology, and pain have important genetic influences. As a result, twin studies have been transformative in changing the research agenda for common spinal disorders.

Furthermore, a combination of cohort, exposure-discordant, and matched case-control twin studies are helping elucidate the effects of suspected environmental factors and have persuasively demonstrated that some factors once thought to have major effects on spinal degeneration (e.g., routine, heavy physical loading) have much more modest influences. Yet, environmental factors are clearly important, particularly for back pain phenotypes, although the specific factors with major effects remain elusive. Twin studies examining gene–environment interactions, which have not yet been widely utilized in degenerative and other spinal conditions, may shed light on such factors and the complex interplay between genetic and environmental factors that surely exists. Finally, much more attention needs to be given to phenotype definition to enhance the success of future twin and other studies of common spinal disorders.

CHAPTER 10

Outcomes Research for Spinal Disorders

SECTION I

James N. Weinstein

Need for Outcomes Research

Outcomes research can be defined simply as "the measurement of the value of a particular course of therapy."[1] It is based on the principle that every clinical intervention produces a change in the health status of a patient that can be measured. The motivation for outcomes research varies depending on one's perspective, but all parties involved in health care have a vested interest in defining outcomes related to medical interventions. Health care providers have a responsibility to provide the highest level of care to their patients, which can be done only if the best treatment for a given condition has been determined through research. Patients need to be well informed about their prognosis, treatment options, and expected outcomes associated with each treatment option so that they can make an appropriate decision with their physician. Private and government payers have the right to demand evidence that the interventions for which they are paying yield improvement in the health of the patients they cover.

The United States has the highest gross domestic product (GDP) in the world and spends a higher proportion of its GDP on health care than any other country in the world, with little evidence to suggest that the level of public health is better than other developed countries.[2,3] Wennberg and Gittelsohn[4] developed the method of small area analysis in which variations in practice patterns, spending, and outcomes could be compared across hospital referral regions. They showed markedly different rates of hospital use between Boston, Massachusetts, and New Haven, Connecticut, for conditions without defined treatment protocols such as back pain, with no discernible differences in outcomes.[5] Using the technique of small area analysis, Fisher and colleagues[6,7] studied the relationship between Medicare expenditures and outcomes in hospital referral regions across the United States, and found no relationship between the level of health care spending and outcomes. The substantial geographic variation in rates of lumbar surgery in the Medicare population was documented by Weinstein and colleagues (Fig. 10.1).[8] These studies have shown that practice patterns vary substantially across different regions, indicating that the "best" practice for many conditions is unknown. The wide variation in the rates of health care use suggests that many regions are not practicing in the optimal zone of use, resulting in "unwarranted" variation due to either "supply-sensitive," "preference-sensitive," or "effective" care, indicating that health services are likely underused in some regions and overused in others.[9–13]

In the past, health care providers have assumed that increased use of health care services was associated with higher-quality outcomes, a relationship that is shown by the upward-sloping portion of the curve shown in Fig. 10.2. Economists have theorized, however, that eventually this curve flattens out such that additional expenditures yield increasingly fewer benefits until there is no marginal benefit (law of diminishing marginal returns).[14] Although it has not been explicitly shown, it is possible that the curve eventually starts sloping downward, indicating that outcomes worsen with increasing use. Such a phenomenon could occur if patients were being inappropriately selected for treatment from which they were unlikely to benefit, but might still experience treatment side effects. The Maine Lumbar Spine Study suggested that such a down-sloping portion of the curve might exist, as outcomes for lumbar intervertebral disc herniation and spinal stenosis were worst in the regions where the rates of surgery were the greatest.[15,16]

Given the wide variation in practice across all of medicine, and spine surgery in particular, policymakers have demanded that the research community perform outcome studies to determine the best practices for treating various conditions. In 2007, a Medicare Evidence Development and Coverage Advisory Committee (MedCAC) questioned the role of fusion for degenerative lumbar conditions in patients older than 65 years and suggested that Medicare could discontinue reimbursement for the procedure unless it could be shown to be effective.[17] In response, Glassman and colleagues[18] analyzed their results of lumbar fusion in this population and found that older patients had equivalent or better outcomes compared with younger patients. Although it is unclear how these data will be acted on, the MedCAC study and response to it

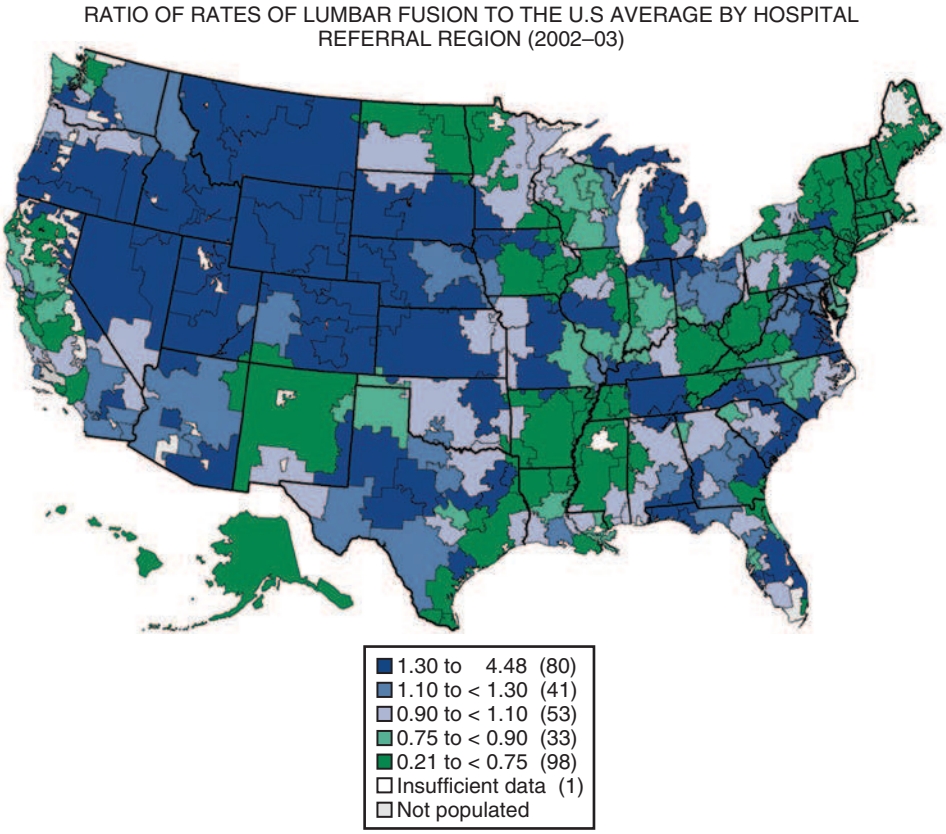

FIG. 10.1 Rates of lumbar fusion in hospital referral regions across the United States in 2002–2003, normalized to average rate. (From Weinstein JN, Lurie JD, Olson PR, et al. United States' trends and regional variations in lumbar spine surgery: 1992–2003. *Spine.* 2006;31:2707–2714.)

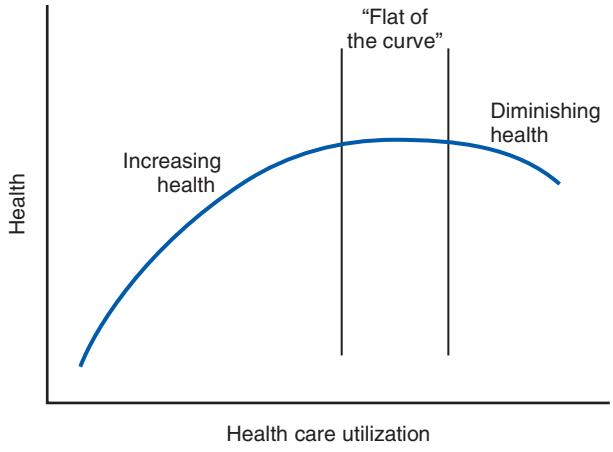

FIG. 10.2 Theoretical relationship between health and resource use. At low levels of use, health increases with use. As use increases, the marginal return decreases until there is no marginal return ("flat of the curve"). In some cases, increasing use could lead to further worse health outcomes.

provide an example of how researchers can respond effectively to policymakers who are looking for evidence to justify health care expenditures. As part of the 2009 economic stimulus package and, more recently, the Affordable Care Act, more than 1 billion dollars has been allocated for comparative-effectiveness health research, suggesting that outcomes and cost-effectiveness research are likely to play an increasingly important role in guiding health policy. This chapter introduces the spine surgeon to some methods of outcomes research, including outcomes measurement, study design, and cost-effectiveness analysis.

Measuring Outcomes in Spinal Disorders

One of the first principles of science is that something must be measured, and a cornerstone of outcomes research is that any change in health status is measurable. Measuring subjective qualities such as pain and function, two important outcomes in patients with spinal disorders, can be quite challenging, however. In the classic literature, outcomes were often physiologic (e.g., motor function), radiographic (e.g., fusion), or subjectively defined by the treating physician (e.g., "poor," "fair," or "good").[19,20] Over the last 30 years, clinical studies have adopted patient-based outcome measures. Outcome measures can be classified as global measures of health (SF-36 Health Survey,[21] EuroQoL[22] Sickness Impact Profile [SIP],[23] and Patient Reported Outcomes Measurement Information System [PROMIS])[24,25] or condition-specific measures (Oswestry Disability Index [ODI],[26] Roland-Morris Disability Questionnaire [RDQ]).[27] High-quality outcome measures need to be practical, precise (reliable), accurate (valid), and responsive.[28]

Practical surveys are of an acceptable length and include easily answered questions so that patients are willing and able to complete them. *Precision*, or reliability, refers to the reproducibility of a survey—will a patient in the same state of health score the same on the outcome measure on different occasions? *Validity* is the ability of the survey to measure the quality that it aims to measure. Assessing the validity of a tool often requires multiple approaches. The score on a new instrument can be compared with a "gold standard" outcome measure to assess its convergent validity. Additionally, the ability of the measure to discriminate between patients in different health states can be evaluated to determine its discriminate validity. Ironically, "face" validity, the concept that the instrument appears to be measuring what it is designed to measure, is fundamental to instrument development and often the weakest form of validity evidence. This is especially true when the group that designed the instrument is evaluating its face validity. Responsive outcome measures are able to detect health status changes in an individual patient before and after successful treatment of low back pain.

In the medical literature, it is commonly held that many of the well-known generic and back-specific outcome measures have been shown to be practical, precise, valid, and responsive, and thus can be considered "validated" outcome measures.[29] From a psychometric perspective, much of this evidence is post-hoc, however, meaning that the instrument's validity is based on its use in a study in which the results showed that one group improved more than another by some statistically significant amount. By this logic, the fact that the tool "worked" (i.e., allowed for a statistically significant difference to be observed) is taken as de facto evidence that (1) the tool is practical because the patients completed it, (2) the tool is reliable because a significant difference between groups was observed, (3) the tool is valid because the goal of the instrument is to document the magnitude of an outcome that was expected to be different for the various treatment groups, and (4) the tool is responsive because the difference in outcomes was detectable. Subsequent studies use these same tools, often for different populations, justifying their use because the instrument has been "validated" in a previous study.

The Spine Patient Outcomes Research Trial (SPORT) intervertebral discs herniation (IDH) study serves as a good example to examine the selection of outcome measures. The primary outcome measures were the SF-36 bodily pain and physical function scales and the ODI (American Academy of Orthopaedic Surgeons MODEMS version). Secondary outcome measures included work status, satisfaction, and the Sciatica Bothersomeness Index.[30] The distinction between the primary and secondary outcome measures was that the study was powered to detect a prespecified difference in the primary outcome measures (i.e., a 10-point difference on the SF-36 scales or ODI), whereas the secondary outcome measures did not factor into the power analysis. As has been recommended, SPORT included a generic (SF-36) and condition-specific (ODI) primary outcome measure.[31] Given the extensive use of the SF-36, ODI, and RDQ in the spine literature, we examine these questionnaires in greater detail.

The SF-36 is among the most commonly used generic health questionnaires, and has been extensively validated across many medical conditions.[32] It consists of 36 questions and can be completed in less than 10 minutes. Responses are scored on eight nonoverlapping scales (physical functioning, role–physical, bodily pain, general health, vitality, social functioning, role–emotional, and mental health), which are summarized as a physical and mental component summary score. All scales range from 0 to 100 (lower scores represent worse symptoms), with the component summary scores transformed to have means of 50 and standard deviations of 10. In looking at the specific scales used in SPORT, the physical function scale is based on ratings of activity limitation (e.g., carrying groceries, climbing stairs, walking), and the bodily pain scale is based on two questions about the severity of pain and the degree to which pain interferes with work. At baseline, the patients in the SPORT IDH randomized controlled trial (RCT) had a mean baseline physical function score of 39.4 (age-adjusted and sex-adjusted norm of 89) and bodily pain score of 26.9 (age-adjusted and sex-adjusted norm of 81), suggesting that they were markedly affected by their disc herniation.

PROMIS is a psychometrically validated, dynamic survey that utilizes patient responses to questions to produce quantitative values to ascertain a patient's state of well-being or suffering.[24,25,33,34] PROMIS aims to improve the quality and precision of measurement of patient-reported outcomes through the utilization of item response theory.[35,36] Item response theory (IRT) is a psychometric method commonly used in education testing. It has recently been expanded to health outcomes research. IRT is fundamentally based on statistical models, which produce calibrations associated with answers to specific questions.[35,36] These calibrations are then processed through computer software in order to select the most informative follow-up question to an initial question, allowing the content of the survey to adapt to the patient's responses to previous questions.[35,36] The PROMIS initiative began in 2004; through continued support from the National Institutes of Health, it has now developed three major instrument types—short forms, profiles, and computer adaptive tests (CATs)—measuring physical, mental, and social health, which have been used across a variety of chronic conditions.[24,25,33,34,37] Short forms are a fixed set of items administered in its entirety. These metrics usually include 4 to 10 items per domain. For instance, the Physical Functioning item bank is comprised of 124 items and has a 10-item short form comprised of a subset of those items. These 10-item short forms have become increasingly popular in the literature for a wide variety of chronic conditions.[37] Recently, Hung et al.[38] reviewed the psychometric properties of the PROMIS Physical item bank and noted that the survey adequately addressed outcomes of patients with spinal disorders with excellent reliability, minimal ceiling/floor effect, and limited item bias. All PROMIS instruments utilize a T-score, for which the mean is 50 and the standard deviation is 10. For most domains, the mean of 50 references the United States general population. In all cases, a high score reflects more of a domain. For instance, a higher score on a physical functioning measure indicates better physical

functioning and thus better health, whereas a higher score in fatigue indicates greater fatigue and, likely, poorer health. In utilizing the T-score metric, the PROMIS-10 physical function short form and the PROMIS-13 CAT fatigue short form were found to have greater precision across a broader range of the respective domains than the SF-36.[39–42] Thus, although still a relatively new entrant, utilization of PROMIS metrics is becoming more popular in the research community and will likely become increasingly common in the spine literature.

The ODI was designed specifically for use in a back pain clinic. It asks one question about the intensity of pain and nine questions about the degree to which pain limits specific activities (i.e., lifting, walking, traveling). Scores can range from 0 to 100, with higher scores indicating more severe disability. The mean score among "normals" is about 10, with mean scores in the 30s for patients with neurogenic claudication and 40s for patients with metastatic disease.[43] In the SPORT IDH RCT, the average baseline ODI score was 46.9, indicating substantial pain-related disability.[44] The ODI has been extensively validated and used in the spine literature, and has been recommended to be used as a back pain–specific questionnaire (the RDQ is the other outcome measure recommended for this purpose).[43]

The RDQ is a 24-item survey developed from the 136-item SIP, with the phrase "because of my back" added to the end of the SIP statements to focus the survey on back-related problems.[27,43] The questions focus primarily on function and pain, with only one question asking about the psychological effects of back pain and none inquiring about social function. Each question is a statement about the effect of back pain on function on the day the survey is taken (i.e., walking, bending, sitting, lying down, dressing, sleeping, self-care), with which the respondent must agree or disagree. The number of positive responses is the score (0–24), with median scores of 11 in a population with back pain presenting to a primary care clinic.[45] The RDQ has been shown to be valid and responsive, although reproducibility has been difficult to show because it refers to symptoms only over a 24-hour period. In comparing the RDQ and the ODI, it has been suggested that the RDQ may be better able to detect changes in function in patients with a mild to moderate degree of disability, whereas the ODI may be better suited to patients with a more severe degree of disability.[43]

Experts have recommended using global health and back-specific outcomes questionnaires.[46] The SF-36 or EuroQoL are recommended for measuring global health in spine patients, whereas the ODI or RDQ are the recommended back-specific instruments. In addition to these formal outcome measures, measuring work status and overall satisfaction with treatment is recommended.

Importance of Study Design in Outcomes Research

The goal of any outcomes research study is to measure results from a study sample and extrapolate those results to understand health outcomes in the real world. The results of research studies are highly dependent on the details of study design, however. Reviewing three RCTs comparing lumbar fusion with nonoperative treatment for chronic low back pain reveals one study that showed a clear advantage for surgery,[47] one that showed only a minor benefit to surgery,[47] and one that reported no benefit for surgery.[48] How can three RCTs asking the same essential question come to three contradictory conclusions? The answer may reflect differences in research methods and details of study design. In designing or evaluating a research study, one must consider the research question, the target population and study sample, the interventions being compared, the outcome measures employed, and the specific study design.

A well-posed research question is the foundation of the entire research project. No elaborate study methodology, new data collection technique, or statistical expertise can make up for a poorly chosen research question. For this reason, sufficient time and energy should be devoted to developing, critically evaluating, and refining the research question. In evaluating the results of a study, one must determine what question was really answered because it may be different than what was suggested by the authors.

When the research question has been specified, the next step is to define the target population and study sample. The *target population* is the group of people to whom the results of the study should be generalizable, whereas the *study sample* is the group of patients actually available for study.[49] The target population is defined by the inclusion and exclusion criteria. There is an inherent struggle between having inclusion and exclusion criteria that are very restrictive yet provide a homogeneous study population (i.e., 34-year-old women with left-sided posterolateral L4–L5 disc extrusions and extensor hallucis longus weakness) and criteria that are less restrictive and yield a more diverse study population (i.e., anyone with a disk herniation). More restrictive studies can specifically evaluate the effect of treatment on specific patient subgroups, whereas less restrictive studies are inherently more generalizable. Defining subgroups that have different outcomes is important to determine the best treatment for individual patients, although it is not usually possible to perform separate trials for each subgroup.[50] Understanding the actual target population is essential to interpreting and acting on the findings of a study.

Most clinical studies evaluate the effect of an intervention on an outcome.[51] Similar to the study participants and outcome measures, the intervention also needs to be clearly defined. The intervention for the control or comparative group also needs to be specified. Differences in the experimental and control interventions may explain some of the differences among the aforementioned studies comparing fusion with nonoperative treatment for the treatment of chronic low back pain. Fritzell and colleagues[47] compared three types of fusion techniques with nonspecific physical therapy and showed a clear benefit to fusion. In contrast, Brox and colleagues[48] compared instrumented posterolateral fusion with a very specific program of cognitive therapy and 3 weeks of intensive physical therapy, and reported no differences in results. These two studies did not compare the same interventions, which may be one reason for the discrepant results.

The specific study design used by a research project can have profound effects on the interpretation of the results. Each study design has inherent advantages and disadvantages that must be weighed when planning an investigation. Although the RCT is considered the gold standard of clinical research designs, it is often the case that mounting an RCT before the preliminary case series, case-control, and cohort studies have been performed would be counterproductive. The high cost in terms of researcher and clinical time often greatly outweighs the results obtained from a poorly planned RCT. Before launching a large RCT, observational pilot studies should be performed to generate hypotheses and reveal challenges (e.g., adequate assessment, compliance with treatment, treatment harms and side effects) that are difficult to anticipate. A unique aspect of the study design of SPORT was its concurrent use of an RCT and observational cohort study that allowed patients to choose enrollment in the randomized or observational arms.[52]

Understanding Threats to Study Validity

In general, threats to study validity have been classified as internal and external (Table 10.1). *Internal validity* is related to the validity of the conclusions of a study within the study sample—was the observed difference between the treatment groups real? *External validity* refers to whether the findings of the study can be generalized to populations and settings outside of the study sample—would the difference observed in the trial be observed in the real world?

Clinical studies generally aim to determine if a specific intervention results in a certain outcome. Although a study may show an association between an intervention and an outcome, this association may be spurious (i.e., the association exists in the study but not in the real world), or the association may not represent a cause-effect relationship (i.e., the intervention was associated with but was not the cause of the observed outcome). The two main causes of spurious associations are chance (random measurement errors) and bias.[53] Confounding is another threat to validity that can obscure the cause-effect relationship between the intervention and outcome being studied. Different types of study designs are prone to different types of inferential errors, which are discussed in detail when each study design is considered.

TABLE 10.1 Internal and External Validity Threats

Internal Validity Threats	External Validity Threats
History: Specific events occurring between first and second assessment in addition to experimental variable	Selection bias: To the extent that patients presenting at study sites are not representative of patients in general
Maturation: Processes within patient operating as a function of time (e.g., favorable natural history)	Reactive or interactive effects: Screening process (informed consent, extra attention, additional procedures to identify inclusion/exclusion criteria) is not done with nonstudy patients
Testing: Effects that testing itself has on subsequent scores	Reactive effects of experimental procedures: Just being in a study may affect patient responses
Instrumentation: Changes in obtained measurements owing to changes in instrument calibration, observers, or raters	Multiple treatment effects: When treatments have multiple components (i.e., surgery, postsurgical rehabilitation) or when patient has multiple treatments (e.g., nonoperative treatment followed by surgery), possible effects of former treatment on latter may influence efficacy
Statistical regression: Lack of reliability in tools, which is especially problematic when patients are selected on basis of extreme scores	
Selection: Biases resulting from differential selection of patients into treatment arms	
Patient attrition: Differential loss of patients from treatment groups (e.g., loss to follow-up, crossover)	
Interactions of above effects: Interactions among above variables may have effects that are mistakenly attributed to treatment	

Chance

When an association is observed between an intervention and an outcome, it is possible that this observation is due to chance rather than to the intervention causing the outcome. Fritzell and colleagues[47] reported that fusion for chronic back pain reduced ODI scores by 11 points, whereas nonoperative treatment resulted in only a 2-point decrease. Although surgery effectiveness may have been responsible for the difference, it is also possible that surgery had no beneficial effect and that the observed differences were due to chance alone. Statistical tests are used to evaluate the possibility that an observed relationship between an intervention and outcome was due to chance. In the case of the study by Fritzell and colleagues,[47] statistical testing showed a statistically significant difference ($P = .015$), indicating that the association between surgery and symptom improvement was probably real. Details about the theories underlying probability testing are beyond the scope of this chapter, and can be found in standard biostatistics textbooks.[54]

Bias

Bias is the other major cause of spurious associations. Bias has been defined as "the non-random-systematic error in the design or conduct of a study."[51] Although numerous types of biases have been identified, most bias is related to patient selection, treatment, attrition, and outcome detection. If the patients enrolled in a study differ from the target population, an association observed in the study may not exist in the target population. If the patients who enrolled in the SPORT IDH RCT had less severe symptoms than the target population, the

benefit of surgery could be underestimated if the treatment effect is less among this group. Performance bias exists when patients are treated differently in ways other than the intervention being studied, with a "cointervention" being the true driver of the association. If patients undergoing discectomy were more likely to be treated with long-term narcotics postoperatively, the association observed between surgery and outcome could actually be due to narcotics.

Attrition bias results when patients drop out of a study in a nonrandom manner that is associated with the group assignment. If patients who failed nonoperative treatment dropped out of the study to receive surgical treatment elsewhere, the outcomes for the nonoperative patients remaining in the study would be spuriously inflated. Bias in outcome detection can occur if outcome assessors are nonsystematic in their evaluation of patients and tend to change their procedures depending on the assigned treatment. Generally, if the outcomes assessor is not blinded to the treatment received, the assessor is liable to be biased (consciously or not) in his or her assessment. Similarly, patients who are not blinded to their treatment may also be biased in self-reported outcomes.

Bias tends to be insidious; investigators should attempt to prevent it in the planning stages and detect it during the analysis. Efforts should be made to ensure that the patients enrolling in the study are similar to the target population to eliminate selection bias. Blinding can eliminate many forms of bias related to treatment and outcomes assessment because patients cannot be treated or assessed differently if the patient and the assessor are unaware of the treatment assignment. Blinding (shams) can often be difficult, however, or potentially unethical in surgical studies.[55] The best way to combat attrition bias is to limit attrition through aggressive efforts to ensure follow-up. After a study has been completed, the authors should consider the role that bias could have played in their findings and address these limitations transparently.

Confounding

Confounders are variables that are associated with the exposure (i.e., the intervention) and affect the outcome (Fig. 10.3). If patients undergoing discectomy are less likely to be depressed than patients undergoing nonoperative treatment, and depression is associated with worse outcomes, the relationship between treatment and outcome is confounded by depression.

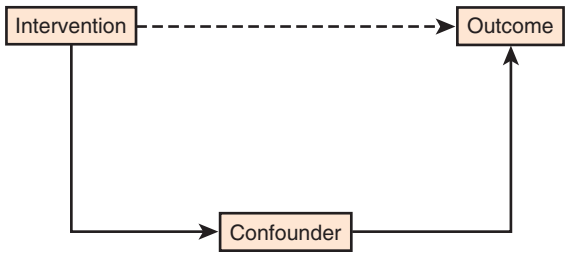

FIG. 10.3 Relationship between intervention, outcome, and a confounder. Although there may be an association between the intervention and the outcome, there may be a third variable, or confounder, that is associated with the intervention but is the actual cause of the outcome observed.

Although the association between better outcomes with surgery is real (i.e., greater than would be expected by chance) in this case, the true cause of the difference may be the better psychological state of the surgical patients rather than the surgery itself. The only way to eliminate confounding is to ensure that the treatment groups are equivalent. True equivalence is never achievable, however, given the vast number of potential differences in patients. The best method to minimize group differences is to randomize in the case of clinical trials, or use methods such as specification or matching in the case of observational studies.

Depending on the nature of the particular study, randomization might be simple (i.e., each subject has an equal chance of being placed in any of the available treatments) or stratified on specific variables of interest given the context of the problem. It is common to stratify patients by gender and age group, ensuring that the various treatment groups are "reasonably" equivalent with respect to these factors before randomly assigning these subgroups to treatment. Randomization does not ensure equivalence for any given finite sample, however. With small samples (≤20), randomization often can fail to produce reasonably equivalent groups. If an investigator randomizes 20 patients, 10 males (M) and 10 females (F), and defines a "fair" split of males to females as 6M4F, 5M5F, or 4M6F, this result is likely to occur 82.1% of the time. More extreme splits occur 17.9% of the time. Thus, with smaller sample sizes, stratified randomization should be considered. Confounding can be a major threat to the validity of observational studies. Strategies to eliminate confounding in observational studies can be used in either the design or the analysis phase; however, potential confounders must be anticipated and measured to be addressed.[53] Specification and matching are techniques that can be used when designing the study. *Specification* involves stipulating a certain level of the confounder as an inclusion criterion. In an observational study comparing discectomy with nonoperative treatment, the investigator could specify that only patients without depression be included to eliminate depression as a potential confounder. The disadvantage of this strategy would be that the results would apply only to patients without depression. Attempting to use this strategy for many confounders would soon become quite limiting. *Matching* is another technique that is often used in case-control studies, in which a control is found for each case that is matched on numerous potential confounders. Although this approach can eliminate the effects of confounding, it also makes it impossible to evaluate the association between potential confounders and the outcome. In addition, matching can be difficult and require a large sample of potential controls to match successfully on many variables.

Analytic techniques are used more commonly than design techniques to address potential confounding. The most straightforward approach is a stratified analysis with a stratum defined for each level of confounder. If many confounders and their interactions are being considered, the individual strata soon contain too few subjects, however, to make meaningful estimates. The most common statistical method used to control for potential confounders is adjustment using multiple

regression. The details of multiple regression analysis and analysis of covariance are beyond the scope of this chapter; readers should consult a standard biostatistics textbook for further information.[54]

Randomized Controlled Trials

The gold standard for evaluating the effect of an intervention on an outcome is the prospective, double-blinded RCT. Most providers are familiar with the basic design of an RCT: a group of patients that have met selection criteria are randomly assigned to either the intervention or the control treatment and followed prospectively to compare outcomes between the two groups (Fig. 10.4). The main advantage to an RCT is that successful randomization minimizes baseline differences between the two groups. To the extent that randomization is successful, the potential for confounding by either measured or unmeasured variables is reduced. As mentioned previously, successful blinding of study participants and investigators should eliminate the effects of observer, detection, and performance biases. The double-blinded RCT is the design that most convincingly shows the cause-effect relationship between an intervention and an outcome because it provides the best defenses against confounding and bias.

RCTs can have substantial limitations and disadvantages. They tend to be prospective studies with large sample sizes, and can be very expensive and time-consuming to perform. By design, they usually address only one primary research question. The generalizability of the study can be limited if the patients who are willing to be randomly assigned are markedly different from the target population. The effects of potentially harmful exposures cannot easily be studied ethically using an experimental design, although some trials involving cessation of exposures presumed to be harmful may be possible. Studies of certain interventions, especially surgery, are difficult to blind, and RCTs that are not blinded are subject to observer, detection, and performance biases. Prospective trials in which definitive treatment is not performed at the time of randomization are potentially subject to crossover between treatment groups.

To maintain the benefits of randomization, results should be analyzed using an intention-to-treat (ITT) analysis. An ITT analysis compares the outcomes between the groups based on the treatment assigned rather than actual treatment received. Patients who cross over are analyzed as part of their assigned treatment group despite receiving the alternate treatment. Crossover typically results in an underestimation of the treatment effect of the intervention. Researchers studying treatments in which crossover is likely, such as surgical versus nonoperative care in patients with back pain, are encouraged to develop recruitment, consent, and treatment procedures to minimize crossover, within the obvious constraint that patients ultimately have the right to change their course of treatment. Finally, RCTs are also subject to attrition bias if patients are lost to follow-up.

To illustrate how these principles affect the interpretation of an RCT, we consider how these issues apply to the SPORT IDH RCT. Data from this study revealed that there were no significant differences between the surgery and nonoperative groups at baseline on more than 25 variables, suggesting that randomization was effective.[44] Given that patients were randomly assigned to either surgery or nonoperative treatment, blinding was considered inappropriate because it would have required a sham surgery with significant risks.[52,53] As such, the possibility of treatment and detection bias must be considered. Greater than 80% of patients in both groups completed the 1-year follow-up, although follow-up decreased to around 75% in both groups at 2 years. The role of attrition bias should be considered for the 2-year data.

The most striking aspect of the SPORT IDH RCT was the high rate of crossover between the treatment groups in both directions, attributable to the elective nature of the procedure and the generous period allowed per protocol for receiving assigned surgery. In the first 2 years of follow-up, 40% of patients assigned to surgery did not have surgery, and 45% of patients assigned to nonoperative treatment did have surgery.[44] As a result, the surgery and nonoperative groups ended up receiving nearly the same treatment, and the ITT analysis revealed no significant differences on the primary outcome measures. Given the high rate of crossover, the ITT analysis alone does not allow strong conclusions to be made based on the RCT.

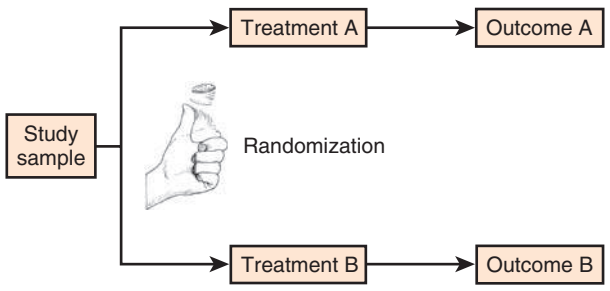

FIG. 10.4 Basic design of randomized controlled trial. Study sample is randomized to different treatments, and outcomes are prospectively determined.

Observational Cohort Studies

The key difference between randomized and observational studies is that the determination of treatment is not randomized in the case of observational studies. Thus, in an observational study evaluating an intervention, the patient and physician determine the patient's treatment. The study groups are defined by the presence or absence of an exposure or intervention, and the outcomes are compared (Fig. 10.5). Cohort studies can be prospective or retrospective, but the group assignment is determined by the presence or absence of the exposure in both cases. The main advantage of a cohort study is that the temporal relationship between exposure and outcome is known, making it unlikely that the outcome was actually the cause of the exposure (this is known as "effect-cause"). This type of study may also have better generalizability to the target population because the patient treatment is

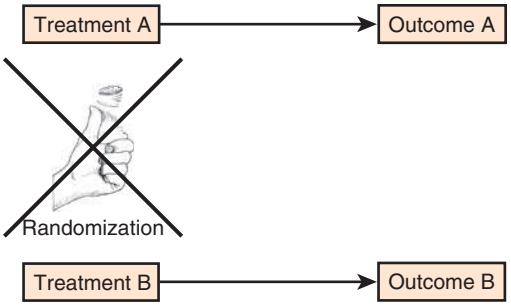

FIG. 10.5 Basic design of observational cohort study. Treatment is chosen by patient and physician rather than through randomization. Study groups are defined by treatment, and outcomes are compared. Cohort studies can be prospective or retrospective.

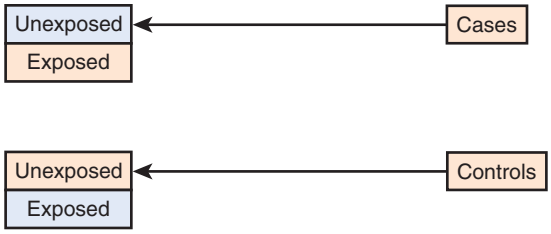

FIG. 10.6 Basic design of case-control study. Study groups are determined by outcomes; patients with a particular outcome are cases, whereas patients without the outcome are controls. This study design looks retrospectively to determine if there is a difference in rate of exposure to a particular variable between cases and controls.

determined in the same manner as for a nonstudy patient. Prospective observational cohort studies are also a very powerful design when randomization is impossible or unethical (i.e., studying a harmful exposure).

Observational studies have many potential disadvantages. Because randomization and blinding are impossible in an observational design, confounding and bias must be taken into account. The two groups being compared often have important baseline differences, some of which can be responsible for confounding. Confounding can be addressed through design-phase and analysis-phase techniques, both of which have been discussed previously. The lack of blinding makes treatment and detection bias possible, and these issues are much more difficult to address. Blinding is often impossible in RCTs comparing surgery with nonoperative treatment, however; thus, the RCT does not always offer an advantage in this regard. Prospective cohort studies tend to require large numbers of patients and can take many years to perform. On the other hand, retrospective cohort studies tend to be much less resource intensive, but evaluation of the exposures and outcomes is limited by what was recorded in the medical record.

Comparison of the SPORT IDH RCT[44] and observational cohort study[56] helps to illustrate the differences in the two study designs. Whereas the ITT analysis of the RCT showed no significant differences between the surgery and nonoperative groups on the primary outcome measures at 2 years, the observational study (and the as-treated analysis of the RCT) showed clinically and statistically significant advantages for surgery on all outcome measures. How should these differences be interpreted? Longitudinal regression was used in the observational analysis to account for potential confounding and attrition related to the baseline variables that were measured. Such an analysis cannot control for potential confounding by unmeasured variables, however. Baseline differences on unmeasured variables could act as confounders and be responsible for some of the differences observed between the surgery and nonoperative groups. Similar to the RCT, the lack of blinding in the observational study limits the control of observer/performance biases. Attrition rates were lower in the observational cohort than the RCT (<20% for both groups at 2 years); thus, the potential for attrition bias is less. Given these considerations, are the results of the observational study valid?

In 2000, Benson and Hartz[57] compared findings between modern randomized and observational studies on various medical questions and found that the results were similar for most studies. In the two instances in which there were different findings between the study designs, the RCTs reported a greater treatment effect than the observational studies. These findings strongly support the validity of well-designed observational studies. Although confounding by unmeasured variables and bias may have resulted in some overstatement or understatement of the treatment effect of surgery for IDH in SPORT, with the numerous potential confounders measured and used to adjust the analysis and the strong effects observed, it seems likely that there was a benefit to surgery.

Case-Control Studies

The case-control study is another commonly used observational design, although it has not been used frequently in the spine literature. In this study design, the groups are defined by their outcomes, and the rates of exposure are compared between the two groups (Fig. 10.6). Typically, cases are identified, a matching control group is assembled, and the rates of exposure to the risk factor of interest are compared between the two groups. The main advantage of a case-control study is its ability to assess risk factors for a rare outcome with a relatively small group of cases in a retrospective fashion. Additionally, the retrospective approach and the ability to examine a large number of predictor variables also makes case-control studies useful for hypothesis generation.

There are many potential pitfalls with case-control studies, however, with sampling and recall bias being the two most difficult to overcome.[58] *Sampling bias* results when the cases and controls are not drawn from the same population. This can be controlled through the use of clinic-based or hospital-based controls, population-based samples of cases and controls (i.e., through disease registries), through the use of two or more control groups, or through the technique of matching, as discussed previously. *Recall bias* can also result when cases are more likely to report exposure to the risk factor of interest, based on their knowledge of the outcome. Recall bias can be minimized through the use of data recorded prior to the onset of the outcome or through the use of blinding.

An interesting feature of case-control studies includes their ability to be "nested" within a defined cohort. This is referred to as a nested case-control or nested case-cohort design. Here, the cohort has typically been assembled for another purpose and, as such, has previously stored images, specimens, and other data, or has been assembled de novo to answer the research question. The investigator would typically measure the outcome variable in this cohort to distinguish cases from controls, and then measure the predictor variables in the banked specimens and images. This allows for comparison of risk factors in the cases and controls. The main advantage of this subtype of case-control study design is that it is especially useful for minimizing costly measurements on serum and other specimens (since these will only have to be conducted on all the cases and a sample of the controls, instead of the entire cohort). Additionally, this design also preserves the advantages of cohort studies that result from collecting predictor variables prior to the occurrence of the outcome.

Although case-control studies have rarely been used in the spine literature, a hypothetical example would be the comparison of the rate of exposure to nonsteroidal antiinflammatory drugs (NSAIDs) between patients with a lumbar pseudarthrosis (the cases) and patients with a successful fusion (controls). This approach might prove useful in evaluating the hypothesis that NSAID use might affect the likelihood of successful fusion. Sampling bias (e.g., differential rates of smoking, diabetes, and other risk factors for nonunion between the cases and controls) and recall bias (patients with pseudarthroses might be more likely to report exposure to NSAIDs) would have to be taken into account.

Case Series

Case series are reports of outcomes for patients undergoing a treatment without any control group. The spine literature is replete with this type of study. No inferential conclusions can be made from case series because there is no control group with which to compare outcomes. Case series should be based on a consecutive series of patients to avoid selection bias in which the investigator includes only patients with desirable outcomes. These studies are useful for hypothesis generating or reporting outcomes on rare conditions. They should not be used to develop treatment guidelines because they lack a control group and do not allow for the assessment of effectiveness of a treatment.

Levels of Evidence

Investigators have created a hierarchy of study designs based on the quality of causal inference that one can make with each study design (Fig. 10.7). Well-controlled RCTs and meta-analyses of such studies are at the pinnacle of the hierarchy. These studies have been labeled level I evidence.[59] Observational cohort studies or RCTs with methodologic shortcomings are level II evidence. Case-control studies are considered level III evidence. Descriptive studies such as case series and case reports are level IV evidence. Expert opinion is considered level V evidence. As shown by the SPORT IDH RCT, all questions are not best answered with a randomized design. In addition, when modern observational studies are compared with RCTs, it has been shown that they do not usually overstate the treatment effect of an intervention.[57,60] Whereas the hierarchy of evidence is useful for comparing study designs in general, the merits of each individual study should be assessed, and high-quality, observational studies should not be discounted.

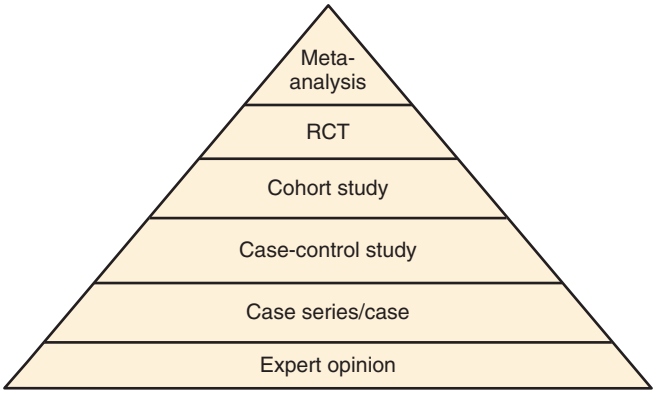

FIG. 10.7 Hierarchy of research designs in evidence-based medicine.

Cost-Effectiveness Analysis

Given the ever-increasing costs of health care, policymakers have recommended that medical interventions be evaluated for their cost-effectiveness.[61] Cost-effectiveness analysis aims to determine the cost to society for the incremental health benefit derived from an intervention that is more costly than an alternative, less effective treatment. Although an RCT can show the efficacy of a treatment, further economic analysis can be performed alongside the RCT to evaluate how much society must pay for the treatment effect. To compare the cost-effectiveness of a wide variety of treatments across many medical specialties, a universal scale of health must be used to measure preference for health outcomes. In cost-effectiveness analysis, the *quality-adjusted life-year* (QALY), which combines length and quality of life in a single number, is the recommended measure of health benefit.

To estimate QALYs, a *utility*, which is a numeric preference rating of health ranging from 0 (equivalent to death) to 1 (perfect health) is used to value the health states associated with a treatment. Classically, utilities have been derived using techniques such as the time trade-off, which essentially determines how much time in a state of suboptimal health people would be willing to trade for a lesser amount of time in perfect health.[61] More recently, techniques have been developed to determine utilities based on standard questionnaires such as the SF-36.[62] QALYs are determined by multiplying utility for each health state by the length of time in each health state and summing up over time. For example, 2 years spent in a poor health state with a utility of 0.5 followed by 10 years in a good

health state with a utility of 0.8 would be equivalent to 9 QALYs ($2 \times 0.5 + 10 \times 0.8$). To compare the benefits of various interventions, cost-effectiveness analysis determines the gain in QALYs associated with an intervention. The advantage of QALYs is that they allow for the comparison of very different health states across medical disciplines.

The other half of the cost-effectiveness equation is cost. Although an intervention typically produces a health benefit, that benefit comes at a cost to society. Determining the cost of an intervention is challenging; thus, many cost-effectiveness analyses use gross costing based on average reimbursements for various procedures. After determining the costs and benefits associated with an intervention, these must be compared with another treatment. This is done by determining the *incremental cost-effectiveness ratio* (ICER). The ICER is defined as the difference in cost between two treatments divided by the difference in utility. Tosteson and colleagues[63] reported that discectomy resulted in a gain of 0.21 QALYs compared with nonoperative treatment at an additional cost of $14,137, which yielded an ICER of $67,319/QALY ($14,137/0.21 QALY). Traditionally, an ICER of $50,000/QALY has been used as a cost-effectiveness threshold because this was the ICER for hemodialysis, an intervention for which society has decided to pay.[64] More recently, some authors have suggested that $100,000/QALY is a more realistic cost-effectiveness threshold because many frequently used interventions fall in the $50,000 to $100,000/QALY range.[63,65,66]

Theoretically, cost-effectiveness analysis should allow societies to maximize the value of their health care expenditures; the United Kingdom has set ICER thresholds to determine which services should be provided by their National Health Service.[67] There is little evidence, however, that health care systems, including systems that currently ration care, have been consistently using cost-effectiveness analysis to guide rational treatment guidelines.[68] As health care spending comes under greater scrutiny and decisions regarding which treatments to provide are made, evaluating the cost-effectiveness of an intervention will be essential.

Future of Outcomes Research: Patient-Specific Recommendations

Since the prior edition of this textbook, the quality of spine outcomes research has improved markedly alongside a more sophisticated understanding of the issues surrounding outcomes research within the spine community. A study of spine-related clinical trials published in 2007 reported that 60% were performed and reported in an acceptable fashion, a result that is better than seen in a general orthopaedic journal.[69] Although this percentage is likely an improvement from years prior, there is further work to be done on the quality of the spine literature. The 4-year and 8-year outcome data from the SPORT IDH study, the largest scale outcomes research study ever performed in the field of spinal disorders, have been published more recently.[70,71] Although this and most large-scale trials are able to determine the treatment effect of an intervention for the "average" patient, it can be difficult to apply the results to clinical practice, in which no patient is "average."

In the case of IDH, there are clearly patients who fail surgical treatment and others who are very successful with nonoperative treatment. Blind application of the results of SPORT to all patients who met the inclusion criteria (symptoms lasting at least 6 weeks, the presence of neurologic findings, and imaging consistent with their symptoms) would result in surgery for all such patients. Although this approach would result in greater clinical improvement than nonoperative treatment, on average, surgery would be performed on some patients who would have improved to an acceptable, and even to a greater, degree with nonoperative treatment. Other patients would fail to improve with surgery and perhaps experience an additional decrease in their quality of life.

To avoid unnecessary surgery on these two groups of patients, models that take individual characteristics and values into account when predicting outcomes are needed. When sufficiently powerful models are developed, individual baseline characteristics, physical findings, and results from imaging studies can be entered into such models to determine the likelihood of success with surgery or nonoperative treatment. Individual patient values should also be considered in defining success and assigning utilities to the various possible outcomes. Such an approach represents the true integration of evidence-based medicine with shared decision making at the level of the individual patient and should be the next step in spine outcomes research.

KEY POINTS

1. With constantly increasing health care costs, policymakers are demanding outcomes research to show the effectiveness of treatments, especially in fields that require expensive technology, such as spine surgery.
2. There is substantial geographic variation in the rates of spine surgery across the United States, indicating that further research is needed to determine which patients are served best with surgery.
3. Chance, bias, and confounding all threaten the validity of conclusions based on clinical research and need to be addressed in study design and data analysis.
4. RCTs can yield the highest level of evidence, although many surgical questions are not amenable to this type of study design. In these cases, well-designed observational studies may be more appropriate.
5. Cost-effectiveness analysis will become more important as decisions need to be made about the use of scarce health care resources.

Introduction

Computational and numeric methods have been used to assess the biomechanical behaviors of biologic systems. The advent and continuous development of powerful computing systems in addition to improvement of the emerging computational packages in computer-aided engineering (CAE) with enhanced modeling features have enabled scientists to develop more rigorous models of biologic systems to predict the behavior of these systems under different biologic conditions. In orthopaedic biomechanics, the latest advances in medical imaging technologies have helped researchers obtain a better resolution of geometric and anthropometric specifications of individual organs in the human body, including micro-scale computational models of the knee, hip, spine, and bone itself.

In addition to ethical considerations, the practical difficulties, restrictions, and cost involved in experimental in vitro and in vivo studies highlight the utility of computational models as complementary tools for studies in orthopaedic biomechanics.

The future challenge will be how to apply these approaches to those areas of science that are not yet considered and how to further improve present generation models to better simulate the couplings and nonlinearities that occur in physical incidents.

One of the most applicable approaches used in biomechanical studies is finite element analysis (FEA), in which the object or system is represented by a geometrically similar model consisting of multiple linked representations of discrete regions. The basic idea for the finite element (FE) method originated from advances made in aircraft structural analysis in the 1940s. Since then, the FE method has become a powerful tool for the numeric solution to a wide range of engineering problems. In this method of analysis, a complex region defining a continuum is broken into simple geometric shapes called finite elements. Material properties and governing relationships are assigned to the elements. With the advances in computational power and computer-aided drawing (CAD) systems, complex problems can now be solved with relative ease. Specialized FE method software—such as Abaqus (Simulia), ANSYS, COMSOL Multiphysics, and others—provides linear, nonlinear, static, and dynamic solutions to many industrial problems.

In general, FEA includes three main steps: preprocessing, analysis, and postprocessing. Preprocessing is the first step in FEA, in which an FE model of the structure is created. Most FEA packages require a topological description of the structure's geometric features as input, which can be in one-, two-, or three-dimensional (3D) form, representing line, surface, or structural elements, respectively. However, 3D models are used in most cases. Design files, CAD models, and preexisting digital scans can be imported into an FEA environment to be utilized for an FEA. Once the FE geometric model is developed, a meshing procedure is used to define and divide the model into small discrete elements. An FE model is defined by creation of a mesh network, which includes the geometric arrangement of elements and nodes. When the FE model is created, the material properties are assigned to the individual parts, and proper interactions and constraints are defined between interacting part and surfaces. Finally, the boundary conditions and loads are assigned to the model.

The next step is analysis, which solves the model to converge for solutions within the predefined boundary, load conditions, and constraints. To better simulate the physical conditions of the problem, different types of analysis, such as static or dynamic (time-dependent) simulation, can be considered. In static simulation, the inputs and outputs are independent of time and the system is solved to balance the load and boundary conditions. In dynamic simulation, time can affect the input and output parameters and the behavior of the model varies over the time. Examples of dynamic simulations are dynamic loading, impact, and long-term creep (or wear).

Once the simulation is finished, postprocessing of the data can be performed using visualization tools. The analysis outputs can be in the form of nodal outputs, including

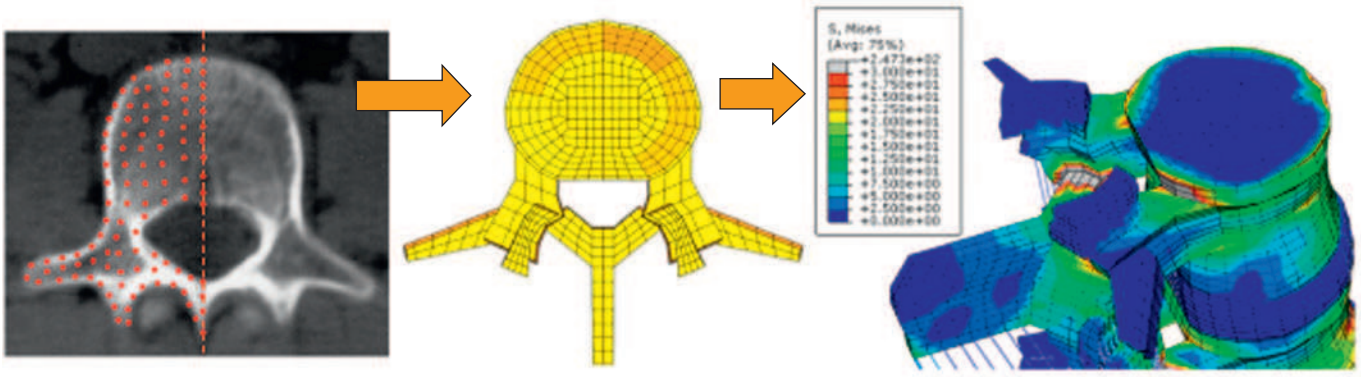

FIG. 11.1 Steps of creating the finite element (FE) model of spine. The computed tomographic images are used to develop a grid at each transverse plane. The coordinates of the nodes are imported to the FE package, and the elements are created. The material properties are defined for individual elements; the loads, boundary conditions, and constraints are defined as the last step in modeling. The model is run and various FE outputs, such as stresses and nodal displacements, are calculated for sections of interest.

displacement at each node and element outputs, such as stresses and strains (Fig. 11.1).

Finite Element Modeling of the Spine

Low Back Pain

The human spine is a complex structure that supports the upper trunk weight and external loads applied to the human body. The spine column also protects the delicate spinal cord and provides adequate flexibility and stiffness to perform various daily activities. The stability of the ligamentous spine is significantly reduced in vivo due to absence of muscles.[1]

Low back pain (LBP) is one of the common musculoskeletal disorders that affects the functionality of the spine. While there are many causes of back pain, the most prevalent causes are muscle strain, degenerative disc disease, spinal stenosis, disc herniation, facet hypertrophy, isthmic spondylolisthesis, degenerative spondylolisthesis, or (rarely) a spinal tumor.

In the United States, LBP is one of the major reasons for disability for people younger than 45 years. More than 80% of Americans suffer from LBP at some point in life. According to an estimate, LBP costs between $100 and $200 billion annually, two-thirds of which is a result of decreased wages and productivity.[1] Thus, there is a need to study the origin of pain associated with the lumbar spine and search for simple, cost-effective, and safe treatment options. While there are a number of avenues that researchers are pursing in this direction, the role of mechanical factors in back disorders is significant. Thus, it is prudent to undertake biomechanical studies of the spine in various conditions: intact-normal, degenerated, surgery, and then "stabilization" of some sort. These issues have been investigated using cadaver models, animal models, and numeric tools. This chapter focuses on the application of numeric approaches in understanding the biomechanics of the human spine, especially the analyses of spinal implants.

The human spine is composed of highly specific tissues and structures, which together provide an extensive range of motion (ROM) and considerable load-carrying capacity.

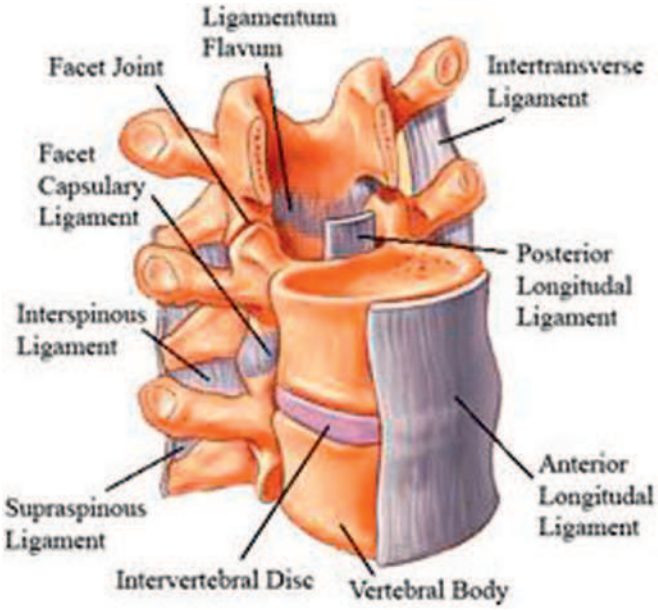

FIG. 11.2 A motion segment in the lumbar spine.

Alteration of the form of these structures with increasing age, injury, or any other reason can have a profound influence on the quality of life. Low back pain is generally associated with degenerative changes occurring in the spine. Mechanical property changes resulting from degeneration are likely contributors to lumbar spine instability that may lead to other pathologies. This instability may be accelerated by injuries or deformities.[2] Vertebral body degeneration and ligament degeneration are degenerative diseases that can occur with age.[3] The intervertebral disc and two facet joints form a three-joint complex and share the majority of the load on the spine.[4] Due to this, degenerative changes of the spine can be initiated as disc degeneration or facet joint osteoarthritis.[5]

In a spine segment (Fig. 11.2), the intervertebral disc and facet joints are the main load-bearing structures in the spine, and thus are most susceptible to mechanical wear and tear. Back pain arising from degenerative disease could be

discogenic or may be directly due to diseased facet joints. The advanced stage of disc degeneration or facet degeneration may call for replacement surgery to achieve spinal stability and symptom relief. Disc arthroplasty and facet joint replacement technologies aim to restore the normal kinematics of the spine by acting as load-bearing devices.[5] Surgery for these devices is highly invasive. Replacing either the disc or the facet joint would be considered a partial joint replacement. As load-bearing structures, there is also a possibility of wear of the device, leading to osteolysis. There is a lack of literature on the kinematic effect of these replacement technologies on the remaining structures of motion segments.

Many cadaveric and experimental studies have been formulated to compare the biomechanical behavior of the intact spine versus the injured or implanted spine. Motion across the segments as well as disc pressure measurements and facet loads have been quantified. However, there are many factors that come into play, such as specimen variability and errors involved in experimental testing. In addition, prototyping of many implants at once is not physically easy. Currently, mathematical models are being widely used to quantify forces and moments acting on the lumbar spine during various activities in life. They can be used to quantify stresses at any area and thus point to the area where a fracture might occur. Almost all results seen in experimental testing can be quantified by mathematical modeling. Hence, the use of a mathematical method such as the FE method is justified for the study of the lumbar spine.

Because of the difficulty in analyzing the spine as a whole, it has been divided into a number of regions (e.g., cervical, thoracic, lumbar), and each area has been analyzed separately in different studies. For example, numerous studies of the lumbar spine have applied the FE models of the entire ligamentous lumbosacral spine (LI–S1) or individual lumbar functional spinal units (FSUs; each functional unit consists of two adjacent vertebrae with connecting ligaments and intervertebral disc) to investigate the biomechanical behavior of the spine.

Some of the previous FE models of the lumbar spine have studied only the response of the motion segments, neglecting posterior elements,[6] while the others did the entire motion segment with posterior elements[7] or multimotion segments or the whole ligamentous lumbosacral spine.[8] It is crucial to bear in mind that the simplifications made in the development of the model—such as in geometry, material definitions, load and boundary conditions, and so on—will directly affect the accuracy of predictions.[9]

Once the FE model is developed, it must be validated with relevant in vivo and in vitro test data. The model to be validated should replicate the crucial features and characteristics of the real specimen in order to be able to be compared to experimental data that may help in fine-tuning the FE model. For components such as ligaments, the experimental test data are required to define the true mechanical behavior as well as failure modes and hysteresis characteristics of the corresponding element in the model. All these will enhance the precision of the FE simulations and outputs and will make them comparable with real behavior of the spine.

There are some specific considerations that should be taken into account in FE modeling of the spine in order to make the FE prediction reliable under a specific loading or motion condition. Following are some of these characteristics[10]:

- The geometry of specific features should match the real case, in which the shape of the construct affects the biomechanical outputs; examples are geometry of discs at different levels with the proper boundary profile in the sagittal plane and the proper simulation of the anterior/posterior disc height and the angle between vertebral endplates at each segment.
- The correct simulation of the lordosis angle due to its main role in the stability of the spine under loads and load sharing across the segments.
- The geometry of the posterior bone and partitioning of the bony elements into cancellous and cortical with proper thickness of cortical bone across the vertebrae.
- Proper definition of the element types for specific features, such as ligaments, which can be defined either by two-dimensional (2D) truss or beam elements connecting to nodes of the model with correct moment arm with respect to the center of the segment. Ligaments can be modeled either as a bundle with appropriate cross-section or as a combination of individual truss elements with cross-section of unity.
- The geometry of the facet articulations with their gap distance and likely asymmetry.
- Contact pattern between the articulating surfaces of facets as a finite large-displacement contact problem with proper sliding (with or without friction) and normal (soft or hard) behavior.
- The disc should be modeled as a nonhomogeneous composite structure, including an amorphous matrix (protoglycan and water) reinforced by collagenous fibers. Proper element types should be used for each area of the disc, that is, the nucleus can be modeled with noncompressible fluid elements, while the anulus can be modeled with solid elastic elements with fibers at proper angles by considering the radial variation of the collagenous fibers' mechanical properties and volume fracture.
- In case a nonstatic simulation—such as dynamic loading, impact, long-term creep and wear—is being considered, the time-dependent behavior of elements and materials needs to be specified.
- The definition of loads and boundary conditions for example, if the study of kinematics of L3–S1 spine is of interest, S1 is fixed in all degrees of freedom and the compressive loads and bending moments are applied at L3 level.

Modeling of the Lumbar Spine

The first intact FE model of the ligamentous lumbar spine that was developed consisted of two motion segments (L3–L5).[11] The geometric data for the L3–L4 motion segment were acquired from 1.5-mm thick computed tomography (CT) scans (transverse slices) of a cadaveric ligamentous spine

specimen. Radiographs and dual-energy x-ray absorptiometry (DEXA) were used to ensure that no osseous abnormalities existed with the specimen and that the bone quality was good. Each region was then divided into several quadrilaterally shaped elements. The four nodes characterizing a particular element were digitized to obtain their X and Z coordinates with respect to the global axes system. The Y coordinate equaled the depth of the corresponding transverse slice on the CT film. The transverse cross-sectional shape of an intact normal specimen is symmetric about the midsagittal plane. Thus, only one-half of the model was digitized; the other half was simulated as a reflection of the first half automatically by the FE software. The coordinate data of elements from different cross-sections were then assembled to generate three-dimensional meshes. The midtransverse plane of the L3–L4 disc was horizontal. A lordotic curve of approximately 9 degrees was simulated at the L4–L5 level of the FE model, based on the anthropometric data. The model validation study was undertaken by Kong.[12]

Then, the L5–S1 disc and the S1 vertebral body were added to the existing L3–L5 model to construct an L3–S1 segment. A total lordotic curve of approximately 27 degrees was simulated across the L3–S1 level with the mid-L3–L4 disc kept horizontal. The concluding L3–S1 model has a total of 27,540 elements and 32,946 nodes (Fig. 11.3). The number of elements and the material properties of the intact L3–S1 model are presented in Table 11.1.

Vertebral Body and Posterior Bone

The vertebral body and posterior bony regions were defined using three-dimensional solid continuum hexagonal elements with eight nodes, each possessing six degrees of freedom. The vertebral bodies were modeled as a cancellous (porous) bone core surrounded by a 0.5-mm thick cortical (dense) bone shell. The appropriate isotropic material properties were defined for the respective regions (see Table 11.1).

Intervertebral Disc

The intervertebral disc was modeled as the anulus fibrosus and nucleus pulposus. The anulus fibrosus was modeled as a composite solid ground substance, reinforced with embedded fibers. The ground substance was made up of 3D solid hexagonal elements. The REBAR option (Abaqus) was used to define the fibers, which were oriented at alternating angles ±30 degrees to the horizontal. The "no compression" option was used for the REBAR elements such that they could transmit

only tension; also, the fiber thickness and stiffness increased in the radial direction. An overall collagenous fiber content of 16% of the annular volume was distributed in the anulus.

The nucleus pulposus was modeled with C3D8 hexagonal elements. Isotropic material property with a stiffness of 1 MPa and near incompressibility simulated with a Poisson's v = 0.4999 was assigned to the nucleus to simulate its hydrostatic characteristics.

Apophyseal (Facet) Joint

Simulation of the facet joints is crucial for the spine model since it drastically affects the outcome of the analysis. In this model, the facet joints were simulated using 20 three-dimensional gap elements (GAPUNI). The facets were oriented at an inclination of 72 degrees from the horizontal plane. An initial gap of 0.5 mm was specified between these elements. Force is transmitted by using the Abaqus "softened contact," which exponentially adjusts the force transfer as the gap is closed. At full closure, the joint assumes the same stiffness as the posterior bone (Fig. 11.4).

Ligaments

All seven major ligaments—interspinous, supraspinous, intertransverse, capsular, posterior longitudinal, anterior longitudinal, and ligamentum flavum—were simulated in the model. The ligaments were modeled using three-dimensional two-node truss elements (T3D2). Hypoelastic material properties were assigned to each of these ligaments, allowing a "neutral zone" to be incorporated in which the ligament provided little stability under minimally applied external loads. The hypoelastic material definition was given by specifying varying Young's modulus and Poisson's ratio along with the strain invariants at the specified strain rate. The material properties of ligaments were taken from the literature, including our own experimental data.[13] The defining elements were aligned along the respective ligament fiber orientation. Although the ligamentum flavum and the longitudinal ligaments experience a prestress at rest, all ligaments were assumed to be unstressed initially. Modeling the ligaments causes nonlinearity in kinematics of the spine model (see Fig. 11.3).

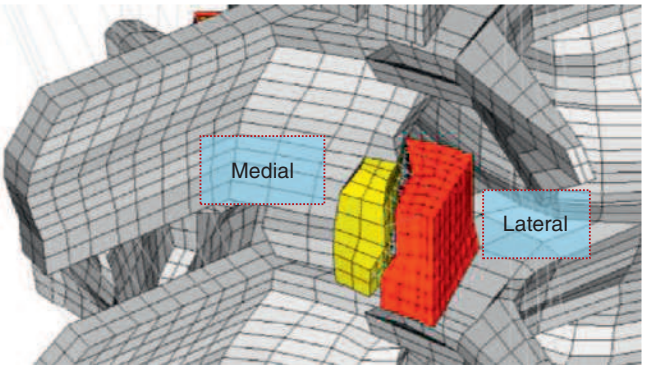

FIG. 11.4 Facet joint in the finite element model of the L3–S1 spine.

The entire process of developing the FE models of the spine has been simplified due to the advances in technology.

The reconstruction of soft tissue and hard tissue geometry from magnetic resonance imaging (MRI) and CT scans is completed through the use of Mimics v15.0 (Materialise). MRI is capable of imaging both hard and soft tissue (vertebrae and intervertebral discs) through manual segmenting. CT scans are capable of autosegmenting hard bone tissue but are difficult to use for reconstruction of soft tissue. The segmented geometry is exported in the form of a standard triangle language (STL) surface file. These files (especially manually segmented geometries) are not smooth and require further processing.

Surface processing of the reconstructed geometry is conducted in Geomagic Studio 2014. This software is a reverse-engineering software that provides surface geometry modifications. After importing the geometry, there are various functions that allow the surface to be precisely smoothed and edited. The smoothing is utilized to be able to achieve uniform meshes that are critical for achieving accurate and stable FE solutions. The editing that is conducted is used to adjust the overlapping surfaces to satisfy the requirements of the FE analysis software.

The prepared surface geometry is then imported into HyperMesh 14.0 (Altair) to create the three-dimensional meshes. These meshes are created such that they have optimal Jacobian and aspect ratios. Multiple mesh densities are created of each body to then perform mesh convergence. Mesh convergence is used to show that the solution of the FE problem is independent of mesh density. This method allows us to utilize accurate mesh with the lowest possible computational expense.

The converged mesh is then imported into Abaqus 6.14 (Simulia), and constructed. The construction of the model consists of assigning material properties to all geometries. Abaqus has the capability of assigning a variety of material types and constitutive models to accurately simulate the linear elastic, plastic, and hyperelastic properties of bones, implants, and soft tissue. Interactions are then generated to tie surfaces together, such as the vertebral endplate to the intervertebral disc. Interactions are also used to generate contact definitions, such as the articulation between a cage and endplate, to accurately simulate the contact force, contact area, stress, displacement, and so on. The appropriate one-dimensional elements are then added to the model to represent the small soft-tissue restraints that are not able to be reconstructed through MRI or CT data. Loading and boundary conditions are then applied to simulate various clinically relevant conditions. The outputs of the model are ROM, stress, strain, force, and contact mechanics in all of the reconstructed and instrumented geometries. Complex subroutines are available to simulate growth and deformities of the spine. Last, both static and dynamic loading scenarios are available to fully capture all studies of interest.

Validation of the Lumbar Model

Formulating an FE model for a biologic system often involves making justifiable assumptions. Validation of an FE model is essential in order to indicate whether the model predictions

are similar to the experimental predictions. Previous biomechanical studies using the intact two-segment FE model were validated with experimental in vitro studies.[12,14–17]

Axial compressive preload acts as the major component of the in vivo preload. The exact degree and magnitude of the net preload relies on the degree of lumbar lordosis and the posture of the individual during physiologic loading. Axial compressive preload affects the load displacement characteristics of the joint.[4] The model was subjected to an axial preload of 400 N as a follower load since it is physiologic. In addition to the axial preload, motion was predicted for all six degrees of freedom with a moment of 10 Nm. Schultz et al.[12] have reported the load-displacement properties in all principal directions with a compressive preload of 400 N. The compressive preload of 400 N was maintained while moments (4.7 Nm and 10 Nm) about the three principal axes were applied individually. Table 11.2 provides a comparison of the model predictions in response to bending and torsional moments compared to those reported by Schultz et al.[12] The predicted facet loads were compared with Yang and King,[17a] Shirazi-Adl and Drouin,[17b] and Kim.[15] Radial disc bulge predictions at L4–L5, measured at the disc mid-height, were compared to previous experimental and analytic results. In response to the compressive preload, the mean lateral disc bulge was 0.12 mm for a 400 N load. Although these values are somewhat low, the values were in the range reported by Dooris et al.[7] Ligament strains were predicted in response to an axial compressive load of 400 N, coupled with bending moments of 5 and 10 Nm about the three principal axes. The trends seen were close to the in vitro work reported by Panjabi et al.[17]

The FE solutions are dependent on the mesh refinement. Using a large number of elements is known to reduce error, and the mesh should be refined until a stage is reached at which the results from the current refinement iteration are similar to the results obtained by the previous refinement iterations. Such a mesh would be an optimized mesh, which enables the model to predict correct results. Further refinement beyond this point can theoretically induce more errors. Thus, the mesh of the L3–L5 FE model was further refined and the L5–S1 segment was added. The results between the L3–L5 model and L5–S1 model exhibited a strong correlation (see Table 11.2).

To further validate the L3–S1 model, a cadaveric study was undertaken recently. The study involved comparing experimentally predicted load-displacement behavior using the Optotrak with FE model predictions.[18] Five fresh ligamentous lumbar L1–S1 spine specimens were used for the experimental tests. Specimens were potted in a rigid base secured to the sacrum and a loading frame likewise was secured to the L1 vertebral body. To determine the load-displacement behavior of the specimen, a set of three light-emitting diodes (LEDs) was attached to each vertebral body (Fig. 11.5). The Optotrak motion measuring system (Northern Digital Inc.) was used to track the spatial location of the LED markers secured rigidly to the vertebral bodies, including the base, during the load-displacement evaluation. The specimen was loaded to a maximum of 9 Nm in all six degrees of freedom. The intact FE model was also subjected to similar loading of 9 Nm as the cadaveric testing. The angular displacement data for the

experimental testing and the FE model were compared across L3–S1, L3–L4, L4–L5, and L5–S1 segments. It was found that the FE model predicted angular displacements across the segments falling within one standard deviation of the experimental data (Fig. 11.6).

Finite Element Model of the Cervical Spine

A full cervical spine (C1–C7) computational model was developed that involved the following steps.

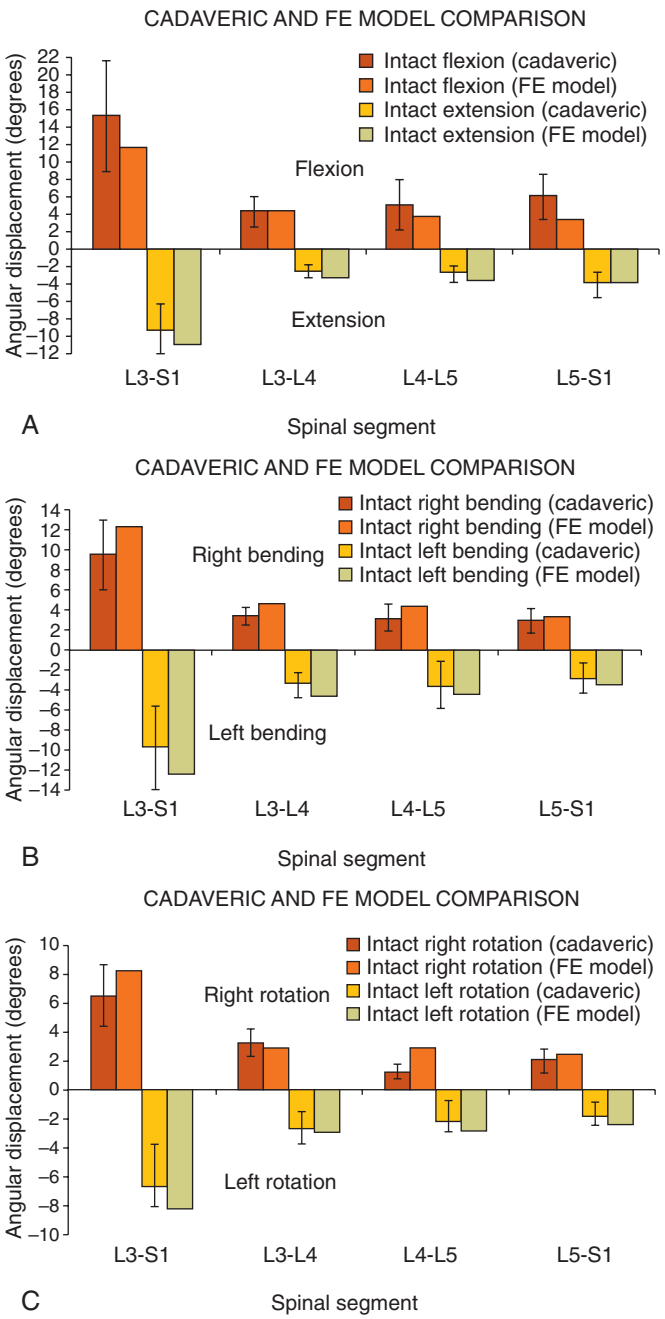

FIG. 11.6 (A) Comparison of the experimental and finite element (FE) model results for flexion and extension in response to a 9-Nm pure moment. (B) Experimental and FE model results are compared in left and right bending in response to a 9-Nm pure moment. (C) Experimental and FE model results are compared in left and right rotation in response to a 9 Nm pure moment.

Conversion of CT and MRI Scans to 3D Solid Model

To construct the geometry of the cervical spine, CT scan images of a woman (25 years old) without any abnormalities with 1-mm slice thickness were obtained from the radiography department of University of Toledo Medical School. Mimics 13.1 software package (Materialise) was used to construct the required 3D structures. For the CT images obtained, bone contrasting and thresholding procedures were done to each bone part, and related masks were developed. Then, by utilizing the region growing tool, the initial geometry was developed (Fig. 11.7). Smoothing, wrapping, and filtering functions were executed to obtain good-quality geometry. A similar procedure was followed to obtain 3D structures of five intervertebral discs (C23, C34, C45, C56, and C67) from MRI scans.

Meshing

Each individual 3D structure was imported into the Iowa FE Mesh software for creating the mesh structure. A series of building blocks was constructed around the 3D structure, assigned a desired mesh density, and projected onto the surface representation, creating a 3D FE model. Finally, the mesh quality module in the software was used to evaluate, and thus develop, the high-quality mesh for the model. Fig. 11.8 shows the meshing procedure for C3 vertebra.

Finite Element Analysis (Using Abaqus Version 6.11)

Abaqus software was used for the FEA. Meshed parts were imported into this software for FEA. Ligament insertion points and material properties of all of the soft and hard tissues were extracted from literature.[18a] Finally, assembling all of these parts and assigning their respective material properties developed the three-dimensional nonlinear full cervical spine FE model.

The intact model contained 217,366 nodes and 181,336 elements. The global coordinate system of the model (X, Y, and Z) was oriented in such a way that the positive Y is from anterior to posterior of the spine, positive X is from right to left of the spine, and positive Z is from bottom to top of the spine.

Vertebral Body and Posterior Bone

Similar to the lumbar model, the cervical vertebral body consists of a thin cortical shell (0.5 mm of thickness) surrounding a softer cancellous core. The posterior region was assigned attributes, which lay between those of the cortical and cancellous regions. Three-dimensional, isoparametric solid elements (C3D8) were used to define the osseous geometry.

Facet Joints

A contact formulation was used to define the contact pattern between articulating surfaces in facet joints with an initial gap of 0.5 mm based on CT imaging and dissection procedures. The contact was defined with an exponentially increasing modulus as the gap distance between the inferior and superior facets decreased, simulating the presence of cartilage in the facet region. The facets were oriented at approximately 45

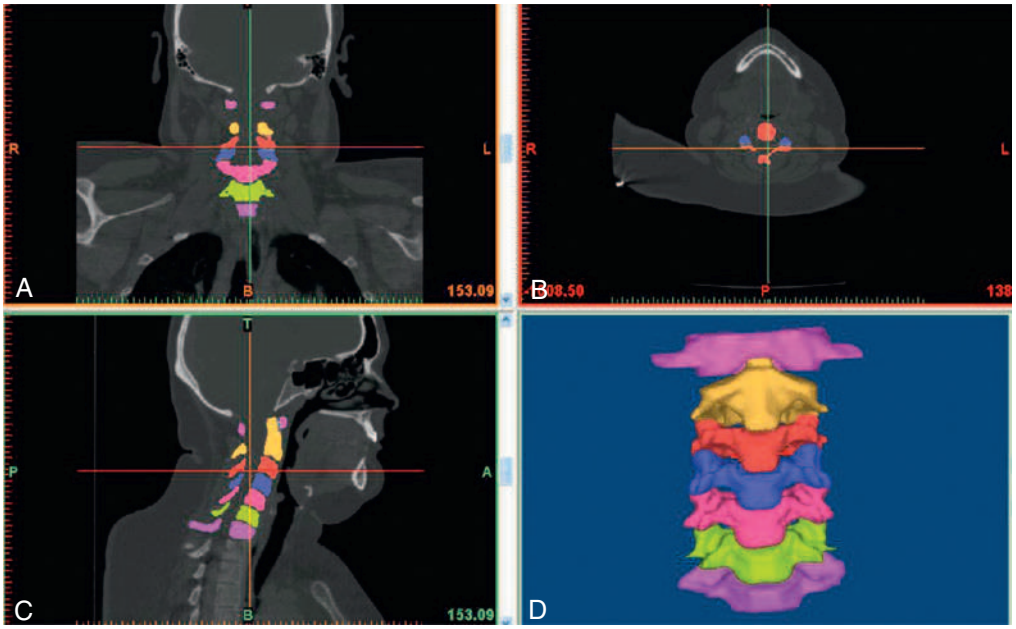

FIG. 11.7 Visualization module of Mimics version 13.1 (Materialise). (A–C) Frontal, axial, and sagittal scan views, respectively, in which bone contrasting, thresholding, and masking were performed for the computed tomographic slices. degrees from the horizontal plane, with some variation in the sagittal plane alignment, according to CT geometry. The facets were also of varying curvatures from right to left sides, indicating the possibility of varying contact during right or left loading modalities from the right to left facets.

Intervertebral Disc and Luschka's Joints

The anulus fibrosus was modeled as a composite configuration in which a series of fibers simulating the lamellae of the disc were embedded in a ground substance surrounding a more gelatinous nucleus region. Each layer of ground substance contained two alternating layers of fibers arranged at ±65 degrees from the transverse plane, with an overall fiber content of 20% of the annular volume assumed. REBAR element type with no-compression option was used to define the fibers. Brick elements were used to model ground substance and the nucleus pulposis was defined as incompressible fluid.

Luschka's joints were modeled as well in the cervical discs. These were simulated around the area of the uncinate processes and the anulus horizontal layers around the uncinate processes.

Ligaments

The ligaments of the lower cervical spine that were modeled include the anterior longitudinal ligament (ALL), posterior longitudinal ligament (PLL), interspinous ligament (ISL), ligamentum flavum (LF), and the capsular ligaments (CAPs). The alar ligament (AL), transverse ligament (TL), anterior and posterior atlantoaxial ligaments (AT-AX, PAT-AX) were modeled for the upper cervical spine. The ligaments were modeled using three-dimensional truss elements with hypoelastic material behavior.

Fig. 11.9 shows a 3D view of an FE model of the C1–C7 spine and all its components. Material properties and

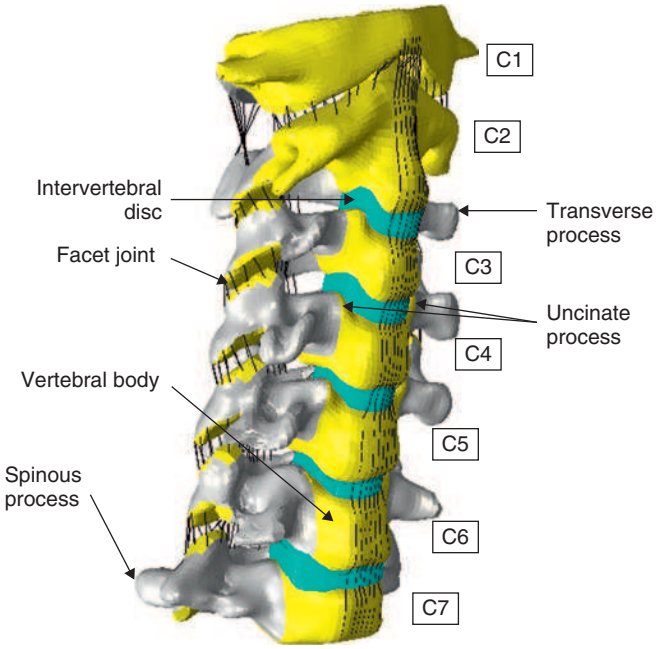

FIG. 11.9 Finite element model of the ligamentous C1–C7 cervical spine.

cross-sectional areas used in defining the various entities in the C1–C7 model are summarized in Table 11.3. These were chosen based on values published in the literature and were assumed to be homogeneous and isotropic.[7]

TABLE 11.3 Element Types and Material Properties for Finite Element Model of Intact C1–C7 Cervical Spine

Element Group Name	Element Type	Young's Modulus (MPa)	Poisson's Ratio	Cross-sectional Area (mm²)
Cortical bone	C3D8	10,000	0.3	–
Cancellous bone	C3D8	450	0.25	–
Posterior bone	C3D8	3500	0.25	–
Anulus ground substance	C3D8	4.2	0.25	–
Anulus fibers	REBAR	–	0.45	–
Nucleus pulposus	C3D8H	1	0.4999	–
ALL	T3D2	15 (<12%) 30 (>12%)	0.3	33.0
PLL	T3D2	10 (<12%) 20 (>12%)	0.3	33.0
LF	T3D2	7 (<12%) 30 (>12%)	0.3	50.1
ISL	T3D2	5(<25%) 10 (>25%)	0.3	13.0
CAP	T3D2	15 (20-40%) 30 (>40%)	0.3	46.6
TL	T3D2	20	0.3	18.0
AL	T3D2	3.0(<17%) 8.5(>17%)	0.3	22.0
AT-AX	T3D2	0.2(<17%) 1.25 (>17%)	0.3	5.0
PAT-AX	T3D2	6.0(<17%) 10.0 (>17%)	0.3	5.0

AL, alar ligament; ALL, anterior longitudinal ligament; AT-AX, anterior atlantoaxial ligament; CAP, capsular ligament; ISL, interspinous ligament; LF, ligamentum flavum; PAT-AX, posterior atlantoaxial ligament; PLL, posterior longitudinal ligament; TL, transverse ligament.

Application of the Finite Element Model of the Spine

One of the main advantages of FE modeling of the spine is its extensive application in simulating the effects of various trauma and spinal disorders on the biomechanics of the spine. Numerous studies have simulated different spinal injuries and compared various biomechanical parameters, such as angular motion and stress distribution across degenerated and adjacent segments, between intact and injured spine models. The outcomes of such analysis have well served engineers in coming up with innovative ideas and solutions in the design of suitable implants to address the pain and restore to normal the biomechanics of the damaged segment. Implants are useful in treatment of spinal injuries when conservative therapies fail to reduce the pain and restore the patient to a normal daily routine. Invasive surgeries aim to remove the pain-causing structures, stabilize the segment, and correct bone failure due to trauma or disease.

Once the FE model of the intact spine is created, it can be easily modified to simulate different injuries by various techniques, such as removing certain elements (e.g., facetectomy, laminectomy), changing the material properties (e.g., laxity in ligaments), or modifying the geometry (disc herniation and degeneration).

For example, spinal stenosis is a progressive degenerative condition that occurs when the articulating facet joints become arthritic and no longer provide necessary stability to the spine. The arthritic facets become inflamed and osteophytic (produce bony spurs), resulting in irritation and impingement of nearby nerves, leading to clinical symptoms. The current nonconservative treatment for spinal stenosis is surgical decompression and spinal fusion with instrumentation to achieve spinal stability and symptom relief. Decompression is a surgical procedure, which is performed to alleviate pain caused by pinched nerves (neural impingement). The surgical procedure for decompression includes removal of part of the lamina (laminectomy), spinous process, facets (facetectomy), ligaments, and/or sometimes part of the intervertebral disc (microdiscectomy).

Although clinical studies have shown that decompression surgery enhances neurologic recovery, pain relief, and mobility, significant destabilization of the spinal motion segment is seen after decompression, especially if the facet joint is removed.

Addition of a posterior fusion system, including pedicle screws interconnected with a rigid rod, is a common procedure to restore the stability of the affected segment.

Though fusion is able to restabilize the implanted segment, it can result in accelerated degeneration of the adjacent motion

segment and morbidity from muscle stripping. Fig. 11.8 shows an L3–S1 model of the spine with a fusion system at the L4–L5 level.

Clinical Application of the Finite Element Models of the Spine

FE analysis has become a cost-effective and efficient means to predict the biomechanics of the spine under physiologic and pathologic conditions. While useful, the model is not without limitations due to the constraints of a biologic system and its associated properties being modeled by a digital representation. The material properties of the ligaments (supraspinous, interspinous, ligamentum flavum, and so on) were obtained from the literature, while the intervertebral disc was modeled as a homogeneous composite ground substance. It can be inferred that the data used to generate the models can be thought of as an "average" of the normal population, just as reference ranges are for determining the upper and lower threshold of certain markers in routine bloodwork.

FE models are based on a number of assumptions, such as the fact that the generated models should apply equally to all members of a population. In clinical practice, this does not often hold true. Just as individual patients may have variations in their spine anatomy, the rate of degeneration and the impact of degenerative processes may vary from patient to patient, making generalizations about the "best" treatment for a particular type of spinal pathology far from simple. Often in clinical practice, patients with a similar degree of degenerative pathology may have widely different clinical manifestations or, in some cases, may be completely asymptomatic. The challenge in making decisions with patients in regard to their pathology rests on the ability of the clinician to integrate biomechanical data derived from FE models, the radiographic data, and the patient's clinical symptoms. Thus, it becomes important to not use computational models alone to determine the appropriate treatment for an individual patient. Additionally, the patients that are seen in practice often are far down the degenerative cascade, at which point surgery may only temporarily alleviate their symptoms before their recurrence due to scarring, nociceptor hypersensitivity, and/or further degeneration.

Another limitation of an FE model is that the stability of the ligamentous spine is less than a spine in vivo due to absence of the muscles and ligaments. The load-bearing qualities and structural support afforded by the muscles and ligaments have been shown to vary greatly, and are influenced by the age and quality of bone, the rate of loading, as well as other physiologic and hereditary characteristics that cannot be modeled by current computational techniques. In addition, there have been observations that cadaveric models may show different biomechanical properties based on preparation, and that the in vivo tissue failure properties may be lower than that predicted by FE models.[19] The importance of the musculature and ligaments and their contribution to spinal stability is emphasized by the recent surge of interest in minimally invasive techniques for arthrodesis that minimize muscle dissection.

Currently, FE models are limited in their ability to evaluate the spine as a whole, and are instead divided into regions (cervical, thoracic, lumbar) to facilitate analysis of their mechanical properties. By isolating these segments and subjecting them to biomechanical analysis, they do not address global spinal parameters, such as sagittal and coronal balance, which have become increasingly important in treating spinal pathology. In addition, the spine's relationship to the pelvis and pelvic parameters—such as pelvic tilt, pelvic incidence, and sacral slope—are currently not addressed by FE models but are used increasingly by surgeons in making treatment decisions that impact clinical outcomes and patient satisfaction.

Because FE models are typically based on a specific subject or an ideal average subject, there is concern regarding the applicability of FEA to clinical practice. Many studies have been conducted with the goal of accounting for intersubject variability as a result of aging and anatomic deformities. For example, patient-specific FE models have been constructed to investigate the risk of femoral neck fracture,[20] account for intersubject variability of biomechanical factors in animal studies,[21] and to support the interpretation of clinical results in follow-up studies. Reggiani et al. reported a preliminary validation of patient-specific FE models with regard to predicting the subject-specific primary stability of cementless implants during preoperative planning.[22]

Although a need remains for a validated model that accounts for injury, deformity, or disease, more recent studies have demonstrated the usefulness of coupling FEA with patient-specific information from clinical CT scans to mechanistically simulate bone failure. This approach has been validated by numerous groups for the spine and hip, and clinically has been shown to be significantly associated with incident and prevalent fracture in multiple cohorts. A study conducted by Kopperdahl et al. has further demonstrated clinical integration of FEA through its use of FEA-based vertebral strength assessments and vertebral trabecular bone mineral density (BMD) to predict incident vertebral fractures in women.[23]

The International Society for Clinical Densitometry (ISCD) has recently developed new official positions for the clinical use of quantitative CT (QCT)-based FEA of the spine and hip, specifically with regard to the management of osteoporosis in adults. According to the ISCD, QCT-based FEA can be used to assess fracture risk, initiate pharmacologic treatment of low vertebral and femoral strength, as well as monitor age- and treatment-related changes to bone strength.[24]

Perhaps the most important application of FE models in the spine is their utility in creating medical devices that are intended to arrest the degenerative cascade. In current clinical practice, a significant proportion of spine procedures are centered around removing offending pathology (laminectomy, facetectomy, corpectomy, and so on) and fusing the levels of interest using implants such as rods and pedicle screws. Over time, the inflammatory cascade that promotes healing fuses the operated levels while placing stress on the adjacent motion segment. While, in many cases, the patient's preoperative symptoms may temporarily improve, symptom recurrence and/or exacerbation in the future is not uncommon due to accelerating the degenerative cascade in the adjacent level. The existence of conditions such as

"failed back surgery syndrome" (FBSS) and patient dissatisfaction after repeat fusion surgery suggest that the data used to create implants and to perform spine surgery are limited in their ability to truly predict the surgical solution that is ideal for a particular patient. Importantly, the data used to generate FE models is from cadaveric spine specimens that have not undergone fusion surgery, making predictions about the rate of degeneration or adjacent-level disease approximations at best.

These developments highlight the advantages of FEA and advance the goal of bringing FEA closer to clinical application. As FE models evolve, the ability to evaluate the spine as a whole, incorporation of global spinal alignment parameters, and including elements such as spinal musculature and ligaments may aid in increasingly accurate predictions of the spine in vivo. It should also be noted that current FE models are based on static imaging and do not incorporate dynamic radiographs (flexion, extension, and lateral bending), which also prove to be important in surgical decision making.

More recently, nonfusion-based spinal implants are being used as an alternative to stabilizing the spine after decompression. Unlike fusion, nonfusion stabilizing systems allow for angular motion, shear stability, and adjusting to the instant axis of rotation of the motion segment during movement. Fig. 11.9 shows the L3–S1 spine implanted with a posterior dynamic stabilizer system (PDS; Disc Motion Technologies). The implant was placed at L4–L5 following the surgical procedure of total facetectomy at L4–L5. The PDS consisted of a pair of metallic (chrome-cobalt) sliding parts (male and female) connected to the spine by titanium pedicle screws at each side.

To simulate the physiologic loading condition on the spine, once the implanted model was created, both implanted and intact models were loaded with 400 N of compressive follower preload plus 10 Nm of moment to simulate flexion, extension, left/right bending, and left/right rotation. Various biomechanical parameters such as motions, intradiscal pressure, and facet loads were compared between the intact and implanted model (Fig. 11.10).

The intervertebral artificial disc is another example of spinal implants recently proposed as a treatment for the degenerated disc. Unlike fusion systems, the total disc replacement (TDR) promises to address facet pain, mimic the motion of the intact spine, and avoid degeneration at the adjacent segment. There are various designs available for discs. Some require an anterior surgical approach for replacement as opposed to others that are placed from the posterior side of the spine. Fig. 11.11 shows a posterior disc system (Disc Motion Technologies), including a pair of cobalt-chrome sliding parts. This disc is placed into the spine following the surgical removal of the facets at the operative level. Since the facets are removed, the spine is restabilized by the addition of a PDS system as previously discussed. The combination of PDS and disc is a 360-degree motion system that is able to restore the motion of the operated segment back to normal. To assess the biomechanics of the implanted spine, FEA was

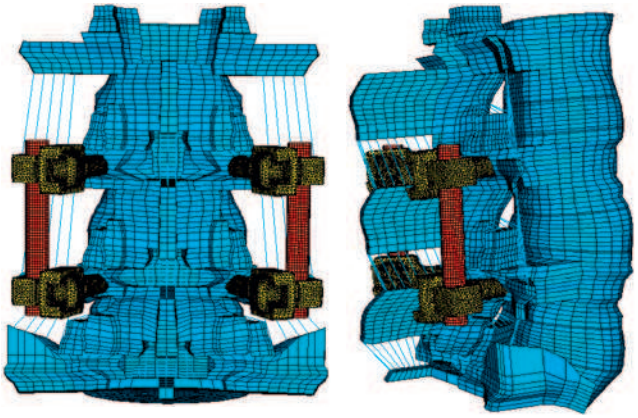

FIG. 11.10 Fusion system at the L4–L5 level of the lumbar spine.

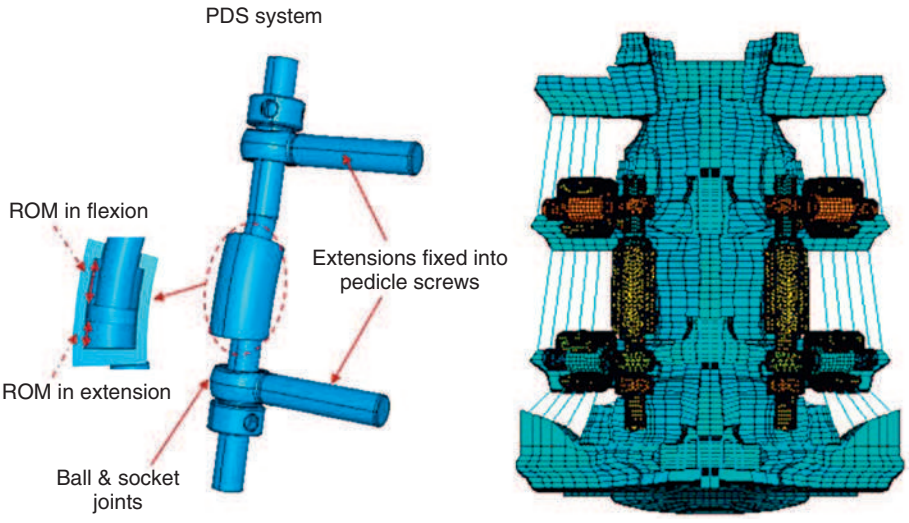

FIG. 11.11 The L3–S1 spine implanted with a posterior dynamic stabilizer system at L4–L5. *ROM,* range of motion; *PDS,* posterior dynamic stabilizer.

used, and motion, intradiscal pressure, and facet loads across segments were calculated and compared between intact and implanted models (Figs. 11.10–11.12).

Conclusion

In addition to its most obvious and time-tested uses, such as the evaluation of early-stage prototypes, FEA is a useful tool in the evaluation of the biomechanical effect of various surgical interventions, including a range of implants—from those that are designed for fusion to motion preservation devices. FEA aids in predicting the behavior of such implants in the long term by means of evaluating some crucial mechanical factors, such as wear and fatigue.

Studies in biomechanics of the spine have shown that FEA and in vitro cadaveric testing are complementary techniques,

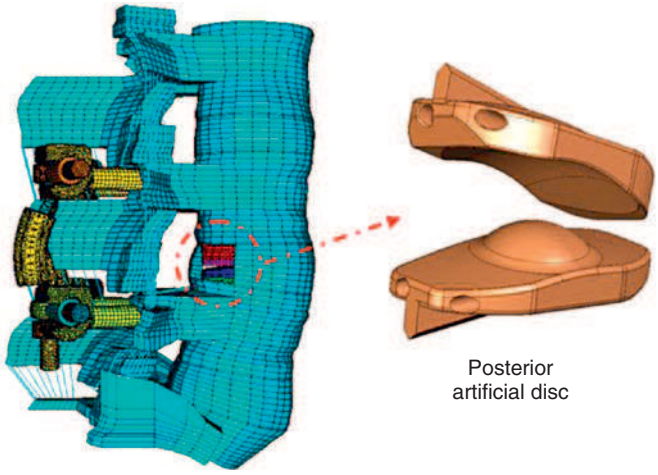

FIG. 11.12 The L3–S1 spine implanted with a posterior dynamic stabilizer and artificial disc at L4–L5.

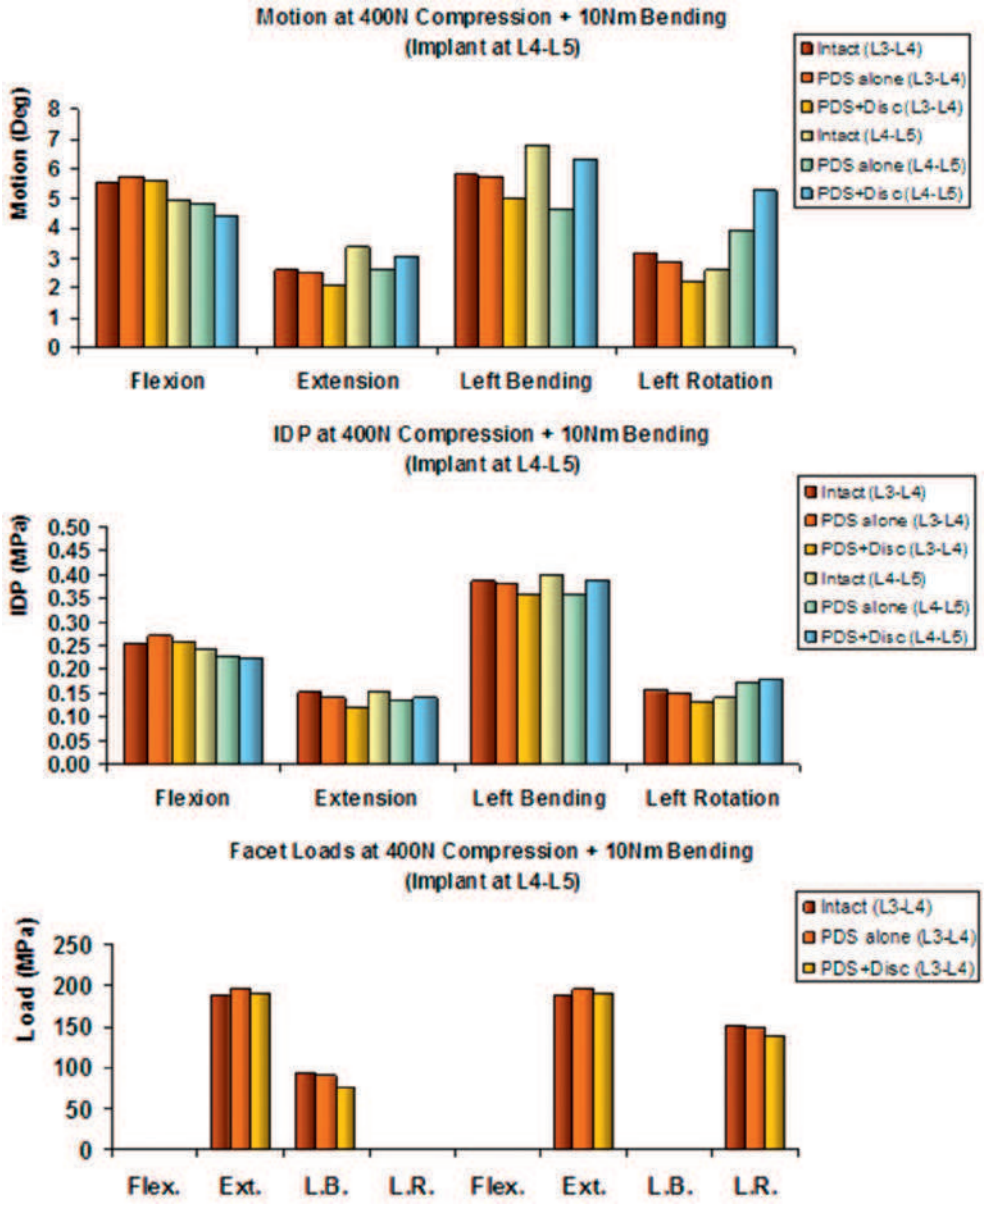

FIG. 11.13 Motion, intradiscal pressure, and facet loads across segments for intact and implanted models. *Ext.,* extension; *Flex.,* flexion; *L.B.,* left bending; *L.R.,* left rotation.

and thus are well suited to characterize the complex biomechanical behavior of the spine and its anatomic structures, including internal stresses/strains of the intervertebral disc, facet joints, and any ligaments of interest. However, like cadaver investigations, FE models have several limitations. For example, they do not account for variations in the geometry of the specimens, such as facet orientation and material properties that vary from specimen to specimen. But, for a given model geometry, the predicted data are in reasonable agreement with the results from the in vitro investigations. Thus, the use of an experimentally validated FE model can provide very useful information for many clinical questions being raised by the use of spinal implants.

One of the most far-reaching and interesting questions for which FEA may be able to provide some insight is in the nature of adjacent-level degeneration. Because the FE method provides the means for simulation of changes in motion and loads over time along with the effects of surgical intervention and changes in geometry and material properties due to degeneration, highly advanced, dynamic models of the spine may be able to replicate the progression of degeneration following surgical intervention and compare it to the natural course of the disease. While this will require considerable advancement in FE modeling techniques, it is perhaps the most promising means of answering the age-old question of whether adjacent-segment degeneration is actually attributable to surgical intervention or solely the manifestation of the underlying disease.

The authors were able to show that in flexion-extension, the range of motion decreased and neutral zone ratio increased with degeneration. In axial rotation, neutral zone and neutral zone ratio increased with degeneration. In lateral bending, the range of motion significantly decreased and the neutral zone ratio increased with degeneration. In all three loading directions, the neutral zone ratio increased, indicating greater joint laxity with degeneration.

Eight well-established finite element models of the lumbar spine (L1–L5) of different research centers were subjected to loading and compared to in vitro and in vivo measurements for intervertebral rotations, disc pressures, and facet joint forces. In pure moment loading, L1–L5 rotations, facet joint forces, and disc pressures fell within report ranges of in vitro motion with similar median values. The authors were able to conclude that the pooled median of various model results can be used as an improved predictive tool over the results of a single model alone.

The authors were able to demonstrate marked differences in intervetebral motion in a finite element model of the degenerative lumbar spine that closely mimics the reported in vitro behavior as a function of degeneration. The mildly degenerated segment showed an increase in motion in all loading cases with further degeneration resulting in decreases in motion.

12 CHAPTER Patient History and Physical Examination: Cervical, Thoracic, and Lumbar

Christopher J. Standaert
Stanley A. Herring
J. David Sinclair

Caring for patients with spine disorders can be extremely challenging for clinicians because of the complexities of spinal anatomy and pathophysiology as well as the multifactorial nature of pain. Despite extensive advances in imaging of and interventions for the spine, a massive medical and social problem related to spinal pain and disability remains. To address the needs of patients with spine disorders and to select appropriate patients for whom specific care may be beneficial, clinicians need to identify the true nature of a patient's problem. Frequently, the patient's problem may extend well beyond any anatomic derangement that can be identified on imaging studies and involve numerous psychosocial factors in the patient's life. Through the history and physical examination, clinicians are able to identify not only the physical manifestations of a spine disorder but also the root causes of a patient's distress, suffering, and disability, all of which ultimately need to be addressed if a successful outcome is to be achieved.

A thorough history and physical examination of a patient with a spine disorder has several aims. From a strictly medical perspective, the examiner must be aware of the full medical context of the patient's complaints and how the complaints may relate to the overall health of the patient. It is imperative to ascertain the presence of an emergent medical problem promptly and to identify patients who need more urgent (or emergent) assessment and care. Clinicians must also identify any secondary medical issues that may directly affect the care of spine-related problems or may be associated with broader health concerns. In a more focused sense, the history and physical examination should allow an examiner to identify relevant spine problems that have led to the issue for which the patient is seeking care (e.g., the source of pain or neurologic loss, anatomic derangements). The history and physical examination also allow the practitioner to understand the level of function and impairment that is associated with the patient's presentation.

Moving beyond the strictly medical context, identification of the factors associated with the patient's pain and disability that pose the dominant barriers to optimal functional recovery is an important goal of the history and physical examination. To decide on the appropriate intervention for a patient, it is imperative to understand what exactly is being treated. Despite all the attention paid to pain, frequently the patient's sense of suffering is the real problem, particularly in patients with chronic pain. The only way to identify the issues behind the presentation of many patients is by asking the right questions. This chapter addresses relevant issues in the history and physical examination in patients with spine disorders, particularly as these issues relate to the assessment of patients seen commonly in clinical practice, and provides information on how to identify patients at risk for ongoing pain despite what seems to be appropriate care for their structural problems.

Differential Diagnosis

The differential diagnosis of spinal pain or related symptoms is enormous when considered in a general sense. Numerous anatomic structures may be associated with pain, multiple local or systemic disease processes can affect the spine, and numerous non–spine-related structures or conditions can result in back or neck pain or mimic syndromes related to spine disorders.[1–5] In addition, numerous psychosocial factors can produce ongoing pain and disability. The ability to process all of the available possibilities and to develop a relatively short list of diagnostic options depends heavily on the ability to obtain a thorough history and physical examination. It is helpful to begin with an understanding of structures in the spine that can be associated with pain and their patterns of pain referral.

From an anatomic perspective, a structure must be innervated to cause pain. In the spine, the list of discrete anatomic structures with sensory innervation (i.e., potential pain generators) includes muscles, tendons, ligaments, fascia, anulus of the intervertebral discs, bone, zygapophyseal joints, dura mater, nerve roots and dorsal root ganglia, and vascular elements.[1,2] All structures of common embryologic segmental origin tend to refer pain in very similar patterns, and the pattern of pain is determined by the nerve supply to the structure.[1] The end result is that there is substantial overlap between the referral patterns for anatomic structures of the same spinal level, such as intervertebral discs and zygapophyseal joints, and dermatomal, myotomal, and sclerotomal referral patterns at many spinal levels (Fig. 12.1). The location

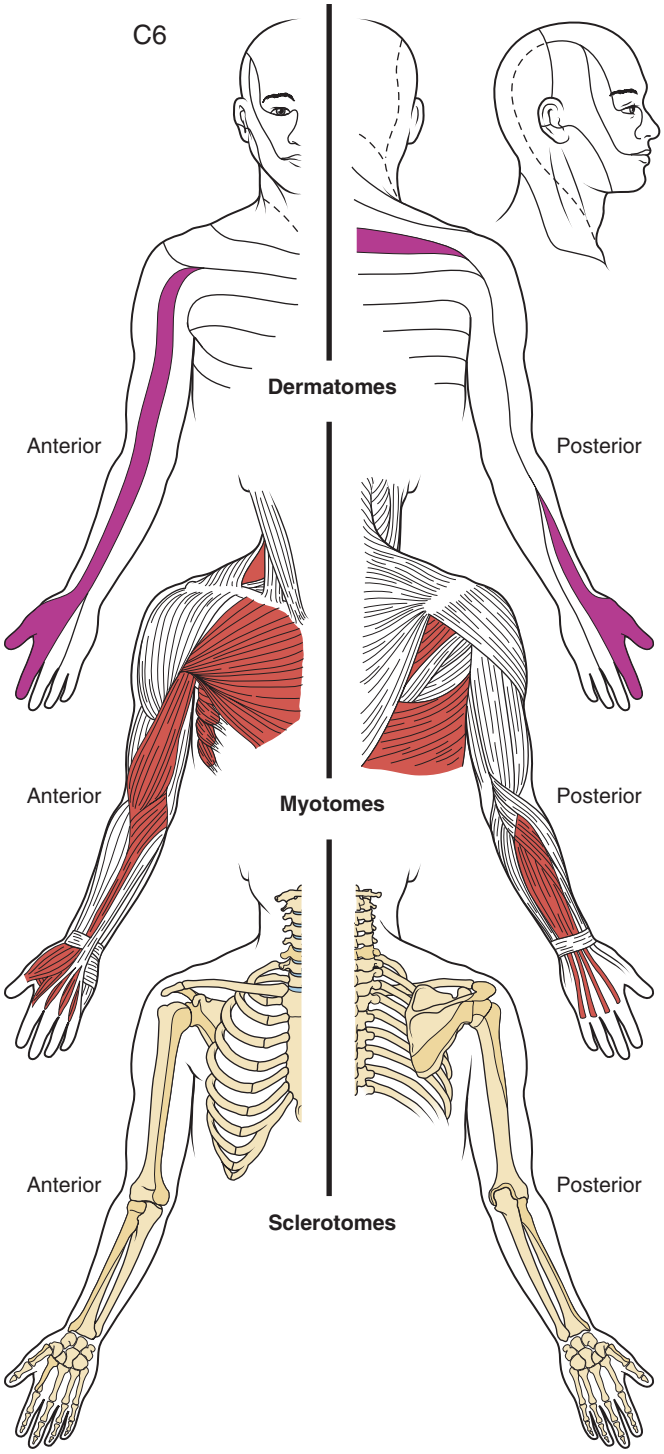

FIG. 12.1 Dermatome, myotome, and sclerotome of C6 level showing substantial overlap in distribution. (From Bland JH. *Disorders of the Cervical Spine: Diagnosis and Medical Management*. 2nd ed. Philadelphia: WB Saunders; 1994.)

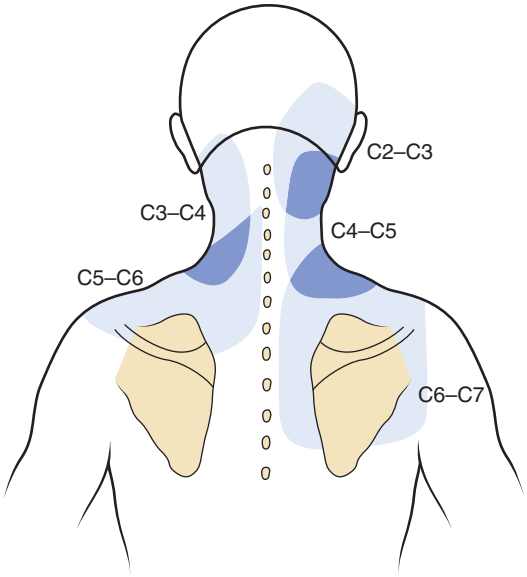

FIG. 12.2 Map of characteristic areas of pain referred from the cervical zygapophyseal joints (C2–C3 to C6–C7). (From Dwyer A, Aprill C, Bogduk N. Cervical zygapophyseal joint pain patterns I: a study in normal volunteers. *Spine.* 1990;15:453–457.)

of pain or radiating symptoms can often be a useful feature in the identification of an affected spinal level, although the location of pain alone does not indicate which particular anatomic structure is the source of the specific symptom.

The zygapophyseal joints are one of the best-studied structures in terms of pain referral patterns and relative prevalence in patients with spinal pain. In the cervical spine, the pattern of pain distribution from the stimulation of specific zygapophyseal joints has been described (Fig. 12.2).[6] Those results were subsequently validated in a study of patients with cervical complaints based on pain distribution and response to diagnostic blocks.[7] Another study using a double-block protocol on patients with persisting symptoms after whiplash injury found that the prevalence of C2–C3 zygapophyseal joint pain in patients with headache was 50%; in patients without C2–C3 zygapophyseal joint pain, the prevalence of symptoms related to the lower cervical zygapophyseal joints was 49%.[8] Although there is far less clinical information on pain associated with thoracic zygapophyseal joints, a similar map of referral patterns has been identified (Fig. 12.3).[9]

In the lumbar spine, there has also been a great deal of attention directed to the zygapophyseal joints as potential sources of pain, although the relative frequency with which they seem to be primary pain generators is less than for cervical zygapophyseal joints causing pain in patients with chronic whiplash. A more recent study noted a 15% overall prevalence of zygapophyseal pain in a group of 176 patients with chronic low back pain using a diagnostic double-block protocol.[10] Although pain associated with lumbar zygapophyseal joints is generally described as occurring with lumbar extension and rotation, the authors of that study did not find any consistent clinical features that were associated with the presence of a positive diagnostic response to injections.[10] Stimulation of lumbar zygapophyseal joints can result in either local axial or, far less frequently, radiating pain, and pain referral patterns have been documented.[11]

Multiple authors have addressed the distribution of pain associated with intervertebral discs. Cloward[12] first described cervical discography and noted that pain that seemed to be emanating from irritation of the anulus resulted in radiating pain into the thoracic or scapular regions in distinct patterns

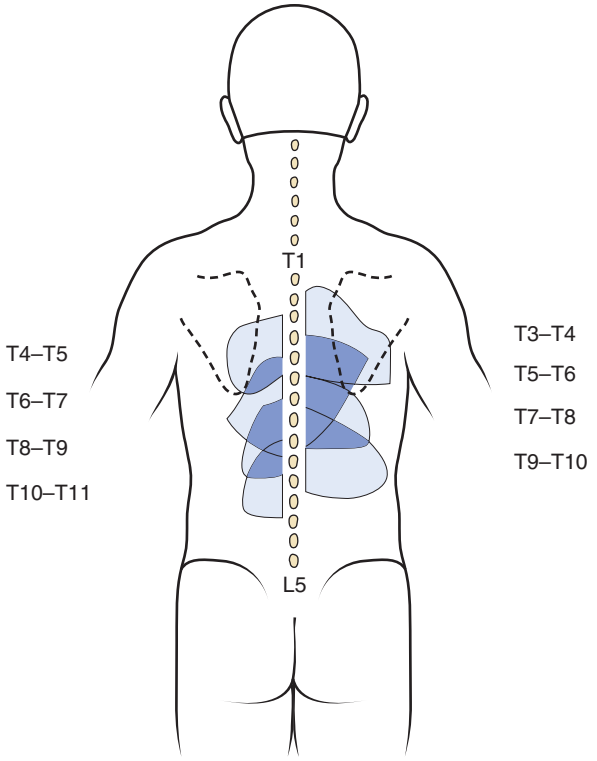

FIG. 12.3 Map of characteristic areas of pain referred from thoracic zygapophyseal joints (T3–T4 to T10–T11). (From Dreyfuss P, Tibiletti C, Dreyer S. Thoracic zygapophyseal joint pain patterns: a study in normal volunteers. *Spine.* 1994;19:807–811.)

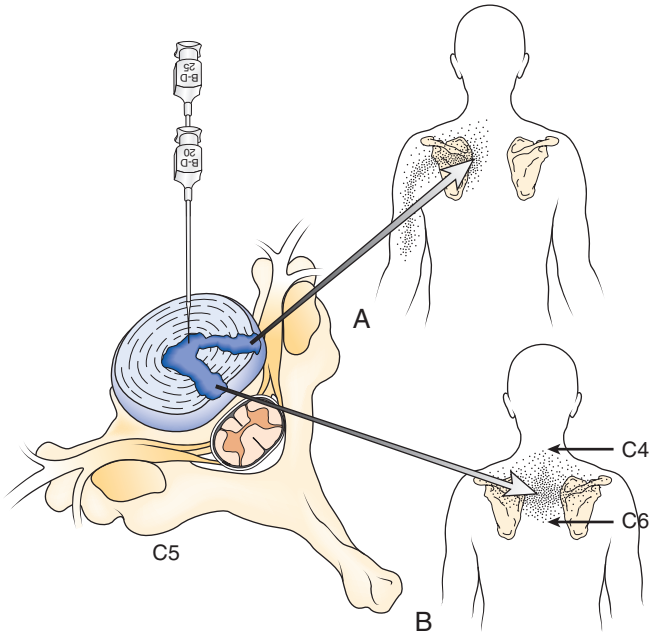

FIG. 12.4 Pain referral pattern from (A) posterolateral and (B) central discs. (From Cloward RB. Cervical discography: a contribution to the etiology and mechanism of neck, shoulder and arm pain. *Ann Surg.* 1959;150:1052–1064.)

(Fig. 12.4). Similar findings were more recently described by others.[13] As mentioned previously, pain referral patterns are similar to patterns noted for cervical zygapophyseal joints, with the level of spine pathology, rather than the actual structure involved, affecting the pain referral pattern.

Other pain referral patterns that should be recognized by all physicians treating patients with spine disorders include patterns related to neurologic injury. These patterns are discussed further later in the section on the neurologic examination, but identifying the dermatomal pattern of pain is central to the assessment of individuals with potential nerve root pathology (Fig. 12.5). Nerve root symptoms include paresthesias, burning, hyperalgesia, aching, analgesia, or pain. The ability to identify a dermatomal pattern to the symptoms can help localize the area of spine involvement.

The clinical utility of pain provocation is uncertain because there are inherent problems with this approach owing to the complex nature of pain perception.[1,14–18] The identification of a "pain generator" in individuals with chronic spinal pain can be difficult. In contrast to cutaneous sensation, nociceptive signals from deep somatic structures—such as joint capsules, fascia, and periosteum—are carried by relatively few primary afferent fibers, resulting in only vague localization of pain.[16] Additionally, there is the issue of convergence, in which a single dorsal horn cell may receive synaptic input from afferent fibers that innervate many structures and can result in multiple structures producing similar patterns of pain perception. This convergence makes it extremely difficult to validate a single entity as the cause of an individual's pain because the stimulation of any one of numerous structures may result in identical perceptions of pain.[16] These issues become even more complex when additional potential neurologic and psychological changes that can occur with chronic pain are involved.

Biomedical Factors and the Medical History

It is essential to obtain a thorough and appropriate medical history from patients presenting with spine disorders or related complaints. The identification of potentially serious problems is one of the most important functions of obtaining a good medical history. Ideally, the medical history also should help the clinician establish a reasonable differential diagnosis that can direct further diagnostic or therapeutic steps. Given the scope and complexities of spine disorders, it can be useful to break down some aspects of the clinical presentation into broad categories. This categorization may allow clinicians to focus their thought process and subsequent efforts more effectively. Useful categories to consider relate to the presence or absence of radiating pain and specific demographic factors. The following categories can help in obtaining a concise medical history.

Red Flags: What Not to Miss

It is essential to identify all conditions that pose a substantial, imminent risk for further harm to the patient. Many authors have identified specific red flags in the history of patients with low back complaints that indicate the presence of such a condition; these include infection, tumor, fracture, cauda equina injury, and progressive neurologic injury, such as motor loss or myelopathy (Table 12.1).[19–22] Red flags for the

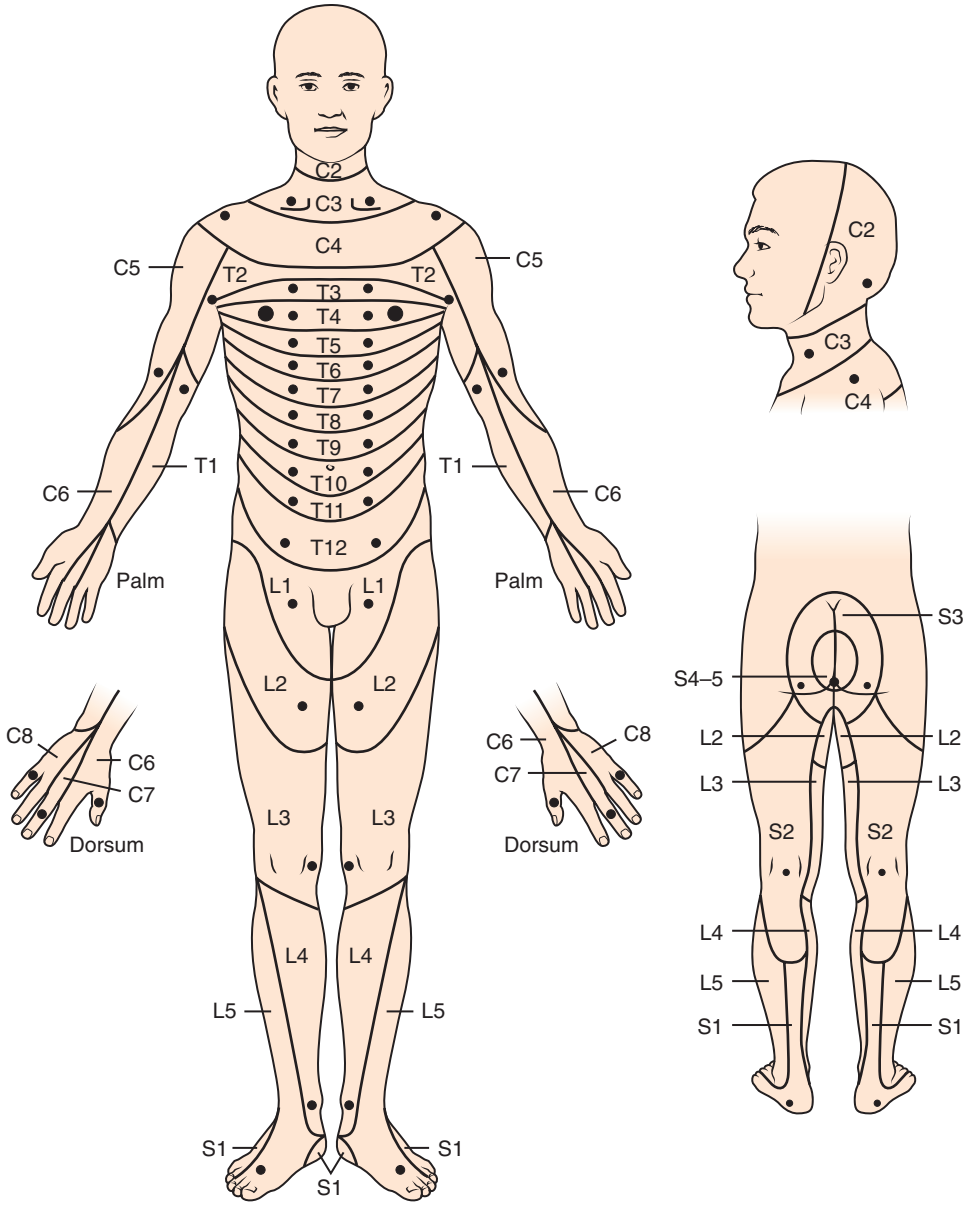

FIG. 12.5 Dermatomal distribution and key sensory points. (From American Spinal Injury Association. *International Standards for Neurological Classification of Spinal Cord Injury [reprint].* Chicago: American Spinal Injury Association; 2008.)

possibility of *cancer* include age older than 50 years, previous cancer history, unexplained weight loss, pain not relieved by bed rest, duration of pain for more than 1 month, and failure of conservative therapy after 1 month.[22] Although widely used clinically, systematic reviews have found limited data to support the use of any individual red flags in the identification of patients with malignancy, with a Cochrane review noting particularly high false-positive rates for factors such as insidious onset of pain, persistence of pain for greater than 1 month, and age greater than 50 years.[23,24] A history of malignancy seems to exhibit the strongest posttest probability for detecting spinal malignancy.[24]

Spine infections—including discitis, osteomyelitis, and epidural abscess—are usually blood-borne from other regions.[22] Important risk factors for infection include the use of illicit intravenous drugs, active or recent infection elsewhere (e.g., urinary tract, pulmonary, skin, dental), and immunosuppression (owing to either medications or illness affecting the immune system).[19,22] Additional risk factors for infection include diabetes and history of tuberculosis or exposure to a region endemic for tuberculosis.

The risk of *fracture* is elevated in patients older than 50 years, particularly patients older than 70 years.[22] Patients with a history of corticosteroid use or known osteopenia or osteoporosis are also at increased risk for fracture. A study of 669 patients greater than 55 years of age presenting to their primary physician identified four patients (1%) with malignancy and 33 (5%) with a fracture, 30 of which were associated with osteoporosis.[25] Trauma, osteoporosis, pain greater than 7 out of 10, and thoracic pain were all associated

TABLE 12.1 "Red Flags": Emergent or Urgent Medical Conditions That Need to Be Identified Promptly in All Patients Presenting With Possible Issues Related to the Spine

Symptom or Finding	Possible Significance
History of cancer	Cancer
Unexplained weight loss	
Age >50 y	
Failure to respond to >1 mo of conservative care	
Duration of pain >1 mo	
No pain relief with bed rest	
Night pain	
History of smoking	
Known osteopenia or osteoporosis	Fracture
History of corticosteroid use	
Age >50 y	
DISH or ankylosing spondylitis	
Trauma (major in younger individual, minor in older individual)	
Fever	Infection
Illicit use of intravenous or percutaneously injected drugs	
Recent or known infection	
Immunosuppressive illness	
Use of immunosuppressive medications	
Tuberculosis exposure	
Progressive weakness in limbs	Cauda equina or spinal cord injury
Progressive balance deficit or loss of coordination	
Bowel or bladder dysfunction or urinary retention	
Sexual dysfunction	
Numbness or paresthesias in perineum or saddle anesthesia	
Significant weakness of major muscle group or progressive motor loss in limb	Severe or progressive radiculopathy

DISH, diffuse idiopathic skeletal hyperostosis.

with the identification of a fracture, with a history of trauma having the strongest predictive value.[25] Trauma and fracture risk are discussed further elsewhere in this book.

Significant *neurologic* injuries include cauda equina syndrome, progressive radiculopathy, or myelopathy. Cauda equina syndrome should be considered in a patient with saddle anesthesia; bowel, bladder, or sexual dysfunction; or significant lower extremity pain and weakness, particularly if bilateral.[19,22] Progressive neurologic loss from nerve root compression is an indication for urgent surgical intervention, thus needs to be identified promptly. Myelopathy can present in various ways, including hand paresthesias or decreased fine motor control; lower extremity weakness or gait instability; sensory alterations in the trunk or extremities; or changes in bowel, bladder, or sexual function.[26]

Historical Features of the Presenting Complaint

Specifying the exact nature of the patient's chief complaint and provocative and palliative factors is an extremely important part of the diagnostic assessment. The examiner must identify the nature, onset, duration, and course of the primary complaint; history of previous injury; character and distribution of symptoms; prior diagnostic testing and treatment; other circumstances surrounding an injury (e.g., perceived fault, the presence of workers' compensation or litigation status); and the degree of pain and disability perceived by the patient. All of these factors are important in establishing an appropriate differential diagnosis and identifying some of the potential barriers to recovery.

Axial Versus Radicular Pain

The distinction between axial and radicular pain is fundamental in assessing a patient with a potentially neurogenic problem. *Axial* pain in the cervical, thoracic, or lumbar region suggests a different etiology, evaluation, diagnosis, and potentially treatment than radicular pain. For all levels of the spine, pathology involving the musculotendinous and ligamentous structures, zygapophyseal joints, vertebrae, and anulus of the intervertebral discs tends to cause axial pain. Other structures in the cervical and thoracic regions that can result in axial pain include soft tissue structures in the neck; vascular structures (e.g., aorta or carotid arteries); portions of the brachial plexus, such as the long thoracic or suprascapular nerves; the proximal portion of the ribs; costovertebral or costotransverse articulations; various structures within the shoulder; and various visceral structures, including the pancreas, gallbladder, lung and pleura, and stomach or duodenum (Fig. 12.6).

Radicular pain radiating into the upper extremities generally has a different etiology. If related to spine pathology, radicular pain implies neural compression from many potential causes, including disc herniation, spinal canal or neuroforaminal stenosis, or intrinsic disease of the spinal cord or nerve roots (e.g., herpes zoster). Radicular pain in the thoracic region can result in a bandlike distribution on one or both sides of the chest wall or abdominal region. Additional structures that can result in radiating upper extremity pain include peripheral nerves, such as the median nerve (e.g., carpal tunnel syndrome); ulnar nerve; portions of the brachial plexus (e.g., lower trunk plexopathies related to true neurogenic thoracic outlet syndrome or a Pancoast tumor); vascular structures; the shoulder; the heart; and musculotendinous, ligamentous, or bony structures in the upper extremities.

For the lumbar spine, the hip and pelvic structures must be considered as potential sources of low back, buttocks, or posterolateral hip pain. Particular sources of low back or buttock pain related to the bony pelvis include the sacroiliac joints, the sacrum (e.g., stress fractures), the ilia, and the hip joints. Other structures and processes that can result in low back pain include the kidneys and ureters; the pancreas; gastric ulcers; vascular abnormalities (e.g., aortic aneurysm); and retroperitoneal processes such as hematoma, endometriosis, or lymphadenopathy associated with malignancy.[27]

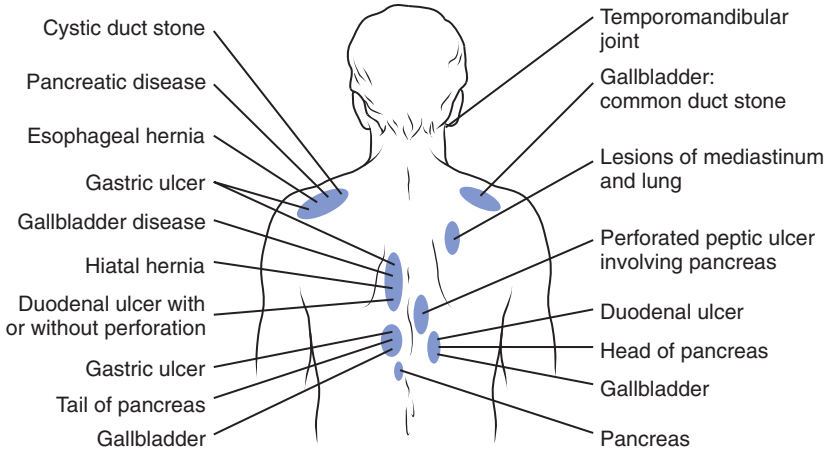

FIG. 12.6 Posterior referral sites from distant visceral or somatic structures. (From Nakano KK. Neck pain. In: Kelley WN, Harris ED Jr., Ruddy S, et al, eds. *Textbook of Rheumatology*. 4th ed. Philadelphia: WB Saunders; 1993.)

As with upper extremity pain, lower extremity radicular pain often has different etiologies and generally implies involvement of the lumbosacral nerve roots, the conus medullaris, or the spinal cord. The lumbar zygapophyseal joints and the sacroiliac joints also may occasionally be associated with radicular leg pain.[11,28] Distal lower extremity symptoms also may arise from intraarticular hip pathology; greater trochanteric bursitis; vascular pathology (e.g., vascular claudication); peripheral nerve injuries; compartment syndrome; local musculotendinous, ligamentous, or bony structures; and pelvic causes, such as endometriosis. Whatever the cause, the presence of leg pain with low back pain appears to increase the overall severity of the clinical state. Compared with those who have axial lumbar pain alone, patients with associated radicular pain experience a lower quality of life, require more resources, and have higher levels of pain and disability.[29] Given this, efforts to identify and appropriately treat the cause of leg symptoms have particular importance.

Patient Demographics

Demographic characteristics—such as age, gender, educational background, occupation, and cultural milieu—are important factors that must be considered in the history of a patient with a spine problem. Age is a primary determinant in establishing a differential diagnosis. Different spine problems appear at different frequencies at different ages. The social and psychological issues of individuals can also be quite distinct at different ages.

Growth and development have a profound impact on the approach to various processes, such as spondylolisthesis, scoliosis, and Scheuermann kyphosis. In contrast to the adult spine, the developing bony spine is relatively more prone to injury than some soft tissue structures. In a study by Micheli and Wood,[30] 47% of adolescents presenting to a pediatric sports medicine clinic were diagnosed with spondylolysis and only 11% had disc abnormalities compared with 48% of adults presenting to a low back pain clinic who were thought to have disc pathology. Generally, symptomatic isthmic spondylolysis is almost entirely seen in older children, adolescents, or young adults, and the rate of pars defects identified in the general population does not change substantially between the ages of 20 and 80 years.[31,32] Although 50% or more of children may be affected by low back pain by age 15 years,[33,34] significant spinal pain in children is uncommon and should raise concern for the presence of serious medical pathology.[35,36] Infection, neoplasm, rheumatologic conditions such as ankylosing spondylitis and juvenile rheumatoid arthritis, and other non-spine sources of pain may be more common in children and adolescents than in adults.[35,36]

In adults, the frequency of certain spine conditions varies by age group. Disc herniations are most frequent during the 4th and 5th decades, although they can affect individuals in their 50s and 60s or children and young adults.[37] Degenerative spinal stenosis and degenerative spondylolisthesis tend to present later in life. As mentioned previously, some medical conditions, including ankylosing spondylitis, spondylitis associated with inflammatory bowel disease, and tumors such as osteoid osteoma and osteoblastoma, tend to manifest in younger adults (20s and 30s). Other conditions—such as osteoporosis, polymyalgia rheumatica, metastatic cancer, or multiple myeloma—tend to occur in older adults (40s and 50s or older; Fig. 12.7).[3,38]

Gender is a factor in many spine pathologies. Osteoporosis is more common in women than in men, and osteoporotic fractures are more common in women. Neck pain also has been noted to be more prevalent in women than in men.[39,40] Rheumatoid arthritis, polymyalgia rheumatica, and endocrine disorders also tend to occur more frequently in women.[38] Spondyloarthropathies, infections, and various spine tumors—such as multiple myeloma, lymphoma, osteoblastoma, and eosinophilic granuloma—occur more frequently in men.

Demographic factors—such as race, ethnicity, and cultural milieu—may also play a role in the prevalence of some spine disorders, but are less well studied. Whites tend to have higher rates of osteoporosis than some other races, and metabolic conditions such as Gaucher disease can be associated with certain ethnic groups.[3] Whites have a higher rate of spondylolysis than African Americans.[31] The prevalence of low back pain also varies in different parts of the world, with

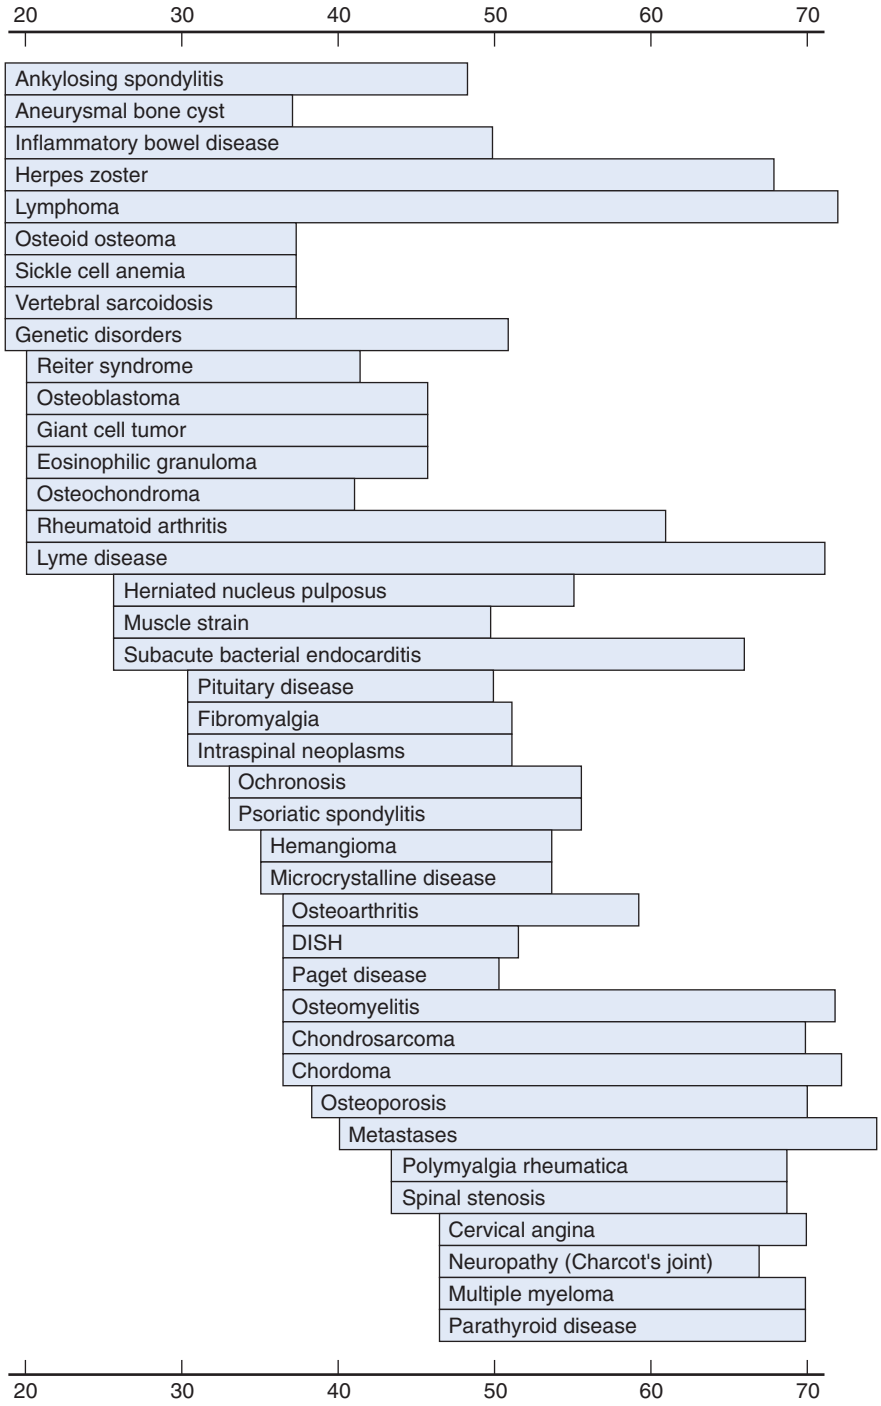

FIG. 12.7 Age at peak incidence of neck pain associated with various disorders. DISH, diffuse idiopathic skeletal hyperostosis. (From Borenstein DG, Wiesel SW, Boden SD. *Neck Pain: Medical Diagnosis and Comprehensive Management.* Philadelphia, WB Saunders; 1996.)

industrialized regions reporting a higher prevalence of low back complaints than rural, low-income areas.[41] Pain perception, disability, and other effects of pain on individuals vary widely and depend on many cultural and social factors.

Past Medical History

In addition to identifying prior surgical procedures, it is important to identify all past and current medical conditions because many medical problems can be associated with spine issues and can affect care of a patient with a spine disorder. As noted previously, a history of cancer, recent infection, or disease processes that affect the immune system or may require immunosuppressive medications can be associated with significant spine problems. Other medical conditions—such as osteoporosis, ankylosing spondylitis, and diffuse idiopathic skeletal hyperostosis—may place patients at increased risk for spine fracture.[42] Some congenital or genetic syndromes, such as Marfan syndrome and Down syndrome, can be associated with spine anomalies that must be identified. Vascular disease,

such as vascular claudication or aortic aneurysm, can produce symptoms that mimic spine pathology. Other disorders—including cardiac or pulmonary disease, renal disorders, skin conditions, gastric ulcers, diabetes, and hepatic disorder—may have an impact on potential treatment options and may preclude certain therapies. Clinicians need to be aware of all facets of a patient's medical history and the potential influence that medical issues may have on the care of the patient.

An additional aspect that must be considered in a patient with a spine disorder is a history of prior injury. Previous spine problems, trauma, and surgery may have important implications for the care of the patient. Details about the type and severity of injury and the type of treatment (including surgery), as well as the patient's response to it, are important historical features. Whenever possible, prior operative reports should be obtained. Short-term and long-term problems potentially can develop after surgery, and it is important to understand the nature of any prior surgery. Such adverse events include adjacent-segment degeneration or instability after a fusion, epidural fibrosis, infection, hardware-related problems, such as loosening, and recurrent disc herniation. A history of multiple or prolonged periods of pain or disability after prior treatments should raise concerns about the chances for success with future treatments.

Family History

The family history is a necessary component of a complete medical history. Although back pain and many other spinal conditions are common in the general population, data suggest possible genetic risk factors for lumbar degenerative disc disease.[43] A family history of rheumatologic diseases, particularly conditions associated with *HLA B-27* (such as ankylosing spondylitis, Reiter syndrome, and inflammatory bowel disease) can suggest a tendency for, or risk of, developing a similar process.[3,44] Other inheritable diseases, including certain neuromuscular diseases, may be associated with progressive spinal deformity, and patients with a genetic predisposition for certain medical conditions (e.g., vascular disease, specific cancers) may also present additional diagnostic considerations.

Obtaining a thorough family history may also allow a clinician to understand potentially complicated or delicate psychosocial aspects of a patient's life. Identifying significant disability in a family member or altered family dynamics from a spine issue may provide useful insight into a patient's expectations, fears, or other psychological features that could have a strong bearing on outcome. By asking about family members and parents, one can begin to understand the nature of family dynamics that may be influencing the presentation of a patient with spinal pain. A history of abuse, the presence of a disruptive home environment, and a history of poor parenting or alcoholism in the family may have a significant future impact on the psychological makeup of an individual. Anger, unmet dependency needs, and problems with trust in authority figures are some of the issues that could result in chronic pain issues. Probing these issues in taking a family history may provide valuable insight into potential barriers to recovery.

Yellow Flags: Predictors of Poor Outcome in the Patient's History

Numerous factors in a patient's history have been identified as potential predictors of poor outcome in the treatment of spinal pain. These factors are known as yellow flags (Box 12.1).[45] The presence of more than one of these factors in a patient is a strong predictor of poor outcome and chronic pain and disability.[45] These yellow flags include issues related to the nature of the patient's injury and general medical health, occupational and social issues, and psychological factors. It is imperative to identify these factors, if present, early in the course of evaluation and treatment of patients with spinal pain because they have been shown to be more powerful predictors of outcome than other biomedical issues.[44–48]

Patients who report more widespread symptoms of neck or back pain, who have more severe pain or disability at the onset of their injury, or who have higher rates of concurrent comorbidities tend to have a higher risk of developing protracted pain complaints or disability.[47–50] For low back pain specifically, dominant medical factors associated with the development of protracted pain or disability seem to be the presence of severe leg pain and a history of prior episodes of low back pain.[47,49,51] In the setting of whiplash, more severe pain or disability, the immediate onset of neck pain, low back pain or headache, and a history of neck pain all predict more protracted problems after the injury, as do less strictly event-related factors, such as a high level of catastrophizing

BOX 12.1 Yellow Flags: Potential Predictors of Poor Outcomes or Persisting Pain and Disability, Particularly When More Than One Is Present

Biomedical Factors

Widespread pain
High levels of comorbidity
Prior episodes of spinal pain (particularly if associated with disability)
Severe radiating limb pain
Poor sleep

Occupational Factors

Poor job satisfaction
Perceived poor-quality work environment
Absence of light-duty alternatives
Short time at current position
Low level of education
Physically demanding work
Extensive time off from work

Psychosocial or Cognitive Factors

Fear-avoidance beliefs
Catastrophizing
Passive coping style
Depression
Anxiety
Somatization
Psychological distress
History of abuse
Self-perceived poor health
Social withdrawal
History of substance abuse

From Gaunt AM. Caring for patients who have acute and subacute low back pain. *CME Bull.* 2008;7:1–7.

and a low educational level (less than a secondary education). Interestingly, accident-related details, including a rear-end mechanism and accident severity, are not predictive of worse outcomes.[52] Some distinct occupational factors that have been shown to be related to the development of chronic pain include heavy physical workload, unavailability of light duties on return to work, perceived poor working environment or job dissatisfaction, a low level of education, and a short time of employment on the job.[47–49,51,53] The amount of time off work from an injury also has a negative correlation with return to work rates.[54,55]

As noted previously, psychological factors seem to play a substantial role in the development of chronic spinal pain. In a review on this topic, Linton[46] noted that psychological variables are clearly linked to the transition from acute to chronic pain and generally have a stronger impact on chronicity than medical or biomechanical factors. Pertinent emotional factors cited include depression, anxiety, distress, and self-perceived poor health. Cognitive and behavioral factors also apparently play a key role in the development of a chronic pain state; these include a passive coping style, catastrophizing, and fear-avoidance beliefs (beliefs that certain activities should be avoided owing to fear of injury). A history of sexual or physical abuse also may be related to chronic pain and disability.[46] A systematic review of psychosocial factors found that psychological distress, depressed mood, and somatization were associated with the transition to chronic low back pain.[56]

Despite the high prevalence of psychopathology in patients with chronic pain, there does not seem to be a premorbid "pain-prone" personality; the depressive features of chronic spinal pain generally seem to arise more as a consequence, rather than a cause, of the pain state.[46,57,58] One study did identify premorbid depression, however, as an independent, robust risk factor for the onset of an episode of troublesome neck or low back pain.[59]

From a strictly surgical perspective, the outcomes of lumbar surgical procedures are influenced by numerous factors completely unrelated to the anatomy or pathophysiology of the spine. The results of lumbar discography are influenced by psychosocial variables to such a large degree that there are concerns about the validity of the procedure.[15] Factors identified as predictors of poor outcome from surgical intervention in the lumbar spine include low level of education, low income at the time of injury, the presence of pending litigation, the presence of an industrial injury, anxiety, neuroticism, and depression.[60–65] Surgical outcomes have also been found to be worse in geographic regions with higher rates of surgical intervention.[66] From a clinical standpoint, it is important to identify predictors of poor outcome or chronicity to provide appropriate care to address these issues and to *avoid* invasive care that is highly unlikely to be helpful and could contribute to the perpetuation of chronic pain and disability.

Obtaining a Psychosocial History

Obtaining information necessary for successful decisions about care requires the spine specialist to evaluate a patient with chronic pain differently from a patient with an acute injury. It is particularly true in treating the patient with chronic pain that the foundation for good decision making is having a good knowledge of the *person* with a back disorder; the spine itself is less important. In other words, it is more important to know about the patient who has the disease than to know about the disease the patient has. This is well borne out in the data presented earlier on prognostic and predictive factors, which generally have much more to do with the psychological state or approach of the affected individual than they do with the actual injury.

It is dangerous to assume that a patient's presenting symptoms are solely the result of the injury that led to the consultation. Patients in whom disability greatly exceeds that expected on the basis of objective findings have been shown to be much more likely to have encountered childhood abuse and conflict, parental job stress, or a difficult divorce. Pain is an experience that is influenced by everything that is currently occurring in the life of the patient. Equally or sometimes more important is everything that has gone on in the patient's life in the past. In a study of more than 25,000 subjects in 14 countries, the World Health Organization found that physical disability is more closely associated with psychological factors than with medical diagnosis.[67] Regardless of the presence of anatomic pathology, it is important to understand that a family member, a stressful circumstance, regular use of opioid analgesics, money issues related to compensation or litigation, and other factors can contribute to a patient's ongoing pain and disability. This comment should not be construed as indicating that the pain is "all in the patient's head," and it is not intended to suggest that the patient is malingering or that the patient's pain is invalid or trivial. Pain and the disability it may produce are complex and multidimensional.

It has been estimated that approximately 50% of patients with chronic pain in rehabilitation and family practice settings have a personality disorder, as documented through structured interviews and psychological testing.[68] Thorough evaluation of patients with back pain needs to include some form of psychological testing because psychological factors play a critical role in patient recovery from illness or injury and the response to surgery or other medical interventions. Ignoring either the physical or the psychological components of pain in diagnosis and treatment is a prescription for failure, disappointment, and dissatisfaction. Several psychological test instruments are available for this purpose.

Additional Assessment Tools

Although there is no substitute for a concise, yet thorough, history, there are some tools that can improve efficiency. Preprinted questionnaires can be used to obtain details of a patient's history. Including some questions about the psychological issues noted previously can facilitate the efficient acquisition of a large pool of information. Other vehicles—such as pain drawings, pain scales, and functional outcome measures—can also be used.

Pain drawings have been used since the 1940s, and research into their significance has provided mixed results.[69] Although

there are data supporting an association between psychological distress and widespread, nonanatomic markings on the pain drawing, there is contradictory evidence in other studies. Data are also contradictory on the usefulness of pain drawings in predicting surgical outcomes.[69] Pain drawings have been assessed using various means and have been shown to have relatively high repeatability.[69,70] Although the presence of widespread or nonanatomic patterns of pain on these drawings may be of some use in identifying pain intensity and the presence of depression or psychological distress, one systematic review did not find evidence to support their use as a formal psychological assessment tool (Fig. 12.8).[69,71,72]

A variety of pain scales may be used in patient assessment. Various visual analog scales have been reported. The Million Visual Analog Scale has been shown to have good reliability, validity, and responsiveness.[73] The McGill Pain Questionnaire has also been widely used and is well validated. This questionnaire provides a quantitative assessment using numerous descriptors of pain over three separate domains that are identified by the test taker and scored.[73] Other scales identifying the "bothersomeness" of pain and the bodily pain item in the Medical Outcomes Study 36-item Short Form Health Survey (SF-36) have also been applied in the assessment of patients with spine disorders.[74]

Numerous functional scales exist, including the Oswestry Low Back Pain Disability Questionnaire, the modified Roland scale, the Neck Disability Index, the Sickness Impact Profile and the related Disability Questionnaire, and the SF-36.[73–77] The Oswestry questionnaire, which uses self-rated functional impairment in numerous activities of daily living, has been shown to be valid and responsive, and is generally easy to administer and score.[73,75] The modified Roland scale, which consists of 24 "yes" or "no" questions regarding the functional impact of back pain, was originally derived from the Sickness Impact Profile, has been well validated, has a high responsiveness, and is very easy to score.[73,74]

Several brief psychological scales are also useful. The presence of fear-avoidance beliefs and catastrophizing are particularly important in the development and maintenance of chronic pain and disability. The Fear-Avoidance Beliefs Questionnaire[78] and the Pain Catastrophizing Scale[79] are validated assessment tools that can be used to quantify these factors.

The Battery for Health Improvement-2 is a self-report multiple-choice instrument designed for assessment of medical patients. It is intended to provide one source of clinical hypotheses that professionals can use to explore the interrelationships between a patient's psychological and medical conditions. The information can be particularly useful in helping to determine factors that may be influencing an inexplicable delay in recovery of an injured patient. The Opioid Risk Tool is clinically relevant and easily employed during the interview.[80]

The Patient-Reported Outcomes Measurement Instrumentation System (PROMIS) is a set of publicly available measures to evaluate patient-reported outcomes through the assessment of physical, social, and emotional health. There is a wide range of measures that have been developed and validated, including a number for pain, emotional distress, alcohol use, and other issues that may be related to chronic spinal pain. There are several composite scales available, including the PROMIS-29, which covers the domains of anxiety, depression, fatigue, pain interference, physical function, sleep, and social functioning.[81] The PROMIS measures have been studied in a vast array of medical conditions, and are likely to play an important role in research and clinical care in the chronic pain population.

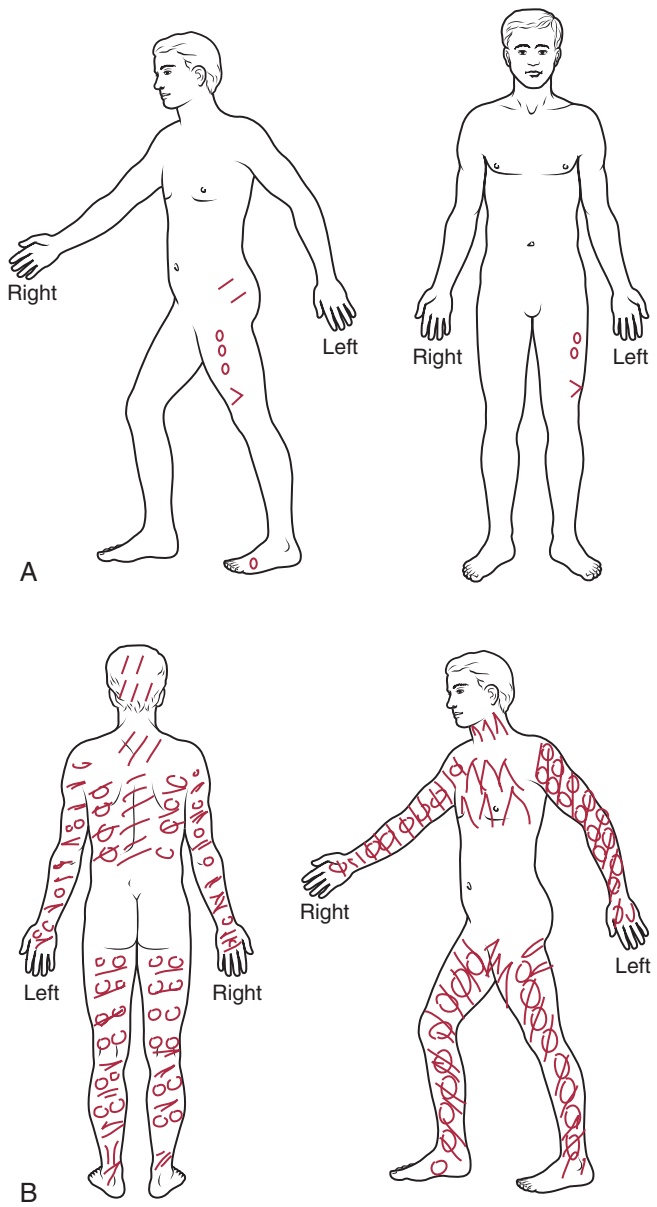

FIG. 12.8 Pain drawings by patients. (A) The patient had radiating pain in an L3 pattern related to intraforaminal disc herniation at L3–L4. (B) The patient had long-standing, widespread pain in nonanatomic distribution.

Physical Examination

After obtaining a complete history, a focused examination can be performed to establish a baseline functional and neurologic assessment, identify pertinent positive and negative findings

that can help narrow the differential diagnosis, and define further issues that may need to be addressed through additional testing. Although a thorough discussion is beyond the scope of this chapter, appropriate portions of a general medical examination need to be included in the assessment of a spinal patient depending on the nature of the presenting issues. Neurologic and orthopaedic examinations of varying degree and complexity are also necessary. This chapter follows a more focused approach to the examination of the spine with a discussion of basic neurologic assessment and relevant provocative maneuvers appropriate to a patient's presenting problem.

Observation

The physical examination starts with observation, which begins when the physician first sees the patient. Movement patterns, preferred postures, inconsistencies, and gait abnormalities should be noted by the clinician and staff members throughout the patient's visit. This observation needs to be done casually during office or facility interactions and during the medical history, then in a more formal manner during the examination. Formal observation should include an examination from the feet to the head. Trunk and appendicular alignment should be noted, paying particular attention to hip and knee alignment. The spine should be assessed for alterations from normal alignment or resting curvature, including scoliosis, kyphosis, alterations in lumbar or cervical lordosis, a lumbar shift, and head and neck alignment with the trunk. Symmetry of shoulder height and scapular positioning should also be noted.

Gait assessment can be done after initial observation, looking specifically for gait patterns suggestive of neurologic deficits, such as a steppage gait associated with footdrop or a wide-based gait suggestive of proprioceptive, cerebellar, or myelopathic pathology. Gait can be tested further by tandem gait testing (heel-to-toe walking). Balance can be assessed by simple observation and performing a single-leg stance with various postural challenges (e.g., crouching on one leg). If a patient has an antalgic gait (i.e., shortened stance phase of the gait cycle), consideration should be given to a musculoskeletal problem involving the hips, knees, or foot and ankle. Generally, patients with a lumbar radiculopathy do not exhibit an antalgic gait pattern.

Spine range of motion (ROM) should be assessed for all relevant spine segments. There is debate as to what constitutes "normal" range of spine motion and the significance of any perceived restriction of motion. In the lumbar spine, ROM has been variably reported by using inclinometry, measuring the distance from the fingertips to the floor, assessing segmental motion, measuring dynamic motion, measuring motion with the pelvis restrained, radiographic measurement, and using variations of the Schober test (measuring the change in distance between a mark over the S1 spinous process and one made 10 cm above this in standing that occurs between standing and flexion).[82–85]

The value of ROM measurements is questionable, however, because some data do indicate that there is no consistent relationship between ROM and physical or functional impairment in subjects with chronic low back pain.[83] ROM generally seems to decline with age, further complicating attempts at establishing normative data.[82] Gross lumbar motions generally include motion from the hips and lower extremities, and any lateral flexion or rotation involves coupled motion at multiple levels, making it difficult to assess these reliably. It is important to examine hip motion, however, because painful and restricted hip motion, particularly in flexion with internal rotation, that mimics the patient's usual pain would generally implicate the hip as a source of pain.

Despite these substantial limitations, it is still important to assess active spine motion in flexion, extension, rotation, and lateral flexion. Along with absolute degrees of movement, the examiner can assess symmetry of motion, preferred movement patterns, pain or symptom reproduction associated with motion, the relative contributions of associated body segments to motion (e.g., hips), motor control, and inconsistencies between movement noted on formal examination and that seen during casual observation or while the patient is otherwise distracted. Generally, patient motion should be assessed actively within the patient's range of comfort. There is little or no role for passive ROM because this adds little to the clinical assessment and may place the patient at risk for further injury.[38]

For cervical and thoracic complaints, it is also important to assess shoulder and scapular motion. Shoulder ROM can be assessed actively by flexion and abduction along with passive motion of the glenohumeral joint. Scapular position at rest and with various arm positions can reveal abnormal movement patterns and may indicate problems with scapulothoracic function, other shoulder joint complex disorders, or neurologic injury affecting the parascapular musculature (e.g., a long thoracic or spinal accessory nerve injury). Scapulothoracic dysfunction of various kinds may also be a source of pain in patients with thoracic complaints.[86] Reproduction of a patient's shoulder region pain by passive shoulder motion, particularly if it is restricted, would generally implicate the shoulder rather than the neck as the source of pain. Patients with a cervical radiculopathy obtain relief with ipsilateral shoulder abduction (the shoulder abduction relief maneuver); patients with intrinsic shoulder pathology often have reproduction of pain with shoulder abduction.

Observation should also include looking for atrophy, edema, vasomotor changes, skin lesions, limb or joint deformity, contracture, and other signs that may have an impact on a patient's care.

Palpation

The relevant areas of the patient's spine and related structures should be palpated with the patient standing or, when appropriate, in side-lying or prone position. Palpation may aid in the localization of the patient's symptoms, the identification of an injured structure, or the identification of associated soft tissue or bony abnormalities. It should be noted whether tenderness is elicited in the midline or to either side of the midline, potentially differentiating between spinal pain and pain from an adjacent soft tissue source.[38] Localized tenderness should

be distinguished from diffuse tenderness, the latter being less consistent with a focal injury.

In the cervical spine, palpation should include the occipital region; the anterior neck; the clavicular, supraclavicular, and scapular regions; and the areas of the associated cervicothoracic musculature.[38] In the thoracic region, palpation should also extend across the posterior ribs to identify focal bony tenderness that may suggest rib pathology rather than spine pathology. Pain with palpation or percussion of the costovertebral angle may suggest renal pathology.[87] Spondylolisthesis can frequently be appreciated by a palpable step-off of the spinous processes in the lumbar spine. In the lumbar region, palpation should include not only the lumbar spine but also the iliac crests, sacrum, sacroiliac joints, ischial tuberosities, proximal hamstring, and greater trochanteric areas, as indicated, to assess for the possibility of contributing problems from these regions. Trochanteric pain may mimic pain from a spine etiology.

Clinicians need to recognize that the ability to accurately identify a spinal level by palpation is quite limited. Multiple studies have confirmed high rates of inaccuracy with manual palpation, which raises concerns for the manual identification of structural problems and for the precise placement of medical instruments for spinal interventions.[88,89]

Neurologic Examination

As with the general medical examination, the neurologic examination may cover a wide range of factors, depending on the particular presenting problem. The most common neurologic manifestations of spine pathology generally involve the spinal nerve roots or the spinal cord, resulting in radicular or myelopathic findings on examination. The symptoms resulting from spine pathology may frequently overlap, however, with symptoms of various peripheral nerve processes, central nervous system disease, or anterior horn cell disease. An examiner needs to be aware of the clinical presentations and neurologic findings associated with these disorders. A full discussion of all relevant examination techniques and neurologic pathology is beyond the scope of this chapter, but can be found in general neurology texts. This section focuses on findings more directly related to spine pathology.

A thorough understanding of dermatomal patterns is essential for all clinicians examining spine patients. As a reference, the key sensory points identified by the American Spinal Injury Association[90] can be helpful in assessing or screening patients with spine pathology (see Fig. 12.5). Soft-touch and pin-prick sensation can be assessed well in most patients; the examiner should distinguish between a dermatomal distribution suggesting nerve root pathology, a stocking or stocking-and-glove distribution suggesting peripheral polyneuropathy, multiple nerve distribution suggesting alternative peripheral nerve pathology, or a nonorganic distribution. Proprioception, vibration, position sense, and temperature sensation may also be tested, particularly when there is concern for a spinal cord or central nervous system process or a peripheral neuropathy.

Motor examination consists of several parts, including strength, tone, coordination, muscle bulk, and involuntary movements.[87] Strength is the modality most generally assessed by clinicians, but all portions of the motor examination may be important in some patients with spine disorders. Involuntary movements may be noted in patients with cervical dystonia or in various neurologic diseases that may affect function, such as Parkinson disease. The presence or absence of focal muscle atrophy should be noted in all patients. The mere presence of focal atrophy implies neurologic injury or disease, and the distribution of atrophic muscles can be helpful in defining the type of pathology present. Fasciculations associated with atrophic muscles imply the presence of lower motor neuron injury. Muscle tone can be affected by many neurologic processes. Reduced tone suggests lower motor neuron involvement, whereas increased tone or spasticity is seen with upper motor neuron disease. Coordination may be disrupted by numerous pathways, generally involving the cerebellum or its pathways, but weakness, proprioceptive loss, and cognitive disturbance may also affect motor performance on tests of coordination. Clinical methods to assess coordination include rapid alternating hand and foot movements and finger-to-nose testing.[87]

Strength testing is generally done isometrically, but sometimes weakness can be better appreciated through dynamic or repetitive movements that address endurance (e.g., multiple single-leg toe raises to assess plantar flexor strength). It is essential to be aware of key muscle groups by myotome and the peripheral nerve origin of those muscles. Important muscle groups and motions associated with cervical and lumbar myotomes are as follows:

C5—elbow flexors, shoulder abductors and external rotators
C6—elbow flexors, wrist extensors and pronators, shoulder external rotators
C7—elbow extensors, wrist pronators
C8—extension of index finger, finger abduction and flexion, abduction of thumb
T1—finger abduction
L2—hip flexion
L3—hip flexion, hip adduction, knee extension
L4—knee extension, ankle dorsiflexion
L5—ankle dorsiflexion, great toe extension, ankle eversion, hip abduction and internal rotation
S1—ankle plantar flexion, toe flexion

Strength is generally graded on a scale of 0 to 5 as follows:[87]

5—active movement against full resistance (normal strength)
4—active movement against gravity and some resistance
3—active movement against gravity
2—active movement with gravity eliminated
1—trace movement or barely detectable contraction
0—no muscular contraction identified

Active movement is generally meant to imply joint motion through the full available ROM. For some muscle groups, patients can often have significant loss of strength that is not detectable by providing manual resistance with the examiner's arms; thus, other test maneuvers may be necessary to identify more subtle weakness. Examples of such maneuvers would be having the patient do a partial squat or arise from sitting

without using the upper extremities to assess for weakness in the knee extensors. The Beevor sign (in which the umbilicus moves craniad during contraction of the abdominal muscles with supine neck flexion) indicates weakness of the lower abdominal muscles.[26]

Reflex testing can further aid in the localization of neurologic injury and help distinguish upper motor neuron from lower motor neuron disease. In lower motor neuron injuries, deep tendon reflexes of affected regions are generally reduced, whereas they are brisk in upper motor neuron injuries. The Babinski response to appropriate plantar stimulation, Hoffman sign in the hand, and clonus all can indicate the presence of upper motor neuron injury. As with other physical examination findings, the sensitivity and specificity of these findings are limited for any particular condition. In a study assessing the prevalence of physical examination findings in cervical myelopathy treated surgically, it was noted that 21% of the patients had no myelopathic findings on examination. Of the findings just mentioned, the Hoffman sign was the most sensitive (59%), whereas the Babinski response had very low sensitivity (13%) but was highly specific.[91] Various other reflexes—including abdominal, cremasteric, and palmomental—can also be used as part of the neurologic examination when appropriate.

Although a neurologic injury often manifests as either an upper or a lower motor neuron lesion, it can also manifest with a mixed pattern of upper and lower motor neuron features, as can be seen with amyotrophic lateral sclerosis. The segmental distribution of commonly tested deep tendon reflexes is as follows[87]:

Biceps reflex—C5, C6
Brachioradialis reflex—C5, C6
Triceps reflex—C6, C7
Patellar tendon reflex—L2, L3, L4
Medial hamstring reflex—L5, S1
Ankle jerk reflex (Achilles tendon)—S1

For the most part, the sensitivity and specificity of isolated tests for sensation, strength, and reflexes are relatively limited in the assessment of spine conditions, particularly when any one single test is considered.[22,85,92] There may be more utility in combining a variety of findings across multiple modalities, especially when the findings are consistently reproducible. The degree of consistency between examination findings, history, imaging results, and self-reported levels of pain and disability for affected patients should always be considered when clinical decisions on care are made.

Special Tests and Provocative Maneuvers

In addition to the standard examination techniques described earlier, various provocative maneuvers and other tests have been used to aid in the diagnosis of patients with spine conditions. The sensitivity and specificity of many of these tests are either unclear or suboptimal, but a working knowledge of their applicability is useful in the diagnosis and management of patients with spine conditions.

The *Lhermitte sign,* although more technically a symptom, is the presence of an electric shock–type sensation radiating into the limbs with cervical flexion. Although first described in a patient with multiple sclerosis, this sign is associated with various spinal cord lesions.[26,38] If elicited with neck flexion, this sign should raise concern for the presence of a cervical cord lesion. If elicited with trunk flexion, this may indicate a thoracic cord lesion.[26]

The *Spurling maneuver* is a test for cervical nerve root compression or irritation. A positive test is elicited by extending, rotating, and laterally bending the head to one side with reproduction of radicular pain into the affected ipsilateral extremity.[26,38] One study comparing the Spurling maneuver with the results of electrodiagnostic testing found that the maneuver had poor sensitivity (30%) but good specificity (93%) in the diagnosis of electrodiagnostically confirmed cervical radiculopathy.[93]

The *Valsalva maneuver* is performed by having a patient hold his or her breath and bear down. A reproduction of the patient's radicular symptoms or spinal pain with this maneuver is believed to indicate a space-occupying lesion, such as a disc herniation, in the spinal canal.[26,38]

Dural tension signs are frequently used to assess lumbar spine pathology. Many different maneuvers have been described. A supine *straight-leg raise* is performed by elevating the leg with knee extended and assessing for the reproduction of pain into the leg. The test is considered positive if pain occurs between 30 degrees and 70 degrees of elevation because no true change in tension on the nerve roots is believed to occur outside of this range.[3,85] Variations on this test include the *Lasègue sign* or *Bragard sign,* which involves raising the leg to the point of symptom reproduction and then lowering the leg slightly and dorsiflexing the foot passively; a positive test results in reproduction of the patient's radiating leg pain.[3,94] Other variants include internally rotating the leg to increase "dural tension," raising the leg with knee flexed and then slowly extending the knee to the point of reproduction of leg pain (also sometimes referred to as the *Lasègue sign*), and either relieving pain by flexing the already extended knee at the point of symptom reproduction or eliciting pain by pressing on the popliteal fossa of the elevated leg with the knee partially flexed (both varyingly called the *bowstring sign*).[3,85,92,94]

Additional tests include the *crossed straight-leg raise,* in which symptoms are reproduced in the symptomatic leg by performing a supine straight-leg raise on the contralateral leg, and the *femoral nerve stretch test* or *reverse straight-leg raise,* in which the patient is prone and the knee is passively flexed, with a positive test reproducing pain into the anterior thigh. A positive straight-leg raise test and its variations indicates tension on the lower lumbar roots and upper sacral root (L4, L5, and S1 nerve roots). A positive femoral nerve stretch test is the equivalent tension sign for the upper lumbar (L2–L4) nerve roots.[3,85,92]

Numerous studies have looked at the sensitivity and specificity of some of these maneuvers. As might be surmised by the varying descriptions and terminology, there are some difficulties with consistency in the literature. Overall, the ipsilateral straight-leg raise test has a good sensitivity of 72% to 97% but a poorer specificity of 11% to 66%.[92] The crossed straight-leg raise test is less sensitive (23–42%) but

more specific (85–100%) than the ipsilateral straight-leg raise.[85,92]

Tests proposed for assessing the sacroiliac joint include the *Gillet, Patrick,* and *Gaenslen tests*. Although the sacroiliac joint can be a source of pain, the diagnosis of "sacroiliac joint dysfunction" is debated as a true pathologic entity. Dreyfuss and colleagues[28] studied numerous supposedly diagnostic tests for this condition, including the Gillet, Patrick, and Gaenslen tests, and compared the responses on these test maneuvers with the results of fluoroscopically guided sacroiliac joint blocks. They found that no historical feature, none of the diagnostic tests performed, and no combination of these tests showed any significant and reliable diagnostic value.

Nonorganic Signs

Chronic pain behavior is often believed to display common physical examination findings suggesting symptom magnification and psychological distress, possibly an expression of suffering.[95,96] Waddell and colleagues[95] defined and studied a group of five findings on physical examination, commonly known as *Waddell signs*. These findings consist of a superficial or nonanatomic distribution of tenderness; a nonanatomic motor or sensory impairment (regional disturbance); excessive verbalization of pain or gesturing (overreaction); production of pain complaints by tests that simulate only a specific movement, such as low back pain that occurs with axial loading on the crown of the head (simulation); and inconsistent reports of pain when the same movement is performed in different positions, such as a straight-leg raise in a seated versus supine position (distraction).[95]

The presence of three or more of these signs indicates a nonorganic component to an individual's pain complaints. The presence of Waddell signs does not mean, however, that there is no significant organic pathology present or that the patient is malingering; objective clinical signs may be present as well. Although some studies have found these maneuvers to be reproducible, an evidence-based review by Fishbain and colleagues[97] noted that these findings do not correlate with psychological distress or secondary gain, and they do not discriminate nonorganic from organic problems. They are associated with poorer treatment outcomes and higher pain levels. Although these maneuvers may be useful, the clinician should be wary of placing too much emphasis on any one part of the physical examination.

Additional Orthopaedic Assessment

Depending on the area of the spine involved, it is frequently important to cover additional areas of the orthopaedic examination. As was previously mentioned, examination of the shoulder complex is often necessary in evaluating the cervical and thoracic spine. Following the concept of the *kinetic chain,* it is also often helpful to assess multiple other joint structures and movement patterns from the feet up through the trunk to the neck, depending on the individual patient's situation.[98] For the lumbar spine, examination of the hip is also generally important, although examination of more distal lower extremity structures and more cranial regions of the spine and upper extremities may be necessary as well. Because other conditions—such as carpal tunnel syndrome, ulnar neuropathy, brachial plexopathy, peroneal neuropathy, and femoral nerve injury (among others)—can masquerade as radiculopathies, examination for these entities is also often indicated. As noted previously, an appropriate history can help greatly in defining the scope of examination necessary to evaluate a particular patient.

There is a large body of literature on manual orthopaedic examination.[99,100] These techniques generally are poorly validated and of uncertain correlation to some of the more "objective" findings noted earlier. A systematic review of the literature on the reliability of palpatory examination maneuvers found that most procedures have moderate or strong evidence for low reliability.[101] The authors noted that "a consistent finding from work in this field is the generally low reliability of palpation-based assessment."[101] These techniques may be helpful in certain treatment paradigms, however, and they may be more useful when symptom response with repeated movements is considered.[101] Another systematic review assessed the literature on chiropractic tests of the lumbar spine and found insufficient evidence on the reliability and validity of these tests to support their clinical role.[102]

Risk Stratification

Distinct from the idea of the evaluation of an individual patient is the concept of risk stratification within a population. Within the clinical array of patients with spinal disorders, there are clearly those who will require more extensive care and/or be at risk for particularly poor outcomes. There is increasing interest in applying screening mechanisms across a population to help identify those patients with a poor prognosis for recovery or in need of more intensive or multidisciplinary care. This type of assessment may be incorporated into a patient's initial evaluation. An example of such a screening approach is the STarT Back tool.[103] Consistent with the data noted earlier on prognostic factors for those with spinal pain, the STarT Back questionnaire consists of nine questions addressing the bothersomeness of pain, the presence of leg pain or concurrent neck symptoms, and the presence of fear avoidance or other generally detrimental belief systems regarding pain.[104] The intent is to separate patients with more limited symptom complexes and better coping skills who will likely do well with standard treatments from those who may require more advanced or complex interventions in order to improve outcomes. In the primary study of the STarT Back tool, the researchers developed and implemented a psychologically driven physical therapy program for the more at-risk population, finding improvements in outcomes for those treated based on risk stratification from those managed without any such tool. They also found that primary care providers did a relatively poor job of appropriately identifying the physical therapy needs of patients without using the questionnaire.[103] The broader applicability of this tool is currently under study, but this type of work highlights the potential benefits of stratifying patients for treatment. This may become an important

component of the medical history for patients with spinal disorders.

Summary

The history and physical examination of a spine patient is a complex undertaking. The nature of the patient's presenting complaints and relevant aspects of the history have a strong bearing on the nature and extent of assessment required. Clinicians caring for patients with spine disorders need to be aware of all of the issues that may affect the presentation of a patient and how these issues can affect the delivery of care. As noted previously, it is of paramount importance to realize that the person presenting with the spine problem is the primary concern, and the spine problem is only secondary. Only by speaking with and directly examining a patient can clinicians truly understand the nature of the problem that they are being asked to address.

KEY POINTS

1. A thorough and appropriate history and physical examination are essential in the assessment of patients with spine disorders to identify the physical manifestations of a spine disorder and the root causes of the patient's distress, suffering, and disability.
2. It is crucial to identify red flags and yellow flags in a patient's clinical presentation. Red flags are factors suggestive of the presence of an urgent or emergent medical issue (e.g., infection, tumor, fracture, cauda equina injury, progressive neurologic loss). Yellow flags are factors associated with poor outcomes and persisting pain and disability.
3. The medical history can be used to narrow down the differential diagnosis and direct further diagnostic efforts through physical examination and other tools.
4. The value of isolated findings on physical examination is limited, although physical examination findings become much more significant in the context of correlating history and imaging.
5. Despite the importance of a thorough medical history, clinicians need to realize that psychosocial factors are a more important predictor of outcome in patients with spinal pain than biomedical factors.

13 CHAPTER Spine Imaging

Todd M. Emch
Jeffrey S. Ross
Gordon R. Bell

Multiple imaging methods with tremendous technologic complexity and sophistication can be used to evaluate spinal pathology. Magnetic resonance imaging (MRI) quickly emerged as the study of choice for many disorders of the spine, with computed tomography (CT) continuing to play a key role, bolstered by newer innovations such as helical scanning and multidetector arrays allowing isotropic voxels and multiplanar reformatting without loss of resolution. This chapter reviews the basic imaging approaches to the spine and their usefulness, both in specific disease states, and in the context of the anatomic categories of spine pathology (extradural, intradural extramedullary, and intramedullary).

Modalities

Radiographs

Routine plain films are universally available and inexpensive, but are limited by an inability to directly visualize neural structures and nerve root or cord compression. Ionizing radiation is used to obtain the radiographic image, which despite the relatively fast time of acquisition, can still be susceptible to motion.[1] Radiographs can be used for evaluation of alignment, status of hardware in the postoperative patient, intraoperative localization, and motion with flexion-extension views.

Radiographs can visualize osseous structures and surrounding soft tissues (i.e., extradural pathology). A routine examination of the spine includes frontal or anteroposterior and lateral views, with additional views such as oblique or flexion-extension also available.[2]

Orthogonal conventional radiography is the first line of evaluation in an instrumented postoperative patient, and plain radiographs are usually obtained at 6 weeks and 3, 6, and 12 months postoperatively.[3] Regardless of which fusion approach is taken, the presence or absence of demonstrable motion or evidence of hardware failure or loosening is a key factor in the evaluation. In the case of posterolateral fusion, arthrodesis is deemed successful if follow-up radiographs show continuity in the fusion mass between the cephalad and the caudal transverse processes. Instrumented interbody fusion is considered fused if any of the following is present:

1. Increased or maintained bony density within the cage implant because of the presence of mature bony trabeculae bridging the interbody space
2. Absence of a halo or a periprosthetic lucency around the implant
3. A sclerotic line between the cage and the vertebral bone because of bone remodeling and new bone formation
4. Resorption of anterior vertebral traction spurs or the presence of bone graft anterior to an intervertebral implant (sentinel sign)
5. Lack of motion on flexion-extension views

Pseudarthrosis or failure of fusion is indicated by progressive loss of disc height, vertebral displacement, broken or loose hardware, and loss of position of the implant or resorption of the bone graft. Flexion and extension views are useful for assessing stability or functional fusion, but the central x-ray beam should pass through the same area in both views.[4]

Myelography

Myelography involves instillation of the contrast agent through either lumbar puncture (midline or oblique approaches) or lateral C1–C2 puncture with subsequent radiographic and CT imaging of the region of interest. The diagnosis of extradural neural compression by myelography is inferred indirectly by changes in the contour of normal contrast agent–filled thecal sac and root sleeves rather than by direct visualization of the lesion.[5] Expansion of the spinal cord (Fig. 13.1) can be visualized as well as intradural extramedullary lesions; however nonexpansile cord pathology cannot be detected with myelography.[6]

The major disadvantage of myelography is its invasive nature and lack of diagnostic specificity.[7] The use of less toxic second-generation, water-soluble nonionic agents has obviated the need for overnight hospitalization after the procedure. Routine postprocedural monitoring of 2 to 4 hours is usually sufficient. Multiple water-soluble agents are available that provide excellent contrast and lower rates of side effects, such as iohexol (Omnipaque) and iopamidol (Isovue).

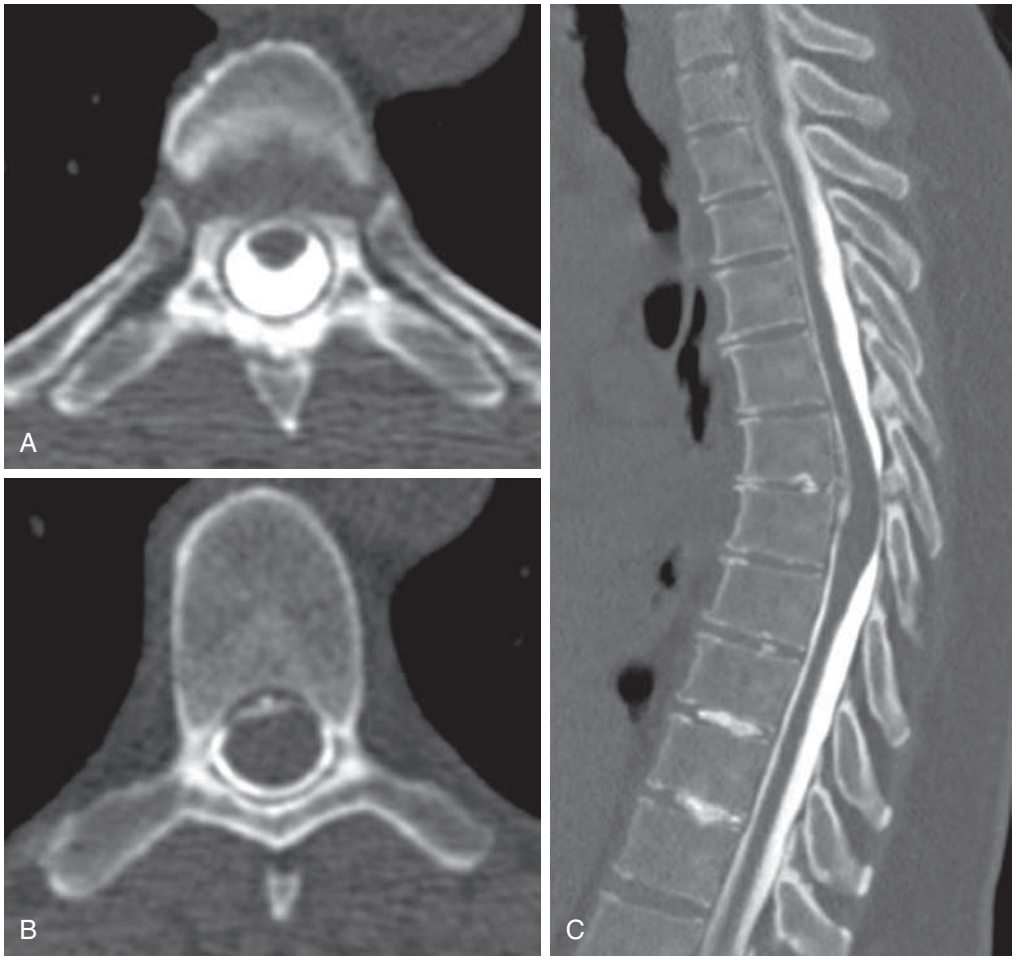

FIG. 13.1 Computed tomographic myelogram demonstrating an intramedullary mass lesion. (A) Axial image demonstrates normal diameter of the thoracic spinal cord. (B) Axial and (C) sagittal images demonstrate fusiform expansion of the mid-thoracic spinal cord in this patient with an ependymoma.

Current water-soluble agents are associated with less toxicity, and their absorption through the theca and arachnoid villi makes their removal unnecessary.[8] Newer nonionic water-soluble agents generally produce mild side effects, although significant adverse reactions can still rarely occur, such as hallucinations, confusion, or seizures. Considerations before myelography include obtaining screening laboratory tests such as platelets, prothrombin time/international normalized ratio, and partial thromboplastin time; medication history of the patients, especially metformin; psychiatric medications, which can lower seizure threshold; and anticoagulants.[9,10]

Computed Tomography

CT permits direct visualization of potential neural compressing structures and provides better visualization of lateral pathology, such as foraminal stenosis.[11-13] An important benefit from a surgical perspective is the ability of CT to distinguish neural compression due to soft tissue from compression from bone pathology.[12,14-16]

Disadvantages of CT include radiation exposure, the effects of partial volume averaging, streak artifacts in the cervical spine caused by the dense bone of the shoulder girdle, and changes in configuration of the spine that occur between successive motion segments.[17] Many of the limitations can be obviated by obtaining multiple thin sections (1.5 to 3 mm) with the gantry tilted to permit imaging parallel to the plane of the disc. Further accuracy is obtained by routinely imaging the spine by CT after the introduction of water-soluble contrast agents (intrathecal contrast medium–enhanced CT).

Reported accuracy rates for CT range from 72% to 91%.[7,12,14,15] Agreement rates between contrast medium–enhanced CT and myelography have been reported to range from 75% to 96%.[12,14] When a discrepancy exists between myelographic and CT findings, postcontrast CT is invariably the more accurate study (Fig. 13.2). Current multirow detector technology is now available that allows for extremely rapid thin-slice acquisitions over long body segments. With this technology, contiguous 3-mm slices can be obtained from L1 to S1 in less than 30 seconds. The acquisition of isotropic voxels allows for multiplanar reformation of the CT data with no loss in spatial resolution. Changes in the windowing and leveling of the images can change the focus onto either osseous structures or soft tissues.[1]

Magnetic Resonance Imaging

MRI can readily evaluate the extradural, intradural extramedullary, and intramedullary spaces and is also the only modality

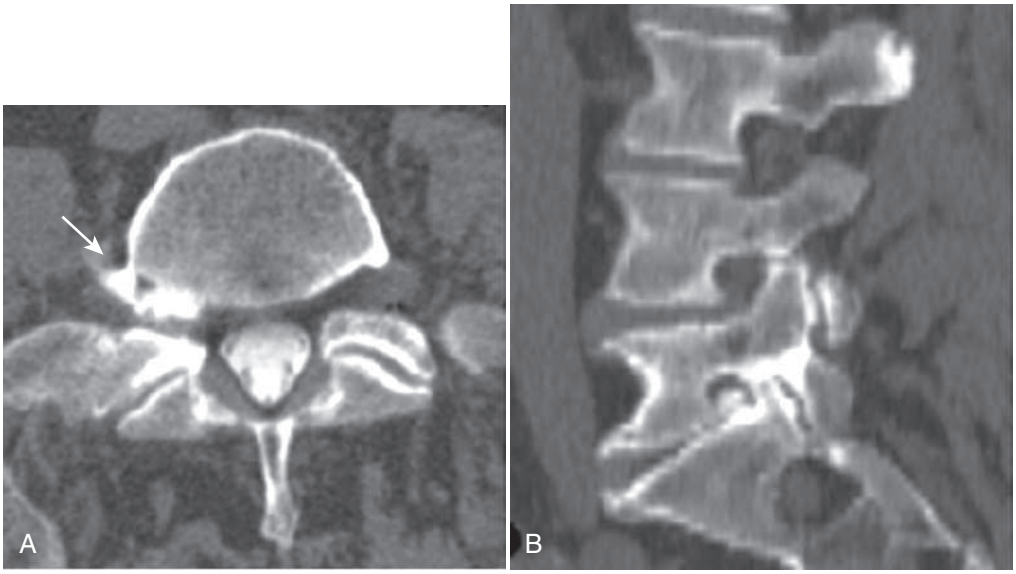

FIG. 13.2 Foraminal stenosis. (A) Axial computed tomographic (CT) scan after myelography shows severe right bony foraminal stenosis with no evidence of central stenosis or herniations (*arrow*). (B) Sagittal reformat of CT data also shows severe foraminal narrowing, in contrast to more normal superior foramen.

that can directly image bone marrow. Since the beginning of its clinical use in the early 1980s, MRI technology has progressed with improved quality and decreased examination times.[18-21]

Routine Magnetic Resonance Imaging

Pulse sequences that constitute a routine spine MR exam include axial gradient recalled echo or T2, T1, and sagittal T2, T1, and short-tau inversion recovery (STIR). Depending on the imaging indication T1-weighted images can also be obtained with gadolinium contrast agents, especially when there is a concern of infection or when there has been a history of spine surgery.[22-30] STIR has shown a high sensitivity for musculoskeletal pathology (Fig. 13.3).[31-33] STIR has been favorably compared with T1-weighted and T2-weighted fast spin-echo (FSE), conventional spin-echo, and fat-saturated FSE in the detection of vertebral metastatic disease.[34-36] STIR may also be used for intramedullary cord lesions. Each examination also includes a scout image that, depending on the type of image, can include much of the abdomen or chest in the field of view (Fig. 13.4).

Dynamic Magnetic Resonance Imaging

CT and MRI are typically obtained with the patient positioned supine. Radiographs can be more readily obtained with the patient standing or in flexion or extension. The rationale for MRI with patients in a sitting position, in flexion or extension, or with axial loading is that these positions are believed to be the positions in which the patient is the most symptomatic. In extension the lumbar spinal canal decreases, as does the cervical spinal canal (Fig. 13.5).[37-40] Axial loading has been shown to decrease the diameter of the lumbar spine.[41] In a study of 200 patients with symptoms of spinal stenosis who underwent MRI with axial loading, 20 showed a decreased diameter of the canal with axial loading. Of those 20 patients, the plan of care was changed in five patients because of the added information of axial loading images.[42]

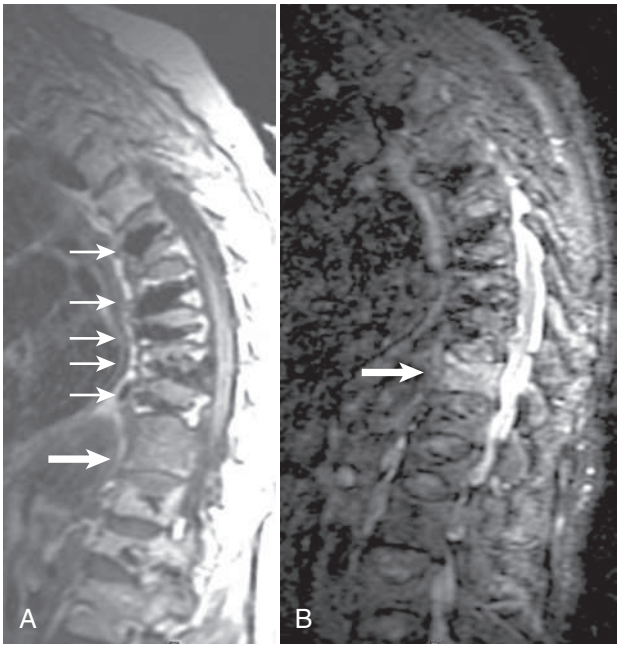

FIG. 13.3 Multiple osteoporotic compression fractures. (A) Sagittal T1-weighted magnetic resonance image through thoracic spine shows multiple collapsed bodies with central low signal reflecting prior vertebroplasties (*small arrows*). The marrow adjacent to methacrylate shows normal fatty signal intensity. (B) T12 body (*large arrow*) shows low signal on T1-weighted image and increased signal on sagittal short-tau inversion recovery image consistent with acute age.

Magnetic Resonance Myelography

MR myelography can be obtained for evaluation for cerebrospinal fluid (CSF) leak in conditions such as intracranial

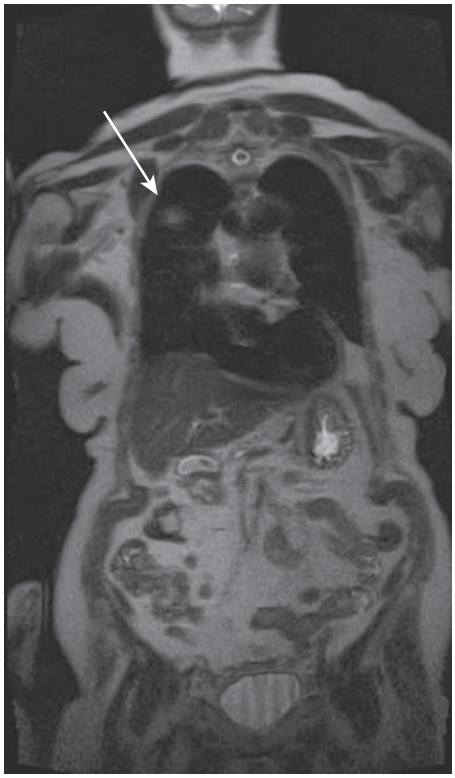

FIG. 13.4 Half-Fourier acquisition single-shot turbo spin-echo scout image obtained during a routine lumbar spine examination demonstrates an unsuspected right upper lobe lung mass *(arrow)*, a possible malignancy.

hypotension. Radionuclide cisternography and conventional CT myelography both use ionizing radiation and are invasive. The technique of MR myelography involves the use of heavy T2-weighted sequences[43] and can readily identify paravertebral fluid collections or spinal diverticuli. Sensitivities for radionuclide cisternography, CT myelography, and MR myelography have been reported to be 55%, 67%, and 86%, respectively.[44-46] Additionally, there has been use of intrathecal gadolinium, although off-label and not approved by the US Food and Drug Administration (FDA), with subsequent MRI that has been shown to be advantageous by multiple authors.[47,48]

Magnetic Resonance Neurography

For evaluation of the peripheral nerves, MRI using T1-weighted images and fat-saturated T2 or STIR images can be used to evaluate for neoplasm (Fig. 13.6), entrapment, or nerve injury.[49] Severity of nerve injury can be evaluated from mild injury (neurapraxia) where there is mild nerve enlargement and T2 hyperintensity to complete nerve transection where the separation of the nerve can be visualized.[49] MR neurography is also useful for evaluation of diffuse peripheral nerve lesions such as neurofibromatosis or the inflammatory or hereditary neuropathies.[50]

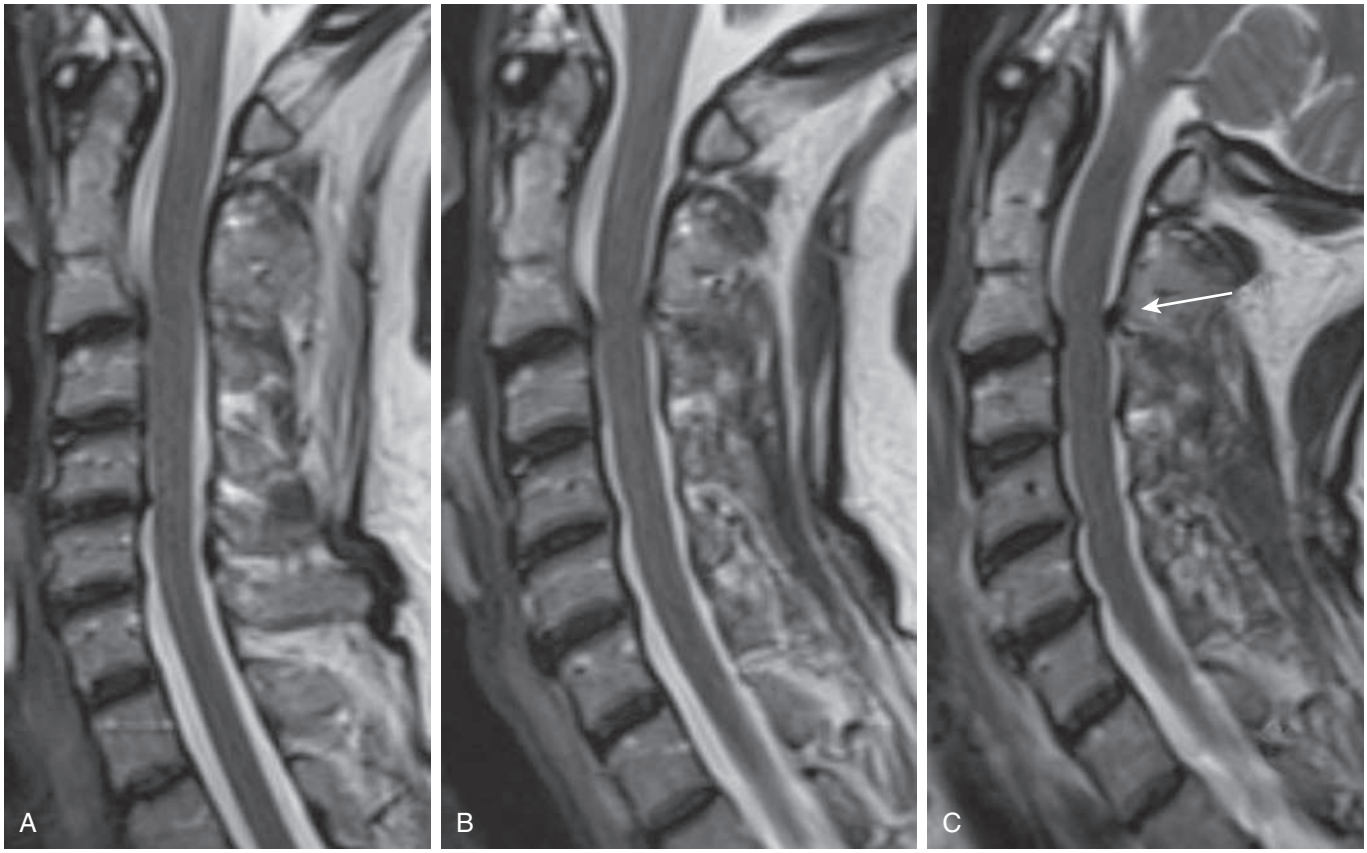

FIG. 13.5 Sagittal T2-weighted images of the cervical spine demonstrate developmental fusion of C2 and C3 vertebral bodies. Images are obtained in (A) flexion, (B) neutral, and (C) extension. There is ligamentous buckling with extension resulting in more profound canal compromise *(arrow)* compared with neutral and flexion positioning.

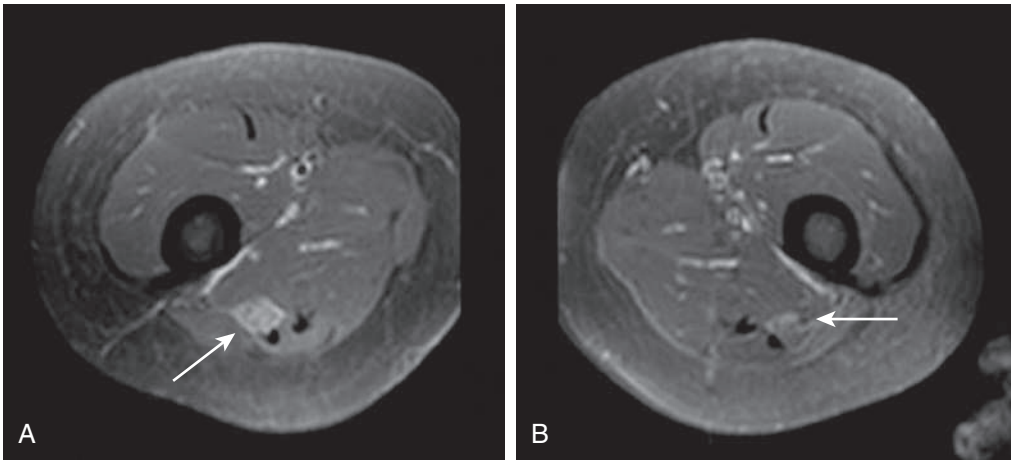

FIG. 13.6 (A) Axial fat-saturated contrast-enhanced T1-weighted images demonstrate asymmetric enlargement and enhancement of the right sciatic nerve *(arrow)*, representing neoplastic infiltration in this patient with leukemia. (B) Normal sciatic nerve for comparison *(arrow)*.

Diffusion-Weighted Imaging

Diffusion-weighted imaging (DWI) is routinely used for brain imaging. However, its use for spine imaging is not routine secondary to multiple technical limitations, including motion artifact and the relatively small size of the spinal cord.[51] Similar caveats apply to diffusion tensor imaging (DTI), in which the diffusivity of water molecules can imply the course of white matter tracts.[52]

DWI of the spine can be applied to the vertebral bodies as well as the spinal cord. Multiple studies have been performed looking at the ability to discriminate benign versus pathologic compression fractures based on DWI; however, the results have been conflicting.[53-57] Evaluation of spinal cord neoplasm or ischemia using DWI has also been described.[58]

DTI of the spine is also fraught with technical difficulties. Applications in regard to suspected neoplasm include both lesion characterization and evaluation of the lesion's margins for surgical planning purposes.[59,60] In cases of cord compression DTI has demonstrated cord injury that is not accompanied by T2-weighted signal abnormalities.[61] In addition, DTI has been shown to be more sensitive than T2-weighted imaging for evaluation of spinal cord inflammation.[62]

Cerebrospinal Fluid Flow Imaging

CSF imaging demonstrates biphasic pulsatile CSF flow with caudal systolic and cranial diastolic flow. Applications include Chiari malformations or evaluation of spinal cord syrinx cavities or tethered cord.[63-66]

Magnetic Resonance Spectroscopy

^{1}H-MR spectroscopy (MRS) uses a conventional MR machine to evaluate metabolites in an area of interest and has been extensively used with brain imaging. MRS for spinal imaging is met with extensive technical challenges, including motion, small size of the spinal cord, distance of the spinal cord from surface coils, and the inherent composition of the immediately surrounding soft tissues and osseous structures, which can result in distortion of the magnetic field.[67] Clinical applications include demyelination[68] and neoplasm.[69]

Magnetic Resonance Imaging Safety and Patient Issues

The specific and important aspects of MRI safety (including patient exposure to the magnetic field and gadolinium-based contrast media) are widely available on multiple websites, and the interested reader is referred to them for detailed answers (e.g., www.MRIsafety.com). Certain implants or metallic foreign bodies can increase in temperature or move, potentially leading to patient harm—hence the need for all patients to fill out a safety screening form before placement in the MRI machine.[70] Recently MRI-compatible pacemakers, although with some stipulations, have been developed.[71]

Bleicher and colleagues[72] found a serious complication rate of approximately 0.03% of gadolinium contrast agents when reviewing records of more than 23,000 patients, attesting to the overall favorable safety profile of gadolinium contrast agents. However, there are two important issues: gadolinium deposition in patients with normal renal function and nephrogenic systemic fibrosis (NSF).

In 2014 Kanda and colleagues[73] correlated a dose-dependent T1 hyperintensity in certain structures intracranially in patients with a history of gadolinium administration. McDonald and coworkers[74] confirmed the presence of gadolinium in the globus pallidus, pons, dentate nucleus, and thalamus in autopsy specimens of 13 patients with normal renal function who all underwent a minimum of four gadolinium contrast-enhanced examinations. Whether the intracranial accumulation of gadolinium is harmful is not clear at this point.[75]

NSF, previously called nephrogenic fibrosing dermopathy, is a systemic disorder of widespread fibrosis that has been tied to prior administration of gadolinium-based contrast agents in the setting of renal disease. The incidence of NSF in the setting of severe renal dysfunction is approximately 1% to 7% after exposure to gadolinium-based contrast material. The FDA has asked manufacturers to include a new boxed warning

on the product labeling of all gadolinium-based contrast agents used to enhance the quality of MRI. The warning states that patients with severe kidney insufficiency who receive gadolinium-based agents are at risk for developing NSF, a debilitating and potentially fatal disease.[76,77] Also, patients just before or just after liver transplantation and patients with chronic liver disease are at risk for developing NSF if they are experiencing kidney insufficiency of any severity. The risk of a patient developing NSF may be minimized by the following steps[76,78-81]:

1. Identify patients with a glomerular filtration rate less than 30 mL/min/1.73 m^2 as at risk.
2. Administer contrast medium to a patient at risk for developing NSF only when the expected benefit clearly outweighs the risk of administration.
3. Perform unenhanced MRI first with proper monitoring so that unnecessary contrast medium administration is avoided.
4. Use the lowest dose of gadolinium-based contrast medium that is feasible for the examination.

Spinal Angiography

Spinal angiography is extremely useful for spinal vascular malformations for the delineation of the vascular supply and for therapeutic treatment.[82,83] Spinal angiography is also used in the pretherapeutic workup of suspected vascular neoplasms involving the vertebral bodies, posterior elements, and spinal canal and is coupled with preoperative or palliative embolization. Spinal angiography should address three areas for the surgeon or interventionalist: (1) the exact location and configuration of the lesion, (2) vascularity of the lesion, including feeding and draining vessels, and (3) regional vascular anatomy.[84]

Spinal vascular malformations are a very heterogeneous group of lesions that have had a wide variety of classification schemes applied to them. One common classification system is from Anson and Spetzler,[85] who classified them as types 1 to 4:

Type 1: spinal dural arteriovenous fistula between the dural branch of the spinal ramus of the radicular artery and intradural medullary vein

Type 2: spinal cord arteriovenous malformation with shunting across an interposed vascular nidus (intramedullary glomus malformation)

Type 3: complex spinal arteriovenous malformation with metameric extension (juvenile malformation)

Type 4: direct arteriovenous fistula (intradural perimedullary fistula)

The most common spinal vascular lesion is a dural arteriovenous fistula (Fig. 13.7). These lesions are thought to be acquired and are particularly present in the thoracic and lower lumbar spine. Spinal dural arteriovenous fistulas are more common in men. There is often a delay from symptom onset to time of diagnosis, averaging 27 months. Clinical findings include weakness (55%), a progressive clinical course (100%), and myelopathy on examination (84%). In the spine, nidus of the fistula is most often located between T6 and T12 or in the sacrum. In 1977, Kendall and Logue[86] definitively identified the site of the arteriovenous shunting within the root sleeve. The symptoms are a result of intramedullary edema and ischemia secondary to increased venous backpressure within the varicose coronal veins. Gilbertson and colleagues[87] and Masaryk and colleagues[88] identified increased signal intensity on T2-weighted images within the cord as the most sensitive imaging finding in spinal dural fistula.

Although imaging, in particular MRI, has become a mainstay for the evaluation of vascular malformations, spinal angiography remains a crucial technique for precise definition of the type of lesion, the overall morphology, the flow characteristics, and the identification of specific feeding vessels.[89] Arterial and delayed venous imaging may be necessary to appreciate fully the venous drainage of the vascular pathology, particularly in arteriovenous malformations and dural fistulas. Arterial films allow examination of abnormal blush or arteriovenous shunting. The normal vascular supply to the cord, in particular the artery of Adamkiewicz, should be defined. In addition to the usual general complications of angiography, embolization to the anterior spinal artery could occur after angiography, which may lead to an ascending paralysis. In general complications are rare, given the small catheters used, nonionic contrast medium, and an improved speed of the examination with digital subtraction angiography.

Technologic advances have allowed high-resolution, high-contrast discrimination MR or CT imaging for evaluation of the spinal arteries, with the goal of minimizing the need for conventional catheter angiography for identification of spinal vascular disease.[90-92] The size of the anterior spinal artery (0.2 to 0.8 mm) and the close approximation of the spinal veins necessitate a sophisticated MRI sequence with bolus gadolinium–based intravenous contrast medium administration. Although various techniques may be used, the three main requirements are a large field of view, high spatial resolution, and high temporal resolution.

In a series of 34 patients, Mull and colleagues[92] showed that contrast-enhanced spinal MR angiography (MRA) could reliably detect or exclude spinal cord arteriovenous abnormalities with a 100% predictive value. The main arterial feeder can be reliably defined by MRA, but small secondary feeders may be missed. The main reasons for obtaining MRA would be for primary identification of a vascular abnormality and to pinpoint the likely site of a feeder for conventional catheter angiography. CT angiography can also define normal and abnormal spinal vasculature.[93,94] The technique requires a multidetector row CT scanner (generally 16) and 1-mm section thickness.

Discography

Discography was originally conceived as a morphologic study of disc herniation but then morphed into a useful but limited test relying on pain provocation through disc pressurization.[95,96] Although discography can accurately define disc degeneration, this procedure is now seen as a physiologic evaluation of the disc consisting of volumetric, manometric, radiographic, and pain provocative challenge.[97,98] This procedure remains quite

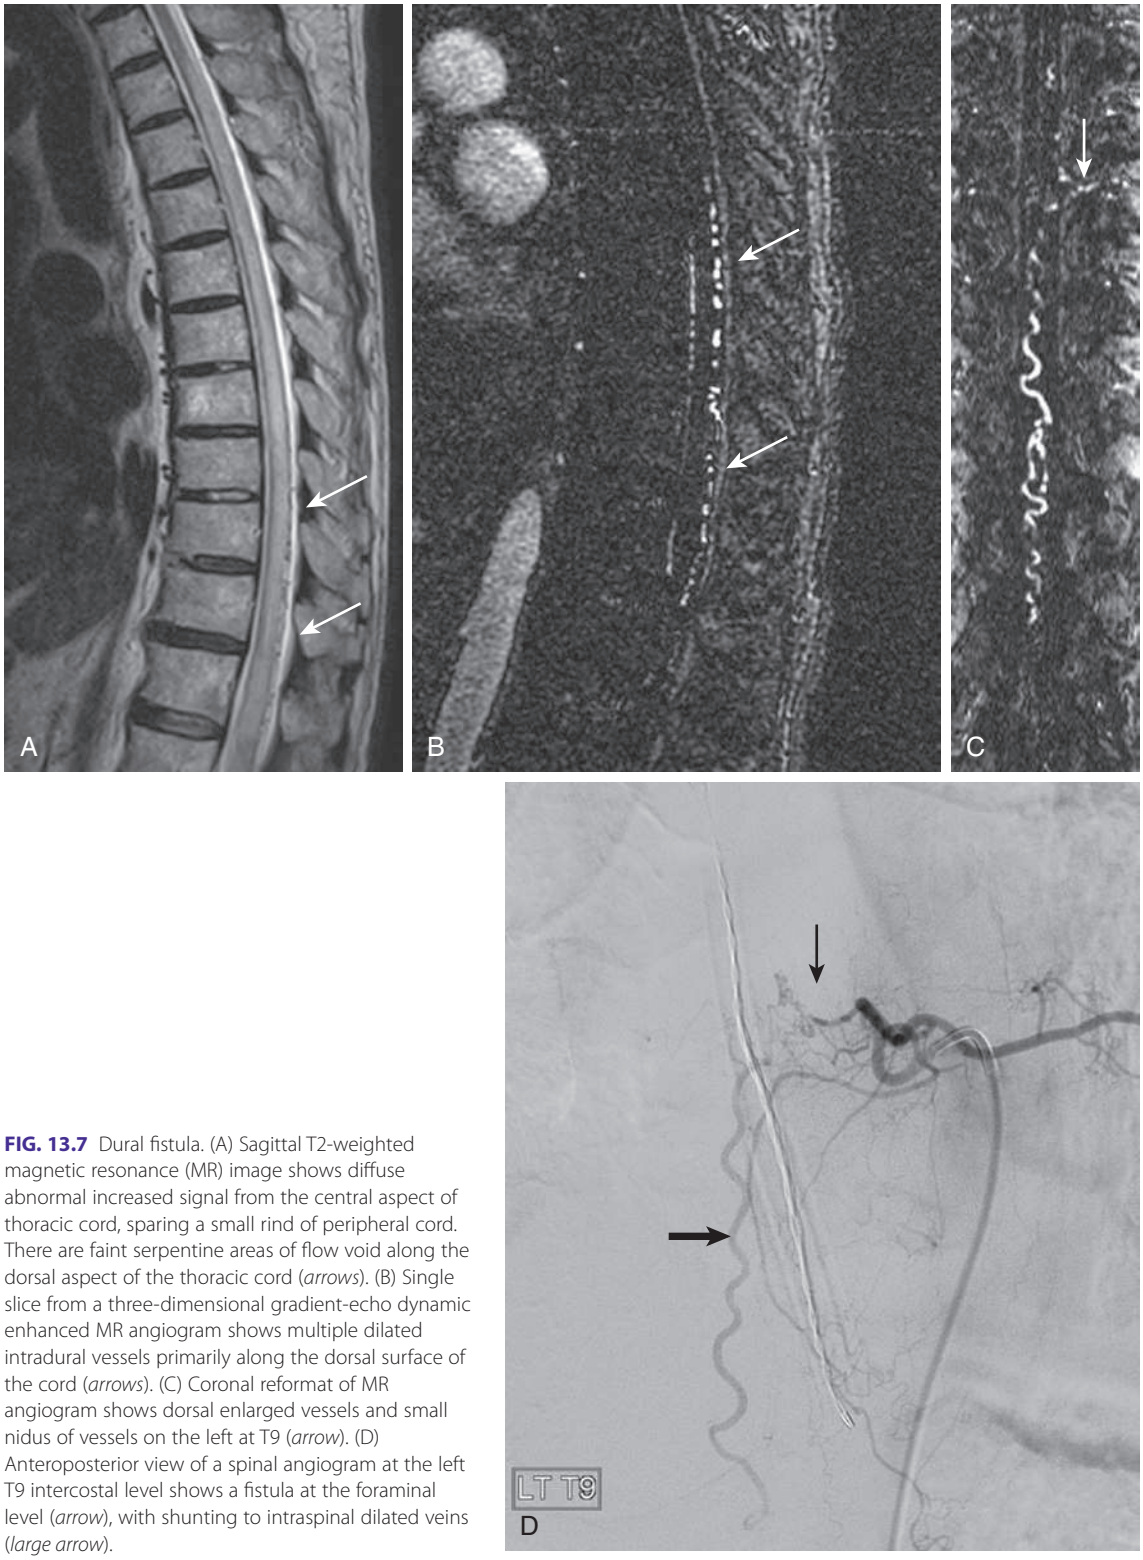

FIG. 13.7 Dural fistula. (A) Sagittal T2-weighted magnetic resonance (MR) image shows diffuse abnormal increased signal from the central aspect of thoracic cord, sparing a small rind of peripheral cord. There are faint serpentine areas of flow void along the dorsal aspect of the thoracic cord (*arrows*). (B) Single slice from a three-dimensional gradient-echo dynamic enhanced MR angiogram shows multiple dilated intradural vessels primarily along the dorsal surface of the cord (*arrows*). (C) Coronal reformat of MR angiogram shows dorsal enlarged vessels and small nidus of vessels on the left at T9 (*arrow*). (D) Anteroposterior view of a spinal angiogram at the left T9 intercostal level shows a fistula at the foraminal level (*arrow*), with shunting to intraspinal dilated veins (*large arrow*).

controversial; it has enthusiastic supporters and detractors and has generated a voluminous literature. Some authors see discography as helpful in identifying internal disc disruption and in verifying painful disc levels before surgery (particularly fusion), whereas others see it as unproven and of questionable benefit.[99-106]

Discography is an invasive procedure and is not performed as a screening technique. Discography is most accurate when the diagnosis of discogenic pain is probable based on appropriate history, physical examination, and imaging.[96] This test is always limited in sensitivity and specificity owing to the subjective report of pain type and location by the patient. According to Tehranzadeh and others,[107-109] indications for discography include the following:

1. Negative MRI, CT, or myelography findings with equivocal findings for disc disease

2. Cases with positive MRI, CT, or myelography findings with disc disease at multiple levels
3. Presence of equivocal MRI, CT, or myelography findings
4. Recurrent back pain in postsurgical patients with difficulty in evaluating scar versus disc
5. Cases of failed back surgery to evaluate painful pseudarthrosis or symptomatic disc
6. Evaluation of spinal fusion disc above or below the fusion level
7. Therapeutic injection of corticosteroid or anesthetic into the disc itself

Nuclear Medicine Examinations

Nuclear medicine examinations commonly performed for spine imaging include bone scintigraphy using technetium 99m (^{99m}Tc) and 18F-fluorodeoxyglucose positron emission tomography (PET) imaging. Other radiotracers are also available, including somatostatin analogs, that are useful with neuroendocrine tumors and meningiomas.[110]

For evaluation of metastatic disease, bone scans image osteoblastic activity and are less useful for aggressive lytic metastases. Sensitivity and specificity range from 62% to 100% and 78% to 100%, respectively. Bone scans require a 5% to 10% change for abnormalities to be detected. Trauma, degenerative changes, infection, and other conditions can also show uptake on bone scans.[111,112] PET imaging measures metabolic uptake and is more sensitive for lytic rather than sclerotic metastatic disease.[111,113,114] Similar to bone scans, PET imaging can show uptake in nonneoplastic conditions such as inflammation, infection, or degenerative change.[115]

Radionuclides most commonly used for detecting inflammatory changes of the spine are ^{99m}Tc phosphate complexes, gallium (^{67}Ga) citrate, and indium-111 (^{111}In)–labeled white blood cells. Although scintigraphy with ^{99m}Tc and ^{67}Ga compounds is sensitive to infection, it is also nonspecific. Healing fractures, degenerative arthritis, sterile inflammatory reactions, tumors, and loosened prosthetic devices can show increased uptake.[116-118] ^{111}In has several advantages compared with other radionuclides, including higher target-to-background ratios, better image quality (compared with ^{67}Ga), and more intense uptake by abscesses. Its main disadvantage is its accumulation within any inflammatory lesion, whether infectious or not.[119] The radionuclide study also takes hours to days to perform.

Imaging Artifacts

Artifacts invariably occur during spine imaging and can either obscure or simulate pathology. Stainless steel implants are known to generate substantial metal artifact with MRI and CT. On CT, metal causes severe x-ray attenuation (missing data) in selected planes. These missing data or hollow projections cause classic "starburst" or streak artifacts during image reconstruction. The resulting distortions often render these studies useless. Materials with lower x-ray attenuation coefficients (plastic, titanium, tantalum, stainless steel, cobalt chrome) produce fewer distortions. Metal composition, mass, orientation, and position of the implant in the body all are important factors that determine the magnitude of image artifact. Titanium wires exhibit the least artifact on CT and MRI compared with cobalt chrome or stainless steel.

FIG. 13.8 Metal artifact. This sagittal T1-weighted magnetic resonance image is severely degraded by fixation hardware (four-level pedicle screws) that does not allow adequate evaluation of the neural foramen.

MRI studies may be severely compromised in the presence of spinal instrumentation, and there can be potential safety and biologic considerations (Fig. 13.8). Many strategies can reduce susceptibility artifacts on MRI, including the use of spin-echo techniques, especially FSE variants over gradient echo; larger fields of view; higher readout bandwidths; smaller voxel sizes; and appropriate geometric orientation of the frequency-encoded direction in relationship to metallic objects (Fig. 13.9).[120,121] Additional MR artifacts can be present, such as motion artifact (Fig. 13.10), flow-related artifact, chemical shift, Gibb's artifact, and aliasing or wrap-around artifact.[122]

Pathology

When interpreting a radiographic examination of the spine, the first step is to identify the abnormality and then arrive at a diagnosis or reasonable differential diagnosis. One of the most critical pieces of imaging information regarding spinal pathology used in forming a differential diagnosis involves determination of whether the lesion is intramedullary, intradural extramedullary, or extradural.

Degenerative Disc Disease

The morphologic findings of degenerative disc are well documented and demonstrated, especially with MRI. There are,

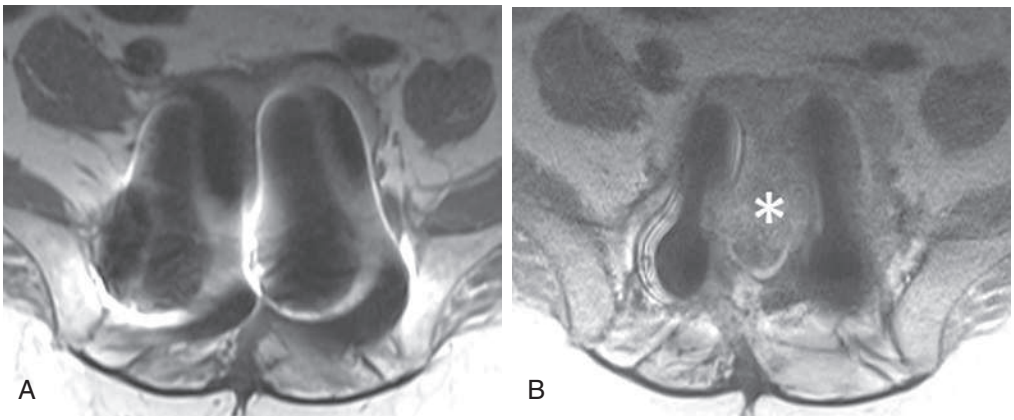

FIG. 13.9 (A) Extensive artifact from posterior instrumentation in this T1-weighted image obscures evaluation of the spinal canal. (B) T1-weighted image with contrast and metal reduction technique demonstrates improved evaluation of the canal with epidural extension of disease *(asterisk)*.

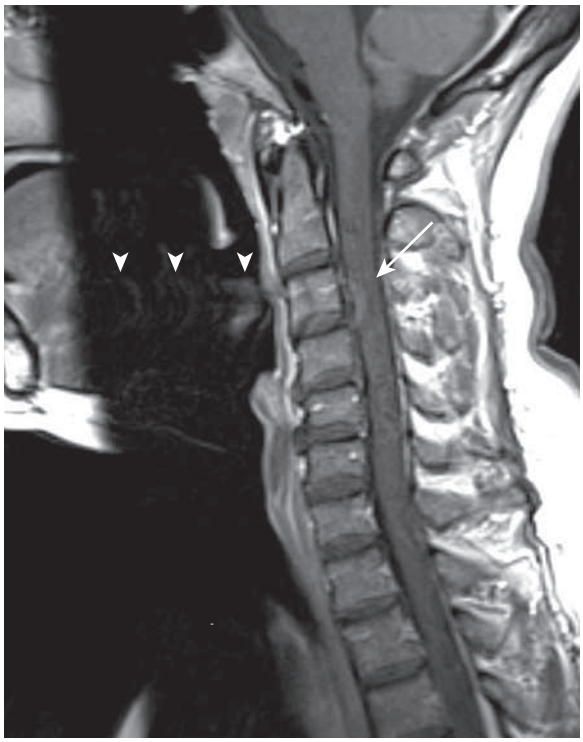

FIG. 13.10 Sagittal contrast-enhanced T1-weighted image of the cervical spine demonstrates apparent signal abnormality/enhancement of the cord at level of C3 *(arrow)*. However, this is motion artifact from swallowing/epiglottis movement with a similar morphologic abnormality tracking outside the cervical spinal cord (arrowheads) conforming to the shape of the epiglottis.

however, many factors to consider before imaging patients who present with uncomplicated low back pain, including that the findings of degenerative disc disease are common in asymptomatic individuals, degenerative disc disease has a favorable natural history, and there is a potential impact on clinical decision making.[123]

The presence of degenerative changes within the cervical and lumbar spine has been shown to be age related and equally present in asymptomatic and symptomatic individuals.[124,125] By the fifth decade of life, 25% of asymptomatic patients have degenerative changes in the intervertebral disc spaces. By the seventh decade, 75% have degenerative changes.[126] Myelograms performed in patients without symptoms revealed abnormalities in 24% of the exams,[124] and MR exams in patients without symptoms demonstrated normal exams in only 36% of cases.[127]

Overall, the natural history of low back pain is favorable, with most patients experiencing improvement within 4 weeks regardless of whether they are imaged.[128,129] Over time, disc herniations can improve or decrease in size and new extrusions can occur after the onset of original symptoms.[130-132]

Multiple studies have shown that imaging in cases of uncomplicated low back pain does not positively affect patient management and that imaging can actually be harmful. Studies of radiographic evaluations have shown that there is little effect on patient management.[133,134] Treatment and diagnosis were not different in patients who were not imaged as opposed to patients who underwent advanced imaging.[135] When comparing patients with low back pain receiving either radiographs or an abbreviated MR imaging protocol, there was no advantage to the MR imaging group.[136] Gillan et al. found no treatment difference between imaging versus no imaging in patients with low back pain.[135] Imaging for low back pain can be associated with potential harm, including radiation exposure if CT imaging is used,[137] potential for increased rates of spine surgery,[138-140] and the potential for patients to have a lesser sense of well-being.[141]

Multiple authors suggest that an imaging study is indicated in the evaluation of a patient with sciatica when (1) true radicular symptoms are present, (2) there is objective evidence of nerve root irritation on physical examination (i.e., positive straight-leg raise test), and (3) the patient has not responded to "conservative management" of 4 to 6 weeks' duration.[142-144] Earlier imaging is considered appropriate if clinical features raise concern regarding malignant or infectious causes or if neurologic findings worsen during observation. These recommendations are based on several studies of successful nonoperative treatment of sciatica.[145-150] Imaging is recommended only for the remaining minority of patients with persistent signs and symptoms who are believed to be surgical candidates or in whom diagnostic uncertainty remains. In the 2009 American College of Radiology appropriateness criteria for

imaging patients with low back pain, imaging patients was noted to be inappropriate if the following were absent: trauma in patients older than 50 years of age, unexplained fever or weight loss, immunosuppression, history of cancer or intravenous drug use, steroid use, age greater than 70 years, progressive neurologic symptoms or loss of function, or symptoms being present for longer than 6 weeks.[151]

Intervertebral Disc

Because of its inherent contrast sensitivity, MRI reveals morphologic abnormalities well and also provides insight into the biochemical changes of the degenerating disc. With aging and degeneration, there is gradual narrowing of the disc space and loss of the normal high intradiscal signal intensity on T2-weighted images. The latter is believed to be secondary to changes in proteoglycan composition within the disc rather than to absolute changes in water content.[152] As degeneration progresses, small fluid-filled fissures or cracks may develop that manifest as intradiscal areas of linear high signal on T2-weighted images.[153-155] Gas and calcification can also develop within a degenerating disc.

Fissures (tears) of the anulus fibrosus can also be visualized with MRI. They appear as small areas of increased signal on T2-weighted images and can enhance after contrast agent administration, presumably secondary to the ingrowth of granulation tissue into the fissure as a consequence of healing.[156] Three types of anular fissures have been described, depending on their orientation relative to the concentric anular fibers.[157] The high frequency of anular fissures seen in association with large disc bulges challenges the concept that the anulus fibrosus is intact in bulging discs but ruptured in herniated discs. The clinical significance of anular fissures is unknown. In patients without nerve root compression, back pain may be secondary to irritation of the nerve endings in the peripheral anulus either from scar tissue within an anular fissure or from a disc herniation; this is referred to as *discogenic pain*. Although this concept is often used to ascribe clinical significance to these lesions, many asymptomatic patients harbor anular fissures.

There is no universally accepted classification system describing degenerative disc disease. A multispecialty task force released recommendations for disc nomenclature spanning the orthopedic, neurosurgical, and radiologic communities.[158] This group has defined a *protrusion* as a herniation that maintains contact with the disc of origin by a bridge as wide as, or wider than, any diameter of the displaced material (Fig. 13.11). An *extruded* disc is a larger herniation in which the diameter of the disc material beyond the interspace is wider than the bridge, if any, that connects it to the disc of origin (Fig. 13.12). A *sequestered (free)* disc fragment is an extrusion that is no longer contiguous with the parent disc. It may reside either anterior or posterior to the posterior longitudinal ligament or rarely may be intradural (Figs. 13.13 and 13.14). A free fragment may be located at the disc level or may migrate superiorly or inferiorly, often lateralized by the thin, sagittally oriented midline septum seen in the lower anterior epidural space.

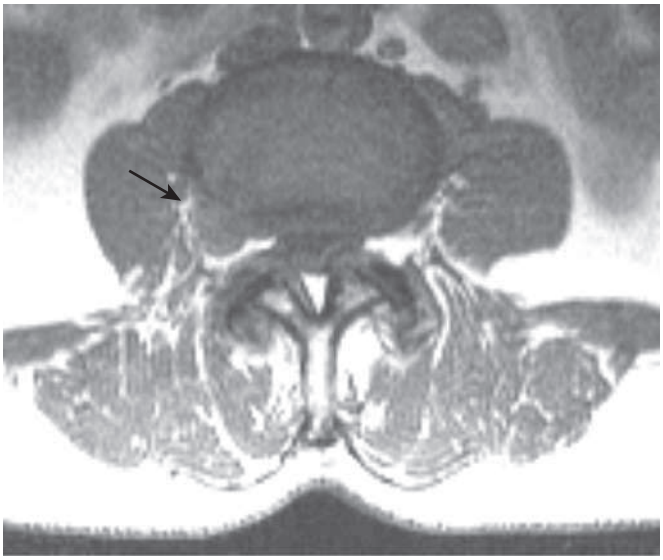

FIG. 13.11 Lateral disc herniation. Axial T1-weighted magnetic resonance image shows well-defined right lateral herniation with no thecal sac compromise *(arrow)*.

FIG. 13.12 Cervical disc extrusion. Sagittal T2-weighted magnetic resonance image shows large disc extrusion at C6–C7 severely effacing the anterior thecal sac and cord. Signal intensity of the cord is normal.

Degenerative Endplate Changes

In addition to these observed changes within the degenerating disc, vertebral marrow signal abnormalities adjacent to the degenerating disc are common.[159] Type 1 endplate change manifests as decreased marrow signal paralleling the endplates on T1-weighted images and increased signal on T2-weighted images. These changes reflect replacement of normal fatty marrow with fibrovascular marrow, which has greater water

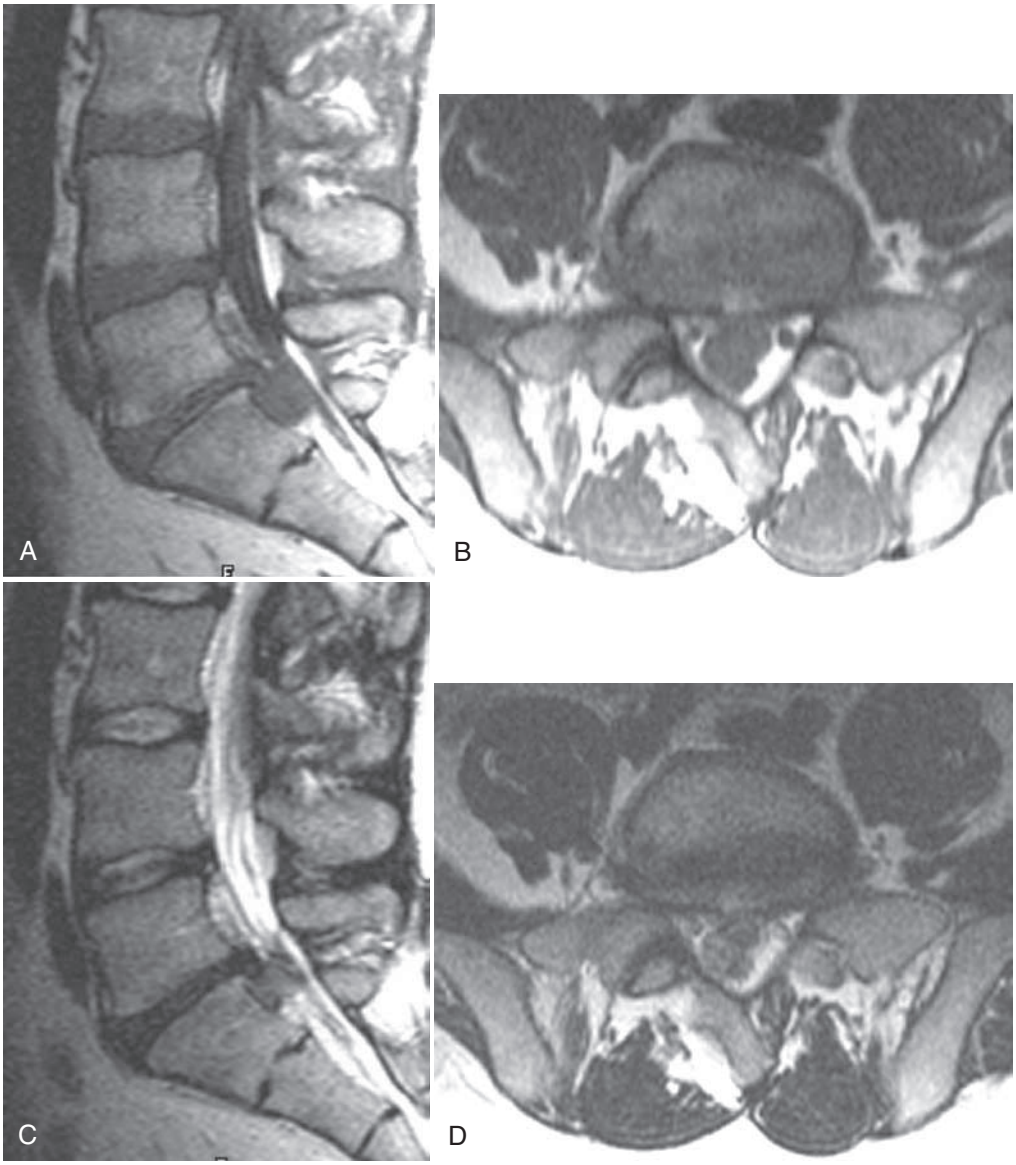

FIG. 13.13 Disc extrusion with free fragment. (A) Sagittal and (B) axial T1-weighted magnetic resonance images show a large central extrusion at L5–S1 extending dorsally and inferiorly, suggesting a free fragment. There is severe effacement of caudal thecal sac. (C) Sagittal and (D) axial T2-weighted images show extrusion as intermediate signal and confirm mass effect on sac.

content. Type 2 endplate changes are slightly more common than type 1 changes, showing increased signal on T1-weighted images and isointense to slightly increased signal on T2-weighted images. Histologically, these changes correlate with fatty marrow replacement. These changes may be preceded by type 1 changes, and often these changes exist in combination at the same level or different levels. Type 3 endplate changes show decreased marrow signal on T1-weighted and T2-weighted images, a finding that correlates with endplate sclerosis seen radiographically.[159]

Recent researchers have suggested that type 1 endplate changes can be secondary to a low-grade infection,[160,161] with one study showing that patients with type 1 endplate changes treated with antibiotics showed improvement over the placebo group.[162]

Lumbar Stenosis

As an anatomic entity, spinal stenosis refers to narrowing of the central spinal canal, neural foramina, or lateral recesses. Most commonly, it is acquired secondary to degenerative disease of the intervertebral disc or facets or both, although developmentally shortened pedicles are an important component of symptomatic spinal stenosis in patients with otherwise mild degenerative changes (Figs. 13.15 and 13.16).[163] Before the development of MRI, plain films and CT were used to diagnose spinal stenosis by measuring the dimensions of the bony canal. At present, such measurements are not commonly performed. These measurements do not take into account the normal anatomic variation between patients or the role of the disc and ligamentum flavum in spinal stenosis and are inaccurate predictors of clinical symptoms. MRI accurately depicts

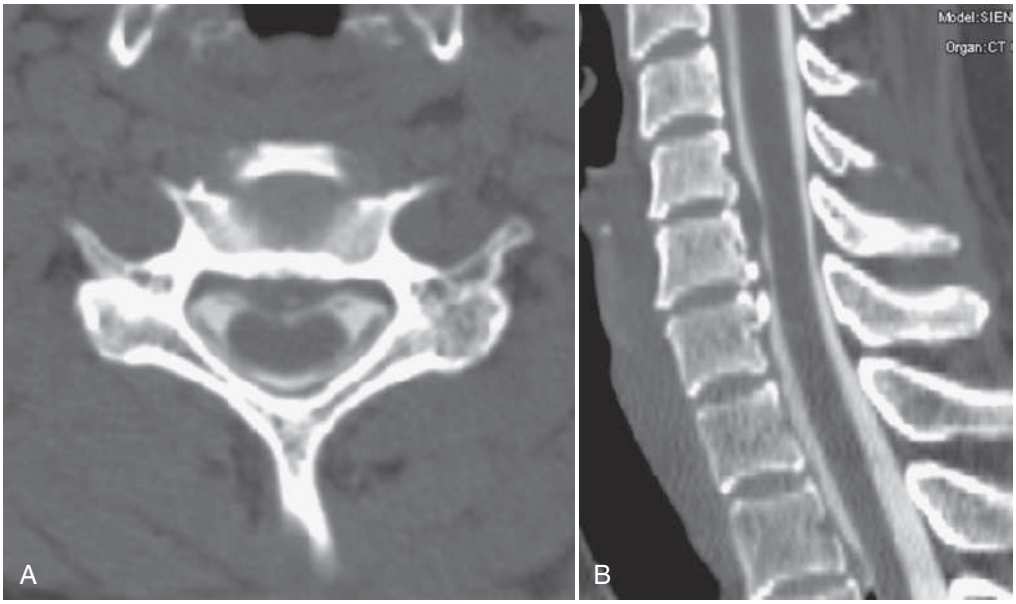

FIG. 13.14 Cervical disc herniation. (A) Axial computed tomographic scan and (B) sagittal reformat after myelography show well-defined extradural lesion at C4–C5 effacing the anterior thecal sac and touching the cord. A small osteophyte is present at C5–C6 with no cord compromise.

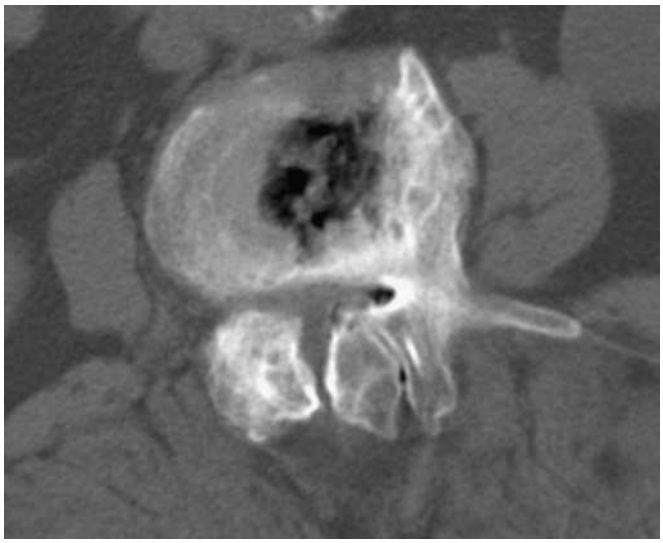

FIG. 13.15 Lumbar canal stenosis. Axial computed tomographic scan at L4–L5 shows marked bony central canal stenosis with mild anterior osteophyte and marked facet hypertrophic degenerative change. The disc is degenerated with vacuum phenomenon.

the degree and cause of thecal sac narrowing in patients with central canal stenosis. Such narrowing is most commonly due to bony and ligamentous hypertrophy.

In addition to central canal stenosis, stenosis of the lateral recess is an important cause of lower extremity pain and paresthesias. The lateral recess is bordered anteriorly by the posterior aspect of the vertebral body and disc, laterally by the pedicle, and posteriorly by the superior articular facet. The root sleeve within the lateral recess is often compressed by bony hypertrophy of the superior facet, often in combination with disc bulging and osteophyte along the anterior border of the lateral recess. Lateral recess pathology can clinically mimic disc herniation. MRI allows differentiation between central and lateral recess stenosis and provides important information for presurgical planning.[164]

Facet Disease

Degenerative disease of the facet joints typically occurs in combination with degenerative disc disease, although facet disease alone may be responsible for symptoms of back pain and radiculopathy. As with any synovial-lined joint, facet joints are susceptible to the development of joint space loss, subchondral sclerosis and cyst formation, osteophytosis, and subluxation. Because of the richly innervated synovium and joint capsule, these changes alone can be a source of pain, or alternatively they can contribute to nerve root impingement by causing spinal stenosis or foraminal compromise. On MRI, degenerated facets appear hypertrophied, sclerotic, and irregular. Enlarged ligamentum flavum is commonly present. Facet degeneration can lead to the formation of synovial cysts that can compress the thecal sac and roots from a posterior direction. Synovial cysts are best depicted on axial images and appear as posterolateral epidural masses adjacent to a degenerated facet, most commonly at the L4–L5 level. Synovial cysts have variable signal characteristics secondary to varying cyst fluid composition and associated hemorrhage, calcification, or gas within the cyst (Fig. 13.17).[165] A peripheral hypointense rim on T2-weighted images related to calcification may be seen. Intravenous contrast medium is useful in suspected cases to define better the lesion and its relationship to the adjacent facet joint and thecal sac.

Instability

The most frequently seen alignment abnormality is spondylolisthesis, which is defined as ventral slippage of a vertebra relative to the vertebrae below. The two most common causes of

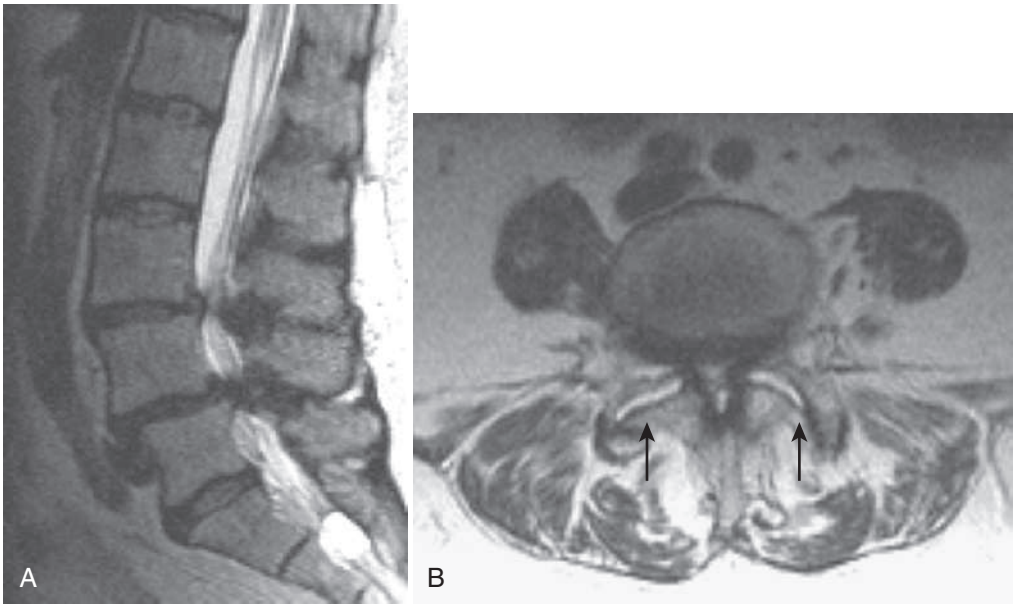

FIG. 13.16 Lumbar canal stenosis. (A) Sagittal and (B) axial T2-weighted magnetic resonance images show severe central canal stenosis at L3–L4 and L4–L5 with marked compression of the thecal sac owing to anterior bulge of the anulus fibrosus and facet hypertrophic degenerative change. There are small bilateral facet effusions *(arrows)*.

spondylolisthesis are bilateral defects in the pars interarticularis (isthmic spondylolisthesis) and facet disease (degenerative spondylolisthesis). The degenerative variety is the most common in older adults.

Because of its ability to obtain direct sagittal images free of overlapping structures and patient rotation, MRI is an accurate method of diagnosing spondylolisthesis. MRI is nearly always performed with the patient supine, however. In that position, a vertebra with subluxation can be normally aligned. A more accurate method of detecting listhesis is by weight-bearing lateral lumbar radiographs. The detection of spondylolysis (pars interarticularis defect without ventral slippage) by MRI can be problematic, and it is generally agreed that plain films and CT are more reliable for its diagnosis. Because MRI is being increasingly used as the first and only imaging modality in evaluating patients with low back pain and radicular symptoms, many cases of spondylolysis are imaged without the benefit of correlative plain films or CT studies.[166] Using MRI, sagittal T1-weighted images are best for showing the pars interarticularis owing to their higher signal-to-noise ratio, the depiction of the pars marrow as hyperintense, and the minimal obliquity of the pars in this imaging plane (Fig. 13.18). If the pars appears normal (i.e., contiguous normal marrow signal), one can be certain that it is intact.[167]

Cervical Radiculopathy and Myelopathy

Various studies have shown that canal size is reduced in patients with cervical spondylotic myelopathy. The normal diameter of the canal from C3 to C7 is approximately 17 mm and can be decreased to 12 mm or less in cervical spondylotic myelopathy. The size that is associated with myelopathy has ranged, however, from less than 10 mm up to 14 mm. Additionally, myelopathic symptoms tend to occur when the canal cross-sectional area is less than 60 mm^2. The ratio of the anteroposterior canal diameter to the vertebral body diameter has been used to assess cervical stenosis. This Pavlov ratio (sometimes referred to as the Torg ratio) is normal if it is 1 or greater.[168] A ratio of 0.8 or less is considered abnormal. As a ratio, however, it can be abnormal not only because of an abnormally small canal diameter (small numerator), but also because of an abnormally large vertebral body (large denominator). This ratio method also does not take into account the size of the spinal cord itself. As an isolated tool, this method is of historical interest only and is useless in evaluating cervical spinal cord compression.

Takahashi and colleagues and others have described areas of increased signal intensity on T2-weighted images within the cervical cord owing to extradural compression, which variously reflects myelomalacia, gliosis, and demyelination and edema (Fig. 13.19).[169] Patients who show areas of abnormal signal within the cord tend to have a worse clinical condition than patients with normal cord signal intensity. These abnormal signal changes can disappear or diminish after surgery to relieve the cord compression.

Postoperative Imaging

Causes of early and delayed failure of surgery are listed in Boxes 13.1 and 13.2. Caution must be used in interpretation of CT, CT myelography, and MRI within the first 6 weeks after surgery owing to the large amount of tissue disruption and edema that may be present producing mass effect on the anterior thecal sac, even in the absence of any clinical symptoms. MRI may be used in the immediate postoperative period for a

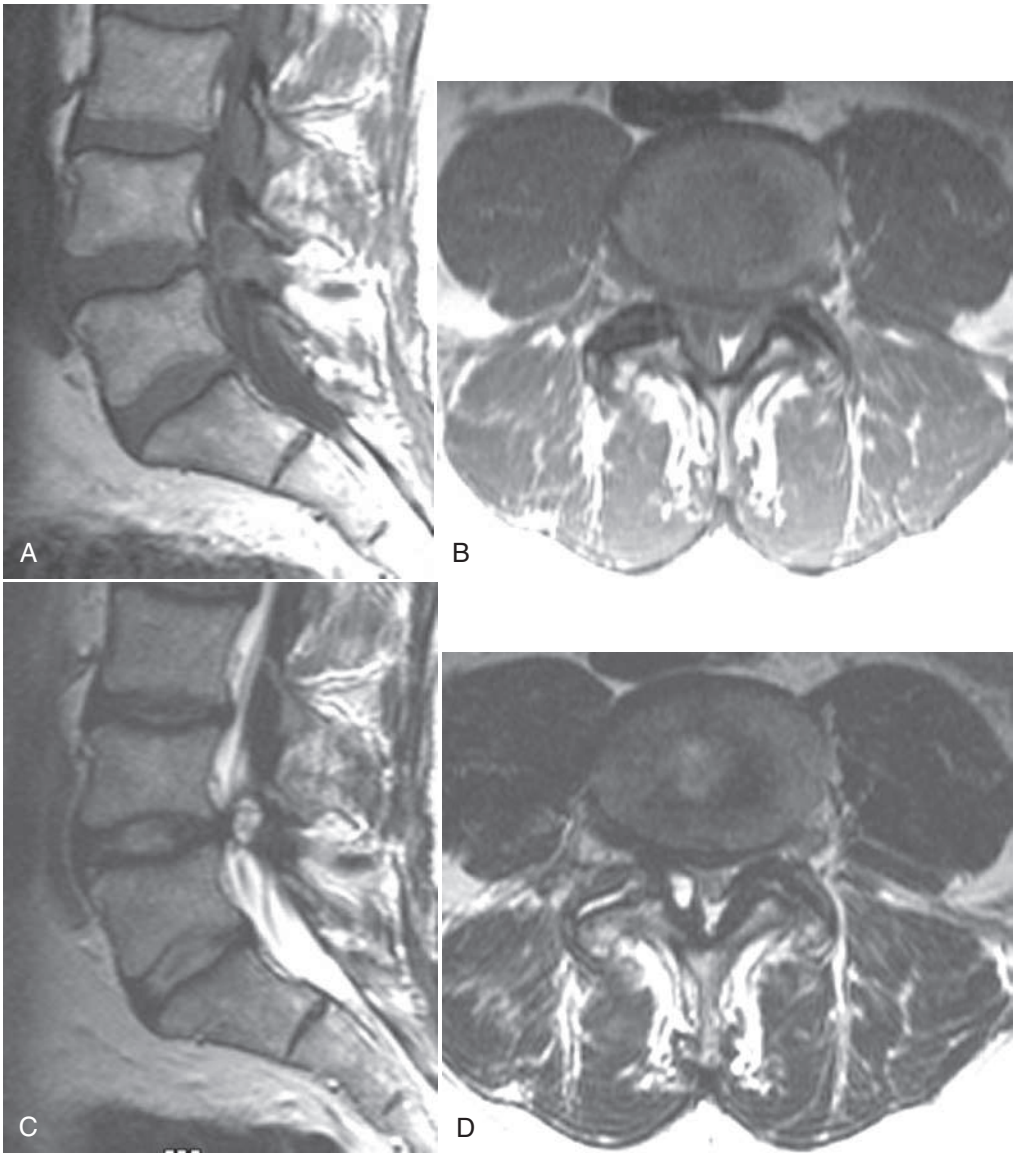

FIG. 13.17 Synovial cyst. (A) Sagittal and (B) axial T1-weighted magnetic resonance images show mass with central low signal centered on the right anterior facet that effaces the right dorsal aspect of the thecal sac. (C) Sagittal and (D) axial T2-weighted images show central high signal of fluid consistent with synovial cyst.

BOX 13.1 Technical Causes of Early Spine Surgery Failure

Hematoma
Infection
Inadequate decompression of bony foraminal or central stenosis
Insufficient removal of herniation
Neural trauma
Unrecognized free disc fragment
Wrong level surgery

BOX 13.2 Technical Causes of Delayed Recurrence of Low Back Pain or Radiculopathy

Arachnoiditis
Epidural fibrosis
Facet arthropathy with foraminal stenosis
Instability
New or recurrent herniation
Pseudomeningocele
Central canal stenosis
Infection

more gross view of the thecal sac and epidural space, to exclude significant postoperative hemorrhage, pseudomeningocele, or disc space infection at the laminectomy site. CT myelography is also a direct way to define a pseudomeningocele and to image the spine when hardware is present (Fig. 13.20).

Small fluid collections are commonly seen in the posterior tissues after laminectomy. The signal intensities can vary depending on whether the collections are serous (follow CSF signal intensity) or serosanguineous (increased signal on T1-weighted images owing to hemoglobin breakdown products). The distinction between small postoperative fluid collections and infected collections cannot be made by MRI morphology or signal intensity. Acute hemorrhage typically shows isointense to increased signal in the epidural space on T1-weighted images and should show diminished signal on

gradient-echo or T2-weighted images. Very acute blood collections may be isointense, however, on T1-weighted and T2-weighted images (Fig. 13.21).

Aside from the various options for instrumentation that are available, different types of bone graft materials are available, some with ramifications when imaging.[170] Bone morphogenic protein (BMP) can produce imaging findings that can be misinterpreted as infection, including prevertebral soft tissue swelling and vertebral body endplate resorption, although these findings typically resolve by 6 months.[171-173]

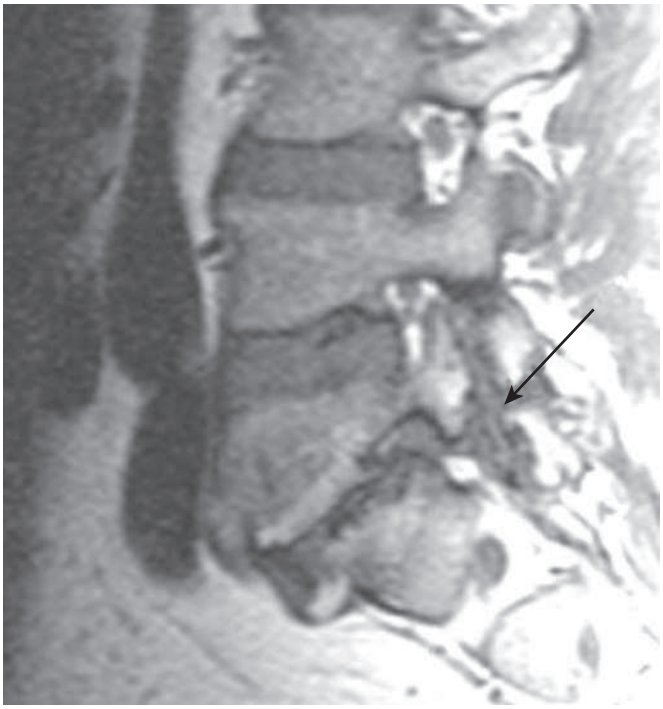

FIG. 13.18 Spondylolysis. Sagittal T1-weighted magnetic resonance image shows disruption of cortical margin of pars interarticularis *(arrow)* at L5–S1 consistent with spondylolysis. There is severe foraminal stenosis at L5–S1.

Epidural Fibrosis and Disc Herniations

The use of contrast medium–enhanced MRI in the evaluation of scar versus disc has been examined by several authors, with reported accuracy rates of 96% to 100% for distinguishing scar from disc.[174] Lumbar epidural fibrosis (scar) is a replacement of the normal epidural fat with postoperative fibrotic tissue, which is capable of binding the dura and nerve roots to the surrounding structures anteriorly and posteriorly. Epidural fibrosis is seen to enhance consistently immediately after injection of contrast material (Fig. 13.22). This enhancement occurs regardless of the time since surgery. Disc material does not enhance on the early postinjection images owing to its lack of vascularity (Fig. 13.23). In cases with a mixture of scar and disc material, scar enhances but the disc material does not enhance on early postinjection images.

Selective fat suppression on T1-weighted images has been used in the evaluation of postoperative patients. Georgy et al.[175] examined 25 patients with recurrent pain after lumbar disc surgery with MRI to evaluate the usefulness of gadolinium-enhanced fat suppression imaging in patients with failed back surgery. The addition of fat suppression to enhanced T1-weighted images improved the visualization of enhancing scar in all cases, helped distinguish scar from recurrent herniated disc, and showed more clearly the relationship of scar to the nerve

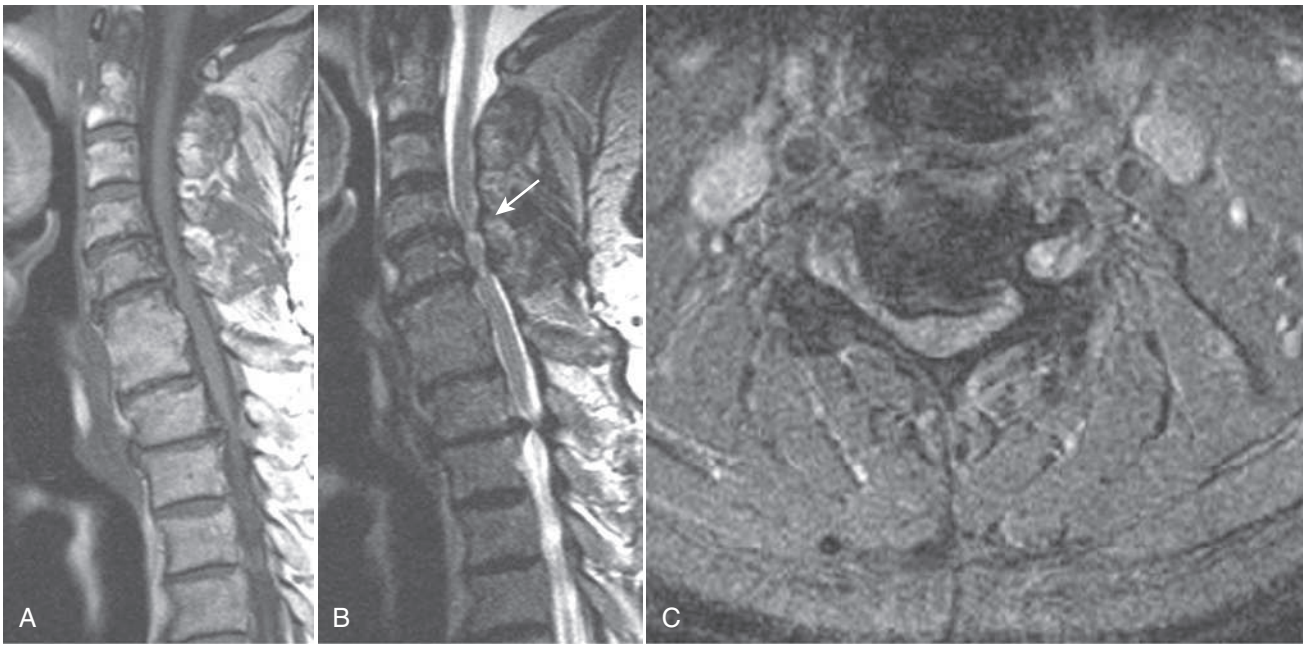

FIG. 13.19 Cervical spondylosis. (A) Sagittal T1- and (B) T2-weighted magnetic resonance images show solid fusion at C6–C7 level with a small osteophyte. There is severe central stenosis of the disc and osteophyte complex and posterior ligamentous hypertrophy at C4–C5, C5–C6, and T1–T2 levels. There is myelomalacia within the cord seen as high signal intensity on the T2-weighted image at C4–C5 *(arrow)*. (C) Axial gradient-echo image at C4–C5 confirms severity of central stenosis owing to broad-based disc and osteophyte.

roots and thecal sac. Overall there are conflicting data as to whether epidural scar is associated or causative of symptoms following back surgery. The presence of scar did not correlate with symptoms in a study of 40 patients.[176] When epidural scar is present in symptomatic patients undergoing reoperation, it is associated with a poor outcome.[177] Others suggest that psychosocial factors rather than the presence of epidural scar correlate better with symptoms.[178]

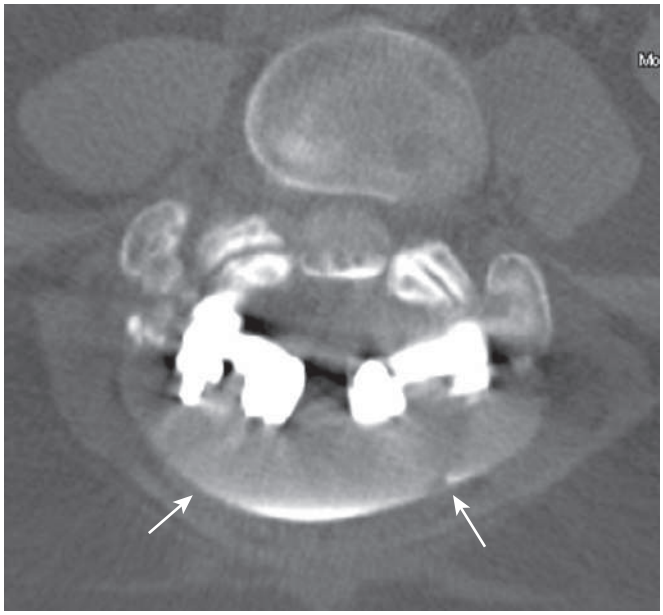

FIG. 13.20 Pseudomeningocele. Axial computed tomographic scan after myelography shows metal artifact from prior pedicle screw fixation. There is pooling of contrast medium around and dorsal to the hardware owing to a large pseudomeningocele (*arrows*).

Stenosis

Bony stenosis has been implicated as a cause of failed back surgery in 60% of cases. Various mechanisms can lead to stenotic changes in the canal or foramina. Their significance may vary, and many of these stenoses are not symptomatic. Examples of mechanisms are as follows:

1. Bony overgrowth after facetectomy may compromise a lateral recess.
2. After posterior fusion, there may be late overgrowth of bone into the posterior or lateral canals.
3. After anterior fusion, bone may extend into the canal or foramen.
4. The narrowing of the interspace after discectomy may allow sufficient facet overriding to produce a decreased size of the lateral recesses or foramina.
5. Postoperative spondylolisthesis can produce focal stenosis.

Arachnoiditis

Spinal MRI can identify the various characteristics of lumbar arachnoiditis, as can CT and myelography.[179-181] These may be classified into three categories or patterns, which can be applied to MRI, CT, or myelography, although a mixture of patterns can occur in any one patient.[182]

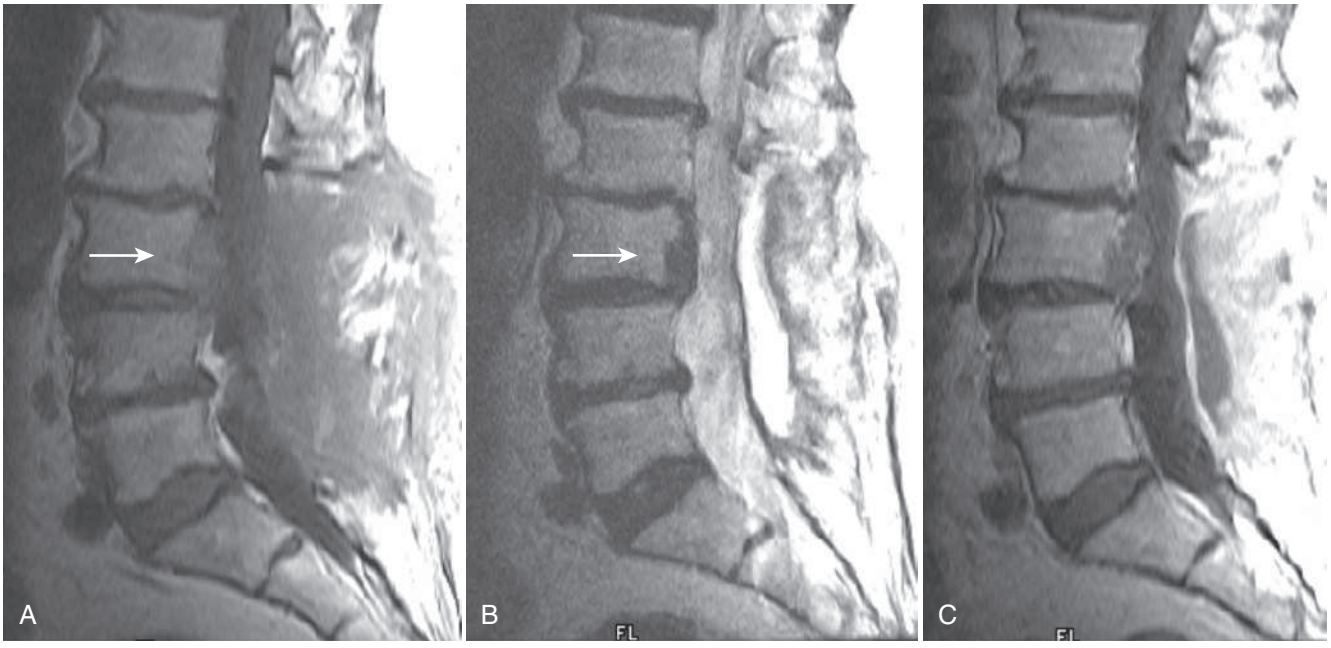

FIG. 13.21 Recurrent herniation mimicking blood. This patient underwent multilevel laminectomy and L3–L4 discectomy 3 weeks before examination. (A) Sagittal T1-weighted magnetic resonance image shows vague anterior epidural mass at L3 and extensive postoperative changes in dorsal epidural soft tissues. (B) Sagittal T2-weighted image shows L3 epidural mass to be of low signal, with effacement of anterior thecal sac. (C) After contrast administration, sagittal T1-weighted image shows slight peripheral enhancement. Differential diagnosis included acute blood (deoxyhemoglobin) and large recurrent herniation. Because of homogeneity of low signal and contiguity with disc space at L3–L4, recurrent herniation was favored. A large herniation was found at reoperation.

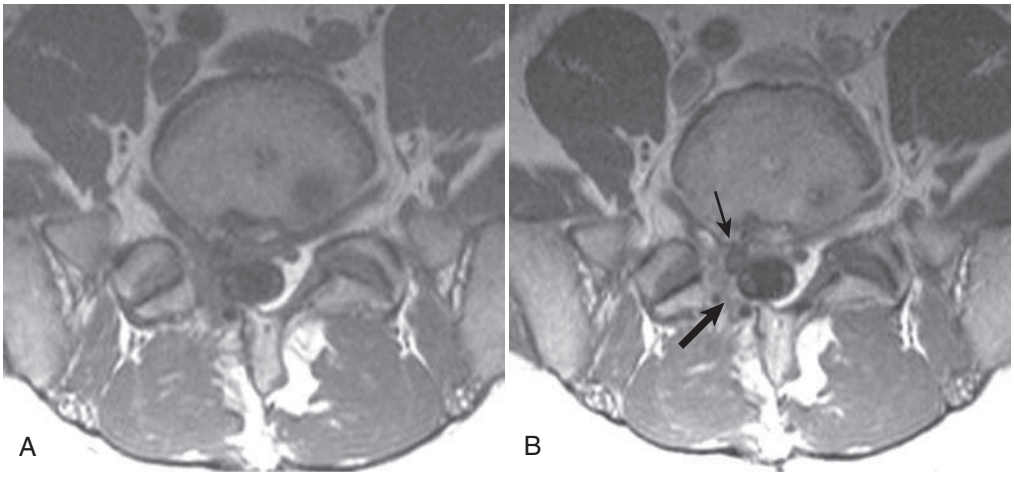

FIG. 13.22 Postoperative epidural scar. Axial T1-weighted magnetic resonance images (A) before and (B) after contrast administration show diffuse enhancement of tissue surrounding the right lateral aspect of the thecal sac *(large arrow)* and exiting the right S1 root *(small arrow)*.

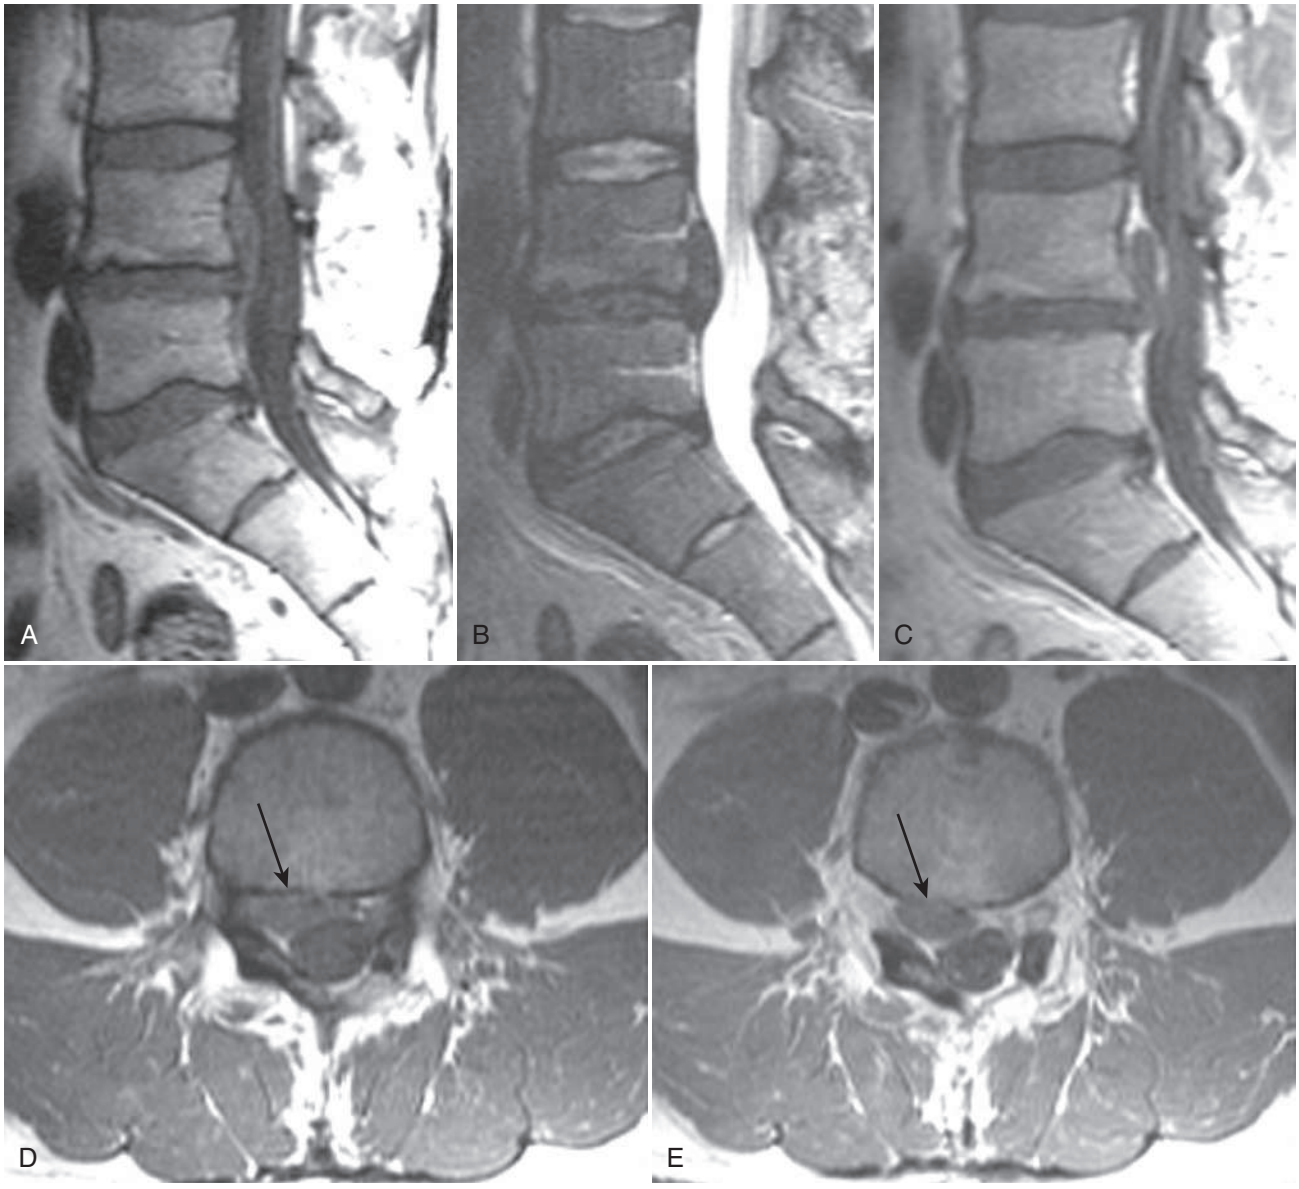

FIG. 13.23 Recurrent herniation. (A) Sagittal T1-weighted magnetic resonance image shows large anterior epidural mass extending dorsal to L4 body from L4–L5 disc space. The patient previously underwent L4 laminectomy and discectomy. (B) Sagittal T2-weighted image shows a large disc extrusion migrating superiorly from the disc space level, reflecting free fragment. (C) After contrast medium administration, sagittal T1-weighted image shows typical peripheral enhancement of large herniation. Axial T1-weighted images (D) before and (E) after contrast administration show peripheral enhancement of the disc component at mid-L4 level *(arrow)*.

The first pattern is central adhesion of the nerve roots within the thecal sac into a central clump of soft tissue signal. Instead of showing their normal feathery pattern, the nerve roots are clumped into one or more cords. This pattern is most easily identified on axial CT myelography or T1-weighted MRI. The second pattern is adhesion of the nerve roots to the meninges, giving rise to an "empty thecal sac" sign. On MRI, only the homogeneous signal of the CSF is present within the thecal sac, and the nerve roots are peripherally attached to the meninges. On CT myelography, only the high-attenuation contrast agent within the thecal sac is visualized, without the nerve roots. In the third pattern, which can be viewed as an end stage of the inflammatory response, the arachnoid becomes an inflammatory mass that fills the thecal sac. On myelography, this type of arachnoiditis gives rise to a block, with an irregular "candle dripping" appearance. MRI shows a nonspecific soft tissue mass, as does CT myelography.

Infection

Infection should be considered in the differential diagnosis for back pain even though it is an uncommon disorder (1% of all cases of osteomyelitis). When infection is considered, accurate imaging is a necessary prelude for microbiologic diagnosis or surgical drainage. Because abnormalities that appear on plain radiographs usually take days to weeks to become apparent, radionuclide studies and MRI have been the primary imaging modalities for diagnosis of vertebral osteomyelitis.

CT has played a minor diagnostic role in cases with bony or soft tissue components and is not considered a mainstay for the diagnosis of disc space infection.[183,184] MRI is more sensitive than either plain films or CT for detecting vertebral osteomyelitis, and it approaches or equals the sensitivity of radionuclide studies (Figs. 13.24 and 13.25).[185,186]

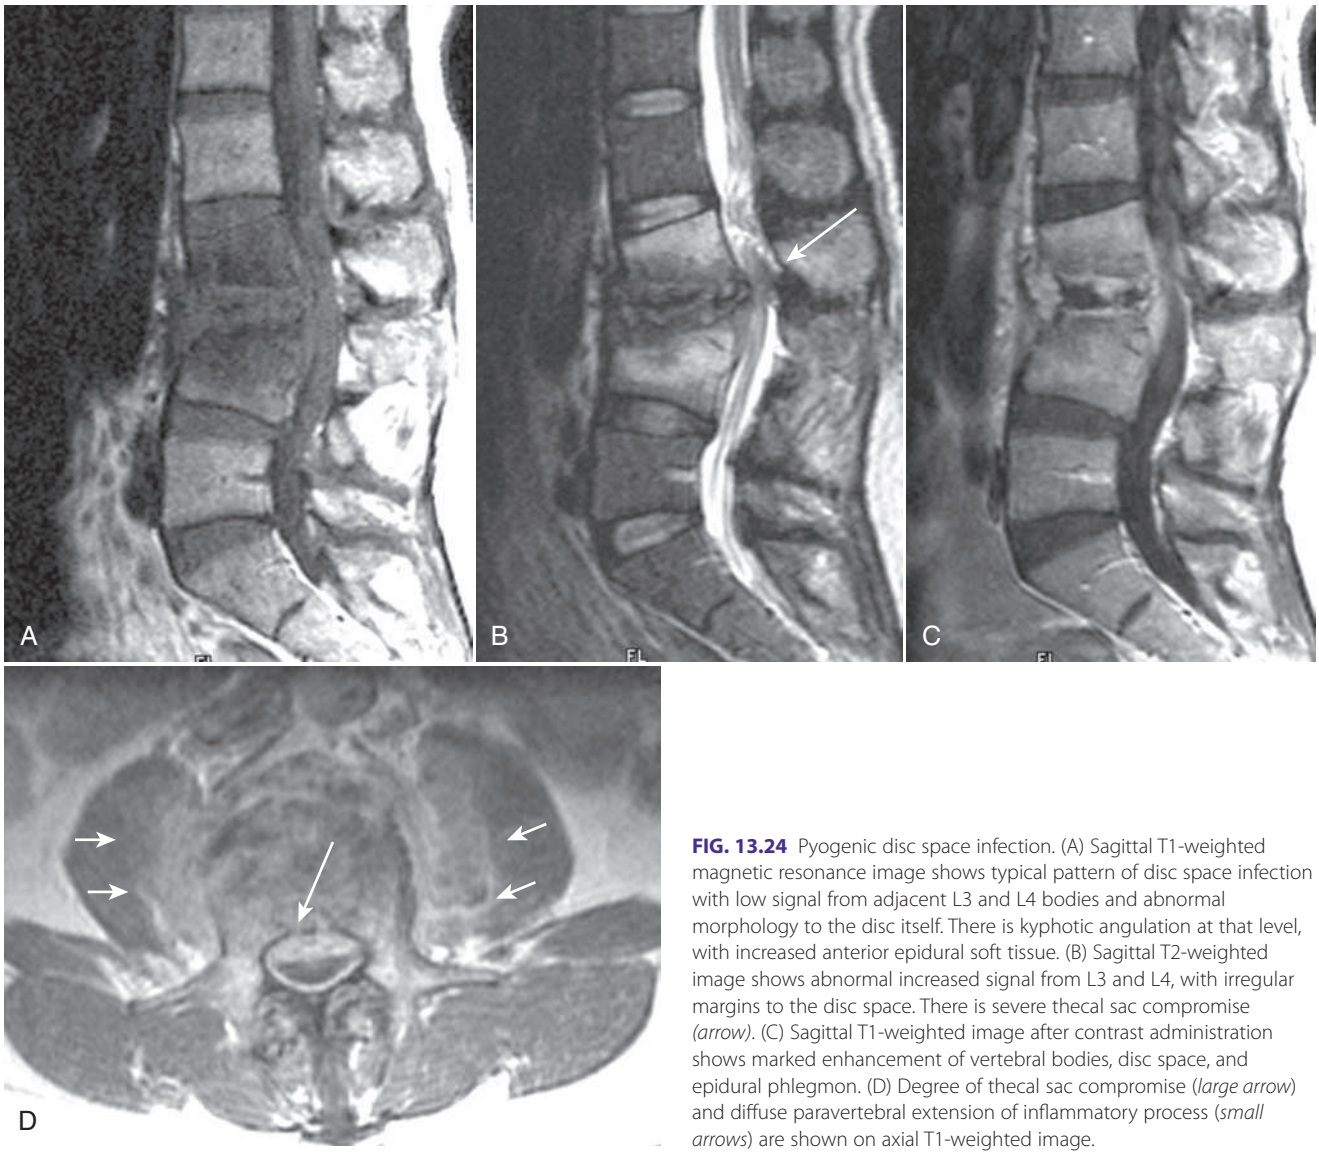

FIG. 13.24 Pyogenic disc space infection. (A) Sagittal T1-weighted magnetic resonance image shows typical pattern of disc space infection with low signal from adjacent L3 and L4 bodies and abnormal morphology to the disc itself. There is kyphotic angulation at that level, with increased anterior epidural soft tissue. (B) Sagittal T2-weighted image shows abnormal increased signal from L3 and L4, with irregular margins to the disc space. There is severe thecal sac compromise *(arrow)*. (C) Sagittal T1-weighted image after contrast administration shows marked enhancement of vertebral bodies, disc space, and epidural phlegmon. (D) Degree of thecal sac compromise (*large arrow*) and diffuse paravertebral extension of inflammatory process (*small arrows*) are shown on axial T1-weighted image.

FIG. 13.25 Early disc space infection. (A) Sagittal T1-weighted magnetic resonance image shows loss of disc space height at L2–L3 through L4–L5 but no overt marrow signal abnormality. (B) Sagittal T2-weighted image shows abnormal increased signal in L4–L5 disc space but no marrow signal abnormality. (C) Sagittal T1-weighted image after contrast administration shows mild patchy L4–L5 disc enhancement and mild endplate enhancement. Differential diagnosis at this time is severe degenerative disc disease versus early disc space infection. (D) Grossly abnormal signal involving L4 and L5 bodies with loss of disc margin was visible 5 weeks later on T1-weighted image. (E) L4–L5 disc now shows more marked increased signal on T2-weighted image.

It is imperative to obtain both T1- and T2-weighted images in the sagittal plane for optimal sensitivity to detect disease. The T1-weighted spin-echo image allows detection of the increased water content or marrow fluid seen with inflammatory exudate or edema. Similar to most pathologic processes, disc space infection or vertebral osteomyelitis results in increased signal intensity on T2-weighted images. The diagnostic specificity of MRI is provided by the signal intensity changes on T1- and T2-weighted images and by the anatomic pattern of disease involvement and the appropriate clinical situation.

On T2-weighted images, the normal intervertebral disc usually shows increased signal intensity within its central portion that is bisected by a thin horizontal line of decreased signal, termed the *intranuclear cleft*. After the age of 30 years, the cleft is almost a constant feature of normal intervertebral discs. Disc space infections on MRI typically produce confluent decreased signal intensity of the adjacent vertebral bodies and the involved intervertebral disc space on T1-weighted images compared with the normal vertebral body marrow. A poorly defined endplate margin exists between the disc and adjacent vertebral bodies. T2-weighted images show increased signal intensity of the vertebral bodies adjacent to the involved disc and an abnormal morphology and increased signal intensity from the disc itself, with absence of the normal intranuclear cleft. These MRI findings are much more typical of pyogenic than of tuberculous osteomyelitis.[187] In a comparative study of patients with suspected vertebral osteomyelitis, MRI had a

sensitivity of 96%, a specificity of 92%, and an overall accuracy of 94%.[185] Scintigraphy with ^{67}Ga and ^{99m}Tc bone scintigraphy had a sensitivity of 90%, specificity of 100%, and accuracy of 94% when combined. In this study, MRI was as accurate and sensitive as radionuclide scanning for the detection of osteomyelitis.

Dagirmanjian and colleagues[188] investigated the sensitivity of MRI findings for vertebral osteomyelitis. They considered the "classic" MRI changes of vertebral osteomyelitis to include decreased signal of disc and adjacent vertebral bodies on T1-weighted images, increased nonanatomic signal of the disc on T2-weighted images, increased signal of the adjacent vertebral bodies on T2-weighted images, and enhancement of the disc and adjacent vertebral bodies. These investigators found 95% of disc space infection levels had typical T1-weighted vertebral body changes, and 90% had increased nonanatomic signal of the disc on T2-weighted images. Only 54% of the abnormal levels showed increased signal of the vertebral bodies on T2-weighted images, however. Although 84% of patients showed the typical T1-weighted vertebral body and T1- and T2-weighted disc changes, only 49% of cases showed the typical T1- and T2-weighted vertebral body and disc findings as originally described. T1-weighted vertebral body, disc, and endplate changes and T2-weighted disc changes are the most reliable findings of disc space infection and vertebral osteomyelitis. In the initial stages of vertebral osteomyelitis, when the disc space is not yet involved, it may be difficult to exclude neoplastic disease or compression fracture from the differential diagnosis using only MRI. Follow-up studies are usually necessary to define the nature of the lesion further.

Boden and colleagues[189] suggested that in the postoperative spine the triad of intervertebral disc space enhancement, anular enhancement, and vertebral body enhancement leads to the diagnosis of disc space infection, with the appropriate laboratory findings, such as an elevated sedimentation rate. A group of normal postoperative patients, however, has anulus enhancement (at the surgical site), intervertebral disc enhancement, and vertebral endplate enhancement without evidence of disc space infection. In these cases, the intervertebral disc enhancement is typically seen as thin bands paralleling the adjacent endplates, and the vertebral body enhancement is associated with type 1 degenerative endplate changes. This pattern should be distinguished from the amorphous enhancement seen within the intervertebral disc with disc space infection.

Staphylococcus aureus is the organism most commonly associated with vertebral osteomyelitis and epidural abscess, accounting for approximately 60% of the cases (Fig. 13.26). *S. aureus* is ubiquitous, tends to form abscesses, and can infect compromised and normal hosts. Other gram-positive cocci account for approximately 13% of cases, and gram-negative organisms account for approximately 15%. Clinical acute symptoms classically include back pain, fever, obtundation in severe cases, and neurologic deficits. Chronic cases may have less pain and no elevated temperature. Rankin and Flothow[190] described the classic clinical course of epidural abscess in four stages: spinal ache, root pain, weakness, and paralysis. Acute deterioration from spinal epidural abscess remains unpredictable, however. Patients may present with abrupt paraplegia and anesthesia. The cause for this precipitous course is unknown, but it is thought to be related to a vascular mechanism (e.g., epidural thrombosis and thrombophlebitis, venous infarction).[191,192]

The primary diagnostic modality in the evaluation of epidural abscess is MRI. MRI is as sensitive as CT myelography for diagnosing epidural infection, but it also allows the exclusion of other entities, such as herniation, syrinx, tumor, and cord infarction.[193,194] MRI of epidural abscess shows a soft tissue mass in the epidural space with tapered edges and an associated mass effect on the thecal sac and cord. The epidural masses are usually isointense to the cord on T1-weighted images and of increased signal on T2-weighted images. Post and colleagues[195,196] recommended that in ambiguous cases either CT myelography or contrast medium–enhanced MRI is necessary for full elucidation of the abscess (Fig. 13.27).

The patterns of MRI contrast medium enhancement of epidural abscess include (1) diffuse and homogeneous, (2) heterogeneous, and (3) thin peripheral. Post and colleagues[196] found that enhancement was a very useful adjunct for identifying the extent of a lesion when the plain MR image was equivocal, for showing activity of an infection, and for directing needle biopsy and follow-up treatment. Successful therapy should cause a progressive decrease in enhancement of the paraspinal soft tissues, disc, and vertebral bodies.[197]

Intramedullary Lesions

Diagnostic considerations of pathology involving the intramedullary space include neoplasm, vascular malformation, syrinx, granulomatous disease, inflammation, or demyelination.[198-200] Radiographs without intrathecal contrast have no value for nonexpansile cord pathology, with late findings of cord neoplasm only inferred by canal expansion or osseous destruction. MR imaging can directly visualize the cord and can characterize nonexpansile cord abnormalities.

The imaging findings of spinal cord neoplasm most commonly include cord expansion, syrinx formation, and enhancement. For low-grade nonenhancing neoplasms there is typically cord expansion.[201,202] When faced with a nonexpansile T2 or STIR hyperintense spinal cord, distribution of signal abnormalities, enhancement, blood degradation byproducts, and its behavior over time (if available) are all useful factors to consider when arriving at an appropriate differential diagnosis. Transverse myelitis tends to involve longer segments of the cord as opposed to multiple sclerosis, which tends to be patchy and involves the dorsal or lateral aspects of the cord. Enhancement should typically resolve by 2 months when present with multiple sclerosis (Fig. 13.28). Spinal cord infarct can involve the ventral gray matter centrally within the spinal cord; subacute combined degeneration has a more posterior distribution.[200]

Neoplasms

The most common intramedullary neoplasms are *gliomas,* principally astrocytomas and ependymomas. *Ependymomas*

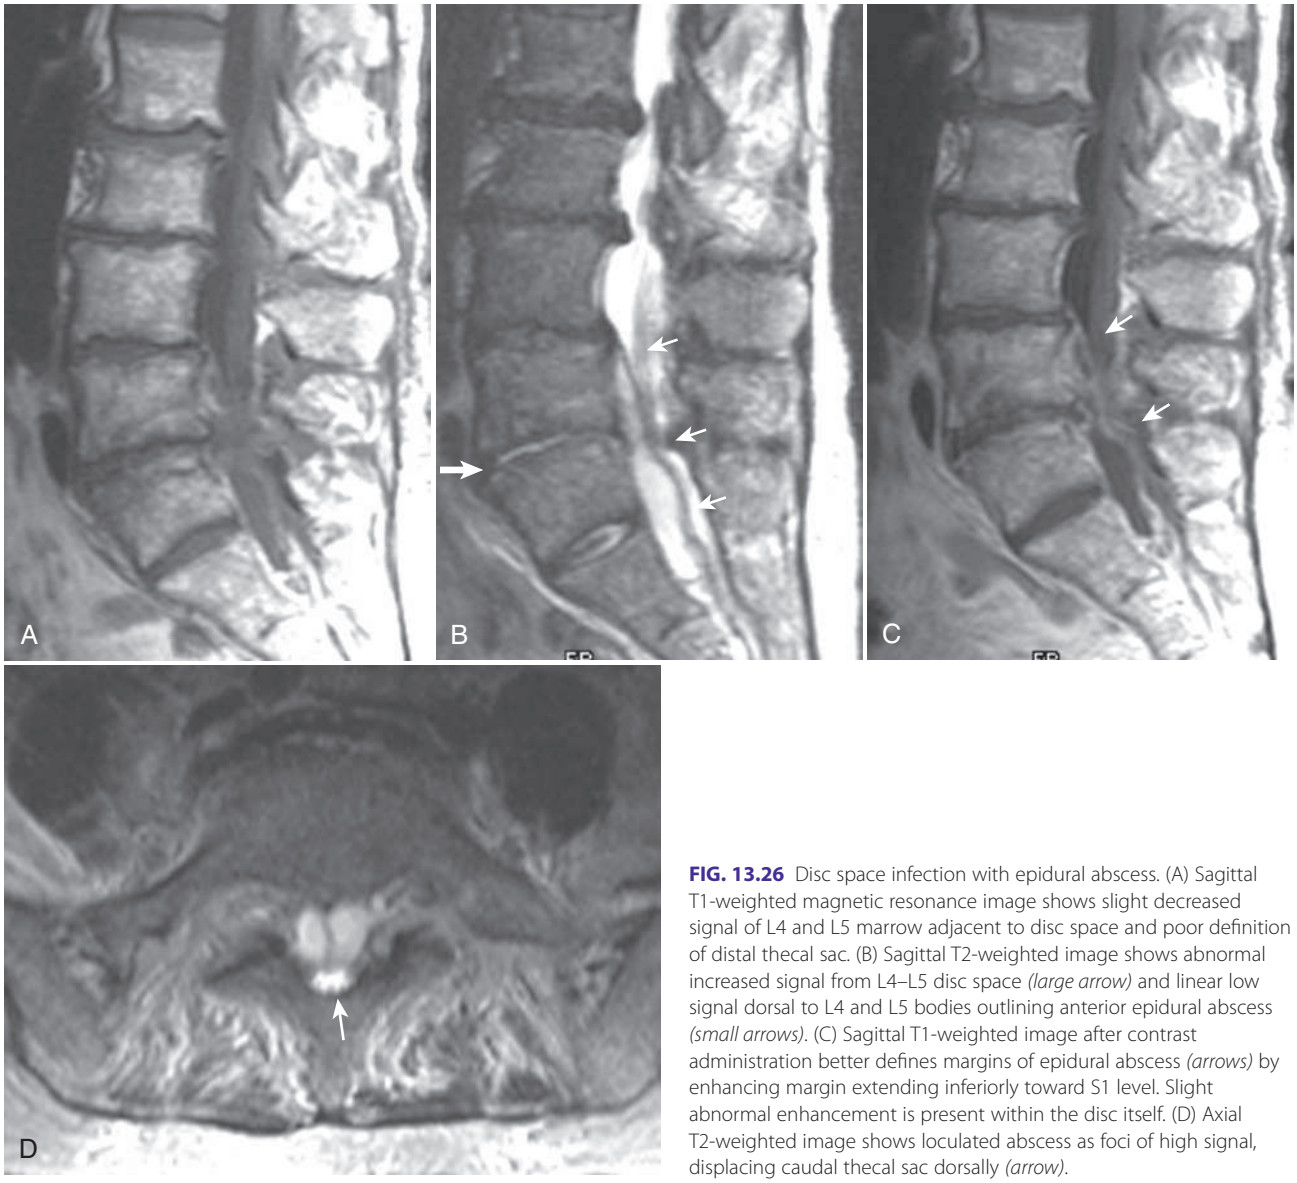

FIG. 13.26 Disc space infection with epidural abscess. (A) Sagittal T1-weighted magnetic resonance image shows slight decreased signal of L4 and L5 marrow adjacent to disc space and poor definition of distal thecal sac. (B) Sagittal T2-weighted image shows abnormal increased signal from L4–L5 disc space *(large arrow)* and linear low signal dorsal to L4 and L5 bodies outlining anterior epidural abscess *(small arrows)*. (C) Sagittal T1-weighted image after contrast administration better defines margins of epidural abscess *(arrows)* by enhancing margin extending inferiorly toward S1 level. Slight abnormal enhancement is present within the disc itself. (D) Axial T2-weighted image shows loculated abscess as foci of high signal, displacing caudal thecal sac dorsally *(arrow)*.

are cited as the most frequent intramedullary tumors in adults (Fig. 13.29). Although ependymomas may involve any portion of the cord, they most commonly involve the conus medullaris and filum terminale and are the most common primary tumor of the lower spinal cord. Patients with these tumors present in the fourth to fifth decades of life, often with back pain.[203,204] A typical appearance is an intradural extramedullary mass involving the filum terminale and cauda equina, although it can appear as fusiform enlargement of the cord itself.[205] Cervical intramedullary tumors may be seen in patients with neurofibromatosis type 2 (Fig. 13.30). These tumors typically enhance and may have intratumoral cysts. The myxopapillary subtype is particularly common in the lumbosacral region, typically appearing as a large, intensely enhancing mass spanning several vertebral levels. In most cases, the tumors appear as intradural extramedullary lesions because of their bulky exophytic growth, which fills the spinal canal. Overall signal intensities are nonspecific, but because of their highly vascular nature, ependymomas often show areas of T2-weighted shortening secondary to the presence of hemosiderin and ferritin, which is strongly suggestive of the diagnosis.[206] They also may manifest as subarachnoid hemorrhage.[207]

Intramedullary astrocytomas constitute 6% to 8% of primary spine tumors, with a peak incidence in the third to fourth decades of life. Astrocytomas produce focal enlargement and occasionally exophytic growth involving the cord. Of these tumors, 75% to 92% are relatively benign, such as grades 1 and 2. Imaging shows fusiform enlargement of the cord over several segments, whereas T2-weighted MRI shows increased signal intensity reflecting tumor and edematous cord. Cysts are often associated with these intramedullary tumors. These cysts may be benign, syringomyelic type of cavities, or actual cysts associated with the tumor.

Hemangioblastomas are unusual cord tumors and typically manifest in the third to fourth decades of life. They are frequently multiple and seen in association with von

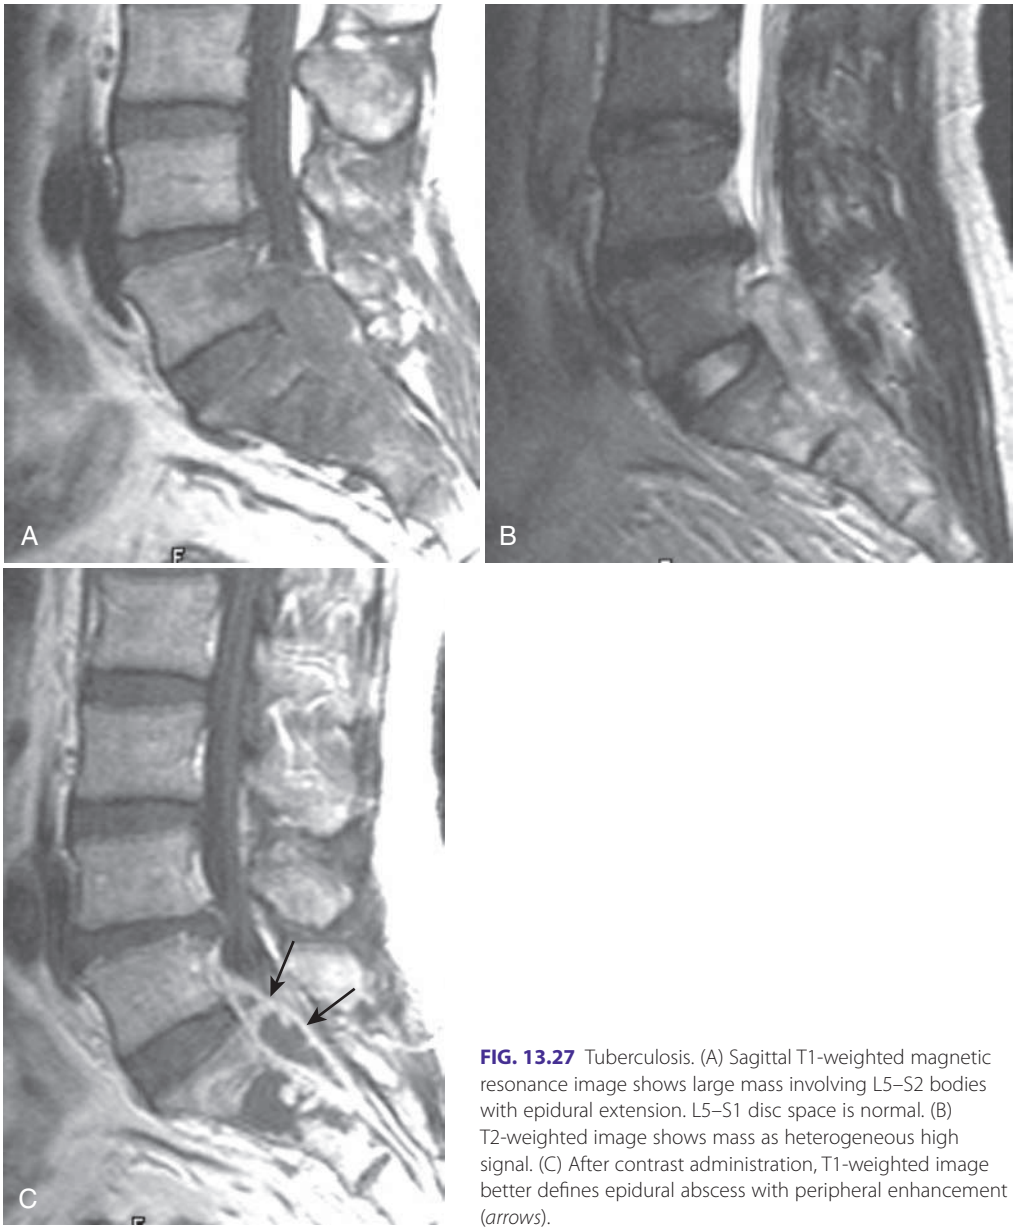

FIG. 13.27 Tuberculosis. (A) Sagittal T1-weighted magnetic resonance image shows large mass involving L5–S2 bodies with epidural extension. L5–S1 disc space is normal. (B) T2-weighted image shows mass as heterogeneous high signal. (C) After contrast administration, T1-weighted image better defines epidural abscess with peripheral enhancement (*arrows*).

Hippel–Lindau disease.[208-213] These lesions most often manifest as dorsal intramedullary masses containing a nodule that enhances, although these vary by the amount of cyst component and solid component. There may be extensive widening of the cord, showing increased signal intensity on T2-weighted images related to cord edema and extending several segments away from the nidus itself.

Occasionally, metastatic disease may manifest as an intramedullary enhancing mass. Carcinoma of the lung and breast is the most common, with melanoma, lymphoma, and renal cell carcinoma also reported.[214,215] Spread of intracranial neoplasms such as ependymoma and glioma may also seed the leptomeninges and produce direct involvement of the cord.[216-218]

Benign intramedullary tumors are uncommon, but *cavernous angiomas* (cavernous malformations) can occur in the cord with typical signal characteristics of speckled increased and decreased signal on T1-weighted images and evidence of hemosiderin deposition on T2-weighted images (Fig. 13.31).

Inflammation

The various causes of inflammatory myelopathies include multiple sclerosis, postviral demyelinating disease, viral infection, pyogenic infection, and granulomatous disease. The archetypal inflammatory lesion is *multiple sclerosis* (Fig. 13.32). The spinal cord is the site of much clinical involvement in patients with multiple sclerosis; however, imaging of the spinal cord has always been subordinate to brain imaging in radiologic investigations of multiple sclerosis. Because some of the clinical disease activity in multiple sclerosis is related to the spinal cord, it is important to correlate cord disease with clinical activity to gain further insights into the nature of disability in these patients and to correlate objective

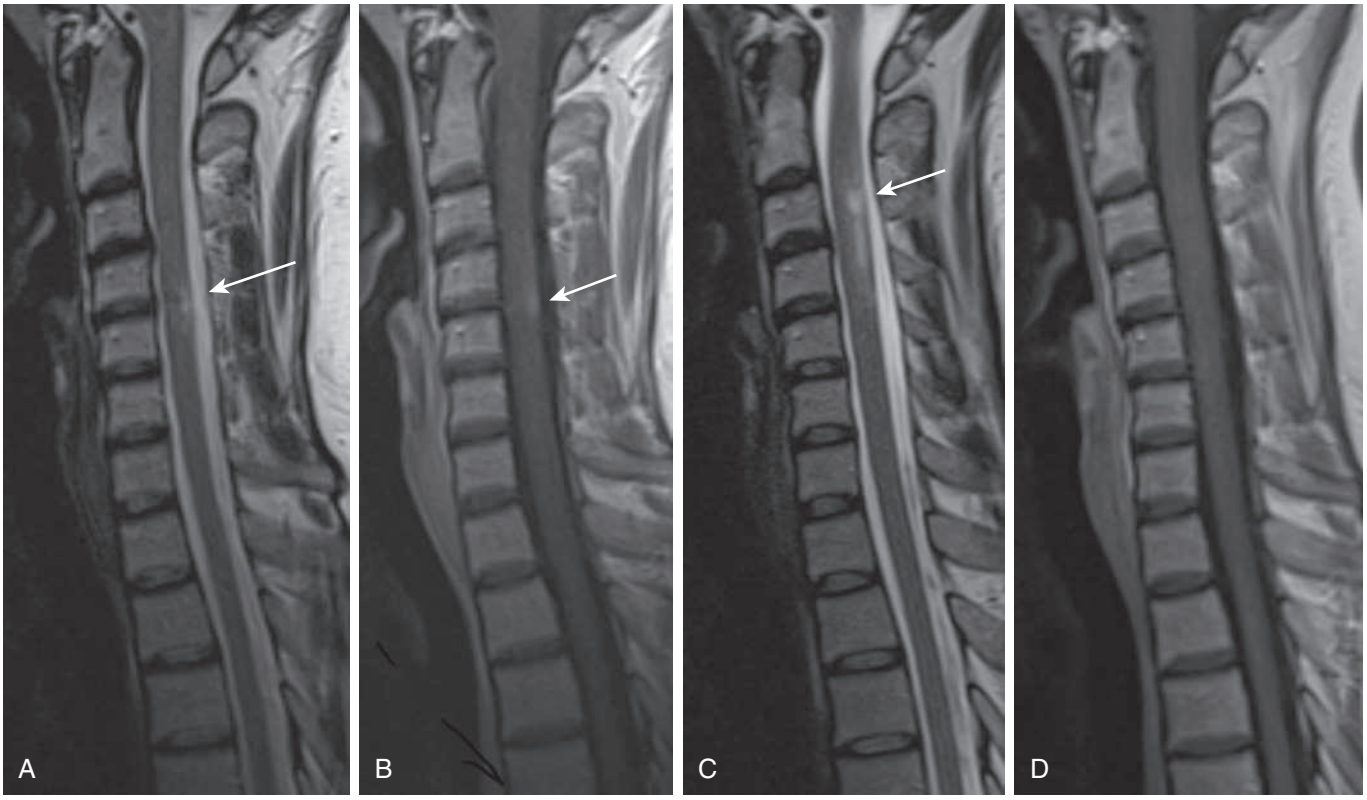

FIG. 13.28 Follow-up imaging is valuable when evaluating lesion behavior over time. (A) Sagittal T2-weighted magnetic resonance image and (B) sagittal T1-weighted contrast-enhanced image demonstrate cord signal abnormality and enhancement *(arrow)*. Follow-up imaging obtained 1 year later demonstrates (C) progression of T2 signal abnormality *(arrow)* and (D) resolution of the enhancement. Findings are consistent with demyelination.

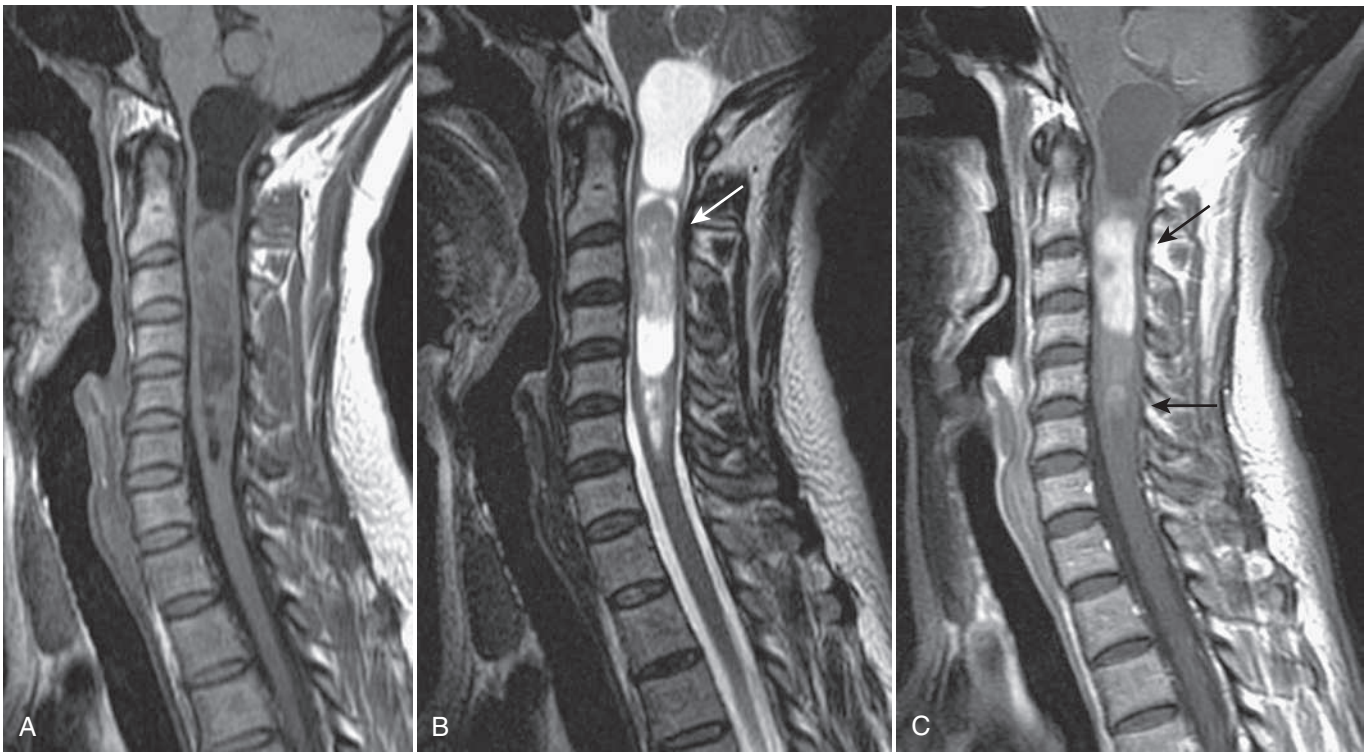

FIG. 13.29 Ependymoma. (A) Sagittal T1-weighted magnetic resonance image shows large cystic and solid intramedullary mass within the cervical cord. A tumor-associated cyst extends to the medulla. (B) Sagittal T2-weighted image shows central solid component *(arrow)* with cephalad and caudad cystic components. (C) Sagittal T1-weighted image after contrast administration shows large enhancing solid component extending down to C5–C6 *(black arrows)*.

improvements in brain and cord lesion burden with changes in clinical disability scoring. Most focal plaques are less than two vertebral body lengths in size, occupy less than half the cross-sectional diameter of the cord, and are characteristically peripherally located with respect to a transverse, cross-sectional reference. Of spinal cord multiple sclerosis lesions, 60% to 75% are present in the cervical region, and more than half of multiple sclerosis patients with cord plaques have multiple plaques. Of patients with cord plaques, 90% have intracranial multiple sclerosis plaques.[200,219,220]

FIG. 13.30 Ependymoma in a patient with neurofibromatosis type 2. Sagittal T1-weighted magnetic resonance image after contrast administration shows multiple intradural extramedullary enhancing masses (schwannomas or meningiomas), combined with a less intensely enhancing mass within the conus (ependymoma).

Intradural Extramedullary Lesions

Intradural extramedullary neoplasms constitute the largest single group of primary spine neoplasms, accounting for approximately 55% of all primary spine tumors. Most of these tumors are benign, with *nerve sheath tumors* and *meningiomas* representing the most common lesions.[218] *Nerve sheath tumors* are the most common intraspinal tumors and are divided histologically into two types: *schwannomas* (i.e., neuromas, neurinomas, and neurilemmomas) and *neurofibromas* (Fig. 13.33). Solitary schwannomas constitute most intraspinal nerve sheath tumors, whereas neurofibromas are almost always associated with neurofibromatosis type 1. Patients with neurofibromatosis type 2 more commonly have multiple schwannomas rather than neurofibromas, however.[221] Isolated nerve sheath tumors can arise anywhere in the spine.[222]

Nerve sheath tumors are easily recognized on MRI as typically isolated, well-circumscribed, solid masses of soft tissue signal intensity on T1-weighted images surrounded by low signal CSF. On T2-weighted images, they are of variable signal intensity. Schwannomas are more vascular and include cystic degeneration, necrosis, and hemorrhage more commonly than neurofibromas. Various local osseous changes, consisting mainly of smooth bony remodeling or foraminal enlargement, are common. Enhancement is almost always present, but the pattern is variable.

Meningiomas most commonly occur in the thoracic spine.[223] As is the case intracranially, there is a female sex predilection, and these lesions occur in a slightly older age group than nerve sheath tumors. Most are entirely intradural and typically are isointense to the neural elements on T1- and

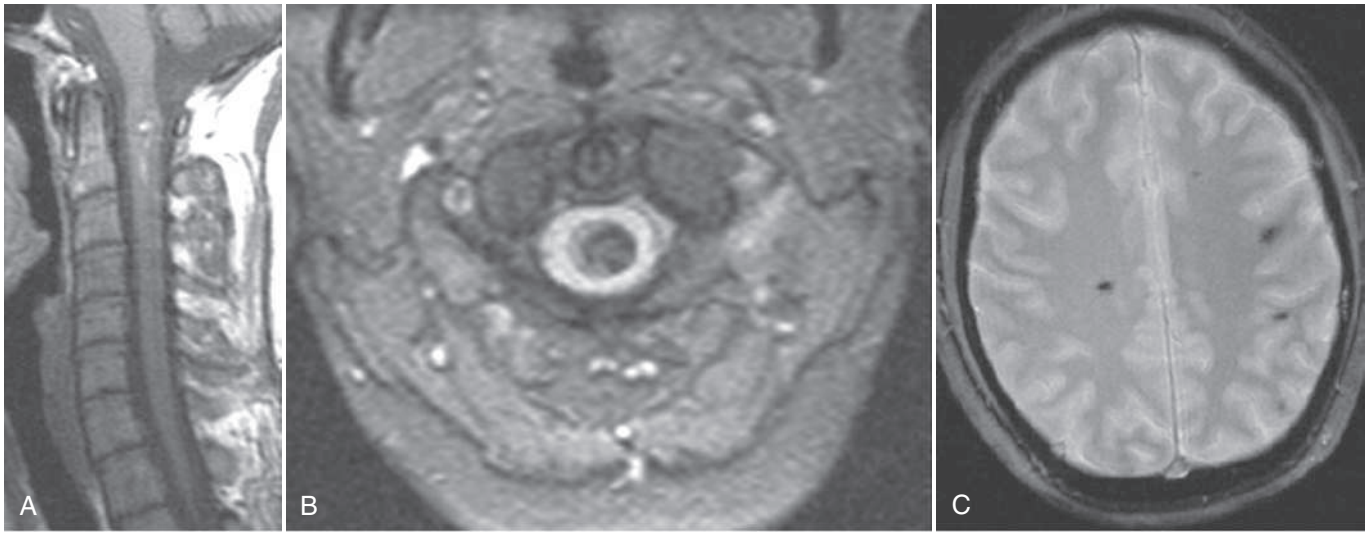

FIG. 13.31 Cavernous angioma. (A) Sagittal T1-weighted magnetic resonance image shows linear focus of high signal reflecting hemorrhage within the cord at C2 level. (B) Axial gradient-echo image confirms blood as focal low signal within substance of cord. (C) Axial gradient-echo image through the brain shows multiple areas of low signal *(dark spots)* reflecting hemosiderin deposition owing to multiple cavernous angiomas.

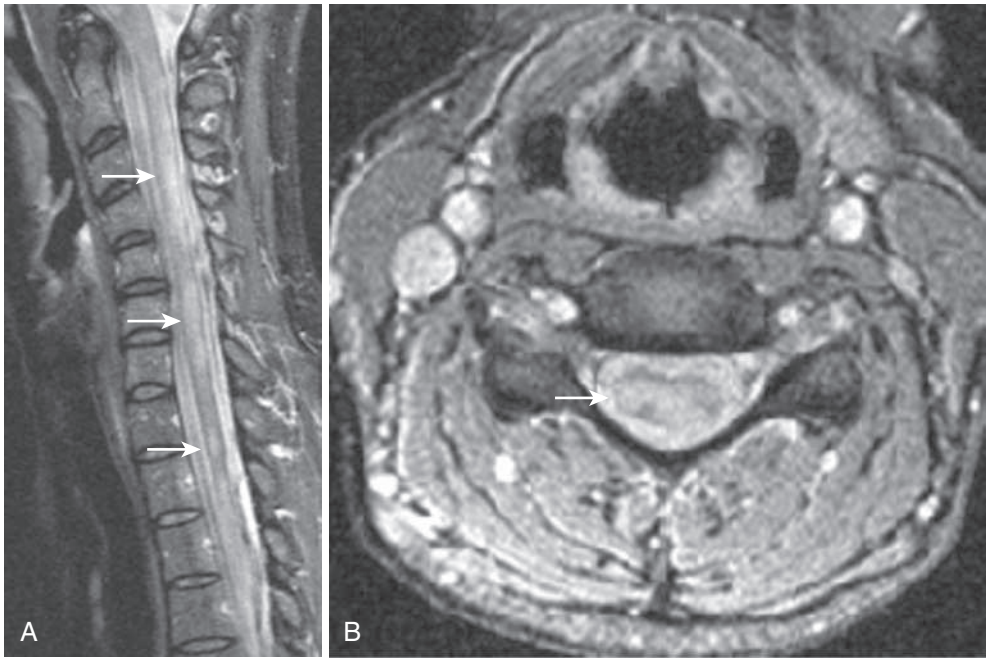

FIG. 13.32 Short-tau inversion recovery imaging for intramedullary inflammatory disease. (A) Sagittal and (B) axial images show multiple foci of abnormal increased signal throughout the cervical cord without expansion, reflecting demyelinating disease *(arrows)*.

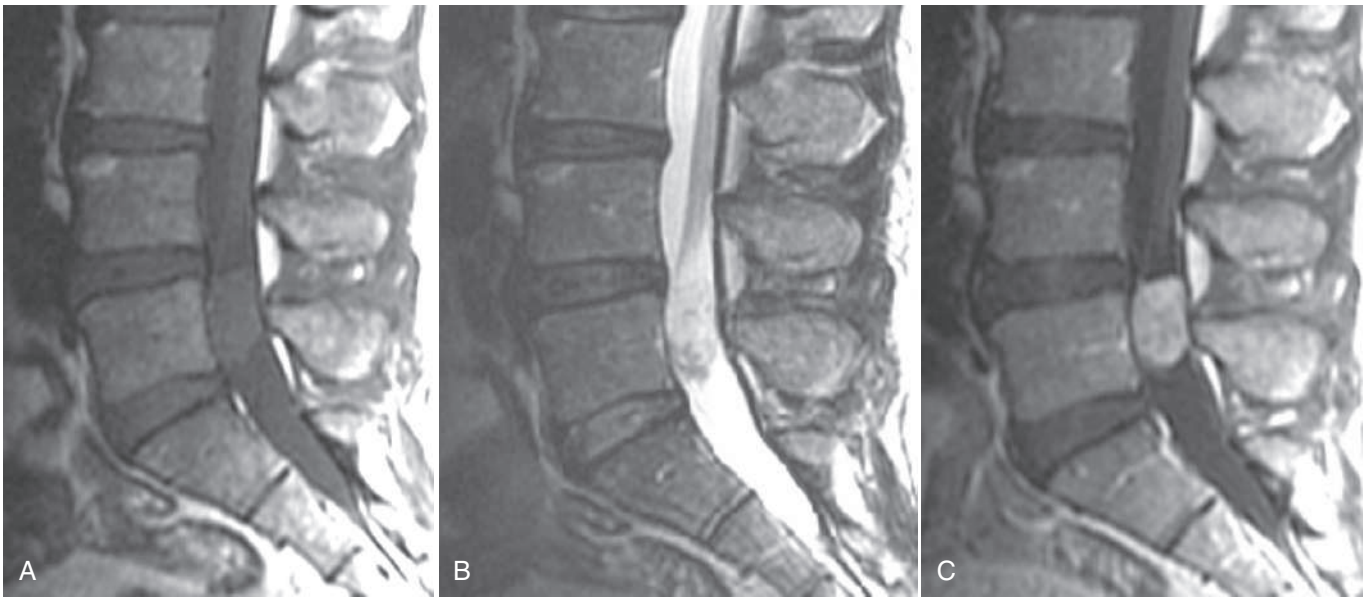

FIG. 13.33 Schwannoma. (A) Sagittal T1-weighted, (B) T2-weighted, and (C) T1-weighted enhanced magnetic resonance images show a round, intensely enhancing intradural mass at the L4 level, displacing the adjacent cauda equina.

T2-weighted images. Meningiomas enhance intensely after gadolinium–diethylenetetramine-pentaacetic acid (DTPA) administration, which may allow demonstration of the typical broad dural base.[224,225]

The last category of intradural extramedullary lesions is the so-called *leptomeningeal* pattern, which includes leptomeningeal metastatic disease, inflammation, and benign granulomatous processes such as sarcoid and tuberculosis (Fig. 13.34).[226] The list of tumors that may seed the CSF is long, but the most common types are cranial ependymomas, glioblastomas, and medulloblastomas (especially in pediatric patients). Additional malignancies that can spread less commonly are ependymoma, pineoblastoma, germinoma, and retinoblastoma. Lesions outside the central nervous system that are capable of spreading along the leptomeninges include carcinoma of the lung and breast, lymphoma, leukemia, and melanoma. Administration of contrast material with T1-weighted images is mandatory and shows a linear and nodular enhancement pattern along the leptomeninges. The overall sensitivity of MRI examinations is low in patients with

FIG. 13.34 Leptomeningeal enhancement. Sagittal T1-weighted magnetic resonance images (A) before and (B) after contrast administration show extensive leptomeningeal enhancement of cauda equina and distal cord surface in a patient with *Staphylococcus aureus* meningitis.

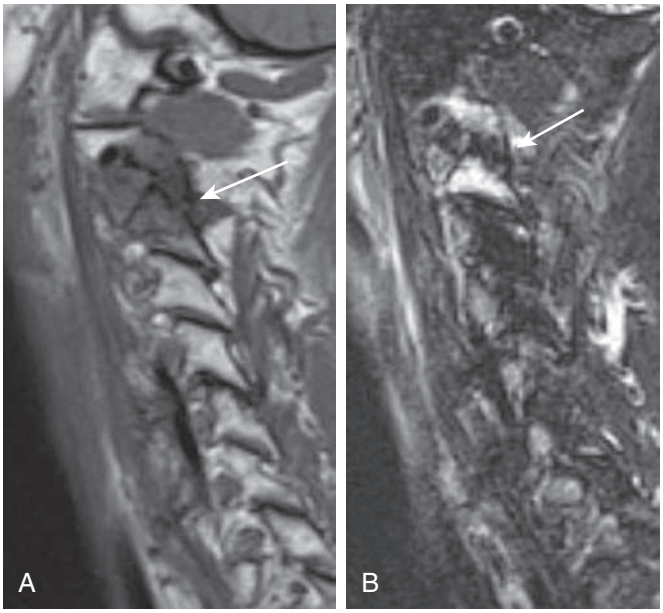

FIG. 13.35 In general, most pathologic marrow (neoplastic, degenerative, or infectious) demonstrates water signal intensity. However, distribution of the signal abnormality can be helpful in arriving at a differential diagnosis. (A) Sagittal T1-weighted image and (B) sagittal short-tau inversion recovery (STIR) image demonstrates abnormal low T1 signal intensity and STIR hyperintensity centered about the C2–C3 facet joint *(arrow)*, which is degenerative or inflammatory in nature rather than neoplastic.

proven histologic evidence of neoplastic seeding, so examination of the CSF remains the gold standard.

Extradural Lesions

Pathology that can involve the extradural space can include degenerative disc disease, epidural hematoma or abscess, or neoplasm extending from adjacent osseous structures.[227]

Bone Marrow Imaging

MR imaging is the preferred modality for imaging the bone marrow when compared with radiographs or CT imaging, although CT imaging can demonstrate osseous destruction or abnormal increased attenuation. Pathologic or abnormal marrow on MR imaging is typically manifested as low T1 signal intensity and T2 or STIR hyperintensity. Distribution of the marrow abnormalities is helpful, as abnormal marrow centered about a joint or articulating surface can be degenerative or inflammatory in nature rather than neoplastic (Fig. 13.35). Complete marrow replacement by low T1 signal intensity can be seen with both metastatic disease and red marrow replacement in patients with anemia.[228] CT imaging can demonstrate the matrix of a lesion (increased attenuation when osteogenic, ground glass for fibrous lesions, or anular calcifications in cartilaginous lesions). Lesions with sclerotic borders tend to be less aggressive compared with lesions with ill-defined or poor margins.[229]

Primary and secondary tumors to the extradural space are well evaluated by MRI and CT (Fig. 13.36). *Metastatic disease* to the spine is the most common type of extradural tumor. Because of its high contrast sensitivity and spatial resolution, MRI is the examination of choice in the detection of osseous metastases (Figs. 13.37 and 13.38).[230,231] Because many metastatic tumors enhance, the routine use of contrast medium–enhanced studies alone is not recommended because the distinction between metastases and normal marrow fat is diminished, occasionally to the point of masking even large lesions (Fig. 13.39). Although diffuse osseous metastases can appear as homogeneous, diffuse, low marrow signal on T1-weighted images, this appearance is not specific.

Ossification of Posterior Longitudinal Ligament

Ossification of the posterior longitudinal ligament (OPLL) begins with calcification followed by frank ossification of the posterior longitudinal ligament in the upper cervical spine (C3–C4 or C4–C5). It may progress inferiorly to the upper thoracic spine (Figs. 13.40 and 13.41).[232] Patients tend to present in the sixth decade of life, are generally older than typical patients with disc disease, and are younger than patients with cervical spondylosis. Presenting complaints include neck pain, dysesthesias, and upper and lower extremity weakness. CT findings often show the bony pathology better than MRI. Hirabayashi and Satomi[233] divided OPLL into four types based on CT: (1) *continuous* OPLL extends between vertebral bodies and crosses multiple disc spaces (27% of cases), (2) *segmental* OPLL is limited to the posterior vertebral body margins (39% of cases), (3) *mixed* OPLL is continuous and segmental (29% of cases), and (4) the remaining 5% of OPLL is restricted to the disc space level.

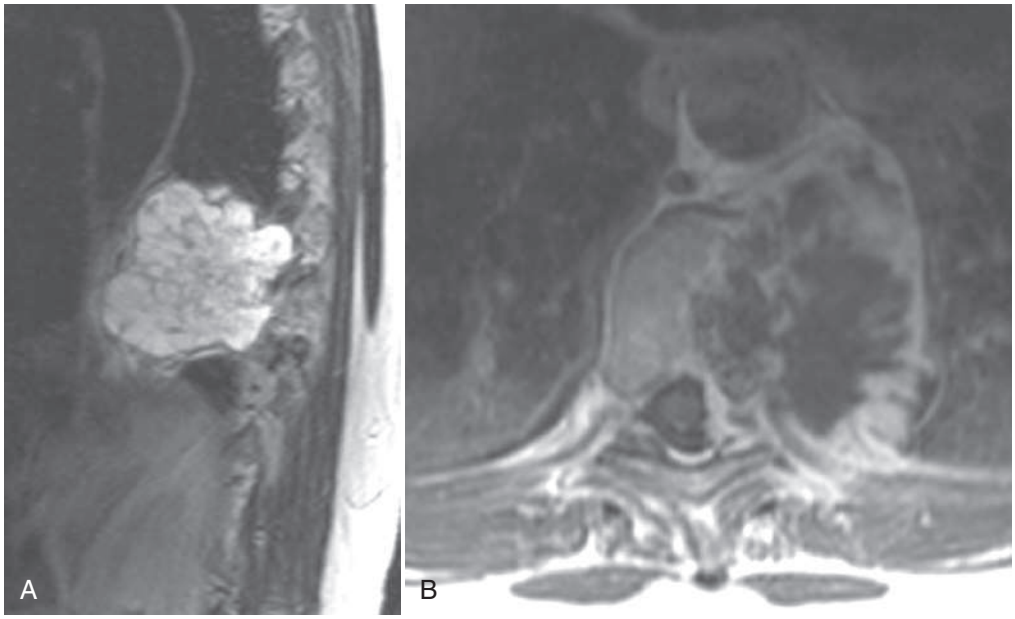

FIG. 13.36 Chondroblastic osteosarcoma. (A) Sagittal T2-weighted magnetic resonance image shows large paraspinal mass with well-defined margins and heterogeneous internal signal typical of cartilaginous lesions, including chordoma. (B) Axial T1-weighted image after contrast administration shows a large, irregularly enhancing mass involving the left lateral aspect of the thoracic body with extension into the paravertebral region. There is left lateral epidural extension of tumor with mild mass effect on the cord.

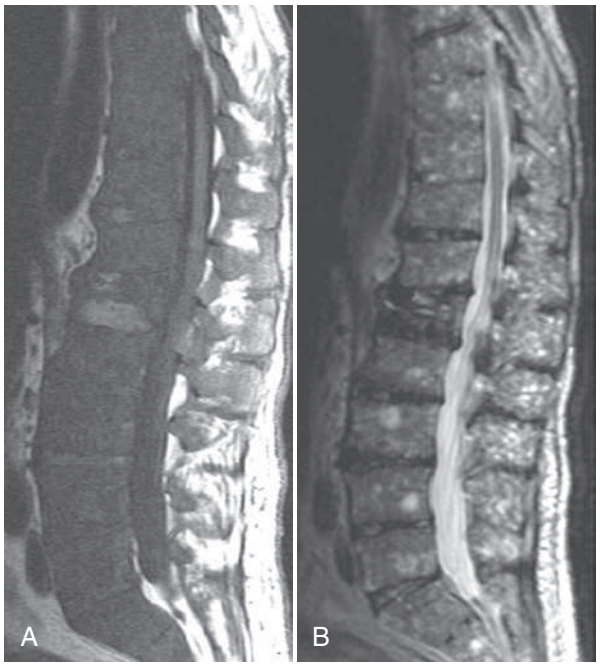

FIG. 13.37 Multiple myeloma. (A) Sagittal T1-weighted magnetic resonance image shows markedly diminished signal from all the visualized marrow of thoracolumbar spine. There is severe compression deformity at L1. (B) Sagittal T2-weighted image shows typical "salt and pepper" pattern of multiple myeloma. No epidural tumor is identified.

Circumferential compression of the cord may result from combined OPLL and ossification of the ligamentum flavum. In continuous OPLL, MRI shows a thick band of decreased signal on T1- and T2-weighted images. The segmental type is more difficult to discern on MRI and shows a thin area of decreased signal intensity, without signal from within the ossification region.

Spinal Cysts

Various investigators,[234-236] including Nabors and colleagues,[235] have clarified the confusing array of terms for spinal meningeal cysts. *Spinal meningeal cysts* are congenital diverticula of the dural sac, root sheaths, or arachnoid that may be classified into three major groups. The first group includes extradural cysts without spinal nerve roots (type I), the second includes extradural cysts with spinal nerve roots (type II), and the third includes intradural cysts (type III) (Fig. 13.42). Type I are diverticula that maintain contact with the thecal sac by a narrow ostium. Type I cysts include extradural cysts, pouches, and diverticula and the so-called *occult intrasacral meningoceles*. Sacral type I cysts are found in adults and are connected to the tip of the caudal thecal sac by a pedicle. Type II meningeal cysts with contained nerve roots are extradural lesions previously called *Tarlov cysts, perineural cysts,* or *nerve root diverticula*. These are generally seen as multiple incidental lesions but are occasionally associated with radiculopathy or incontinence. Type III meningeal cysts are intradural lesions most commonly found on the posterior subarachnoid space and have been called *arachnoid diverticula* or *arachnoid cysts*. These are lined by a single layer of normal arachnoid cells and filled with CSF.

Trauma

Studies have shown that if strict criteria are followed, patients who arrive at the emergency department with a collar in place can be clinically evaluated as to whether plain films are required.[237,238] Patients with cervical fractures typically have

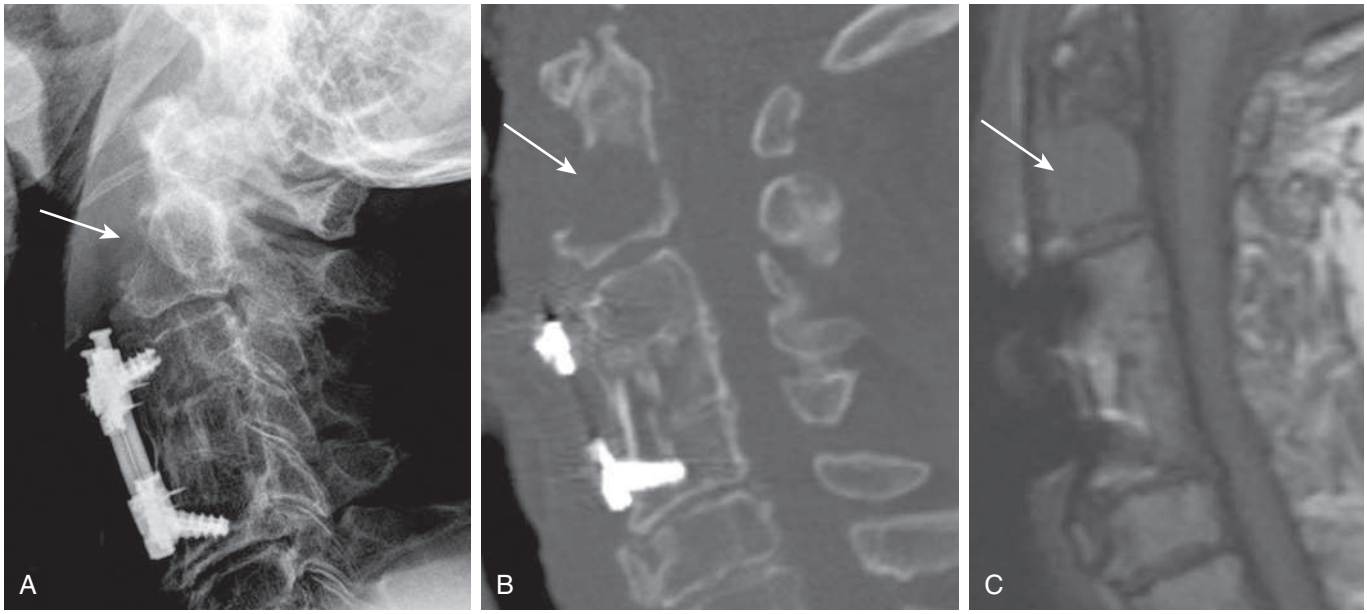

FIG. 13.38 Metastatic disease. (A) Lateral radiograph of the cervical spine demonstrates subtle cortical irregularity *(arrow)*, which is much more apparent on (B) computed tomographic and (C) magnetic resonance imaging *(arrows)*.

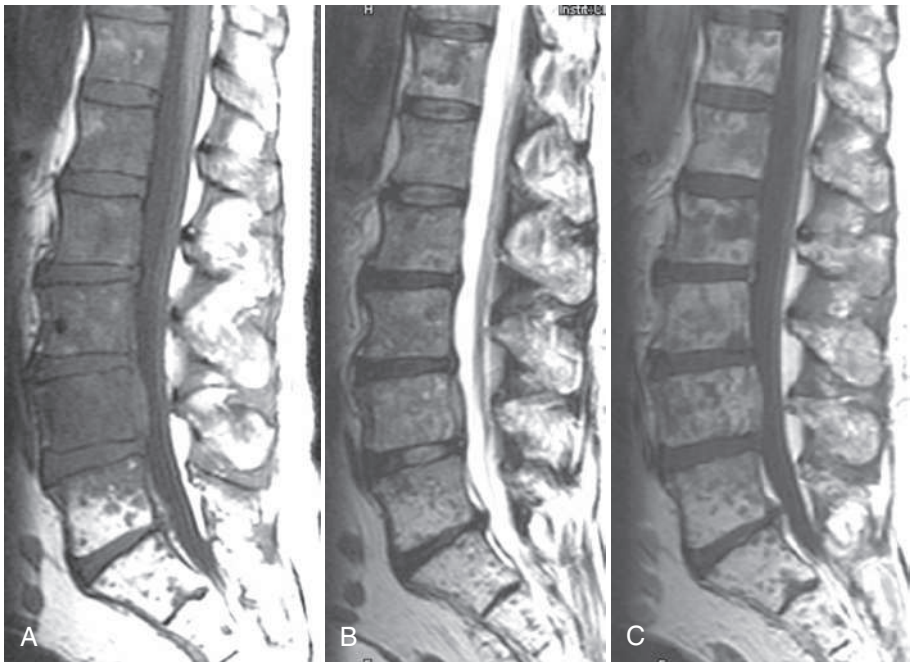

FIG. 13.39 Diffuse metastatic disease. (A) Sagittal T1-weighted magnetic resonance image shows diffuse abnormal decreased marrow signal from L4 through L1 bodies. There is residual fatty marrow replacement involving L5 and the sacrum from prior radiation therapy. There is mild anterior epidural extension of tumor at L4. (B) T2-weighted image shows mass effect of epidural tumor but tends to minimize marrow signal abnormality. (C) After contrast material is administered, T1-weighted image shows less marrow abnormality owing to enhancing tumor mimicking fatty marrow signal.

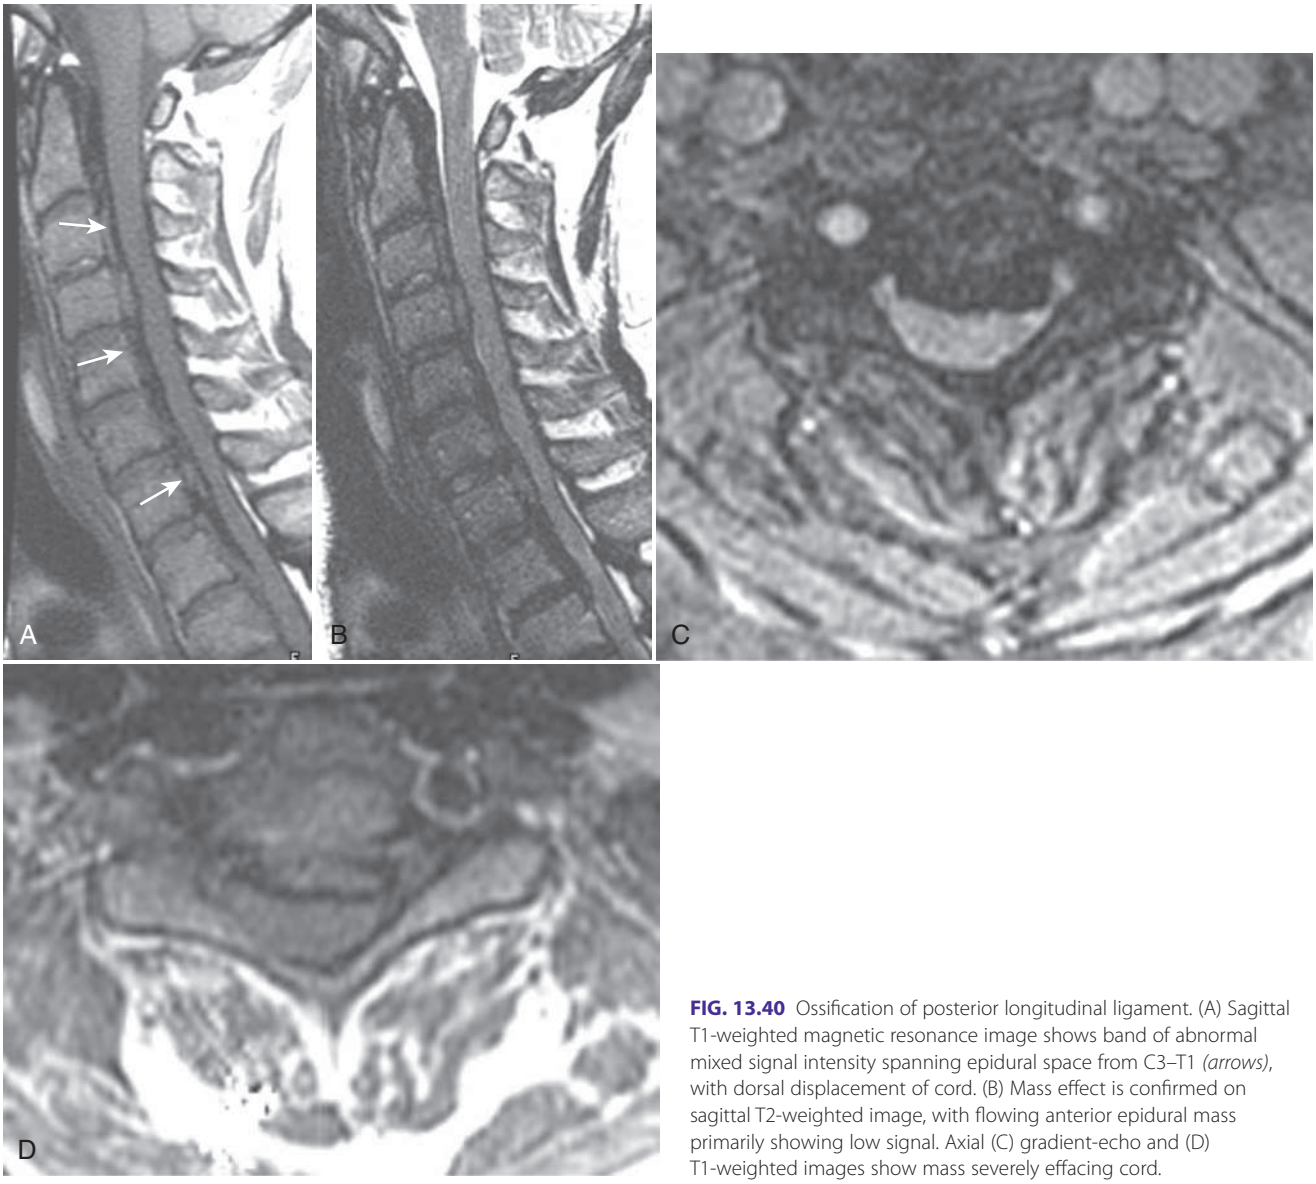

FIG. 13.40 Ossification of posterior longitudinal ligament. (A) Sagittal T1-weighted magnetic resonance image shows band of abnormal mixed signal intensity spanning epidural space from C3–T1 *(arrows)*, with dorsal displacement of cord. (B) Mass effect is confirmed on sagittal T2-weighted image, with flowing anterior epidural mass primarily showing low signal. Axial (C) gradient-echo and (D) T1-weighted images show mass severely effacing cord.

at least one of the following: intoxication, neck tenderness, altered level of consciousness, or a painful injury elsewhere. Indications for CT in evaluation of the cervical spine include further evaluation of known or questionable fracture on plain films and evaluation of areas inadequately seen on plain films.[239,240] Techniques vary from institution to institution, but slice thickness is generally 1.5 to 2 mm, sagittal and coronal reformats, soft tissue and bone windows, with no intravenous contrast material. The sensitivity of CT to detect fracture is 78% to 100%.[241,242] CT is particularly useful in diagnosing posterior element (laminar) fractures. The use of spiral thin-section techniques (1 to 1.5 mm) with multiplanar reformats should enable sensitivity approaching 100%. Most institutions use CT as the primary screening study in patients with multiple areas of trauma, bypassing plain films.[243,244] When imaging the cervical spine with radiographs, the average time to complete the examination approaches 22 minutes as opposed to an average time of 12 minutes with CT imaging.[245,246] Plain films with flexion and extension can be of use in defining instability in patients with persistent pain or soft tissue swelling without a definite fracture on the initial plain film evaluation.

MRI allows direct visualization of cord abnormalities, which cannot be identified by any other imaging modality. MRI can define intramedullary hematoma, intramedullary edema and contusion, disc herniations, ligamentous injury, and epidural hemorrhage (Fig. 13.43).[247-250] Hemorrhage within the first week is seen as low signal on T2-weighted images related to deoxyhemoglobin. Contusion without hemorrhage is identified as high signal on T2-weighted images and as isointense or decreased signal on T1-weighted images. Ligamentous disruption is seen as loss of the usual low signal from the anterior and posterior longitudinal ligaments, with increased signal on T2-weighted images in the adjacent tissues.[251,252]

The most common area of traumatic involvement in the lumbar spine is the thoracolumbar junction, which acts as a fulcrum for spine motion and is susceptible to unstable

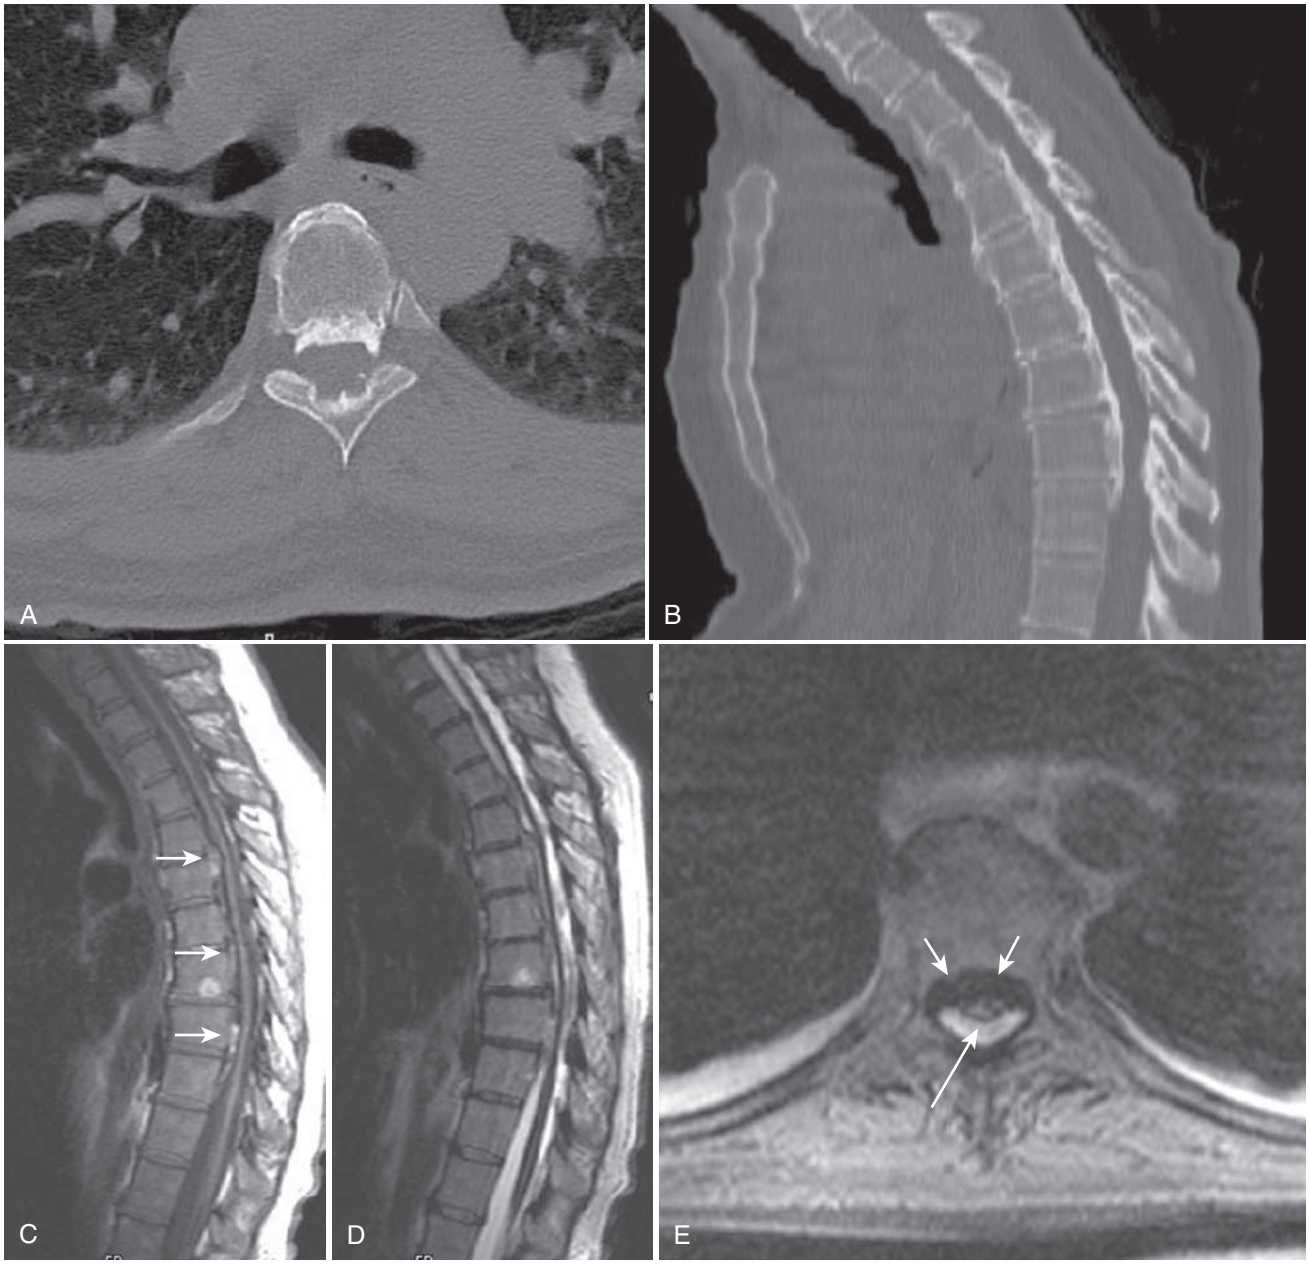

FIG. 13.41 Thoracic ossification of posterior longitudinal ligament. (A) Axial computed tomographic (CT) scan and (B) sagittal reformat show large flowing bony mass encompassing the anterior epidural space throughout the mid-thoracic spine. Sagittal (C) T1-weighted and (D) T2-weighted magnetic resonance (MR) images are more difficult to interpret without CT guidance because the heterogeneous anterior epidural signal could reflect blood or fatty marrow (*arrows*). MR images do show the degree of mass effect on the thecal sac and cord. (E) On axial gradient-echo image, the cord is atrophic and there is diffuse hemosiderosis of the cord surface seen as linear low signal *(long arrow)*, with ossification of the posterior longitudinal ligament mass of very low signal within anterior epidural space *(short arrows)*. There are small bilateral pleural effusions.

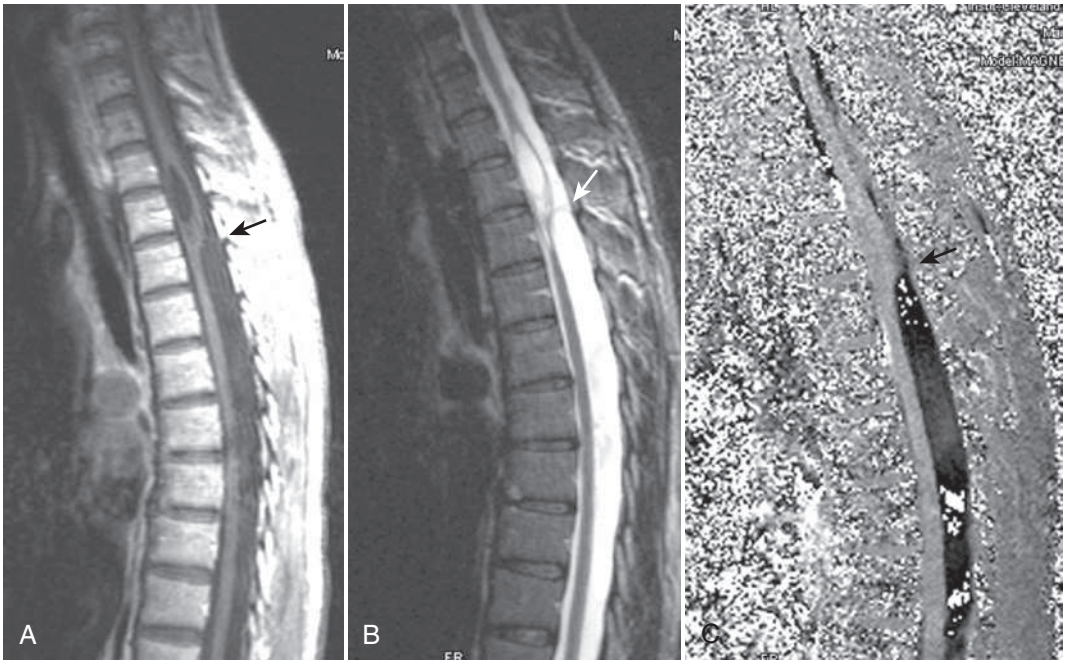

FIG. 13.42 Arachnoid cyst and syrinx. (A) Sagittal T1-weighted magnetic resonance image through the thoracic spine shows a ventrally displaced cord with abruptly expanding dorsal margin at T4 level *(arrow)*, with a small syrinx seen as linear low signal within the cord. (B) Sagittal T2-weighted image shows a thin line of low signal at the cephalad margin of the dorsally expanded cerebrospinal fluid (CSF) space *(arrow)* with a "windsock" pattern reflecting an arachnoid cyst margin. (C) Single sagittal image from a cine CSF flow series is encoded to show upward motion as dark areas. This technique outlines the abrupt change in CSF flow pattern at the top of the cyst *(arrow)*.

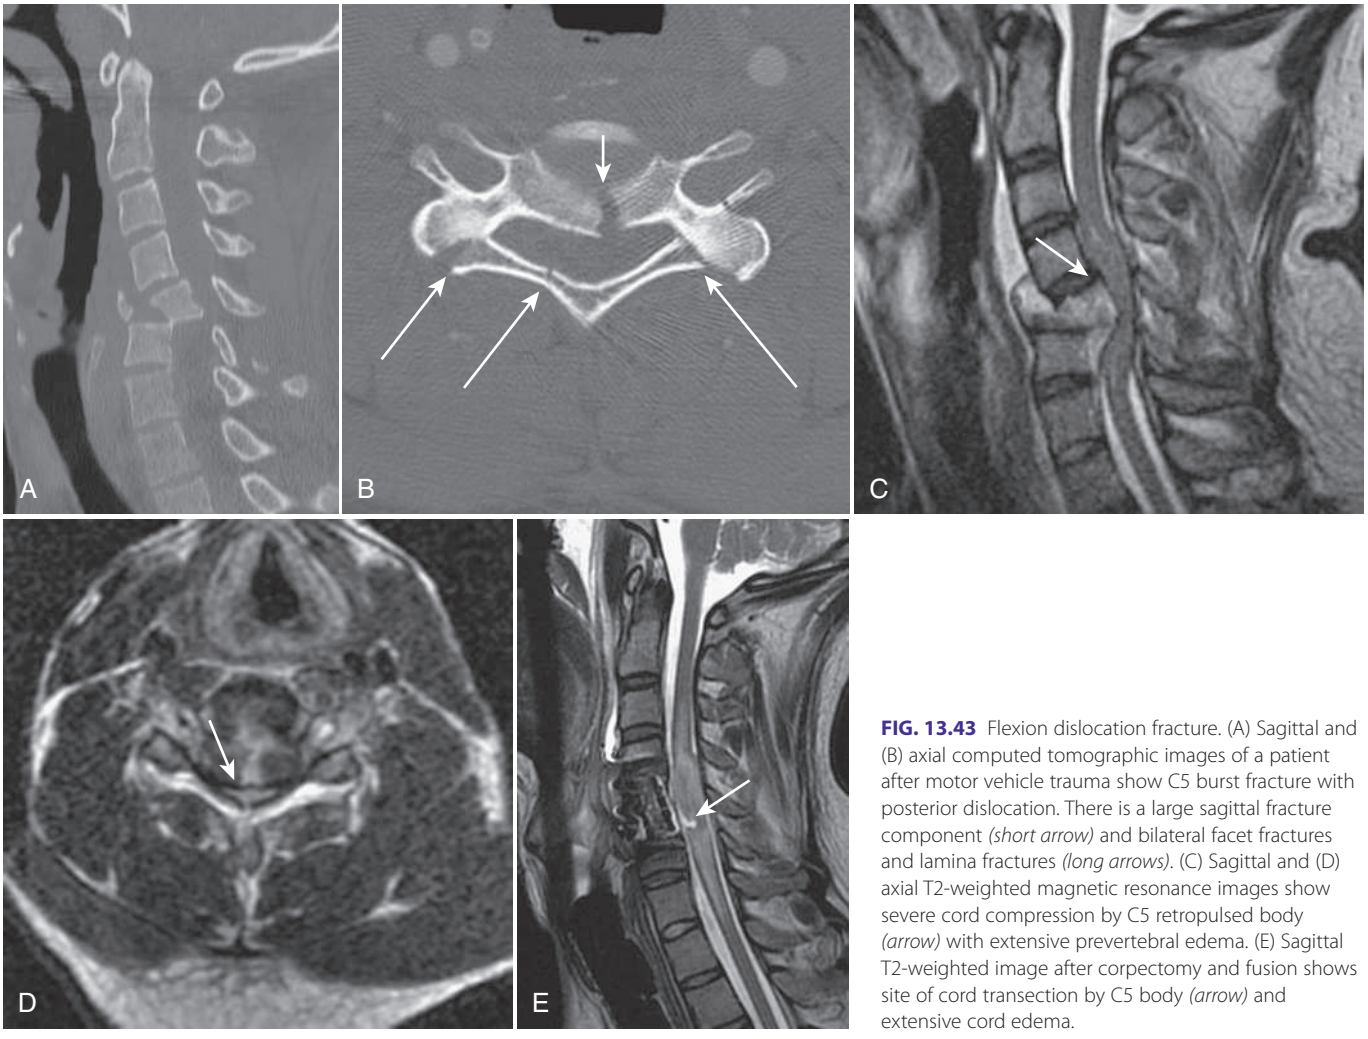

FIG. 13.43 Flexion dislocation fracture. (A) Sagittal and (B) axial computed tomographic images of a patient after motor vehicle trauma show C5 burst fracture with posterior dislocation. There is a large sagittal fracture component *(short arrow)* and bilateral facet fractures and lamina fractures *(long arrows)*. (C) Sagittal and (D) axial T2-weighted magnetic resonance images show severe cord compression by C5 retropulsed body *(arrow)* with extensive prevertebral edema. (E) Sagittal T2-weighted image after corpectomy and fusion shows site of cord transection by C5 body *(arrow)* and extensive cord edema.

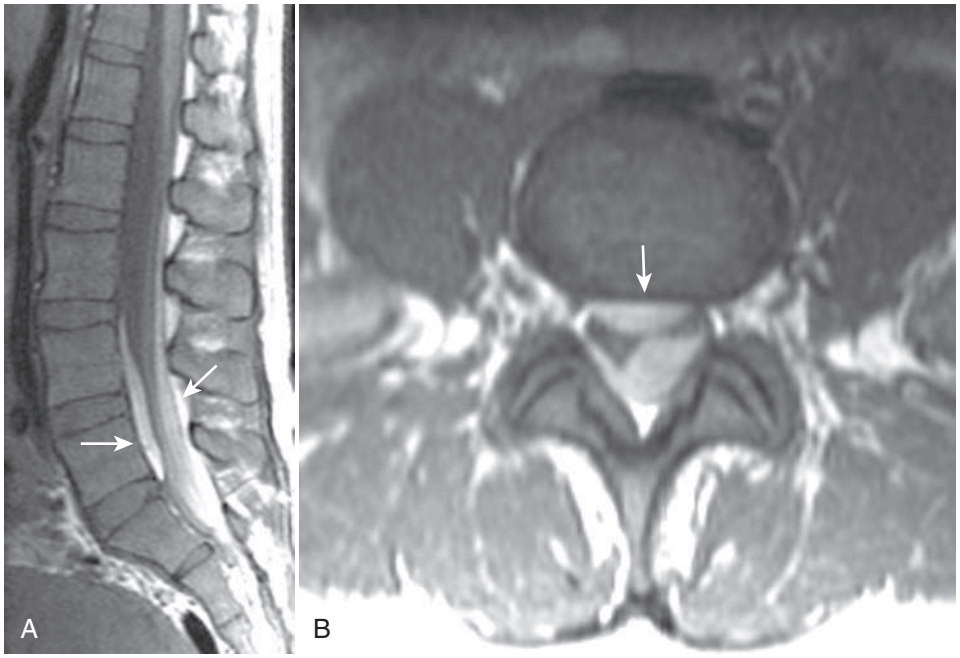

FIG. 13.44 Subdural hemorrhage. (A) Sagittal and (B) axial T1-weighted magnetic resonance images show high signal blood along dural margin from L3 to S1 *(arrows)*. Axial image shows that the exterior margin of blood is delimited by dura, so it must be either subarachnoid or subdural in location. Loculation on the axial view is typical for a subdural location.

traumatic injury. The thick, sagittally oriented lumbar facets minimize rotational injury, but flexion and axial loading injuries often occur. The forces may combine to produce flexion-compression injuries or the so-called *burst fracture*. Burst fractures are notable for instability and a predisposition for displacing fracture fragments posteriorly and causing spinal cord compression.[253,254] CT remains the method of choice for the detection of retropulsed bony fragments and for the demonstration of fractures of the posterior elements.[255] In trauma patients when CT imaging of the chest, abdomen, and pelvis is obtained, the existing image data set can be processed to evaluate the spine, negating the need for additional image acquisition and resultant radiation exposure.[256]

A hyperflexion injury occurring in the lumbar spine is the seat belt or Chance fracture, which is associated with rapid deceleration motor vehicle accidents. This type of trauma produces a horizontal fracture through anterior and posterior elements.[257,258] The anterior component may be through the vertebral body or through the disc itself. Although CT is more sensitive than MRI for detecting bony abnormalities, MRI is often superior for evaluating soft tissue structures. In particular, the spinal ligaments show focal discontinuity on T1-weighted images and areas of increased signal intensity on T2-weighted images.

Hemorrhage

Epidural spinal hematomas occur most frequently in elderly adults but can occur at any age.[259-261] Epidural spinal hematomas are broadly classified into two groups: nonspontaneous and spontaneous. Nonspontaneous epidural spinal hematomas may result from spinal taps, spinal anesthesia, trauma, pregnancy, bleeding diathesis, anticoagulant therapy, spinal hemangiomas, vascular malformations, hypertension, and neoplasms. The history can often be revealing, yet these tumors commonly occur merely from an episode of sneezing, bending, voiding, turning in bed, or other mild trauma. Epidural spinal hematomas can be localized or can spread anywhere along the spinal column. Blood more commonly accumulates posterolaterally.

Subdural hemorrhage is capable of producing severe and irreversible neurologic deficits, and acute surgical intervention may be needed. Spinal subdural hematomas can have a typical configuration (Fig. 13.44A).[262,263] As opposed to epidural hematomas, which tend to be capped by fat, subdural hematomas are located within the thecal sac and are separate from the adjacent extradural fat, the vertebral bodies, and the posterior elements. Axial images are useful in defining the epidural fat surrounding the thecal sac as well as the blood relating to the interior of the sac with subdural hematomas. These may be loculated anteriorly and posteriorly within the thecal sac. The loculation can take the form of a "Mercedes Benz sign," showing a trefoil configuration (Fig. 13.44B).

KEY POINTS

1. Metal artifact on MRI can be reduced with use of FSE, larger fields of view, higher readout bandwidths, smaller voxel sizes, and appropriate geometric orientation of the frequency-encoded direction in relationship to the metal.
2. The most common spinal vascular lesion is the dural fistula, and the most sensitive MRI finding is increased signal on T2-weighted images within the cord.

3. The most critical imaging information regarding spinal neoplasms used in forming a differential diagnosis involves determining whether the lesion is intramedullary, intradural extramedullary, or extradural.
4. CT remains the method of choice for detecting retropulsed bony fragments and for showing fractures of the posterior elements.
5. MRI is useful in the immediate postoperative period for evaluating fluid collections including hemorrhage and for showing mass effect on the thecal sac, cord, and cauda equina but not for defining residual disc material.
6. Paravertebral enhancement on fat-suppressed axial T1-weighted images is very helpful in defining early disc space infection.
7. The apparent size of neural foramina on axial gradient MR images is critically dependent on the sequence echo time; longer echo times give susceptibility artifact, which may give the false appearance of stenosis.
8. Synovial cysts are very difficult to identify on T1-weighted images and require T2-weighted images or intravenous contrast medium enhancement, or both, for definition.
9. Early disc space infection and degenerative disc disease with type 1 endplate change can be indistinguishable by MRI alone.
10. Acute spinal hemorrhage may show no characteristics of "blood" on MRI owing to the lack of susceptibility effect of oxyhemoglobin.
11. OPLL may be missed on T1-weighted images by merging into the low signal of CSF.
12. Use of contrast medium may mask spinal bony metastatic disease by causing the enhancing tumor signal to match that of adjacent normal fatty marrow.

14 CHAPTER Electrodiagnostic Examination

Jinny Tavee

The electrodiagnostic examination is comprised of two parts: the nerve conduction studies (NCSs) and the needle electrode examination (NEE). Together, they assess the peripheral sensory and motor nervous system. *Sensory* NCSs assess the integrity of dorsal root ganglion (DRG) cells (usually residing within the intervertebral foramina), their axonal projections within mixed sensory and motor nerve trunks, and arborizations into individual nerve fibers innervating sensory organs subserving primarily vibration and proprioception. *Motor* NCSs assess the integrity of anterior horn cells (in the anterior region of the spinal cord), their axonal projections within pure motor or mixed nerve trunks, arborizations into individual motor nerve fibers, the neuromuscular junctions, and attached muscle fibers.

The electrodiagnostic examination is best conceptualized as an extension of the neurologic examination of the peripheral nervous system. In the setting of abnormalities identified in the neurologic history and examination, the electrodiagnostic examination can be valuable in (1) confirming the clinical impression, (2) investigating the presence of other conditions in the differential diagnosis, and (3) localizing the precise site of a focal nerve trunk lesion not clearly defined on clinical examination.

The electrodiagnostic examination can discriminate between the two main types of pathologic responses that can affect nerve fibers: axon loss (neurotmesis and axonotmesis) and demyelinating conduction block (neurapraxia). In cases of axon loss, the electrodiagnostic examination has the potential of discriminating acute, subacute, and chronic nerve lesions. It can identify early evidence of reinnervation and can quantitatively track the reinnervation process over weeks to months. In the setting of diffuse signs and symptoms, the electrodiagnostic examination can discriminate among generalized sensory and motor polyneuropathy, myopathy, and diffuse motor axon loss processes, such as motor neuron disease.

A well-executed electrodiagnostic examination can confirm or refute the presumptive diagnosis and can provide a screening assessment for other peripheral nerve and muscle conditions that could reasonably be the cause of the patient's symptoms. In that way, the electrodiagnostic examination should be thought of as an electrodiagnostic consultation and not solely a test to rule in a specific diagnosis. Qualified electrodiagnostic consultants usually are board certified in electrodiagnosis, clinical neurophysiology, or neuromuscular medicine, having completed an approved training program and having shown competence by examination. The electrodiagnostic examination must be interpreted by the individual performing the study, because there is no single machine-generated tracing (as would be the case for an electrocardiogram or electroencephalogram) that can be interpreted simply by reviewing data collected elsewhere.

Pathophysiology

The clinical practice of electrodiagnosis is based on numerous precepts that are derived from the pathophysiology of nerve and muscle function. These provide the basic principles that define the clinical utility and limits of this procedure.

Regardless of etiology, most focal nerve lesions—including lesions at the root level—result in either *axon loss* or *demyelination*. Axon loss produces nerve transmission failure along the affected fibers; focal demyelination causes either conduction block or conduction slowing at the lesion site, depending on its severity. One fundamental difference between these two types of lesions is that focal demyelination remains localized and does not materially affect the segments of the axon proximal or distal to the lesion. In contrast, an axon-loss lesion results in wallerian degeneration, which eventually involves the entire course of the nerve affected.

Because axon loss and demyelinating conduction block stop nerve impulse transmission across the lesion site rather than merely slowing it, both can result in clinical weakness and sensory abnormalities whenever they affect a sufficient number of motor and sensory axons. However, demyelinating conduction slowing does not affect muscle strength. This is because all of the nerve impulses ultimately reach their destination, although slightly later in time than they normally would.[1]

The electrodiagnostic examination assesses the integrity of large sensory and motor nerve fibers, but not small fibers, as the electrical fields that they generate are too small to reach the recording electrodes in routine studies. For this reason, pain alone cannot be assessed because that sensory modality is mediated through small C-type nerve fibers. When pain is

associated with large nerve fiber dysfunction, such as weakness, electrodiagnostic testing is more valuable.

General Concepts of Electrodiagnostic Examination

Nerve Conduction Studies

NCSs are the first component of the electrodiagnostic examination. During the NCS, a peripheral nerve is stimulated, resulting in an electrical response generated directly by the nerve itself (as with a sensory response) or the muscle that it innervates (as with a motor response). The duration and intensity of the stimulus are gradually increased until a maximal response is generated. These responses are recorded using surface electrodes placed over the skin and then analyzed. During each study, valuable information is produced regarding the number of functioning nerve fibers, the speed of conduction along those fibers, and their relative rates of conduction.

Three basic types of NCS are available: motor, sensory, and mixed (Fig. 14.1). Motor and sensory NCSs are generally performed on every patient. Mixed NCSs are typically used in the evaluation of specific disorders, such as carpal tunnel syndrome, and are of limited value in the evaluation of spine-related nerve pathology. NCS protocols vary depending on the diagnosis in question, and can be tailored to help exclude other diagnoses in the differential. Most electrodiagnostic laboratories have a routine protocol for a general study of the upper extremity (Table 14.1) and lower extremity (Table 14.2).

Motor Nerve Conduction Studies

For motor NCSs, the recording electrode is placed over the muscle belly, and the reference electrode is affixed over the tendon. The nerve supplying that muscle is stimulated; the resulting motor nerve response is a compound muscle action potential (CMAP), a biphasic waveform that represents summated muscle fiber action potentials (Fig. 14.2). In routine

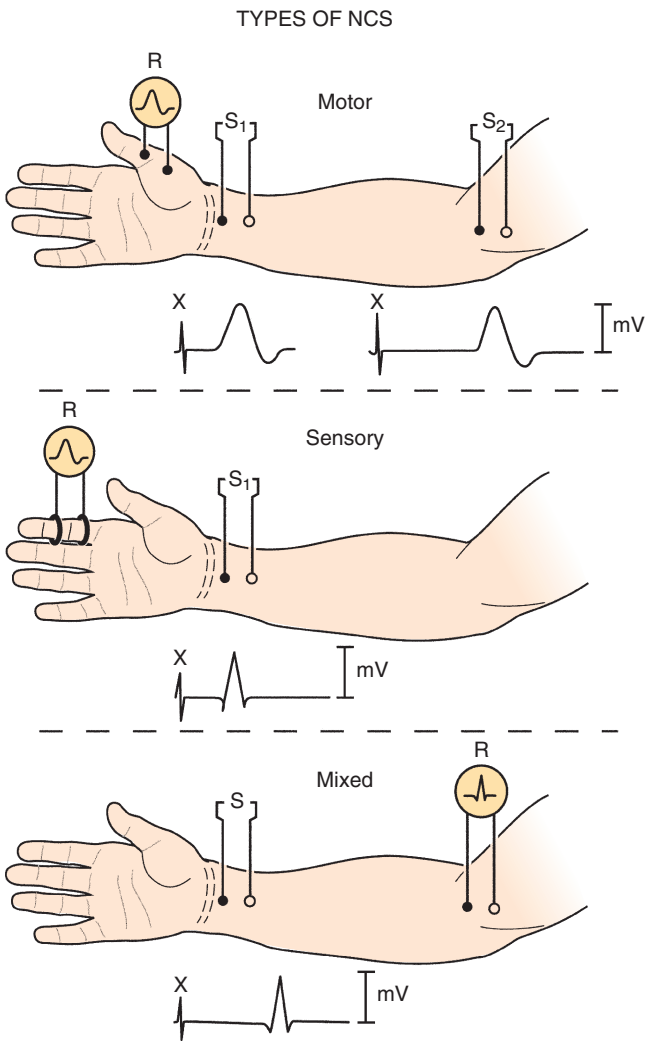

FIG. 14.1 Three basic types of nerve conduction studies: motor, sensory, and mixed (S_1 and S_2 are stimulation sites, R is the recording site, and X overlies the shock artifact.) (Modified from Isle M, Krauss G, Levin K, et al. Electromyography/Electroencephalography. Redford, WA: Spacelabs Medical; 1993:4.)

TABLE 14.1 Nerve Conduction Studies in the Upper Limb

Motor	Sensory
Standard	
Median: thenar (C8, **T1**) Ulnar: hypothenar (**C8**, T1)	Median: index (C6, **C7**) Ulnar: fifth (C8)
Nonstandard	
Ulnar: first dorsal interosseous (C8, T1) Radial: extensor indicis proprius (C8) Radial: brachioradialis (**C5**, **C6**) Musculocutaneous: biceps (C5, **C6**) Axillary: deltoid (**C5**, C6)	Median: thumb (C6) Median: middle (C7) Ulnar: hand dorsum (C8) Radial: thumb base (**C6**, **C7**) Lateral antebrachial cutaneous: forearm (C6) Medial antebrachial cutaneous: forearm (T1)

The nerve being studied is listed first, followed by the recording site, then the root innervation (motor) or derivation (sensory). **Bolded** root provides major innervation.

TABLE 14.2 Nerve Conduction Studies in the Lower Limb

Motor	Sensory
Standard	
Peroneal: extensor digitorum brevis (L5–S1) Tibial: abductor hallucis (S1)	Sural: lateral ankle (S1)
Nonstandard	
Peroneal: tibialis anterior (L5)	Superficial peroneal sensory: dorsum ankle (L5)
Tibial: abductor digiti quinti pedis (S1) Tibial: gastrocnemii (S1)[a]	Saphenous: medial ankle (L4)[b] Lateral femoral cutaneous: lateral thigh (L3, L4)[b]
Femoral: quadriceps (L3, L4)	

The nerve being studied is listed first, followed by the recording site, then the root innervation (motor) or derivation (sensory).
[a]M component of H response.
[b]Studies are technically difficult to perform.

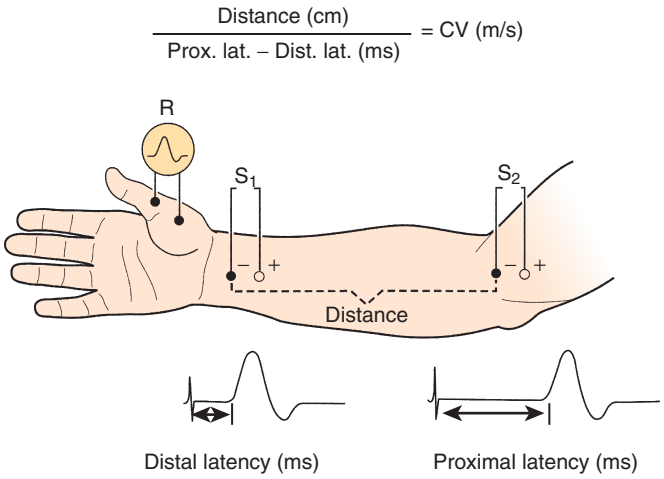

FIG. 14.2 Various components of the motor nerve conduction study assessing the median nerve. Dist. lat., distal latency; Prox. lat., proximal latency. (Modified from Isle M, Krauss G, Levin K, et al. Electromyography/ Electroencephalography. Redford, WA: Spacelabs Medical; 1993:40.)

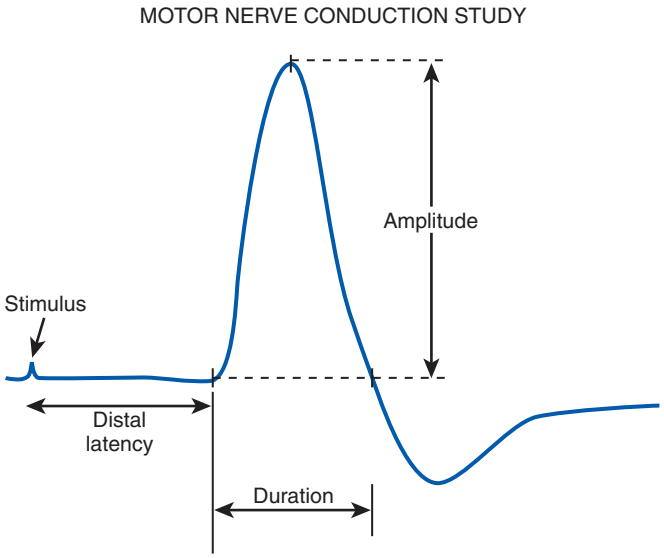

FIG. 14.3 Compound muscle action potential. Distal latency is measured from the stimulus to onset of the negative response. Amplitude is measured from the baseline to the negative peak.

motor NCSs, small muscles of the hand and feet serve as recording muscles; the nerves supplying them are stimulated at two separate points along their course. For the upper extremity, the wrist (distal) and elbow (proximal) are used as stimulation sites. For the lower extremity, the ankle (distal) and knee (proximal) are used as stimulation sites.

Numerous parameters are assessed with each CMAP obtained, including amplitude, latency, and conduction velocity (Fig. 14.3). The CMAP *amplitude* represents the number of nerve fibers that responded to the stimulus and are capable of conducting impulses to the recorded muscle.[1,2] It is measured from baseline to negative peak (negative being up) and reported in millivolts. The *latency* is the time interval between the instant that the nerve was stimulated and the onset of the CMAP, and is reported in milliseconds. The *conduction velocity* is the speed of transmission over the fastest

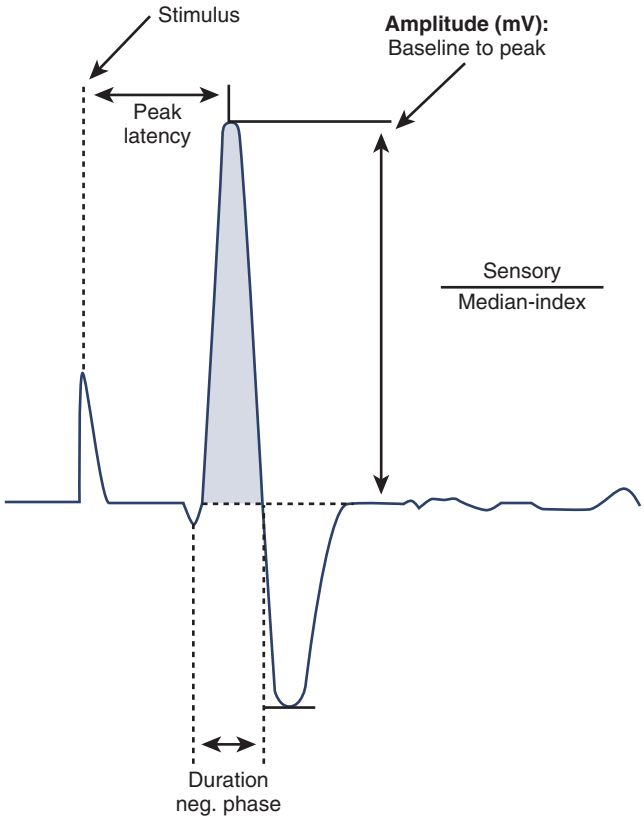

FIG. 14.4 Sensory nerve action potential. Peak latency is measured to the onset of the negative phase. Amplitude is measured from the baseline to the negative peak.

conducting nerve fibers assessed and is reported in meters per second. Conduction velocities are calculated by dividing the distance traveled along a nerve segment (as determined by surface measurements) by the latency difference between the responses to proximal and distal stimulation. Normal conduction velocity in the upper limb is greater than 50 m/s; in the lower limb, it is greater than 40 m/s.

Sensory Nerve Conduction Studies

For sensory NCSs, a sensory nerve or the sensory component of a mixed nerve is stimulated at one point with recording electrodes placed distally, usually on the fingers or on the ankle with routine studies. This stimulation results in a sensory nerve action potential (SNAP), which is a biphasic or triphasic waveform that represents summated nerve action potentials. In contrast to CMAPs, which are generated by motor units and are measured in millivolts, SNAPs are generated directly by the nerve fibers. SNAPs are 100 times smaller and are measured in microvolts. Generally, only two sensory NCS measurements are reported: (1) the *amplitude,* which is the height of the response measured from baseline to negative peak and represents the number of sensory axons that depolarize; and (2) the *peak latency,* which is the time interval between the moment that the nerve was stimulated and the negative peak of the response, reported in milliseconds (Fig. 14.4).[1]

Late Responses (H Responses and F Waves)

Two special studies, the H response and the F wave, are NCSs used to measure the time in which nerve impulses travel proximally to the spinal cord along the peripheral nerve trunk and then back down the limb to the recorded muscle after distal stimulation of the nerve. Because the potentials seen with both of these techniques are much delayed after nerve stimulation compared with potentials seen with standard NCSs, they are referred to as late responses.

The *H response* is the electrophysiologic correlate of the Achilles tendon reflex and is named after Hoffmann, who first described it in 1918. To obtain the H response, the tibial nerve is stimulated in the popliteal fossa using low voltage to activate sensory fibers (as opposed to motor fibers), which carry the nerve impulse proximally to the spinal cord (Fig. 14.5). The fibers synapse there with motor neuron cells to complete a monosynaptic reflex arc. The nerve impulse travels down the motor efferent nerve to the gastrocnemius, where the recording electrode captures the response. Although the amplitude and the latency of the H response are analyzed, the amplitude is more reliable for diagnostic purposes in my laboratory.

The *F wave* was first described by Magladery and McDougall in 1950 and was named the F wave because it was first recorded from muscles in the foot. In contrast to H responses, F waves are not a component of a reflex arc because the nerve impulses recorded travel only along motor axons. F waves are produced when, after distal motor nerve stimulation, some of the impulses passing antidromically up the motor axons cause a few of the motor cell bodies in the anterior horns to backfire; the resulting nerve impulses travel back down the motor axons to produce submaximal muscle activations that are recorded several milliseconds after the initial CMAP as F waves. Several consecutive responses from the same muscle are elicited, and the shortest latency time usually is used for diagnosis. Also, in contrast to H responses, F waves can be elicited with any of the standard motor NCSs.

Needle Electrode Examination

NEE is the second and oldest component of the basic electrodiagnostic examination. During this procedure, a recording needle electrode is inserted into various muscles, and the electrical activity being generated in them is evaluated on a visual and audio display system via a differential amplifier. NEE records activity in muscle (1) at rest during needle insertion, (2) at rest without needle movement, and (3) during voluntary muscle activation.

Insertional Phase

During the *insertional phase,* the electrical activity resulting from needle movement in a relaxed muscle is evaluated. In a normal muscle, each needle insertion and advancement

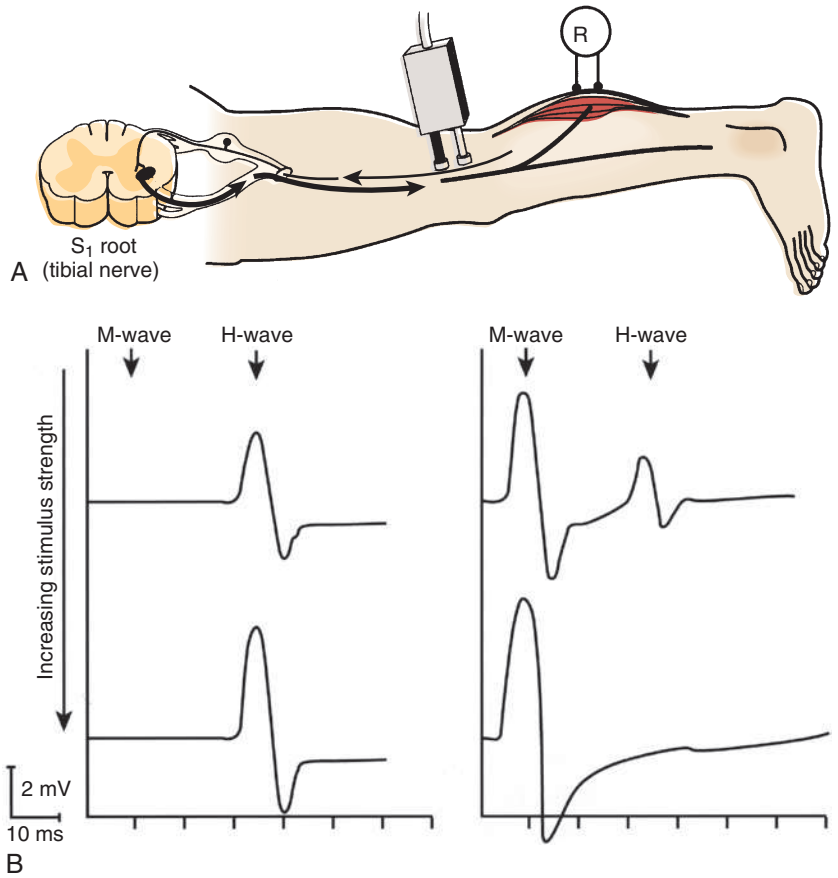

FIG. 14.5 Standard lower limb H response. (A) With minimal stimulus strength, only the H wave is elicited. (B) As stimulation strength increases, the M wave appears and becomes progressively larger, while the H wave progressively loses amplitude.

injures a few individual muscle fibers, which generate a small burst of electrical potentials called *insertional activity*. These electrical potentials prove that the needle electrode is in a viable muscle because they are not seen if it is in subcutaneous tissue, fat, or severely fibrotic muscle. In the context of peripheral nerve fiber lesions, if the NEE is performed on a partially denervated muscle a few days before spontaneous fibrillation potentials appear (discussed later), the insertional activity is abnormal in that unsustained trains of insertional positive sharp waves are seen.

At-Rest Phase

During the *at-rest phase,* electrical silence ordinarily is noted. With neuromuscular pathology, various types of spontaneous activity may be discernible. Only three of these are relevant to spine-related nerve disease: fibrillation potentials, fasciculation potentials, and complex repetitive discharges.[2–4]

Fibrillation potentials are spontaneous, usually regularly firing action potentials of individual muscle fibers. Although nonspecific in that they can be seen with neuropathic and myopathic disorders, their presence indicates denervation. Fibrillation potentials typically appear in the form of a biphasic spike if the tip of the recording needle electrode is near the denervated muscle fiber. Alternatively, they may appear as a positive sharp wave if the needle has injured the abnormal muscle fiber. In the setting of nerve lesions, fibrillation potentials are not present at the onset of motor axon loss. Instead, they are first seen 14 to 35 days after axon degeneration has been initiated; the most widely cited average time is 21 days. When established, fibrillation potentials persist until the denervated muscle fibers generating them either reinnervate or degenerate for lack of a nerve supply. The latter usually occurs 18 to 24 months after the initial nerve fiber injury.

Fibrillation potentials are the most reliable and objective manifestation of active or recent motor axon loss. They can be neither produced nor abolished voluntarily by the patient. They are very sensitive indicators of such loss because the degeneration of a single motor axon can result in hundreds of individual muscle fibers fibrillating within a given muscle, depending on the innervation ratio of the latter. Fibrillation potentials objectively can show that motor axon loss has occurred when the lesion is far too mild in degree to produce clinical muscle weakness, atrophy, or loss of CMAP amplitude on motor NCS.[3] Showing fibrillation potentials in a myotome distribution has been the principal method of identifying root lesions in the electrodiagnostic laboratory for more than half a century.[5,6]

Fasciculation potentials are spontaneous action potentials of an individual motor unit. Unlike fibrillation potentials, they are indicative of motor unit *irritation* rather than denervation; only intact motor unit potentials (MUPs) can generate them. They are encountered far less often than fibrillation potentials, being restricted essentially to radiculopathies, anterior horn cell disorders, radiation-induced plexopathies, a few entrapment neuropathies, polyneuropathies, and, most often, the syndrome of generalized benign fasciculations.

Complex repetitive discharges are produced when a single muscle fiber is depolarized and that depolarization is spread by ephaptic transmission to adjacent muscle fibers, which reactivate the initial muscle fiber. A recurrent cycle of firing is established. These potentials have a bizarre configuration and fire at high frequency. For many years, they were known as *bizarre high-frequency discharges*. Although they are abnormal, they are nonspecific, being seen with neuropathic and myopathic disorders. Generally, they appear when there is grouped atrophy (i.e., denervation, reinnervation, and subsequent denervation) and are evidence of chronicity. Although these potentials are not helpful in localization, they are frequently encountered on NEE of the cervical paraspinal muscles in patients with chronic cervical root lesions.[3]

Activation Phase

After the muscle is evaluated at rest, the patient is asked to contract the muscle. This contraction results in the generation of MUPs, which represent the summated electrical activity produced by contracting muscle fibers of a single motor unit. MUPs are assessed in regard to their recruitment pattern and appearance.

Recruitment

Recruitment of MUPs refers to the orderly increase in number and firing rate of activated motor units as force is increased during contraction of muscle. On initial activation of the muscle with minimal force, a single motor unit fires at its basal rate of 5 to 10 Hz. As the force is increased, additional units are recruited, and the firing rate gradually increases by 5 Hz with each additional unit—up to 20 to 30 Hz. With progressively increasing force, spatial and temporal recruitment occurs, resulting in a full interference pattern in which the screen is obscured by the firing patterns of several MUPs.

Reduced MUP recruitment, also known as a *neurogenic MUP firing pattern,* is observed whenever numerous motor units in the muscle being sampled cannot be activated on maximal effort because either conduction block or axon loss affects their axons. The fewer MUPs seen on maximal effort, the weaker the muscle is clinically. MUPs that are capable of firing are noted to do so in decreased numbers and often faster than their basal firing rate of 5 to 10 Hz.[3,7] The rapid rate of firing of the still functioning motor units is important because, similar to fibrillation potentials, it is unequivocal evidence of involuntary interruption of motor axon impulse transmission. Conversely, if the muscle was weak because of an upper motor neuron lesion or because voluntary effort was simply submaximal (e.g., because of malingering or pain on activation), incomplete MUP activation would be seen—that is, MUPs would fire in equally decreased numbers but at a *slow to moderate rate*.

Morphology

The amplitude, duration, and configuration of MUPs are important morphologic characteristics that are assessed during the activation phase. Together, these features reflect the number and size of muscle fibers within a motor unit and their ability to fire in synchrony. Patient age, technical details (e.g., filter setting, type of needle used), and the specific muscle being examined are some of the factors that affect the appearance of MUPs. Based on quantitative analyses, normal ranges for MUP morphology are available for comparison, which vary

depending on the patient age and proximity of the muscle to the trunk. A normal MUP has a triphasic waveform appearance.

With chronic nerve lesions, the process of reinnervation of denervated muscle fibers can occur as the result of regeneration of the nerve trunk from the point of nerve transection or (when the nerve transection is not total) by collateral nerve branch sprouting from remaining intact nerve fibers close to the denervated muscle fibers. The latter process is much faster because nerve fiber regeneration occurs at the rate of about 1 mm/day. On NEE, manifestations of reinnervation include resolution of fibrillation potentials; return of activation of motor unit action potentials with voluntary muscle contraction; and appearance of polyphasic, enlarged (so-called neurogenic) motor unit action potentials, reflecting the increased number of muscle fibers attached to surviving nerve fibers owing to collateral sprouting.

Chronic neurogenic MUP changes generally develop about 4 to 6 months after an axon loss injury has occurred because it takes this much time for such configurational remodeling to occur. After chronic neurogenic MUP changes develop, they can persist indefinitely. With many remote, proximal neurogenic lesions (e.g., radiculopathies and, particularly, poliomyelitis), they are the sole electrical residuals detected during the entire electrodiagnostic examination.[3,7,8]

Electrodiagnostic Findings in Radiculopathy

The electrodiagnostic examination has been used to assess patients with possible radiculopathies for more than 50 years. Root lesions were one of the first focal peripheral nerve fiber disorders for which the diagnostic utility of NEE was shown.[5,6] For many years, lumbosacral radiculopathies were the most common reason for referral to the electrodiagnostic laboratory.[9,10] Although several other electrodiagnostic procedures have been introduced over the past half-century, NEE remains the mainstay for diagnosing radiculopathies. The amplitudes of motor NCS are also helpful when root damage is severe, extensive, or both.[8,9]

Radiculopathies are most commonly caused by nerve root compression secondary to degenerative spine changes, disc herniation, or rupture. The type of nerve pathology at the lesion site depends on the nature of the injury and degree of nerve compression. When the injury results in significant motor axon loss, NEE shows numerous abnormalities, including the presence of fibrillation potentials in corresponding myotomes. Demyelinating conduction block may also be inferred by findings on the electrodiagnostic examination. In many cases of nerve root disease, the electrodiagnostic examination can provide invaluable information regarding localization, severity, age of the lesion, and nerve pathophysiology.

Nerve Conduction Studies

Routine Studies

Axon loss occurs when the axon is disconnected from its cell body. The motor cell body (anterior horn cell) resides in the anterior zone of the spinal cord; the sensory cell body (DRG) resides outside the spinal cord, either within individual intervertebral foramina or within the spinal canal (intradural and intraarachnoid) (Fig. 14.6). A disc protrusion causing severe compression of a motor and sensory nerve root within the spinal canal disconnects the anterior horn cell from its motor axon, but if the DRG is distal to the point of compression, the extraspinal sensory axons remain connected to their DRG and do not undergo degeneration (see Fig. 14.6). In that setting, motor NCSs show amplitude loss, but sensory NCSs are normal despite marked clinical sensory impairment with few exceptions.

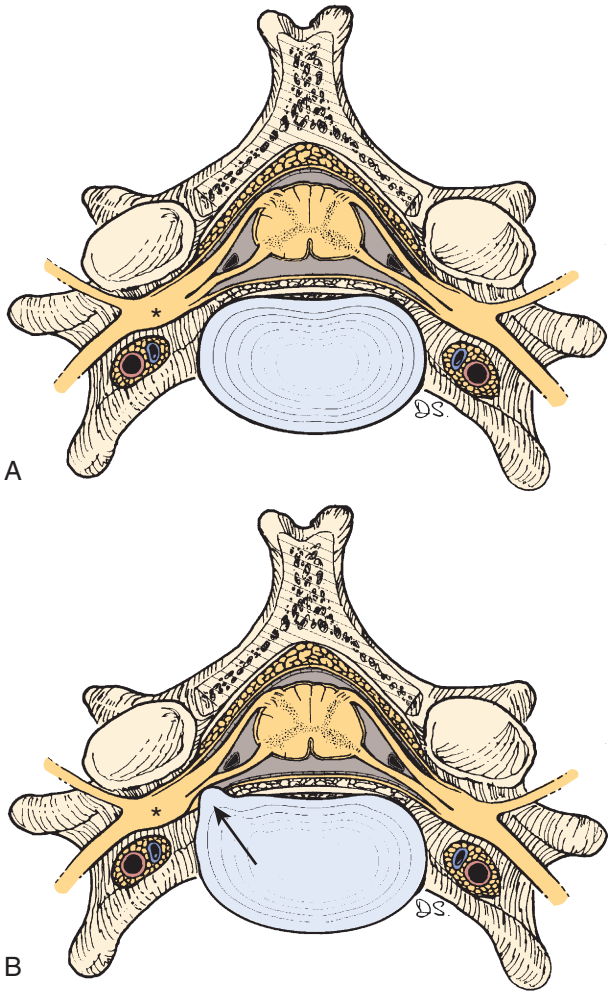

FIG. 14.6 Cross-sectional views of cervical region, showing (A) relationship of dorsal root ganglia (*asterisk*) to surrounding structures and (B) usual site of disc herniation (*arrow*). Preganglionic sensory root fibers usually are compromised.

One exception is seen with nerve root pathology that extends beyond the intraspinal canal. A mass lesion (e.g., meningioma) or infiltrative process (e.g., malignancy, inflammatory cause, or infection) that progresses distally along the nerve root to involve the DRG can result in decreased SNAP amplitudes. The other exception is when the DRG resides inside the intraspinal canal, proximal to the intervertebral foramina; this has been found to occur in the lumbosacral region. Based on cadaveric, radiographic, and magnetic

resonance imaging (MRI) studies, 3% of L3 and L4 DRG are intraspinal, about 11% to 38% of L5 DRG are intraspinal, and 71% of S1 DRG are intraspinal.[11] As a result, root lesions in the lower spine, particularly lesions involving the L5 root, can affect the corresponding SNAP amplitude, which in the case of an L5 lesion is the superficial peroneal SNAP (discussed later). SNAP peak latency and nerve conduction velocity are never involved in radiculopathy, however.

The CMAP amplitude is the only portion of motor NCS that may be significantly affected in radiculopathy. Because it is a measure of the number of viable, conducting nerve fibers, the CMAP amplitude can be decreased with severe motor axon-loss lesions. The ulnar CMAP amplitude would be reduced in a severe C8 radiculopathy. In chronic lesions, reinnervation changes, such as collateral sprouting, can contribute to the CMAP amplitude and may lead to normal or near-normal values over time.

In many cases, motor NCSs remain relatively unaffected in radiculopathies for two reasons. First, most radiculopathies result in only partial nerve injuries. For the CMAP amplitude to be significantly reduced on motor NCS, about half of the motor axons within the peripheral nerve trunk need to be lost or injured. Second, the myotomes of the affected nerve root must be accessible to stimulation and recording. The ulnar-innervated hand muscles may be examined for a C8 radiculopathy, and the biceps and deltoids are available for assessing a C5 radiculopathy. Muscles innervated by C6 and C7 nerve roots cannot be reliably examined with routine motor NCSs, however, owing to technical factors and overlap in innervation.

Late Responses

Although the H response and F wave are theoretically helpful in the evaluation of the damaged proximal nerve root segment, there are technical limitations to each procedure that can hamper their utility in the evaluation of a radiculopathy.[7,9] Because the H response is elicited by stimulating the tibial nerve in the popliteal fossa while recording from the gastrocnemius/soleus muscle group, as described previously, it is highly sensitive and very useful in the evaluation of S1 radiculopathy. In axon loss lesions affecting the S1 nerve root, the amplitude may be either reduced or absent. The normal value of the H amplitude, as defined by my electrodiagnostic laboratory, is 1 mV, with abnormal values being either less than 1 mV or reduced by 50% compared with the contralateral response. Additionally, the H response may become abnormal at the onset of nerve root injury and remain so until the injury is resolved or may remain abnormal despite resolution of clinical symptoms.[7]

A major limitation of the H responses is that they are frequently absent bilaterally in patients older than 60 years, in patients with polyneuropathies, and in patients who have had lumbar laminectomies even when the S1 roots reportedly were not within the operative field. Also, when the H responses are abnormal, they do not localize to the S1 root because the lesion could be at many other points along the extended neural pathway that the impulses traverse (e.g., S1 spinal cord segment, sacral plexus, sciatic nerve, and proximal tibial nerve). When H responses are abnormal, they remain so indefinitely in many cases.[8,9]

Despite these limiting and confounding factors, H responses are very helpful in the evaluation of a possible lumbosacral radiculopathy because they are seldom normal with S1 root lesions. Part of their high sensitivity may be because, in contrast to all other constituents of the electrodiagnostic examination, they evaluate the preganglionic components of the S1 sensory root fibers.[8,9] Although most electrodiagnostic physicians agree on the value of H responses, they disagree regarding which component (amplitude or latency) of the H response is likely to be abnormal.[9,12–14]

Ideally, F waves should be able to detect demyelinating conduction slowing along the motor fibers at the root level.[9,15,16] However, this is not the case in practical application. They are often normal in unequivocal cases of radiculopathy, and even when abnormal, they do not provide any additional information because the abnormalities are already clearly seen on NEE.[4,7] Therefore, F waves are of no significant value in the evaluation of root lesions.

Needle Electrode Examination

Because NCSs and the late responses generally are normal with isolated root lesions (except for the H response with S1 radiculopathies), NEE usually is the sole component of the electrodiagnostic examination that is beneficial in detecting a radiculopathy. The diagnosis depends on finding abnormalities on NEE in a root or *myotome* (all the muscles that receive innervation from a single spinal cord segment or root). These abnormalities include insertional positive sharp waves, fibrillation potentials, a reduced or neurogenic recruitment of motor units, and changes in the motor unit morphology (e.g., increased duration, amplitude, and polyphasia).

The most widely used criterion for diagnosing radiculopathies by NEE is that abnormalities should be found in two, and preferably more, limb muscles innervated by the same root but different peripheral nerves. In addition, muscles in the limb not innervated by the damaged root, but rather by the roots contiguous to it, should appear normal. For instance, a patient with a C7 radiculopathy should have fibrillation potentials or other signs of denervation in the triceps (radial nerve) and pronator teres (median nerve), but not the abductor digiti minimi or deltoid muscles. Needle electromyography (EMG) not only should be tailored to the clinical question and the patient's symptoms, but it also should include a comprehensive survey of a sufficient number of muscles (proximal and distal when possible) to make a reliable diagnosis of a radiculopathy.

Numerous myotome charts derived from radiographic, cadaveric, and electrodiagnostic studies have been established to help guide the electrodiagnostic physician in choosing the best muscles to examine for each patient (Figs. 14.7 through 14.9). A radiculopathy screen in my laboratory consists of an examination of at least seven muscles, including the paraspinals, to help with localization in the upper extremity (Table 14.3) and lower extremity (Table 14.4). The presence of fibrillation potentials in the paraspinals is typically indicative of an

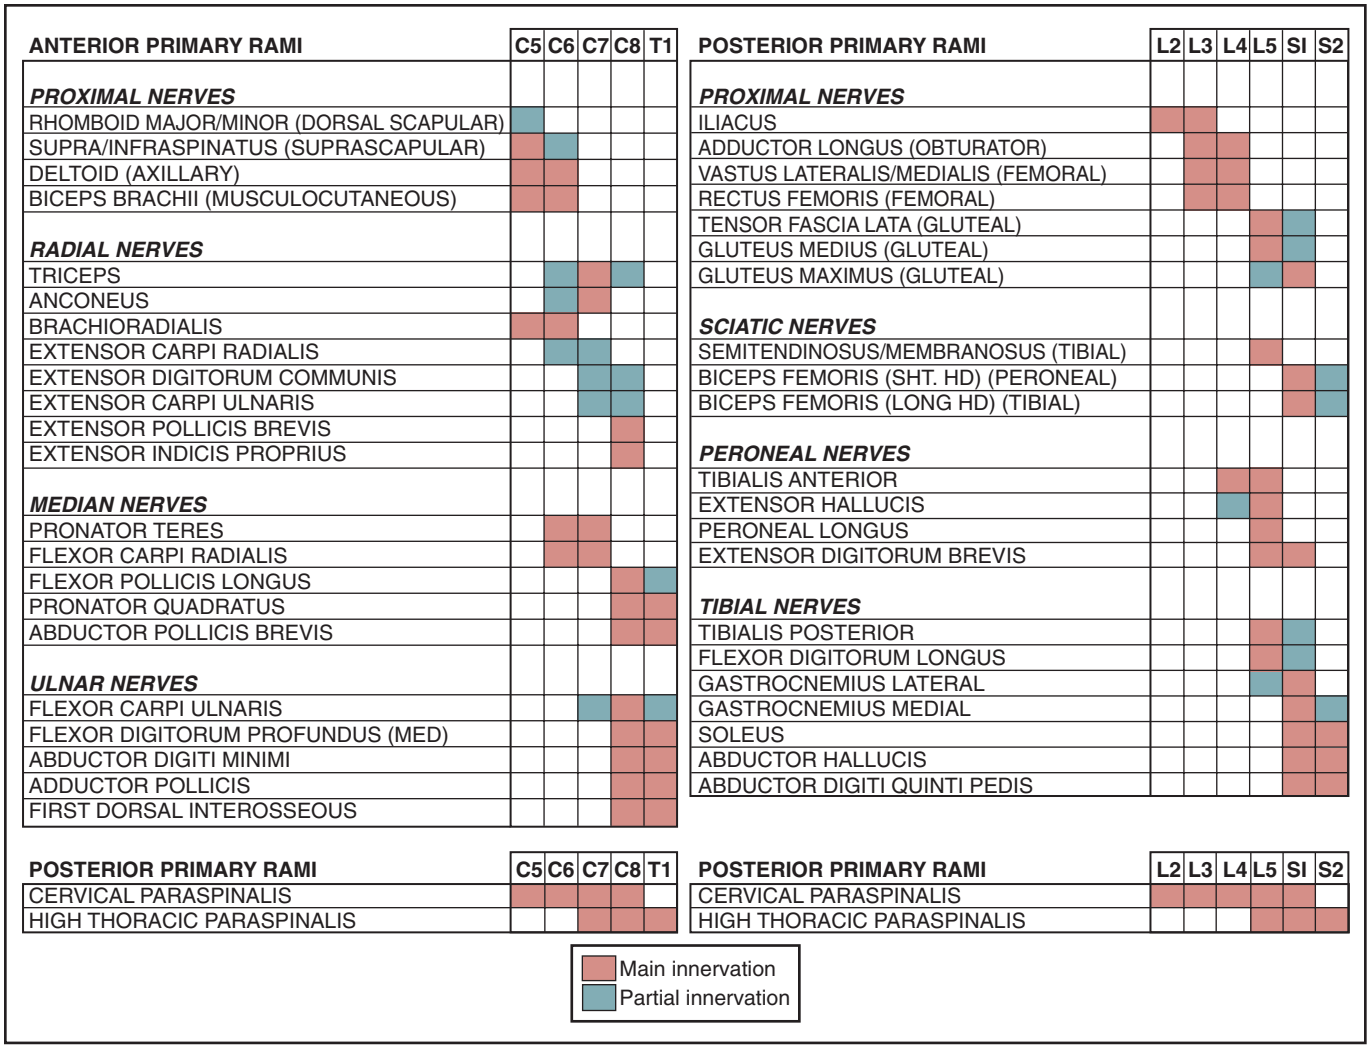

FIG. 14.7 Traditional myotome chart. (From Wilbourn AJ, Aminoff MF. Radiculopathies. In Brown WF, Bolton CF, eds. *Clinical Electromyography*. 2nd ed. Boston: Butterworth-Heinemann; 1993:192.)

TABLE 14.3 Screening Needle Electrode Examination for the Arm

Muscle	Root Level	Nerve Trunk
First dorsal interosseous	C8	Ulnar
Extensor indicis proprius	C8	Posterior interosseous (radial)
Flexor pollicis longus	C8	Anterior interosseous (median)
Pronator teres	C6–C7	Median
Triceps	C6–C7	Radial
Biceps	C5–C6	Musculocutaneous
Deltoids	C5–C6	Axillary
C7 paraspinal	Overlap

Muscle	Root Level	Nerve Trunk
Abductor hallucis	S1	Tibial
Medial gastrocnemius	S1	Tibial
Biceps femoris (short head)	S1	Peroneal
Extensor digitorum brevis	L5–S1	Peroneal
Flexor digitorum longus	L5	Tibial
Gluteus medius	L5	Superior gluteal
Tibialis anterior	L4–L5	Peroneal
Rectus femoris	L2–L4	Femoral
S1 paraspinal	Overlap	

axon-loss lesion localized to or near the intraspinal canal, excluding the possibility of a plexopathy or more distal lesion. Paraspinal fibrillation potentials are most valuable for the support of radiculopathy when they are present at only one or two contiguous segmental levels and absent at levels above, below, and contralaterally.

Many limitations can reduce the value of the paraspinal examination. First, there is overlapping innervation of most paraspinals, which prevents accurate localization of fibrillation potentials to one specific segment or root. Second, even in proven radiculopathies, fibrillation potentials may be absent owing to reinnervation or sampling error. Third, paraspinal fibrillation potentials may be seen in diabetic patients, in patients with a prior history of spine surgery, or in some asymptomatic elderly patients. Finally, paraspinal denervation

BOX 14.1 Appropriate Timing of the Electrodiagnostic Examination

- When aiming for a single comprehensive study, reliable interpretations can be made from nerve conduction studies (NCSs) and needle electrode examination (NEE) obtained any time after 3 wk from onset of symptoms.
- For earliest possible information about an axon-loss lesion, reliable interpretations can be made from NCSs obtained after 10 days from onset of symptoms.
- For earliest possible information about a demyelinating conduction block lesion (neurapraxia), such as might be the case for perioperative peroneal or ulnar neuropathy owing to positioning on the operating table, reliable interpretations can be made from NCSs obtained any time after onset of symptoms
- In the setting of preexisting symptoms of peripheral nerve disease, such as diabetic polyneuropathy, it is reasonable to consider baseline electrodiagnostic examination (NCS and NEE) immediately after the onset of new symptoms of a potential iatrogenic cause. This study is to assess the nature of preexisting abnormalities before acute changes from new symptoms are visible on electrodiagnostic examination. This is especially useful if a medicolegal issue may arise from new symptoms, because it would be valuable to differentiate preexisting nerve pathology from any procedure-related changes. A second study is necessary when sufficient time has elapsed to assess a new lesion.

BOX 14.2 Timing of Nerve Pathology: Neurophysiologic Concepts

- After transection of the motor nerve trunk, nerve conduction response amplitude from electrical stimulation distal to the transection point decreases from day 3 through days 5 to 8 after transection. For sensory nerve fibers, response amplitude decreases progressively from day 5 through days 9 to 11, coinciding with evolution of wallerian degeneration of nerve fibers. For this reason, identifying maximum axon loss cannot be assessed by nerve conduction studies until at least 11 days have elapsed since the date of nerve injury or onset of symptoms.
- As Wallerian degeneration of the motor nerve fiber reaches completion, the attached muscle fiber becomes denervated, leading to breakdown of the neuromuscular junction. Over 2 to 3 weeks, membrane changes occur along the muscle fiber, resulting in spontaneous, continuous action potential propagation along the muscle fiber, recognized during needle electrode examination (NEE) as fibrillation potentials. About 3 weeks must elapse after an acute axon-loss event before fibrillation potentials can be reliably visualized on NEE.
- The process of reinnervation of denervated muscle fibers can occur as the result of regeneration of the nerve trunk from the point of the nerve transection, or (when nerve transection is not total) by the collateral nerve branch sprouting from the remaining intact nerve fibers close to the denervated muscle fibers. The latter process is much faster because nerve fiber regeneration occurs at rate of about 1 mm/day. On NEE, manifestations of reinnervation include resolution of fibrillation potentials, return of activation of motor unit action potentials with voluntary muscle contraction, and the appearance of polyphasic motor unit potential changes.

is not specific to radiculopathy and is seen in other disorders, including diseases of the muscle (e.g., inflammatory myopathy) and the anterior horn cell (e.g., amyotrophic lateral sclerosis). Nonetheless, NEE of the paraspinal muscles is an integral portion of the electrodiagnostic examination and should be routinely performed in all patients with suspected nerve root disease.

The timing of needle EMG is also crucial. Fibrillation potentials do not appear in a denervated muscle until 2 to 3 weeks after the onset of the initial injury and in some patients may require 4 to 6 weeks to develop.[11] Consequently, the findings on NEE performed earlier than 3 weeks after onset of a radiculopathy are likely to be false-negative or, at best, indeterminate, even if subsequently they would be positive for a root lesion. It is optimal to wait at least 3 weeks after the onset of symptoms before performing NEE. Guidelines that help the clinician decide the best timing of a study to obtain maximal information are provided in Box 14.1. These are based on the neurophysiologic concepts of axon loss as described in Box 14.2.

Determining Duration of Radiculopathy: Acute Versus Chronic

Information regarding the duration of a radiculopathy is often derived by findings on NEE. Whenever evidence of an isolated compressive root disorder of recent onset is detected on the electrodiagnostic examination, the typical combination of findings is as follows: (1) motor NCSs are normal (unless the degree of axon loss is severe); (2) sensory NCSs are normal; (3) with S1 root involvement, the H response usually is abnormal; and (4) NEE discloses fibrillation potentials in several muscles that are innervated by the compromised root unaccompanied by changes in the size and configuration of the MUP.

In contrast, when chronic neurogenic MUP changes (polyphasic configuration with increased duration and amplitude) are the prominent finding on NEE with only a few fibrillation potentials, the lesion is likely to be chronic. When the chronic neurogenic MUP changes are limited to distal muscles within a myotome in the absence of fibrillation potentials, the radiculopathy is likely to be static and remote.

Finally, when fibrillation potentials and chronic neurogenic MUP changes are found in a myotome distribution, the diagnostic possibilities include a chronic, progressive radiculopathy or an acute root lesion superimposed on a remote lesion. The latter possibility is the more likely choice if fibrillation potentials are found in proximal muscles (e.g., the glutei and hamstrings with L5 or S1 root lesions), in addition to more distal muscles in the same myotome.[7–9]

When the previous factors are considered, it is apparent that whenever the classic NEE presentation of a radiculopathy is encountered—fibrillation potentials in most or all of the muscles constituting the myotome—the root lesion in question usually is of more recent onset, and motor root axon loss has been substantial. Whenever other circumstances prevail, as is far more commonly the case, fibrillation potentials usually are found in only some, if any, of the muscles of the myotome. They are typically seen in the more distal muscles. Fibrillation potentials generally are important only if they are present; their absence in any specific muscle does not exclude the diagnosis.[8,9]

Determining Severity of Radiculopathy

The severity of a nerve root lesion is based on motor NCSs and NEE. The degree of reduced MUP recruitment seen on

NEE correlates with the degree of muscle weakness and, in combination with the CMAP amplitude reduction (in muscles that can be assessed with NCS), the degree of axon loss. The amount of fibrillation potentials seen in a muscle is a subjective measure and does not correlate as well with the degree of axon loss.

Electrodiagnostic Findings at Specific Root Levels

Cervical Radiculopathy

Lesions of the cervical nerve roots account for 36% of all radiculopathies.[9] In clinical and radiographic studies, the most common root affected is at the C7 level (70% of the time) followed by C6 (19% to 25%), C8 (4% to 10%), and C5 (2%).[9,16–18] The electrodiagnostic examination presentations with C5 radiculopathies are typically manifested as abnormalities in the spinati, deltoid, biceps, and brachioradialis muscles. NCSs are typically unhelpful because proximal muscles are not assessed during routine studies, although the biceps and deltoid muscles are amenable to NCS and may show reduced CMAP amplitudes when axon loss is sufficiently severe.

C6 radiculopathies do not have a single, discrete appearance. Rather, they have two very different ones, which imitate those of C5 and C7 root lesions. Manifestations of C5 root lesions may also be seen with some C6 radiculopathies.[19] C7 lesions are diagnosed by the presence of abnormalities in some muscles innervated by radial and median nerves: the triceps and anconeus (radial) and the pronator teres and flexor carpi radialis (median). As stated before, NEE abnormalities sometimes are seen in the same combination of upper limb muscles with C6 root lesions as well.

In contrast, C8 radiculopathies have a very characteristic electrodiagnostic presentation, manifesting as abnormalities in ulnar-innervated muscles, the extensor indicis proprius, and the flexor pollicis longus.[19] Nonetheless, they can sometimes be confused with combined axon-loss lesions of the posterior interosseous nerve and the ulnar nerve whenever the ipsilateral ulnar SNAP is of low amplitude or cannot be elicited (e.g., because of advanced age or a coexisting polyneuropathy). For uncertain reasons, the axon loss that occurs with many C8 radiculopathies is exceptionally severe, so much so that the CMAPs recorded from the ulnar nerve–innervated hand muscles, particularly the hypothenar, are low in amplitude. Some of these patients never regain normal hand strength.

Differential Diagnoses

Findings on NEE of cervical radiculopathies can look identical to brachial plexopathies (Table 14.5). In particular, lesions affecting the C5 and C6 roots may resemble upper trunk plexus lesions, whereas lesions of the C8 and T1 roots can mimic lower trunk lesions. There are two critical parameters on the electrodiagnostic examination that can discern the two types of lesions. The first parameter is NEE findings in the paraspinals. With nerve root lesions, the paraspinal muscles show fibrillation potentials but are spared in a lesion of the brachial plexus. The second parameter is the assessment of the SNAPs. In radiculopathies, the lesion is located within the intraspinal canal and proximal to the DRG, which results in normal SNAPs. In plexopathies, the lesion is distal to the DRG, producing reduced amplitude or absent SNAPs.

Clinically, this second parameter is especially important when distinguishing a radiculopathy from neuralgic amyotrophy, which commonly affects proximal shoulder girdle muscles (e.g., the spinati and the deltoids) derived from C5 and C6 roots. Abnormally reduced or absent SNAP amplitudes of the lateral antebrachial cutaneous sensory nerve and median sensory branch recording from the thumb and index finger point to a plexus lesion.

Likewise, carpal tunnel syndrome can resemble C6 and C7 radiculopathies clinically but are easily distinguished by the presence of abnormalities seen in the triceps and pronator teres and other muscles proximal to the hand or outside of the median nerve territory. In contrast, C8 radiculopathies may be difficult to discern from an ulnar mononeuropathy, especially in the setting of partial lesions in which the ulnar SNAP is unaffected. Finding abnormalities in C8-innervated radial muscles is important in this setting. Finally, unless a rotator cuff injury results in entrapment of a nerve innervating proximal muscles located in the shoulder girdle (e.g., suprascapular nerve), the electrodiagnostic examination would show no abnormalities.

TABLE 14.5 Disorders Commonly Confused With Compressive Radiculopathies

Roots	Entity
Cervical	
C5, C6	Upper trunk brachial plexopathy Neuralgic amyotrophy Axillary/suprascapular neuropathies Motor neuron disease Rotator cuff tear
C6, C7	Carpal tunnel syndrome
C8, T1	Lower trunk brachial plexopathy Ulnar neuropathy Motor neuron disease
Thoracic	
T1	Neurogenic thoracic outlet syndrome
Lumbosacral	
L2–L4	Diabetic amyotrophy Lumbar plexopathy Femoral neuropathy
L5	Sacral plexopathy Peroneal neuropathy Motor neuron disease
S1, S2	Sacral plexopathy Sciatic neuropathy Tibial neuropathy
Bilateral (L5), S1, S2	Polyneuropathy

Thoracic Radiculopathy

Radiculopathies in this region are difficult to assess by electrodiagnostic examination because there are relatively few

muscles in each myotome, and only some of them can be sampled. With suspected thoracic radiculopathies, only the paraspinal and abdominal muscles are sampled routinely; the intercostal muscles are typically not studied for fear of entering the pleural space. Generally, if NEE abnormalities are seen, no attempt is made to identify a specific root lesion. Instead, the localization is limited to upper thoracic, midthoracic, or lower thoracic root involvement. Most patients found to have thoracic radiculopathies have diabetes mellitus, and the pathology is probably root infarction or ischemia rather than compression. In any case, these radiculopathies often produce very severe axon loss and frequently apparently involve two or more adjacent roots.[9,20,21] T1 radiculopathies are quite rare and typically produce changes only in the lateral thenar muscles.[22]

Differential Diagnoses

Although neurogenic thoracic outlet syndrome may technically be considered an extraspinal radiculopathy affecting the T1 nerve root and to a lesser extent C8, it has classically been categorized as a lower trunk brachial plexopathy (see Table 14.5). The preferential involvement of the T1 nerve root leads to prominent abnormalities of the abductor pollicis brevis muscle and the medial antebrachial cutaneous sensory response, both of which are heavily innervated by T1. In contrast, the ulnar-innervated segments, which are predominantly innervated by C8, are sometimes spared or only mildly affected. Abnormalities in the abductor pollicis brevis are evident on motor NCS (manifested as decreased CMAP amplitude) and NEE (fibrillation potentials or neurogenic recruitment pattern), whereas the medial antebrachial cutaneous SNAP is reduced or absent. The latter abnormality is helpful in distinguishing this syndrome from a typical T1 radiculopathy.

Lumbosacral Radiculopathy

Nerve root lesions are most commonly seen in the lumbosacral spine—more than two-thirds of all radiculopathies occur in this region.[7] In contrast to lesions involving the cervical roots, it is difficult sometimes to localize lumbosacral radiculopathies accurately to a vertebral level with the electrodiagnostic examination. This difficulty is primarily due to anatomic reasons. Given their long intraspinal course, lumbosacral nerve roots may be injured anywhere along their tract from the T12–L1 vertebral level where they are formed, down through the canal into the cauda equina, and the site where they exit from their respective foramina. The L5 nerve root can be compressed by a central disc herniation at the L3–L4 level, a posterolateral disc herniation at the L4–L5 level, or foraminal stenosis at the L5–S1 level. Additionally, when nerves are affected at the level of the cauda equina where the fibers are compact, a single lesion in this location can result in injury to multiple roots bilaterally. It is important to perform comparison NEE of the contralateral limb when any abnormalities are seen to exclude the possibility of subclinical nerve root involvement.

L2, L3, and L4 radiculopathies are generally considered together because of the myotome overlap of the thigh muscles and the paucity of muscles that are innervated solely by one individual nerve root. Localization of an L2 root lesion is difficult because only the iliacus muscle may show abnormalities on NEE. Lesions at these levels typically produce denervation changes in the quadriceps, thigh adductors, and iliacus. With L4 lesions, abnormalities may also be seen in the tibialis anterior occasionally.

The most common lumbosacral radiculopathies involve the L5 and S1 roots. Lesions of these two roots are most amenable to recognition on electrodiagnostic examination. In addition, the L5 nerve root is the most common single radiculopathy seen.[3] L5 radiculopathies produce abnormalities in the tibialis anterior, flexor digitorum longus, and posterior tibialis in greater than 75% of surgically proven cases.[23] In a more recent study, 100% of patients with L5 radiculopathies, which were also surgically proven, showed abnormalities in the peroneus longus and tensor fascia lata.[24] Changes may also be seen in the extensor digitorum brevis, gluteus medius, and semitendinosus.

An exception to the rule that SNAPs are not affected in radiculopathies has been found to occur with some L5 root lesions. As stated before, SNAPs are typically spared in radiculopathies because the lesion is situated proximal to sensory cell bodies (DRG), which lie in the intervertebral foramina *outside* of the intraspinal canal. However, at the level of the lumbosacral spine, the DRG is sometimes found proximal to the intervertebral foramina *within* the intraspinal canal, leaving them vulnerable to injury from a herniated disc or other degenerative spine condition. Based on cadaveric, radiographic, and MRI studies, 3% of L3 and L4 DRG are intraspinal, 11% to 38% of L5 DRG are intraspinal, and up to 71% of S1 DRG are intraspinal.[24–26] Thus, in some cases, the L5 nerve root may be affected distal to the DRG, resulting in an abnormal superficial peroneal SNAP. In one retrospective study, six patients with clinical and radiographic evidence of an L5 radiculopathy were found to have reduced amplitude of the ipsilateral superficial peroneal SNAP along with denervation changes in the L5 myotome.[27] This condition has not been found with S1 nerve root lesions, in which the sural SNAP remains normal despite the higher percentage of DRG located within the intraspinal canal.

S1 radiculopathies are the second most common root lesion encountered. Needle EMG may show abnormalities in the gastrocnemii, abductor hallucis, abductor digit quinti pedis, glutei, and biceps femoris short head. In addition, the H response is either absent or reduced in amplitude.

Differential Diagnoses

As seen in the cervical spine, it is often difficult to clinically distinguish lesions of the lumbosacral nerve roots from lesions of the lumbar and sacral plexuses (see Table 14.5). L2–L4 radiculopathies can look identical to lumbar plexopathies, whereas L5–S1 nerve root lesions closely resemble lesions of the sacral plexus. In both cases, the combination of fibrillation potentials in the lumbosacral paraspinals and preserved

sensory nerve conduction responses (lateral femoral cutaneous and saphenous SNAPs for L2–L4 lesions and sural and superficial peroneal SNAPs for L5–S1 lesions) points to the diagnosis of radiculopathy.

A major limitation is encountered when SNAPs are absent bilaterally. In the workup of a lesion in the lumbar plexus versus an L2–L4 nerve root lesion, the sensory nerve conduction responses are not consistently obtainable from a technical standpoint, even in normal individuals. Likewise, in the evaluation of a sacral plexus versus an L5–S1 lesion, SNAPs may be absent in elderly patients or patients with a history of a polyneuropathy. In both instances, the diagnosis rests on a single crucial finding: the absence or presence of denervation in the paraspinals. This finding in itself is unreliable, as noted earlier, in that paraspinal fibrillation potentials may be present rarely in normal individuals older than 60 years, in patients with a history of prior spine surgery, and in patients with diabetes. Denervation changes may be absent because of early reinnervation or sampling error. As a result, in patients with bilaterally absent SNAPs (owing to technical or other reasons), the final electrodiagnostic impression may be inconclusive.

For similar reasons, bilateral S1 radiculopathies, particularly when chronic, may be confused with distal axon-loss polyneuropathies. In younger patients (<60 years old), an absent sural response combined with abnormalities seen in the intrinsic foot muscles on NEE typically indicates the presence of a polyneuropathy rather than S1 radiculopathy.

Electrodiagnostic Findings of Other Spine-Related Disorders

Cauda Equina Syndrome

Multiple lumbosacral radiculopathies are encountered with some frequency. Typically, the involvement is bilateral and often asymmetric.[10,20] Most of these lesions are attributable to midline lumbar disc protrusions or lumbar canal stenosis. Characteristically, S1 and S2 roots, being the most medial of the roots supplying the lower limbs, are affected. In many patients, more extensive lumbosacral root involvement occurs; a common combination is bilateral S1 and S2 root compromise accompanied by unilateral or bilateral L5 root involvement.

The electrodiagnostic findings most commonly seen consist of a mixture of low-amplitude CMAPs and normal SNAPs on NCS, along with fibrillation potentials and MUP dropout on needle EMG (Fig. 14.10). On NEE, the abnormalities often are more severe in muscles located distal to the knees. With some substantial lesions of recent onset, they are just as prominent in the more proximal muscles. Whenever the disorder is subacute or chronic, fibrillation potentials usually are accompanied by chronic neurogenic MUP changes. Low lumbar or high sacral paraspinal fibrillation potentials often are found bilaterally with more acute lesions, but are undetectable with many chronic ones. Typically, the H responses cannot be elicited, and even the M components of the H responses, recorded from the gastrocnemius/soleus muscles, are quite low in amplitude.

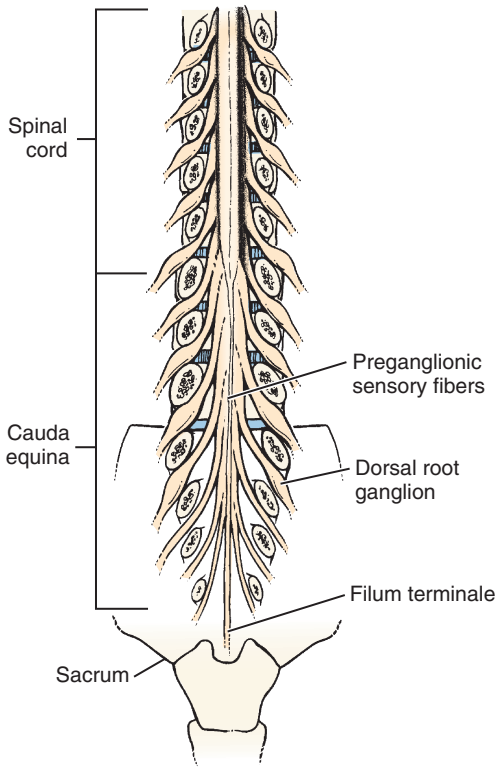

FIG. 14.10 Coronal view of inferior spinal cord, cauda equina, and surrounding structures. Dorsal root ganglia are located in the intervertebral foramina so that all the sensory fibers composing the cauda equina are "preganglionic." Axon-loss lesion of cauda equina generally has no effect on lower limb sensory nerve conduction studies, regardless of its severity.

Lumbar Canal Stenosis

Lumbar canal stenosis has no single characteristic electrodiagnostic presentation. Rather, the findings are extremely variable, depending on the degree of axon loss affecting the lumbosacral motor roots. At one extreme are patients who experience only intermittent, short-lived symptoms that often can be relieved completely by various maneuvers (e.g., sitting, flexing at the waist). In these patients, the electrodiagnostic examination often is completely normal. At the opposite end of the spectrum are patients who have substantial cauda equina lesions with severe, bilateral, fixed motor and sensory deficits. These lesions produce the electrodiagnostic presentation described previously.

Between these two extremes are numerous different electrodiagnostic patterns: (1) two or more radiculopathies, far more often bilateral than strictly unilateral; (2) a single radiculopathy, typically S1, that is sometimes detected in the less symptomatic or asymptomatic limb; (3) unilateral or bilateral absent H responses alone; (4) NEE changes restricted to just one or two limb muscles, most commonly those innervated by the S1 roots; or (5) fibrillation potentials limited to the paraspinal muscles.[9,19]

Myelopathy

The effect that a focal myelopathy has on the electrodiagnostic examination depends principally on whether the

anterior horn cells or their existing fibers are compromised at the level of the lesion. If only the descending corticospinal tracts of the spinal cord are affected (upper motor neuron lesion), the only abnormality found on the electrodiagnostic examination concerns the MUP firing pattern of muscles receiving innervation from spinal cord segments caudal to the lesion. In these muscles, the MUPs show no or incomplete activation (i.e., they fire in decreased numbers at a slow to moderate rate).

In contrast, if the anterior horn cells or the intramedullary fibers derived from them are involved, the electrodiagnostic findings are those of a focal intraspinal canal lesion that is characteristically bilateral, but often asymmetric. How prominent the electrodiagnostic changes are with such focal disorders depends mainly on where the lesions are located along the spinal cord. Lesions situated in C5–T1 segments and L4–S2 segments produce substantial abnormalities on motor NCSs and NEE, and generally are readily recognized as intraspinal canal lesions. All such disorders result in low-amplitude CMAPs or CMAPs that cannot be elicited and normal SNAPs on NCS, accompanied by fibrillation potentials, MUP dropout, and, depending on lesion duration, chronic neurogenic MUP changes on needle EMG. Conversely, lesions involving T2 through L3 segments result only in NEE changes (i.e., motor NCSs using various limb muscles as recording sites are normal). Finally, lesions involving the upper cervical cord segments (C1–C4) have essentially no electrodiagnostic manifestations because that region of the spinal cord cannot be assessed.[27]

Postlaminectomy Electrodiagnostic Findings

Electrodiagnostic examinations are obtained frequently on patients who have undergone neck or back surgery. The specific diagnostic benefit derived from such assessments varies considerably, depending on the reason for referral and the time that has elapsed since operation. Overall, such postoperative studies are of limited value, however, unless they are obtained after very remote surgery to diagnose a recent-onset lesion. In the immediate postoperative period (first 10–14 days after surgery), the electrodiagnostic examination can reveal preexisting abnormalities because any NEE changes observed during that period, with the exception of a reduced MUP recruitment, are caused by a lesion that predated the operation.

During the early postoperative period (3 weeks to 3–4 months after surgery), the electrodiagnostic examination is of considerable benefit in assessing patients with postoperative weakness, principally because a normal CMAP amplitude recorded from a weak muscle (e.g., the tibialis anterior, resulting in footdrop) 7 or more days after onset of symptoms virtually excludes motor axon loss as the cause. The remaining possibilities include a proximal conduction block (neurapraxia), an upper motor neuron lesion, or hysteria or malingering. In the rare patient who develops nonorganic weakness postoperatively, the electrodiagnostic examination can prove that the symptoms are not the result of significant nerve fiber damage.

The electrodiagnostic examination usually cannot answer reliably the early postoperative question: "Was the root adequately decompressed?" Axon loss features of radiculopathy persist for weeks to months or indefinitely. Even an electrodiagnostic examination performed 2 to 3 months postoperatively is not likely to show significant improvement compared with a preoperative study. An exception is radiculopathy resulting from conduction block at the root level, which may resolve rapidly after the pressure is relieved. With an S1 radiculopathy, an H response that could not be elicited preoperatively may reappear in the early postoperative period. Similarly, on NEE, reduced MUP recruitment (and clinical weakness) could resolve rapidly in the affected muscles postoperatively.

An electrodiagnostic examination can be valuable in identifying root damage as the cause of new or worsening weakness in the postoperative period. The extent, amount, and distribution of fibrillation potentials provide information when compared with the preoperative study.

Cervical Root Avulsion

Root avulsions, which are usually restricted to the cervical region, differ from the typical single compressive radiculopathy principally in the degree of axon loss that results. Because the entire motor supply from one or both roots innervating the particular muscle has been disrupted, that muscle is severely or totally denervated. If it is used as a recorded muscle during motor NCS, the CMAP obtained is of very low amplitude, if it can be elicited. Similarly, during needle EMG of that muscle, fibrillation potentials are abundant, and MUPs are either absent or, if present, quite sparse and show reduced recruitment. Sensory NCS responses derived from the same roots are normal because the sensory roots are interrupted proximal to their DRG. Fibrillation potentials are often not found in the appropriate paraspinal muscles in patients with cervical avulsion injuries; thus, their absence does not exclude this diagnosis.[9]

Acknowledgments

I acknowledge the late Dr. Asa J. Wilbourn for his contributions to the original version of this chapter.

KEY POINTS

1. The electrodiagnostic examination is an essential tool in the evaluation of radiculopathy. When performed by an experienced electrodiagnostic consultant, the electrodiagnostic examination can confirm the diagnosis and determine the localization, lesion duration, and severity.
2. The electrodiagnostic examination assesses the integrity of large sensory and motor nerve fibers, but not small fibers, such as small C-type fibers that mediate pain. Therefore, pain alone cannot be assessed by electrodiagnostic testing. Electrodiagnostic testing is more valuable when pain is associated with large nerve fiber dysfunction, such as weakness.
3. For a comprehensive study, the electrodiagnostic examination should be performed at least 3 weeks after the onset of symptoms.

4. The most widely used criterion for diagnosing radiculopathies by NEE is that abnormalities (e.g., fibrillation potentials or neurogenic MUP changes) should be found in at least two limb muscles within the same myotome that is innervated by different peripheral nerves.
5. Sensory nerve conduction responses are typically normal in radiculopathy owing to the location of the DRG outside of the intraspinal canal, distal to the site of the nerve lesion. In contrast, amplitudes of the motor NCS may be decreased when root damage is severe, extensive, or both.

CHAPTER 15

Intraoperative Neurophysiologic Monitoring of the Spine

SECTION II

Dileep R. Nair
Ajay Gupta

The primary objective in intraoperative neurophysiologic monitoring is to identify and prevent the development of a new neurologic deficit or worsening of a preexisting neurologic injury to a patient who is undergoing surgery. The aim of most spinal cord monitoring is to prevent intraoperative injury that results in irreversible paraplegia or quadriplegia. Due to the inability of performing a neurologic examination in an anesthetized patient, intraoperative neurophysiologic monitoring is used to determine the patient's neurologic status during surgery. By evaluating the responses produced by the patient's nervous system to a variety of stimulation, the integrity of that neural pathway can be monitored. These recordings are started prior to surgery, referred to as baseline recordings, then continued throughout the surgery. Any significant changes or fluctuations from these baseline values are then used to determine whether any significant neurologic injury has occurred. With this strategy, the patient's own responses serve as the control for the detection of any abnormalities that may occur during the surgery. The term *significant change* is used in reference to the degree of changes seen in the neurophysiologic recordings. Changes termed *significant* have been shown to correlate well with intraoperative injury to the nervous system. However, it is also possible that some of these significant changes may also arise from other changes in physiologic parameters, anesthetic parameters, or possibly technical issues. It is then up to the intraoperative neurophysiologic monitoring team to determine whether the significant changes noted in the neurophysiologic responses are truly related to the surgical procedure at hand. The challenge to the intraoperative neurophysiologist and the monitoring team is to alert the surgeon of these changes as early as possible and to evaluate and rule out various technical and nonsurgical causes that may also affect the responses being recorded.

Key to the success of intraoperative neurophysiologic monitoring is a good understanding of the capabilities and limitations of the neurophysiologic tests being monitored. These limitations should be understood not only by the intraoperative neurophysiologist but also by the anesthesiologist and surgeon. For seamless integration of intraoperative neurophysiologic monitoring into the intraoperative team, a good working relationship among the intraoperative neurophysiology team, anesthesiologist, and surgeon is imperative. This allows for rapid communication between teams and a quick resolution of issues, thus optimizing the benefits of intraoperative neurophysiologic monitoring for the patient.

One of the first issues to address when planning for intraoperative neurophysiologic monitoring is to determine the types of neurophysiologic tests to perform on a particular patient undergoing surgery. This is accomplished by understanding the type of surgery the patient will undergo, the types of intraoperative injuries that may occur, and the mechanisms of how these injuries occur in surgery. By planning ahead with these issues in mind, the team can also attempt to anticipate the type of changes that could occur as well the risky periods during surgery when these changes would be likely. Ideally, they would prospectively plan for interventions to reduce intraoperative neurologic injury.

Intraoperative Monitoring of the Spinal Cord

Somatosensory-evoked potential (SEP) monitoring has been used for many years to monitor spinal function intraoperatively during a variety of surgeries involving the spine (e.g., corrective surgery for scoliosis or other congenital deformities, removal of intraspinal tumors or arteriovenous malformations). This monitoring modality has been shown to reduce the incidence of neurologic damage in large-scale studies of experienced monitoring teams.[1] SEPs only monitor sensory transmission through the dorsal column pathways. In other words, this modality does not provide a direct measure of motor function. In addition, it is important to be aware that the dorsal columns receive their blood supply from the posterior spinal arteries, whereas the anterior spinal arteries supply the motor pathways. Therefore ischemic damage to the spinal cord from an anterior spinal artery may go undetectable with SEP monitoring.[2,3] Therefore a significant change in SEP monitoring might mandate further assessment of the patient's motor function by waking the patient up during surgery to evaluate leg and arm motor function (the "wake-up test"). The disadvantages of this strategy include the lack of online

intraoperative motor function assessment as well as the anesthesia risks associated with performing the wake-up test. An alternative is monitoring the motor pathway through the recording of motor-evoked potentials (MEPs).

MEP monitoring has been performed in the past by directly relying on stimulation of the spinal cord.[4] Spinal cord stimulation can be done with the use of epidural electrodes inserted after a laminectomy or by percutaneous intraspinous needle electrodes. The epidural electrodes are invasive and often require placment by a skilled anesthesiologist. Percutaneous intraspinous needles are difficult to place accurately and thus may not achieve adequate or consistent stimulation of the spinal cord. In addition, there is the question of whether MEPs generated through spinal cord stimulation arise solely from propagation through the motor pathway or if multiple pathways are involved in their generation.[5,6] There are reports of MEP monitoring in which spinal cord stimulation resulted in no significant intraoperative changes but yet a postoperative neurologic motor deficits occurred (so-called *false-negative result*).[7] It has been suggested that motor cortex stimulation with transcranial electrical stimulation would provide a more reliable methodology for monitoring the motor pathways. This technique has become a routine modality in spinal cord monitoring along with SEPs.

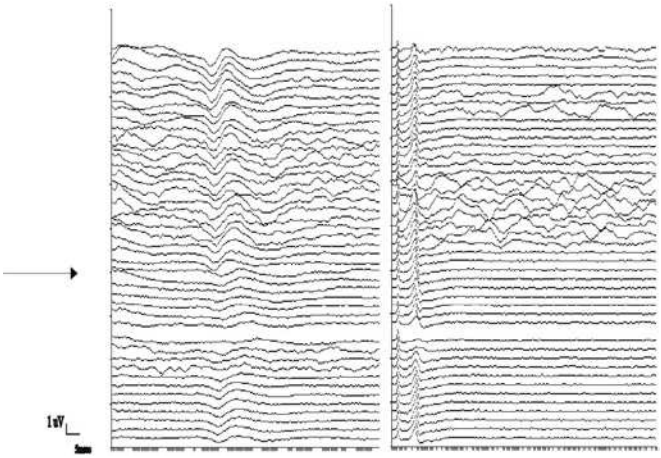

FIG. 15.1 Significant amplitude change in cortical response due to ischemic etiology. The stack on the left shows the leg cortical response; the stack on the right shows the popliteal fossa response. Both were obtained after left posterior tibial stimulation. The baseline responses are shown at the top of the stack and the end of monitoring is shown at the bottom of the stack. A drop in the leg cortical amplitude can be appreciated at the point depicted by the *arrow*. Note the popliteal fossa responses are intact during this time. There is a return of the response by the end of surgery seen at the bottom of the stack. This change was attributed to an ischemic change to the cord with the retractor placed over the left iliac artery. The responses returned when the retractor was adjusted away from the artery.

Somatosensory-Evoked Potential Monitoring

The use of SEPs in intraoperative monitoring of complex spine surgeries began in the early 1970s.[8] Although SEP monitoring primarily evaluates the integrity of the posterior columns, it is often used to give an overall assessment of the spinal cord based on the assumption that many intraoperative mechanisms of injury affect the spinal cord diffusely. An example of such an injury is spine distraction during scoliosis surgery. In addition, ischemic injury may initially result in a more diffuse dysfunction of the spinal cord that could be detected by SEPs (Fig. 15.1). SEP responses are thought to pass through both large fiber somatosensory pathways of the dorsal column as well as possibly the anterior spinothalamic tract. This may be another reason why anterior spinal artery ischemia could be detected by this technique.

Generators of the Somatosensory-Evoked Potential Responses

The cortical response for the lower extremity is called the P37 potential. The generator of this response arises from the primary somatosensory cortex of the leg, which is located in the mesial parietal cortex. The cortical response for the upper extremity, which is generated from the primary somatosensory cortex of the hand, is called the N20 potential (Fig. 15.2). Two important characteristics of these waveforms include (1) amplitude, which is recorded in microvolts and determined by either a baseline to peak or peak to trough measure of the waveform, and (2) latency, which is recorded in milliseconds and is the time interval from the stimulus to the occurrence of the potential. An amplitude change from the initial baseline measure to a decrease of more than 50% is often termed a significant change in SEP amplitude.[9] Significant latency changes in SEP monitoring consist of a 10% prolongation beyond the baseline latency value (Table 15.1).[10] Although these deviations from the baseline measures are thought to be significant, they should be interpreted with caution, taking into account various factors that include the evolution of the changes (e.g., a trend toward worsening is an ominous sign) and various other intraoperative factors that include length of the surgery, type of anesthetic agent, and temperature effects. It is also important to remember that significant latency and amplitude changes can occur in isolation. It is quite common to see a significant amplitude change without any associated latency changes. The most significant change is a complete loss of the cortical potential.

TABLE 15.1 Significant Changes in Different Monitoring Modalities

Type of Study	Significant Changes	Highly Significant Changes
Somatosensory-evoked potentials	Amplitude <50%; latency >10%	Complete loss of amplitude
Motor-evoked potentials	Increase threshold voltage >50–100 V	Complete loss of amplitude
Pedicle screw stimulation	Current intensity <7–10 mA	

Another measurement made in posterior tibial or peroneal nerve SEP monitoring is the popliteal fossa (PF) potential. This is a nerve action potential that is recorded as the impulses pass under the popliteal fossa in the peripheral nervous system. This measurement ensures that an adequate stimulus has been applied. If the PF response is absent in addition to an absent leg cortical (P37) response, the changes seen may

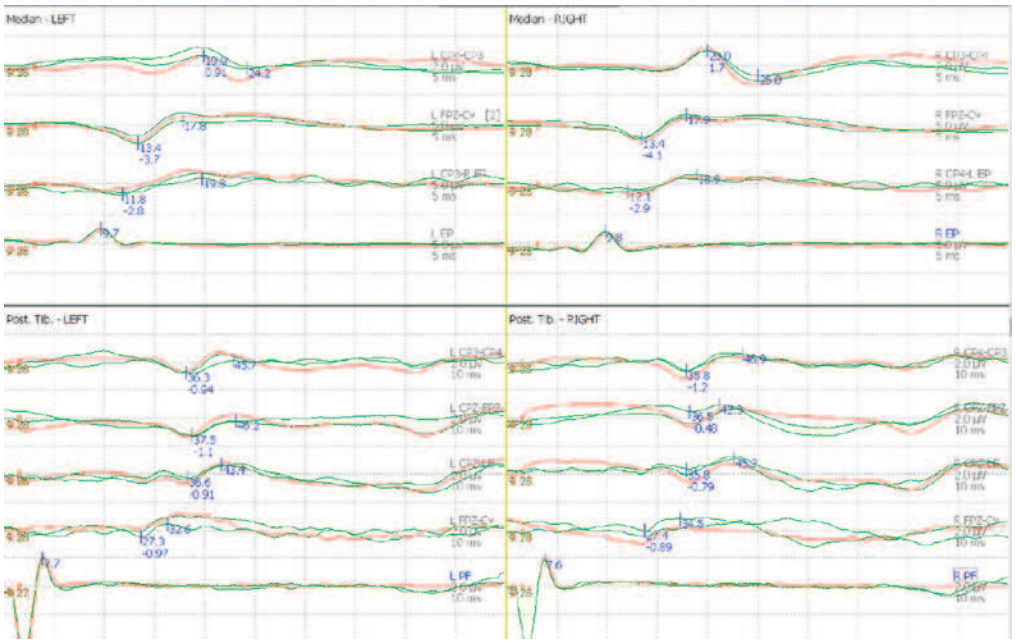

FIG. 15.2 Typical morphology of the cortical generators of median nerve and posterior tibial nerve somatosensory-evoked potential (SEP) waveforms are shown. Note that the display time is different between the two modalities. Median nerve SEP is shown in a 5 ms per division display and posterior tibial nerve SEP is shown in a 10 ms per division display.

not be a result of a lesion at the level of the spinal cord. In this case, the change may be either technical (e.g., the stimulating needles may have dislodged) or the leg may be ischemic (e.g., in the case of femoral artery catheterization during thoracoabdominal aneurysm surgery or direct compression of the peripheral nerve) (Fig. 15.3).

Another posterior tibial stimulation SEP response that can be monitored is the P31/N34 complex, often termed the *subcortical response,* because the generator for these responses is at the level of medulla and midbrain. These responses are relatively more resistant to the effects of anesthesia compared with the cortical P37 response (see Fig. 15.2). The same is true for the subcortical potentials from median nerve stimulation (P14/N18) potential. In pediatric cases, the subcortical potentials may also be better formed and more easily monitored than cortical responses. Some of this effect may be the result of the variation of myelination in the younger age groups and more significant effects of anesthetics on these patients. Moreover, these differences from the adult morphology can persist into the early teenage years. Other factors affecting the responses include core body temperature changes. It is not uncommon for the core body temperature to change more than 1°C. The cooling affects the limbs disproportionately to the core body temperature, which can result in slowing of conduction.

Motor-Evoked Potential Monitoring

A variety of methods have been used to monitor spinal motor pathways during surgery, as mentioned earlier. Most of these methods involve recording of electromyographic (EMG) readings from appropriate muscles in response to stimulation of a motor pathway rostral to the operative site. The difference among the various methods is the nature of the stimulation. There are three basic categories of stimulation: rostral spinal stimulation, transcranial magnetic stimulation, and transcranial electrical stimulation (TCES). Magnetic stimulation is effective in nonanesthetized patients for motor pathways evaluation, but the suppression of cortical responsiveness under anesthesia (mainly inhalational anesthetics) renders this method less effective for surgical use. In addition, the equipment used for magnetic stimulation is expensive, bulky, and has a tendency to overheat.

Noninvasive stimulation of the brain using TCES was first reported in 1980.[11] Soon after, single-pulse TCES was used in monitoring motor pathways.[12-17] Because of the effects of general anesthesia, single-pulse stimulation was found to be less reliable in recording MEPs.[18-22] With the introduction of the multipulse technique for motor pathway monitoring, reliable and robust MEP recording can now be obtained in most patients using specific general anesthesia protocols.[23-27] Multipulse techniques require that neuromuscular blockade not be used during this part of the monitoring. Occasionally the use of partial neuromuscular blockade may still allow for TCES moniotring.[28] This method reportedly achieves more reliable stimulation of the motor cortex intraoperatively and is more resilient to the effects of general anesthesia.

The methodology of MEP monitoring has been revolutionized by the use of multipulse TCES. Previous methods for MEP recording used a variety of stimulation and recording techniques. Spinally elicited neurogenic responses were used and were putatively stated to be a result of activation of the motor pathways in the spinal cord. Recent evidence has suggested that these spinally elicited neurogenic responses are

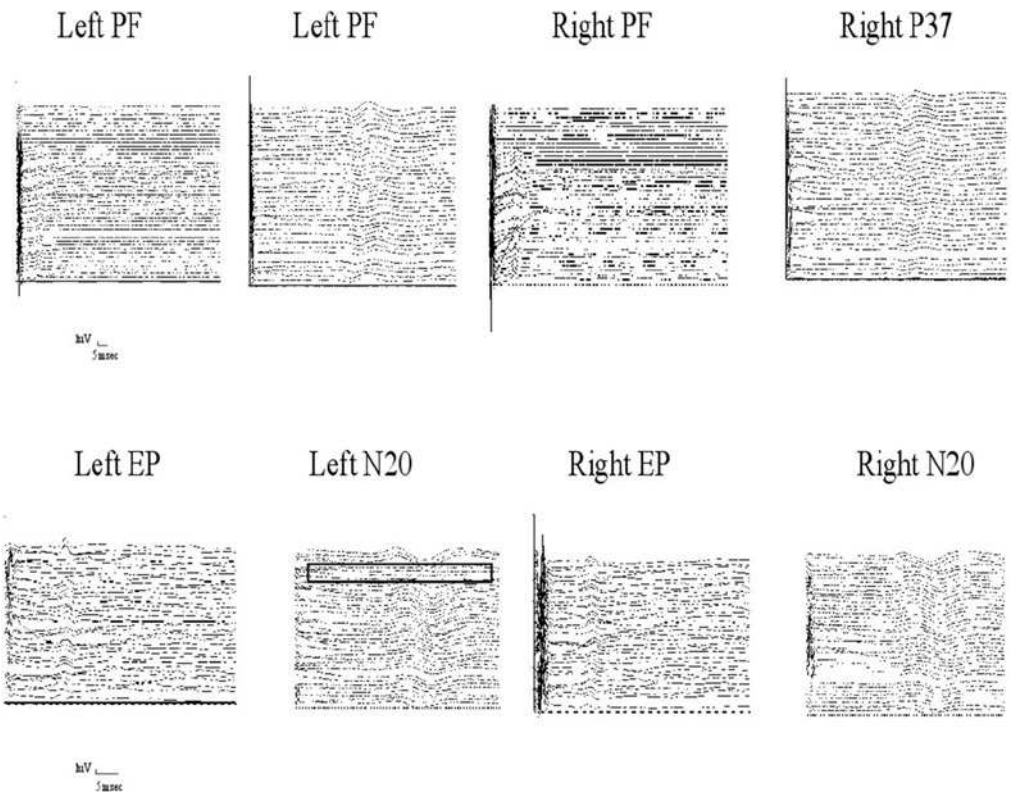

FIG. 15.3 Significant change in left N20 cortical amplitude due to arm positioning and nonsignificant latency prolongation of all cortical responses due to anesthetic effect. The top row of stacks shows popliteal fossa (PF) and leg cortical (P37) responses from the posterior tibial stimulation, first from left-side stimulation and then right-side stimulation. The bottom row of stacks shows Erb's point (EP) and arm cortical (N20) response from median nerve stimulation, with the left side shown first followed by right-side stimulation. There is a drop in the left N20 amplitude (the *rectangular box*). At this point there is also a loss of the left EP response. This change was attributed to left arm malposition. When the left arm was repositioned, the response returned to baseline. Also noticeable in all the leg and arm cortical responses from both left and right sides is mild prolongation of latencies in the stacks, but these latencies all returned to baseline by the end of surgery. These changes are likely from an anesthetic effect because they are bilateral, affecting both the arm and left responses in a spine operation, which was performed at the L3–S1 level.

generated through activation of the sensory pathways and retrograde activation of the alpha motor neurons. In a collision experiment using stimulation of the spinal cord followed by stimulation of the posterior tibial nerve at various interstimulus intervals, the neurogenic responses were abolished, suggesting that the potentials were colliding in the spinal cord.[6]

At the beginning of TCES-MEP monitoring, threshold voltages for each side of the body and amplitudes of MEPs are calculated.[23] The motor cortex on the side of the brain receiving the anodal stimulus is typically the first region to activate at the lowest stimulus threshold. The initial current used is typically 100 V, with a train of stimuli delivered to the cortex. Following stimulation, a MEP response is monitored in the muscles contralateral to the side receiving the anodal stimulus. If no response is seen, the voltage is typically increased by 50-V increments and the process is repeated until an MEP response is seen in all the muscles contralateral to the anodal stimulus. This voltage is called the *threshold voltage* for that side. The highest amplitude of the myogenic response below the level of surgery is also noted. Typically, amplitude measures for myogenic responses are best recorded as the area-under-the-curve measurements or simply documented as either presence or absence of the myogenic response. This procedure is repeated after reversing the anodal-cathodal configuration using a switch box. The voltage used for TCES-MEP recordings typically does not exceed 500 V. Note that the anticipated latency of the EMG responses ranges from 20 to 40 ms or more depending on the patient's height, owing to the conduction time in the descending motor pathways. Latency values have not always been found to be reliable indicators of significant change in TCES monitoring in clinical practice. Another advantage of the multipulse technique is that it requires no averaging. A train of pulses elicits a clear response of sufficient amplitude, which requires no averaging.

Two different methods of recordings can be used. In myogenic MEPs, responses can be recorded directly from the muscle (either a surface electrode or needle electrodes placed within the muscle). In spinal cord MEPs, responses may be recorded directly from the spinal cord with use of an epidural catheter electrode that records a direct D wave and a volley of indirect I waves. Using single-pulse TCES, recording both D and I waves is frequently required, meaning a D wave could be recorded when a myogenic MEP is not yet seen. This is because a series of D and I waves is required for

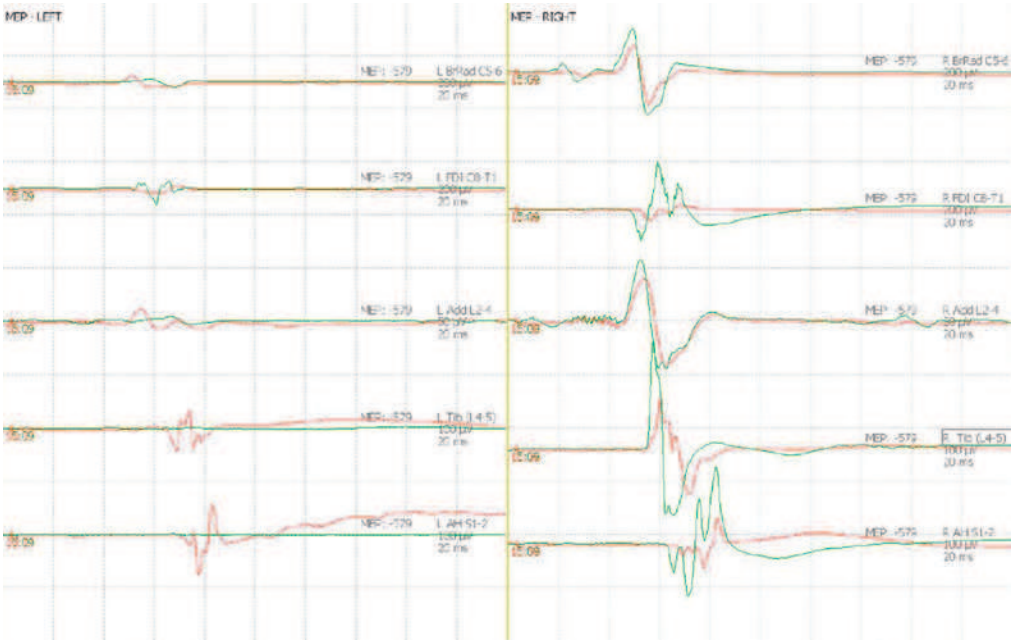

FIG. 15.4 Significant change in transcranial electrical motor-evoked potential (MEP) response during spinal instrumentation. The figure shows transcranial MEP responses from the left and right muscle groups. The traces in red represent the responses at baseline (at the beginning of surgery). The first two muscle groups on each side of the figure represent upper extremity MEP response from the brachioradialis (BrRad) and first dorsal interosseous (FDI). The lower three traces on each side represent the responses from the lower extremities on each side of the body: adductors of the thigh (Add), tibialis anterior (Tib), and adductor hallucis (AH). The green traces represent the most recent acquisition and show the change from baseline over the left lower extremity muscle groups. Notice the MEP responses of the left tibialis anterior and adductor hallucis are absent, whereas they are preserved in the left upper extremity and adductor of the thigh as well as both lower and upper extremity of the right side of the body. This is consistent with injury to the left lower lumbar and sacral nerve roots (L5, S1, S2).

the alpha motor neurons to generate a myogenic response. The spinal recorded responses can also be recorded with full muscle relaxation, whereas myogenic responses require either no or very little muscle relaxation, even with the multipulse technique.

Determining significant changes during the course of surgery typically is most reliable if there is an absolute loss of myogenic responses to stimulation (Fig. 15.4). Some authors have also suggested that amplitude drops of MEP to 25% of baseline amplitude values are predictive of motor pathway impairments.[29] Significant changes can also be determined by a change of voltage required to obtain MEPs of greater than 50 V beyond baseline thresholds used in obtaining MEPs at the beginning of monitoring (see Table 15.1).[30]

Clinical Use of Intraoperative Monitoring

SEPs have become a useful modality in monitoring scoliosis surgery and have been shown to reduce the risk of neurologic deficits, especially when used by surgeons experienced in neurophysiologic monitoring. The occurrence of definite neurologic deficits in the presence of unchanged SEP recordings has been estimated to be approximately 0.063%.[31] Intraoperative neurophysiology can play both a neuroprotective (through the detection of early changes) and an educational role during surgery.[32] Surgeons who use intraoperative neurophysiologic monitoring over time may begin to understand which specific surgical techniques have a higher propensity for damaging the neurologic system. In this way surgeons may find methods to avoid the use of high-risk techniques.

Many surgeons have found that TCES-evoked MEP monitoring during spinal surgery is a safe and reliable method of monitoring corticospinal tract activity and is indispensable for these surgeries.[33] There has been no evidence that TCES has resulted in the development of new-onset epilepsy or brain damage. There are some risks associated with TCES monitoring, including tongue or lip laceration and, rarely, mandibular fractures. The use of a soft bite block may prevent these injuries. Relative contraindications include epilepsy, cortical lesions, convexity skull deficits, raised intracranial pressure, cardiac disease, intracranial electrodes or shunts, cardiac pacemakers, and other implantable biomedical devices.[34]

A study that looked at the reproducibility of various monitoring methods during scoliosis surgery found that MEPs could be obtained in 80% of patients compared with SEPs, which could be obtained in 93% of patients.[35] In spinal surgery, MEPs obtained from upper and lower extremities were consistently recorded in 22 patients with multipulse stimulation using trains of 3 to 6 pulses separated by 2 ms, with responses measuring more than 100 μV in all but one patient. These responses persisted with nitrous oxide concentration of up to 74%. One patient had loss of responses from one lower limb in which increased weakness was noted for a few days after surgery; in three patients there was an

increase in weakness or spasticity without any accompanying intraoperative MEP changes.[36] In another study,[37] MEPs during TCES were reproducibly recorded during spinal surgery in 40 patients with partial neuromuscular blockade. In two patients there were some significant changes in the motor potentials that correlated with postoperative neurologic deficits. No postoperative neurologic deficits were observed in nine patients in whom MEP amplitudes decreased to less than 20% of baseline values.[37]

TCES-induced MEPs have been used to monitor cases of intramedullary spinal cord tumor resection. In 32 consecutive patients, MEPs were elicited in 19 patients before myelotomy, and three of these patients had MEP amplitude decrease below 50% from baseline, all of whom had postoperative neurologic deficits.[38]

In a review of 160 patients undergoing scoliosis surgery, a combination of SEP and transcranial MEP monitoring was successfully recorded in 81% of the patients, with changes seen in 5% of monitored cases that was reversible after taking appropriate surgical corrective measures. None of these patients had new postoperative deficits or worsening of preexisting deficits. This combination of techniques was considered safe, reliable, and accurate and made the wake-up test unnecessary.[39]

Use of TCES-evoked MEPs has been relatively easily accomplished with an anesthetic combination of narcotic drip accompanied by nitrous oxide. The use of isoflurane in addition to this combination resulted in a tendency for deterioration of amplitude of the MEP responses.[40] MEPs elicited by TCES are more feasible with total intravenous anesthesia compared with balanced anesthesia using nitrous oxide, isoflurane, and fentanyl. Some of the suppressant effects of balanced anesthesia can be overcome with higher stimulation intensities and repetitive stimulation.[41]

Pedicle Screw Stimulation

Intraoperative assessment during pedicle screw insertion can be used to avoid nerve root trauma from a misdirected screw. The integrity of the pedicle screw placement can be assessed by its direct electrical stimulation with simultaneous myogenic response recordings from the appropriate myotomes. Using a direct monopolar nerve stimulator, with serial increments of the level of current intensity from 1 to 20 mA, triggered EMG recordings can be performed (Fig. 15.5). Absence of a myogenic response up to 10 mA is thought to be indicative of an intact pedicle. The presence of a pedicle breach is suspected by a stimulation-induced myogenic response below 7 to 10 mA (see Table 15.1).[7]

Summary

Intraoperative neurophysiologic monitoring of the spinal cord can be used to help detect the early occurrence of neurophysiologic changes, thereby allowing corrective action to reduce the incidence of neurologic injury to patients undergoing spine surgery. In our opinion, the most important aspects of successful intraoperative monitoring include the following:

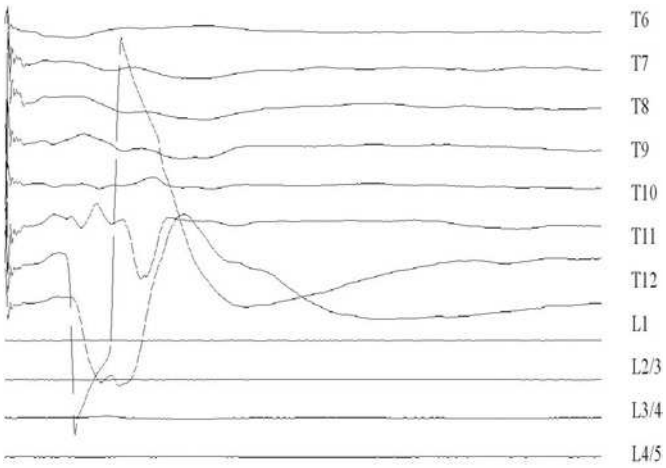

FIG. 15.5 Nonsignificant triggered electromyographic (EMG) response with pedicle screw stimulation. Pedicle screw stimulation of the T12 screw shows threshold of triggered EMG response at an intensity of 12 mA.

1. Availability of the right equipment to allow multimodality recordings (e.g., combinations of EMG, SEP, and/or MEPs)
2. Presence of a highly skilled and experienced technical and neurophysiologic team that will ensure for optimal technical recordings and accurate interpretation of any changes that may occur
3. Rapid communication between the neurophysiologic team and the surgical/anesthesia teams
4. A knowledge of both the functional anatomy of the structures to be monitored and the limitations of the techniques to be used

The combination of different monitoring techniques, such as SEP and transcranial MEP monitoring, has enabled better interpretations of the neurologic status of the spinal cord. The newer techniques of MEPs with TCES have gained widespread acceptance as a standard clinical intraoperative neurophysiologic application. MEPs have allowed for a more accurate assessment and interpretation of the functional status of the motor pathways at various levels of the neuraxis.

PEARLS

1. One key to the success of intraoperative neurophysiologic monitoring is a good understanding of the capabilities and limitations of the neurophysiologic tests being monitored.
2. One of the first issues to address when planning for intraoperative neurophysiologic monitoring is to determine the types of neurophysiologic tests to perform on a particular patient undergoing surgery.
3. SEPs only monitor sensory transmission through the dorsal column pathways; they do not provide a direct measure of motor function.
4. In SEP monitoring an amplitude drop of greater than 50% and latency prolongation of more than 10% are considered significant. The most significant change is a complete loss of the cortical potential.
5. MEP monitoring is a more direct technique that evaluates the motor pathway. Motor cortex stimulation with TCES provides a more reliable methodology for monitoring the motor pathways.

PITFALLS

1. Significant changes in SEP monitoring can involve significant latency and amplitude changes that can occur in isolation.
2. If there is an absence of the peripheral response in SEP monitoring, a technical cause to the change must be ruled out.
3. There has been recent evidence to suggest that these spinally elicited neurogenic responses are generated through activation of the sensory pathways and retrograde activation of the alpha motor neurons.
4. Latency values have not always been found to be reliable indicators of significant change in TCES monitoring in clinical practice.
5. The use of inhalational agents has a tendency to deteriorate MEP amplitudes.

KEY POINTS

1. The aim of most spinal cord monitoring is to prevent intraoperative injury that results in irreversible paraplegia or quadriplegia. Due to the inability to perform a neurologic examination in an anesthetized patient, intraoperative neurophysiologic monitoring is used to determine the patient's neurologic status during surgery.
2. The term *significant change* is used in reference to the degree of changes seen in the neurophysiologic recordings. Changes termed *significant* have been shown to correlate well with intraoperative injury to the nervous system.
3. SEP monitoring has been used for many years to monitor spinal function intraoperatively during a variety of surgeries involving the spine, such as corrective surgery for scoliosis or other congenital deformities and removal of intraspinal tumors or arteriovenous malformations. SEPs only monitor sensory transmission through the dorsal column pathways.
4. A variety of methods have been used to monitor spinal motor pathways during surgery. The methodology of MEP monitoring has been revolutionized by the utilization of multipulse TCES. Two different methods of recording MEPs can be used. In myogenic MEPs, responses can be recorded directly from the muscle. The second method involves recording responses directly from the spinal cord with use of an epidural catheter electrode that records a direct D wave and a volley of indirect I waves.
5. A combination of SEP and transcranial MEP monitoring can be used to successfully monitor the spinal cord. This combination of techniques is considered safe, reliable, and accurate and may obviate the need for the wake-up test.
6. Intraoperative assessment during pedicle screw insertion can be used to minimize the risk of nerve root trauma from a misdirected screw. The integrity of pedicle screw placement can be assessed by directly stimulating the screw and by simultaneously recording myogenic responses from the appropriate myotomes.

16 CHAPTER Targeting Pain Generators

Richard Derby
Lee Wolfer
Zachary McCormick

Spinal pain is very common, exacting a significant toll for the individual and society. Spine pain with a significant recurrence has lifetime prevalence estimated between 24% and 80%,[1,2] an annual prevalence of 15% to 45%, and a point prevalence of 18% to 30%.[3,4] Low back pain and neck pain are the first and fourth most common reason for disability among adults in the United States,[1,2,5] and both low back and neck pain rank within the top five reasons worldwide.[6] Chronic low back pain alone has been estimated to account for more than $100 billion in health care expenditure per year.[7] The prevalence of individuals seeking care for low back pain has increased significantly since the early 1990s. From 1992 to 2006, the prevalence of patients presenting with chronic impairing low back pain increased from 4% to 10%.[8] Targeting pain generators through precision diagnostic methods is the first step toward appropriate and effective treatments for chronic spinal pain.

Much of the epidemiologic data on low back pain are nonspecific, meaning that a cause cannot be found in most cases. Despite evidence to the contrary in the 21st century, these older, inaccurate epidemiologic studies continue to be quoted by current authors. One of the oldest epidemiologic studies commonly quoted was published more than 40 years ago by Dillane and colleagues[8] and was based on a retrospective practice audit of data gathered more than *50 years ago*. Dillane and colleagues[8] reported that they could not detect a cause for low back pain in approximately 80% of female and 90% of male patients with acute back syndrome. These authors did not report the use of any radiographic studies and apparently relied solely on history and physical examination.[9] They diagnosed approximately 11% of male patients and approximately 4% of female patients with low back "strain." Until more recently, the only tools to diagnose the etiology of low back pain have been history, physical examination, and sometimes radiographs or computed tomography (CT).

In 1982, Nachemson[10] reviewed the literature on chronic low back pain. In perhaps the most frequently quoted epidemiologic study on the cause of chronic low back pain, he reported that in only 15% of cases could a pathoanatomic explanation be found for patients with chronic low back pain (>3 months). As stated in the study, "probably very little can be done at our present state of ignorance to treat these patients and to improve their natural histories."[10] Low back pain is a symptom, not a diagnosis, in the same way that abdominal pain is a symptom and not a diagnosis. In acute cases of low back pain, this nonspecific diagnosis usually suffices because most cases of acute, first-time low back pain resolve with minimal intervention. However, when low back pain becomes chronic, recurrent, and disabling, the clinician must diagnose the source of the pain so that an appropriate treatment plan may be devised.

When a source of pain is not obvious, diagnosis often depends on who makes the diagnosis and sets the reference standards by which the diagnosis is "proven." Who is right? For that matter, can anyone reliably diagnose the cause of chronic benign spinal pain? Many authors argue that chronic benign spinal pain is largely due to exaggerated functional complaints and irreversible central nervous system sensitization,[11] making pain self-perpetuating and diagnosis all but impossible. These contentions are not often supported by primary studies,[12] however, and authors and clinicians question this diagnosis.[13,14]

Interventionalists developed and refined precision, fluoroscopically guided diagnostic interventional spine procedures in the 1980s and 1990s[15] to diagnose and treat nonspecific spinal pain more effectively. Fluoroscopically guided block procedures are now considered the reference standard to confirm a tissue diagnosis.[16] Out of the previous era of "ignorance," many diagnostic protocols have been validated and standardized.[17,18] Using the results of precision-guided diagnostic procedures, surgeons identify spinal segments for fusion at various stages of the degenerative cascade.[19] Most surgeons still depend on an accurate diagnosis of a specific pain generator to select appropriate therapy[20] because surgical results for chronic benign pain syndromes without a reversible anatomic cause are generally poor.[21]

The debate continues regarding diagnostic injections as new research emerges, along with better treatment options. Spinal pain is a complex interaction of many biopsychosocial factors. Chronic spinal pain may originate from one or more spinal levels and different anatomic structures in the anterior, middle, and posterior columns. Spinal pain also varies over time. Pain can be caused by abnormal mechanical stress on normal tissue affected by structural deformity, normal mechanical stress

on injured tissues, minor stress on chronically inflamed and sensitized tissues, damaged nerves, and a varying combination of all of these. Chronic pain causes a greater or lesser degree of central sensitization and—together with a multitude of functional factors, including the requirement for copious amounts of opiates—often makes accurate diagnosis difficult. Nevertheless, it can be argued that most chronic axial spinal pain is due to accumulated repetitive strain or low-grade trauma,[22] acute injuries to the major underlying structures and their supporting ligaments, or both. Ongoing stimulation from these peripheral structures to a greater or lesser extent maintains a state of peripheral and central sensitization. In time, adaptive responses within the posterior, middle, and anterior columns may attenuate, exacerbate, or cause new sources of pain.

Despite this complexity, specific tissue pain generators can be hypothesized based on history, physical examination, imaging studies, and response to directed treatment. Interventional procedures are used to test the hypothesis that pain is related to a structural abnormality hypothesized by clinical and imaging findings. (The word *hypothesis* is used loosely here; arguably, one can only confirm a *clinical impression* using diagnostic blocks. A hypothesis is confirmed using a study protocol that can show approximately <5% probability that the findings are due to chance.) Foremost, interventional procedures are perhaps best used to refute one's hypothesis that a particular structure is painful. That is, diagnosis is made through the process of systematically excluding various tissue causes of axial and extremity pain in the posterior, middle, and anterior columns.[21]

This chapter presents primarily evidence-based standards and some expert opinions for confirming or refuting one's hypothesis that a particular structure, structures, or segments are a source of spinal pain.[17] A discussion of pain resulting from "red flag" conditions, such as fracture, tumor, infection, systemic diseases, or referred from nonspinal structures, is not included; likewise, "yellow flag" conditions (psychosocial factors) are not discussed in detail. Evaluation of the anterior column using provocative discography is discussed elsewhere; the discussion in this chapter is focused on diagnosis of pain originating from the posterior and middle columns, in particular, pain originating from the zygapophyseal joint and sacroiliac joint in the posterior column and from the nerve root, dorsal root ganglion, and dura in the middle column. The diagnostic use of injection procedures is explored but not their therapeutic value other than the diagnostic value of response or nonresponse to treatment. Finally, and most important, this chapter is not a systematic review. The interested reader is referred to numerous systematic reviews on the diagnostic value of spine injections.[3,17,18,22–28]

Diagnostic Analgesic Injections as Reference Standard

The belief that chronic benign spinal pain is difficult to diagnose is supported by the low specificity and sensitivity of the history, physical examination, and various imaging modalities as the reference standard for diagnosing chronic benign spinal pain[12,29,30] and a bias that chronic pain is to a greater rather than lesser extent a neuropathic process with central sensitization.[21] If one uses interventional diagnosis with precision fluoroscopically guided procedures as a reference standard for identifying pain, however, one can arrive at a tissue diagnosis in approximately 70% to 80% of cases.[31,32] Which approach is right? Truth usually lies somewhere in between.

The primary treating physician or consultant needs to formulate the diagnosis based on the available information and must be prepared to defend the diagnosis to contracted physician reviewers. Understanding the strengths and weaknesses of diagnostic analgesic data may help the practitioner decide whether the risk-to-benefit ratio of obtaining such information is appropriate for any given circumstance. Perhaps more important, the process of investigation itself may lead to a better understanding of the patient's capacity to respond appropriately to a technically successful surgical or interventional procedure.

The rationale for zygapophyseal joint blocks is based on the anatomic fact that the innervation of zygapophyseal joints (medial branches) is known and that zygapophyseal joints are capable of causing pain.[17] Local anesthetic blocks rely on the specificity of anesthetizing a single or limited number of structures or nerves and on the patient's capacity to distinguish clearly a reduction in preblock pain after anesthetizing one or more structures. Injection of a limited volume of local anesthetic into a zygapophyseal joint or its nerve supply is relatively specific for anesthetizing a joint and its capsule. Similarly, local anesthetic injected into the disc should anesthetize nociceptors within radial annular fissures that communicate with the nucleus. When anesthetizing the nerve root within the middle column, the block is less specific for axial pain relief because several structures may be partially blocked (e.g., dorsal root ganglion, ventral rami, sinuvertebral nerve, posterior longitudinal ligament).

Anesthetizing a structure does not reveal the cause of pain; anesthetizing the nerve supply simply relieves pain. This is an important concept. The cause of pain should dictate the type of treatment, and the treatment is only as good or bad as its success in eliminating or modulating the cause. If the cause of pain in the case of a specific zygapophyseal joint is synovial inflammation, one would expect short-term to intermediate pain relief after the intraarticular injection of corticosteroids. If a patient's pain is due to mechanical or neuropathic causes, there is no reason that corticosteroids would be effective other than the expected duration of the local anesthetic. There is no reason that there should be longer-term pain relief except for the expected rate of placebo response or reported pain relief secondary to spontaneous pain regression.[33] That is, relief of pain during the local anesthetic phase does not distinguish irreversible neuropathic pain from reversible nociceptive pain. In the case of chronic radicular pain, significant relief of pain for several weeks after the injection of corticosteroids would suggest that there is a reversible structural cause.[34]

Testing Protocols for Diagnostic Injections

As essential as precision technique is in the performance of diagnostic blocks, so is standardized assessment. Standardized

diagnostic block evaluation sheets should be filled out for each patient; detailed postprocedure assessment protocols and sample evaluation instruments are available in the Spine Intervention Society Practice Guidelines.[18] Preprocedural and postprocedural evaluation should be performed by unbiased personnel and checked by the physician. It is recommended that the patient fill out a body pain diagram with pain scores (visual analog scale [VAS]) before and after the procedure. Additionally, the patient should rate current pain levels with various movements (e.g., lumbar flexion, extension, side-bending, sitting, and standing).

Evaluation after the procedure includes VAS scores with the same positions and maneuvers and a subjective report of percent relief of pain. The patient's narrative response should corroborate with VAS score, and any discrepancies should be explained. With medial branch blocks, relief of pain may vary according to the mass of drug reaching the nerve, and one may not reliably achieve a long-acting block; however, relief for less than 1 hour is unconvincing. In the case of selective nerve root blocks, it is often useful to have the patient distinguish between axial, proximal (shoulder or buttock), and extremity pain, the caveat being that a diagnostic block may not significantly reduce axial pain, but that does not mean that the block was unsuccessful. Some patients also need to be counseled to ignore injection site pain. Specific provoking maneuvers should be evaluated, such as the Spurling test for cervical radiculopathy and three or more sacroiliac joint provocative maneuvers before and after the procedure. Ideally, the patient would be tested at approximately 15 minutes after a lidocaine block and approximately 30 minutes after a bupivacaine block. Additional evaluations at 1 and 2 hours after block are useful but may depend on availability of staff.

The patient may be sent home with a pain diary to keep for 6 to 8 hours after the procedure. For any diagnostic injection, a patient should have at least approximately 5/10 intensity of pain to be able to judge the degree of relief reliably. A subject should have at least 50% relief for a positive response to be considered; at least 70% relief is more convincing. In regard to selective nerve root blocks, no more than two levels should be checked on one session. Depending on the importance of refuting or confirming whether a particular nerve is symptomatic, one may choose to inject the most probable source of pain or a level that it is hoped can be proven nonpainful.

A common problem encountered when attempting to identify the etiologic structure of pain with a diagnostic injection occurs when the nature of pain is intermittent or determined by prolonged activity. For example, a patient may experience significant symptoms late in the day or after an hour of prolonged standing or sitting. If this patient were to present to the office for a diagnostic block early in the morning, pain may not be present, clouding the ability of the patient to report relief (or lack thereof) after a diagnostic block procedure. If such is the case, the patient may be asked to perform provocative maneuvers that typically incite pain prior to the diagnostic block procedure. Repeated or sustained extension and rotation movements may be useful in these situations for posterior structures such as zygapophyseal joints or spinal nerve root–mediated pain related to central canal or neural foraminal stenosis; repeated flexion maneuvers may be helpful to incite spinal nerve root pain of presumed discogenic etiology. These maneuvers can then be repeated after the block procedure, and the patient is queried as to the relative reduction of pain with these movements compared to preblock testing. Alternatively, the patient can be rescheduled with instructions to perform activities (i.e., prolonged standing, walking, or sitting) that typically provoke pain and also to stop taking analgesic medications prior to the appointment for diagnostic blocks. If a patient's pain varies by time of day, the block procedure may be scheduled to accommodate this pattern, and if pain typically peaks well after clinic hours, a longer-acting local anesthetic (i.e., bupivacaine) should be used. Particularly in such situations, patients must be instructed to keep thorough pain diaries for the 6 to 8 hours following the diagnostic block procedure.

Confounding Factors

Sedation

An important, potentially confounding factor when performing diagnostic blocks concerns the use of sedation. Logically, one would assume that administration of opiates and sedatives before a diagnostic block would increase the false-positive rate; however, Manchikanti and colleagues[35] found that this proportion of patients was relatively small and that there was no difference with use of saline, opiate, or sedative. In a randomized study of 60 patients, these authors titrated medication to relaxation using saline, midazolam, or fentanyl. They found that only 50% of patients receiving sodium were relaxed, whereas 100% of patients receiving either fentanyl or midazolam were relaxed. In all groups, 10% of the patients reported greater than 80% pain relief with active motion testing. Even so, typically, one limits or omits sedation before a diagnostic injection, however. If the patient is anxious or especially if the patient routinely takes significant doses of opiates and may be in early opiate withdrawal owing to NPO status, the patient could be sedated and tested after the administration of a judicious dose of opiate.

Biopsychosocial Factors

More recently, authors have reiterated the importance of shifting the concept of "backache." Kikuchi[36] recommended changing the term *spinal disorder* to *biopsychosocial pain syndrome* and the term *morphologic abnormality* to *mechanical, functional disorder*. According to Kikuchi,[36] morphologic and structural abnormalities do not always explain all of a patient's pain, and chronic backache should not be seen as an isolated spinal disease. A significant amount of scholarship has been devoted to enumerating the psychosocial factors associated with spinal pain. In a classic study comparing workers with symptomatic disc herniation (requiring surgery) versus asymptomatic workers, significant differences were found in three areas: presence of nerve root compromise, psychosocial factors (depression, anxiety, marital status, self-control), and work perception (satisfaction, job loss, occupational stress,

intensity of concentration).[37] Of the risk factors, two of three were functional, not morphologic.

We agree with this model and acknowledge that psychosocial factors have a significant impact on spinal pain; we also acknowledge the importance of treating the "bio" component of the *biopsychosocial syndrome*. Today's spine specialists readily acknowledge that patients often benefit from a multidisciplinary approach to treatment. Research continues to investigate the best way to treat patients with chronic spinal pain and significant psychosocial comorbidities.

Although the long-term results of treatment for chronic axial back pain may be influenced by various psychosocial factors,[38,39] the possible effect of psychosocial factors in determining the patient's tested perception of pain and functional improvement with treatment does not indicate that the diagnosis was incorrect. In many cases, when a "biologic" pain generator can be correctly identified and treated, the psychosocial distress resolves. If it is true that psychological variables determine whether a patient admits relief on various testing instruments, does the evidence of physiologic distress noted on test scores reverse when the patient's chronic pain is relieved?

Wallis and colleagues[40] studied 17 patients after whiplash injury with a single symptomatic cervical zygapophyseal joint who were enrolled in a randomized controlled trial of percutaneous radiofrequency neurotomy. At 3 months after the procedure, all patients whose pain was relieved had complete resolution of preoperative psychological distress; in contrast, all but one of the patients who did not experience pain relief continued to experience psychological distress. Manchikanti and colleagues[41] found no correlation between somatization disorder and inappropriate Waddell signs and symptoms to response in pain relief after a comparative double-block protocol for diagnosing zygapophyseal joint pain. Derby and colleagues[42] found no difference in response to pressure-controlled disc stimulation between patients with abnormal psychometric Distress Risk Assessment Method scores and asymptomatic volunteers.

Posterior Compartment: Zygapophyseal Joint and Sacroiliac Joint

The zygapophyseal joint and sacroiliac joint are the two primary structures within the posterior compartment that are sources of chronic spinal pain. In addition, hip and shoulder pain may cause symptoms similar to spinal structures and localized injections into these joints with preblock and postblock active examination can help differentiate hip and shoulder pain from spinal pain. Although soft tissues may be painful, for the purpose and brevity of this chapter, these structures are considered a secondary source of pain in most chronic spinal conditions.

Zygapophyseal Joint

Each spinal segment is composed of a three-joint complex: the intervertebral discs and two posterolateral zygapophyseal joints.[41] The word *apophysis* is Greek, meaning an "offshoot" or a "bony protuberance."[43] Anatomically, the zygapophyseal joint is an outgrowth of the vertebral body. The zygapophyseal joints are formed by the articulation of the inferior articular process of one vertebra with the superior articular process of the inferior vertebra. Zygapophyseal joints have classic synovial joint features: hyaline cartilage surfaces, a synovial membrane, and a surrounding joint capsule.[44] Zygapophyseal joints have varied morphology and function based on their location within the spine. Although the intervertebral disc is loaded primarily in flexion, the zygapophyseal joints are loaded in extension and lumbar rotation.[45,46] The orientation of the zygapophyseal joint varies based on the requirements of regional spine function. Lumbar zygapophyseal joints are situated sagittally to limit axial rotation and to allow flexion and extension, whereas the cervical and thoracic zygapophyseal joints are oriented coronally to limit shearing forces on the disc. Innervation is via the medial branches of the dorsal ramus in most locations.

Pathophysiology of Zygapophyseal Joint Pain

Traumatic injury to lumbar and cervical zygapophyseal joints is common and probably occurs to a lesser extent to the thoracic joints consistent with the relative degree of load bearing in extension at these levels. In the setting of trauma, there is a clear pathophysiologic difference between zygapophyseal joints and nontraumatic controls. Zygapophyseal joint sections from autopsy specimens of individuals with a past history of trauma but dying of natural causes show significant age-related, gender-related, and trauma-related changes in the bone, cartilage, and soft tissues, including subchondral sclerosis, fibrillation and splitting of cartilage, and cartilage length differences, versus subjects with no history of trauma.[47] Histologic sections of the lumbar zygapophyseal joints of mostly motor vehicle accident victims revealed fractures of the superior articular process, central infarctions of the subchondral bone plate, and capsule tears, including the ligamentum flavum.[48,49] Most tissue sections (77%) show soft tissue injuries, and approximately 30% (11 of 33) show fractures and infarctions. Sections from the cervical spine in trauma victims show similar injuries to the zygapophyseal joint articular cartilage and annular lesions in the intervertebral discs and cartilaginous endplates (Fig. 16.1).[50] In the lumbar and cervical spines, lesions were found exclusively in the trauma patients and in none of the patients in the control group.[47,50,51]

Many of these pathoanatomic findings are occult on routine radiographs, CT scan, and magnetic resonance imaging (MRI) but may be the cause of ongoing neck pain in survivors of motor vehicle accidents or other significant trauma. In a small study with short-term follow-up (approximately 3 months), Eisenstein and Parry[52] examined zygapophyseal joints in 12 patients who underwent successful fusion for zygapophyseal joint–mediated pain (diagnosed by provocation arthrography, intraarticular blocks, and negative discography) versus controls and found histologic changes similar to changes of chondromalacia patellae and osteoarthritis of large joints. The most frequent finding was focal full-thickness cartilage

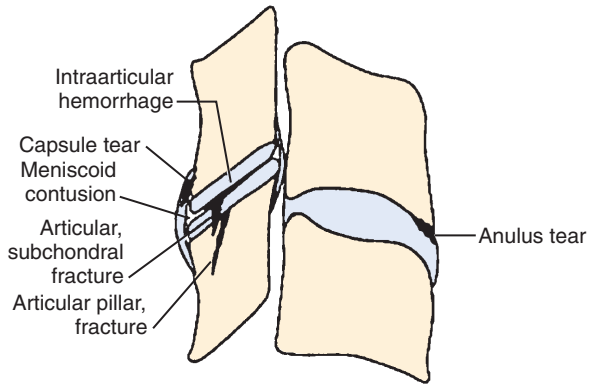

FIG. 16.1 Postmortem studies of motor vehicle victims reveal the following sites of injury; many of these injuries may not be visible on routine MRI. (From Bogduk N, McGuirk B. *Management of Acute and Chronic Neck Pain: An Evidence-Based Approach*. Philadelphia, PA: Elsevier; 2006.)

necrosis or loss of cartilage with exposure of subchondral bone; osteophyte formation was absent in all specimens.[52] Degenerative histologic findings alone do not make a definitive diagnosis of zygapophyseal joint syndrome, however. Ziv and colleagues[53] reported a high proportion of coarsely fibrillated and/or ulcerated zygapophyseal joints in fresh cadaveric spines from young adults (30–50 years old); such degeneration remains constant throughout adulthood.

Traumatic and repetitive injury leading to painful "facet (zygapophyseal joint) arthritis"[49] may cause pain because zygapophyseal joints and their capsules are heavily innervated structures subject to high stress and strain during spinal loading.[54] Joints comprise free and encapsulated nerve endings containing substance P and calcitonin gene-related peptide.[55–57] Substance P, calcitonin gene-related peptide, and immunoreactive sensory and autonomic nerves are found in zygapophyseal joint synovial membranes.[58] Zygapophyseal joint capsules contain low-threshold mechanoreceptors, mechanically sensitive nociceptors, and silent nociceptors.[59] These low-threshold and high-threshold mechanoreceptors fire when the joint capsule is stretched or compressed; their firing can be suppressed by injected lidocaine and hydrocortisone.[60] In animal models, induced inflammation decreases the threshold of nerves within the joint capsules and causes elevated baseline discharge rates.[60] In animal models of knee arthritis, acute inflammation sensitizes fine articular afferents, which become active at rest and respond more vigorously to routine painless joint range of motion.[61]

Excessive stretching damages the zygapophyseal joint capsules and causes axonal swelling, retraction balls, and inflammation.[59] The result is hyperexcitability and spontaneous firing, which are synonymous with neuropathic pain. Capsular injury during a whiplash injury may cause persistent neck pain secondary to chronic capsular overstretching. Animal studies suggest that zygapophyseal joint capsule strains comparable to strains previously reported for whiplash kinematics and subcatastrophic failures of this ligament activate nociceptors within the capsule.[62–66] In addition, chronic capsular loading in animals may cause central inflammation, resulting in mechanical hyperalgesia and, in some cases, centrally maintained pain.[57,64,67,68]

Animal studies showing central sensitization are consistent with the widespread hypersensitivity documented in whiplash patients. Although focal sensitization to mechanical stimuli may be found 3 months after whiplash injury, which mostly resolves by 6 months, some patients develop persistent pain with symptoms that are consistent with chronic neuropathic pain.[69] Patients with persistent pain at approximately 6 months show signs of more widespread hyperalgesia[70] and hypersensitivity to cutaneous and muscular stimulation in the neck and lower limb consistent with central hypersensitivity.[11,71]

If chronic pain originating from injury to the zygapophyseal joints is due to capsular stretch and maintained by central hypersensitivity, local anesthetic with or without corticosteroid should suppress nociceptive input for the duration of the local anesthetic effect and, in some cases (e.g., similar to a sympathetically maintained pain state), for days to weeks.[72] If most of a patient's pain is due to mechanical and central causes, there would be no reason why local anesthetic and corticosteroid would be more effective than local anesthetic alone.[73–75] Former and latter logical outcomes are supported in prospective and randomized controlled trials,[75] although alleviating pain with medial branch blocks was shown in one study to relieve pain for an average of several months.[76,77]

Decreasing peripheral input 6 months or longer by heat ablation of medial branches relieves pain[78,79]; the pain typically returns within the expected time it takes for the medial branches to regenerate. Such prolonged relief of pain, if accompanied by resolution of widespread hypersensitivity, would imply that central hypersensitivity is reversible when the peripheral source of input is interrupted. That is, if there is a concern that persistent central hypersensitivity would lead to failure of a proposed localized or segmental stabilization procedure, resolution of widespread and local hypersensitivity after medial branch neurotomy might predict that decrease in nociceptive input by surgical stabilization would be successful. Zygapophyseal joint pain often occurs at more than one segment, however; adjacent or skipped level sources of zygapophyseal joint pain must be identified, especially when considering surgical fusion or arthroplasty.

When cadaveric lumbar spines are anteriorly fixated at one level, motion is transferred to adjacent segments, causing increased capsular stretch in the adjacent zygapophyseal joints.[80] In extension, cervical arthroplasty models exhibit significant increases of zygapophyseal joint force at the treated level. In the fusion model, the zygapophyseal joint forces decrease at the treated segment and increase at the adjacent segment.[81] Failure to recognize symptomatic pathology at an adjacent level or the same level may lead to early or late return of pain. This is not a failure of the diagnostic blocks; it is a failure to obtain a thorough diagnosis.

Rationale for Control Blocks in Diagnostic Zygapophyseal Joint Intraarticular and Medial Branch Blocks

Can a diagnosis of zygapophyseal joint syndrome be made without injections? The diagnosis of zygapophyseal joint pain is typically hypothesized based on clinical findings and

imaging studies. Most clinicians rely on a variety of criteria, such as localized unilateral pain that is worse in extension, pain worse in the morning and better with gentle movement, concordant pain provoked with palpation approximately 1 cm lateral to the midline over the zygapophyseal joints, and imaging studies showing signs of zygapophyseal joint degeneration. A "facet (zygapophyseal joint) syndrome"[82] diagnosed by clinical findings alone has not been substantiated; rather, a reference standard of pain relief after placebo-controlled anesthetic blocks is necessary.[25,29,83] The current best evidence has not found any individual clinical finding or cluster of findings that can predict response to the reference standard of pain relief after local anesthetic block of the medial branches or intraarticular zygapophyseal joint block.

The purpose of diagnostic zygapophyseal joint blocks is to establish the diagnosis or rule it out, similar to a liver biopsy of a suspicious lesion. Diagnostic zygapophyseal joint blocks are a tertiary intervention in patients with chronic pain that has not resolved with time and conservative care. The current standard for the diagnosis of zygapophyseal joint–mediated pain is the use of controlled differential (double) blocks to confirm or refute one's hypothesis that the zygapophyseal joint is a pain generator. Because of the high false-positive rates of single diagnostic blocks, a single block does not constitute a diagnosis, and control blocks are essential to decrease the incidence of false-positive responses.[84] The reported false-positive rate of a single diagnostic block ranges from 17% to 63%.[85] In a retrospective review of 438 patients using a double-block paradigm requiring 80% relief, the false-positive rates for a single diagnostic block were 45%, 42%, and 45% for the cervical, thoracic, and lumbar regions, respectively.[85]

Although Cohen and colleagues[86] showed that treatment results after medial branch neurotomies were not changed by requiring a placebo control, the current published standard of interventional societies requires a confirmatory block before making a diagnosis of zygapophyseal joint–mediated pain.[17] The best-studied double-block protocol requires a difference in pain relief that is of concordant duration to the duration of action of the local anesthetic used to anesthetize the medial branch nerves—typically, greater than 2 to 3 hours for lidocaine and 4 to 6 hours for bupivacaine.[87,88] Because the goal is to have a placebo control and because consent and patient compliance issues hinder using a saline block control, one may argue that any prior diagnostic injection in which the patient reports no relief is a valid control block, especially because the patient and the physician were anticipating relief. Because many insurance companies in the United States no longer authorize or consider double blocks medically necessary, the occurrence of a previous "negative" block evaluation could be the negative control.

When the treatment is relatively benign, convincing relief with physician and staff testing after zygapophyseal joint or medial branch injections in an older patient with clinical symptoms consistent with zygapophyseal joint pain may not justify confirmatory injections.[86,89] A young patient who has little or no zygapophyseal joint abnormalities, who is on a significant dose of narcotics, and who reports less-than-convincing

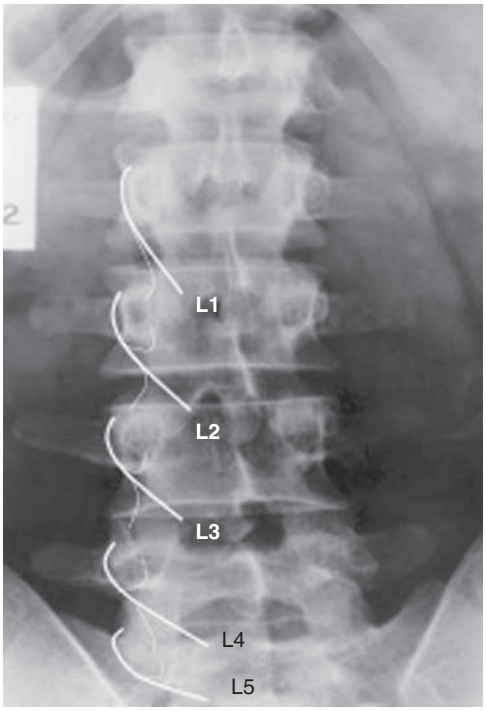

FIG. 16.2 Anteroposterior radiograph of the lumbar spine showing course of medial branches of L1–L4 dorsal rami, L5 dorsal ramus, and their articular branches to lumbar zygapophyseal joints. Medial branches are blocked at the junction of the superior articular process and transverse process. (From Bogduk N, ed. *Practice Guidelines for Spinal Diagnostic and Treatment Procedures.* San Francisco, CA: International Spine Intervention Society; 2004.)

approximately 80% relief should undergo a second confirmatory injection before considering interventional or surgical treatment based on the block results.

The rationale for how many levels and which levels to test is being debated. Levels are typically chosen based on known pain referral patterns, prevalence studies, and localized manual palpation. Using a comparative double-block control, Manchukonda and colleagues[85] found that, most often, two joints were symptomatic in the lumbar spine and three adjacent joints were symptomatic in the thoracic and cervical spine. The most logistically efficient and least costly method is to rule out zygapophyseal joint pain globally on the side or sides of the patient's pain and at the proximity of approximately two to three adjacent levels. One would inject (in the case of lumbar spine) the L2, L3, and L4 medial branch nerves and the dorsal ramus of the L5 nerve root in order to block the L3–L4, L4–L5, and L5–S1 zygapophyseal joints (Fig. 16.2 shows medial branch anatomy of the lumbar spine; Fig. 16.3 shows a lumbar medial branch block). If no relief occurred, there was no evidence that the higher joints were involved, and if one is confident that the zygapophyseal joints were denervated, one can eliminate zygapophyseal joint pain from the diagnosis. If the result is positive, one can perform more selected denervation on a confirmatory injection. Although this could be argued to be the most efficient method, many third-party payers in the United States limit injections to two levels per session.

A total of 0.5 mL of contrast dye is injected along the medial branch. SAP, superior articular process. (Courtesy Richard Derby, MD.)

Diagnostic Accuracy

The features of a test that indicate its diagnostic accuracy are sensitivity and specificity. From these measures, the false-positive and false-negative rates and predictive value can be derived. *Sensitivity* refers to the ability of the test to identify correctly patients with the disease. Several factors that affect sensitivity should be discussed. Vessels accompany the medial branch as they course around the waist of the superior articular pillar, and injecting local anesthetic into a vessel rather than around the nerve may cause a false-negative response.

Kaplan and colleagues[90] reported that medial branch blocks may fail because of venous uptake. Venous uptake occurred in 7 of 20 (35%) medial branch blocks. If venous uptake was encountered, repositioning of the needle resulted in joint anesthesia only 50% of the time. When venous uptake was encountered, the subjects were brought back for a later injection. These findings stress the importance of using contrast medium for medial branch blocks and carefully observing the flow pattern. Kaplan and colleagues[90] also found that in 11% of cases they were unable to anesthetize the joint, even in the absence of venous uptake. Medial branch blocks in the lumbar spine would have an 11% false-negative rate. This may have been due to anomalous or collateral zygapophyseal joint innervation or insufficient volume of local anesthetic reaching the target nerve, which may be shielded by an ossified mamalloaccessory ligament. This occurs in approximately 10% of patients.[91,92]

Rarely discussed is the consistency with which one may expect a longer duration of action of bupivacaine versus lidocaine. Although bupivacaine has a longer duration of action than lidocaine, the mass of drug reaching the nerve is the most important variable, and one cannot guarantee that the same amount will be available on consecutive sessions. In addition, most patients are not kept in the recovery area for the duration of local anesthetic to be evaluated, and the duration depends on a patient's self-reporting, which may or may not be consistent between injections. Lord and colleagues[88] showed that, using a double-block comparative standard, 65% of patients failed to recognize the difference in duration of pain relief but did accurately distinguish a separate placebo-controlled block with saline. This underscores the importance of instructing the patient to keep a diligent pain diary for the 6 to 8 hours following diagnostic blocks and then to report this information the following day in order to minimize recall bias.

The crucial factors for specificity of the diagnosis of zygapophyseal joint pain are accurate targeting of the intended structure under fluoroscopy, confirmed by contrast medium, and the delivery of the appropriate volume of local anesthetic. Intraarticular joint blocks are specific, unless there is a medial capsular tear or injection of excessive volumes (>1 mL injected into a lumbar zygapophyseal joint or 0.3 mL injected into a cervical zygapophyseal joint), which may rupture the capsule and spread medially into the epidural space.[93,94] Many early studies of zygapophyseal joint intraarticular blocks used 2 to 8 mL per injection. When reviewing negative studies regarding zygapophyseal joint injections and the systematic reviews that still quote these studies, the discerning reader should check the total volume of injectant used.[94,95] Destouet and colleagues[94] found that volumes of injectant of 0.5 to 1.5 mL commonly ruptured the superior recess of the capsule and extravasated. In later studies, Destouet and colleagues[94] aspirated the 0.5 to 1.5 mL of contrast dye before adding local anesthetic and steroid. Cadaveric studies performed with variable volumes of methylene blue injected into the zygapophyseal joint (1–4 mL) showed that the dye extended not as expected into the paraspinal tissues but rather into the epidural space and around the spinal nerves.[96] Moran and colleagues[96] described the zygapophyseal joint capsule as thick dorsally, whereas anteriorly the zygapophyseal joint synovial membrane is contiguous with the ligamentum flavum and the adipose tissue in the superior recess is in direct contact with the adipose tissue around the spinal nerve. Clearly, extravasation of local anesthetic through the anterior aspect of the zygapophyseal joint capsule and subsequent anesthesia of potential pain generators outside of the zygapophyseal joint—such as the adjacent spinal nerve root, posterior longitudinal ligament, or sinuvertebral nerve—can potentially affect the diagnostic specificity of the block procedure.

In contrast, randomized controlled studies validate the specificity of medial branch blocks for relief of zygapophyseal joint–mediated pain.[97] To maintain the specificity of medial branch block, a low volume of local anesthetic is used to anesthetize a specific cervical[97] or lumbar medial branch.[90,93] If volumes greater than 0.5 mL are used, the close proximity of the lumbar lateral and intermediate branch to the medial branch potentially might increase false-positive rates by blocking paraspinal soft tissues (ligaments or muscles or both).[22,98] In addition, volumes greater than 0.5 mL on the superior edge of the lumbar transverse process may spread onto the dorsal and ventral spinal nerves.[37] Decreasing input into the central nervous system by anesthetizing any structure or nerve could relieve pain by decreasing or modulating

central input. Although this is a probable confounding factor, the reference typically cited is the study by North and colleagues,[99] which reported an unacceptably high false-positive rate for diagnostic blocks in patients with low back pain. The conclusion reached by that author group was that diagnostic blocks had limited specificity. Their protocol clearly lacked diagnostic specificity, however. They used an excessive 3 mL volume of bupivacaine for the medial branch blocks. Because 0.5 mL of local anesthetic placed too close to the superior edge flows onto the exiting root, the reported decrease in sciatic pain was more likely due to anesthetizing the spinal nerve and not a false-positive effect of neuromodulation.[93]

Because patients in the study by North and colleagues[99] reported an average relief of 75% to 80% after anesthetizing the sciatic nerve, operators must be aware that blocking this nerve anywhere along its course may result in the report of pain relief. As previously mentioned, relief of pain for the duration of the local anesthetic effect cannot distinguish between reversible inflammatory or compressive causes of pain and nonreversible neuropathic causes of pain.

Although North and colleagues[99] found that 3 mL of local anesthetic placed into muscles at several levels has relatively minimal effect on sciatic pain, some authors question whether anesthetizing the needle track increases false-positive responses.[22] Patients probably report more pain relief when the needle track is anesthetized. Rather than a false-positive response, one would expect better pain relief when patients are not experiencing lingering needle-related pain at the same time as pain relief resulting from anesthetizing the zygapophyseal joints.

Lumbar Spine: Zygapophyseal Joint Syndrome

History

In 1911, Goldthwait[100] reported that zygapophyseal joint asymmetry could cause lumbago, sciatica, and paraplegia. Ghormley[101] first coined the term *zygapophyseal joint syndrome* as a cause of referred pain and the sciatica resulting from direct nerve root compression by the zygapophyseal joint. Badgley[102] first described the zygapophyseal joint as an independent source of referred pain in greater detail. Mooney and Robertson[82] described "facet (zygapophyseal joint) syndrome" referral patterns by injection of hypertonic saline into the lumbar zygapophyseal joints of patients with positive diagnostic blocks. Subsequently, Mooney and Robertson[82] were the first to use radiographically guided intraarticular injections with local anesthetic and corticosteroid. They reported complete pain relief in approximately one-fifth of patients presenting with low back and leg pain. Dreyfuss and colleagues[93] were the first to describe an effective lumbar medial branch block technique. Using this technique, Kaplan and colleagues[90] showed that pain resulting from zygapophyseal joint capsular distention could be successfully blocked in approximately 90% of cases by medial branch anesthesia with 2% lidocaine versus saline.

Lumbar Zygapophyseal Joint Pain

Lumbar zygapophyseal joint pain is common and seems to become more prevalent as patients age and as the duration of chronic back pain increases. The prevalence is directly inversely correlated, however, to the stringency of the reference standard. Prevalence studies consistently find the zygapophyseal joint as a common source of pain, but diagnosis using a single anesthetic block has a potential high placebo rate versus a double-block comparative control requiring a longer duration of relief after lidocaine versus bupivacaine.

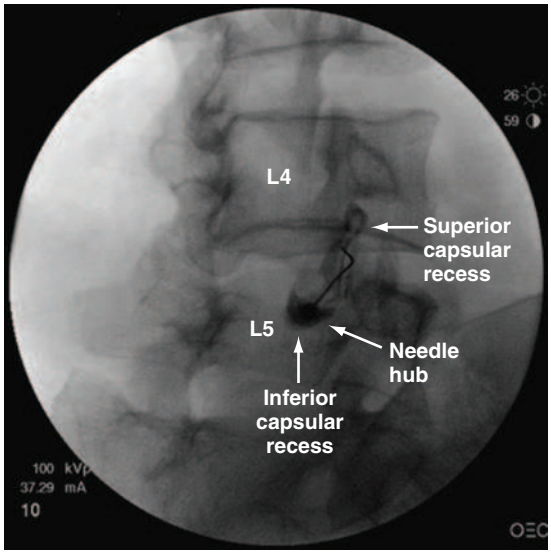

FIG. 16.4 Right L4–L5 zygapophyseal joint intraarticular injection. Note the filling of the superior and inferior subcapsular capsular recesses with contrast dye (*arrow*). The needle hub partially overlies the inferior capsular recess. (Courtesy Richard Derby, MD.)

Studies reporting the prevalence of zygapophyseal joint pain report figures ranging from 15% to 52%. In 1994, Schwarzer and colleagues[103] established the prevalence of zygapophyseal joint pain using a double-block comparative protocol in 96 patients with a mean age of 38 years and mean duration of low back pain of 16 months mostly secondary to work-related injuries and trauma presenting to two tertiary US clinics. (Fig. 16.4 shows a lumbar intraarticular zygapophyseal joint block.) These authors found that the combination of discogenic pain and zygapophyseal joint pain is uncommon. In a group of 176 patients, 47% had initial relief with a screening lidocaine block, but only 15% had 50% or greater relief with a confirmatory block.

Manchikanti and colleagues,[104] also using a double-block protocol but requiring 75% pain relief and a differential response, reported an even higher initial response of 81 of 120 (67.5%) to lidocaine medial branch blocks and a much greater percentage (45%) of the total reporting longer 75% relief after confirmatory bupivacaine medial branch blocks. This patient group was older than Schwarzer's group, however, with a mean age of 47 years and with a longer mean duration of low back pain of 47 months. The false-positive rate for one block was 41%. In a later study, Manchikanti and colleagues[105] revised the prevalence of zygapophyseal joint pain downward from 45% to 27% (95% confidence interval [95% CI], 22–32%). Schwarzer and colleagues[106] studied an older group of patients with a mean age of 57 years referred to an Australian rheumatology clinic with low back pain for an average of 7 years. A

diagnosis of zygapophyseal joint pain was made in 40% (95% CI, 27–53%). Requiring 90% relief of original pain, the prevalence was 32%; requiring 100% relief, the prevalence was 11%. Manchikanti and colleagues[105] reported an even higher prevalence of 52% zygapophyseal joint pain in a group of patients 65 years old or older.

No consistent history, physical examination, or imaging findings correlated to positive block responses have been found. In the early 1980s, uncontrolled single, variable injectant volume, intraarticular zygapophyseal joint injections were used as the reference standard for identifying lumbar zygapophyseal joint pain; these authors reported correlations with various history or physical examination findings.[52,107] Some studies[108,109] reported that a cluster of five of seven features (*Revel criteria*) could predict a 75% decrease in pain after a single intraarticular block. The seven items in the cluster are age older than 65 years, pain well relieved by recumbency, no exacerbation of pain with coughing and sneezing, no exacerbation of pain with forward flexion, no exacerbation of pain with extension, no exacerbation of pain with rising from flexion, and no exacerbation of pain with the extension-rotation test. Subsequent well-conducted studies did not replicate these studies.[32,110] As mentioned, most of these earlier studies used single medial branch blocks, which have been reported to have 25% and 38% false-positive rates for the diagnosis of zygapophyseal joint pain.[111,112]

Newer studies of clinical correlations refined the technique with an appropriate injectant volume and a confirmatory double-block paradigm with either a second intraarticular injection or a medial branch confirmatory injection with bupivacaine lasting longer than the pain relief after a prior lidocaine block[30,96,106,111,113–115] These studies did not find any clinical correlates with history or physical examination. In particular, extension and rotation were not predictive of response. A systematic review of all published studies comparing clinical outcome after local anesthetic blocks and clinical signs and symptoms found no consistent clinical features with a high specificity.[12] The review found several clinical features with a high sensitivity, however, which may be cautiously used to *exclude* the diagnosis of zygapophyseal joint–mediated pain. These features include pain not increased with cough, pain not relieved with recumbency, and pain that can be centralized.[50] There are no consistent reproducible history or physical examination criteria that predict a positive response to a zygapophyseal joint block. History and physical examination are better at ruling out zygapophyseal joint–mediated pain than diagnosing zygapophyseal joint pain.

The current best evidence also shows that radiologic imaging, with a few more recent exceptions, does not correlate with response to zygapophyseal joint blocks. Conflicting evidence that radiologic imaging may predict outcome from uncontrolled lumbar zygapophyseal joint blocks may be partially due to lack of rigor in the reference standard used to define a positive response in earlier studies.[22] In 1979, Carrera[115] reported that 73% ($n = 63$) of patients describing pain relief after uncontrolled intraarticular injection of 2 to 4 mL of local anesthetic had CT evidence of lumbar zygapophyseal joint disease versus 13% who had no evidence of disease. It is well accepted, however, that injectant volume should not exceed 1 mL; otherwise, the injection loses specificity, with a leak/extravasation of local anesthetic and potential contact with the adjacent spinal nerve root or other possible pain generators located outside of the zygapophyseal joint, as described earlier.[96]

A large study by Jackson and colleague[116] of 390 patients found no relationship between imaging and pain relief after uncontrolled intraarticular lumbar zygapophyseal joint injections. Supporting the findings by Jackson and colleagues,[116] Schwarzer and colleagues,[106] in the only study using placebo-controlled injection, found no correlation between CT findings and a positive response comparing local anesthetic with saline blocks in 63 patients when more stringent criteria of controlled injections were used as the reference standard. Similarly, Cohen and colleagues[117] found no relationship in 192 patients between MRI findings of zygapophyseal joint hypertrophy or degeneration and response to medial branch neurotomies based on positive response to a single medial branch block. Kawaguchi and colleagues[118] likewise found no significant relationship between low back pain symptoms and radiographic abnormalities in a group of 106 patients with rheumatoid arthritis.

The intriguing bright spot on the horizon is the finding that where MRI or single photon emission computed tomography (SPECT) shows imaging findings consistent with either "inflammation" or "edema," a stronger correlation emerges (Fig. 16.5). Although not confirming the diagnosis of zygapophyseal joint pain with a reference standard, Friedrich and colleagues[119] more recently found that an estimated 14% (21 of 145) of patients with low back pain had MRI evidence of zygapophyseal joint edema, and follow-up MRI scan showed "almost perfect" agreement between change in pain and a reduction in intensity of edema on sagittal short-tau

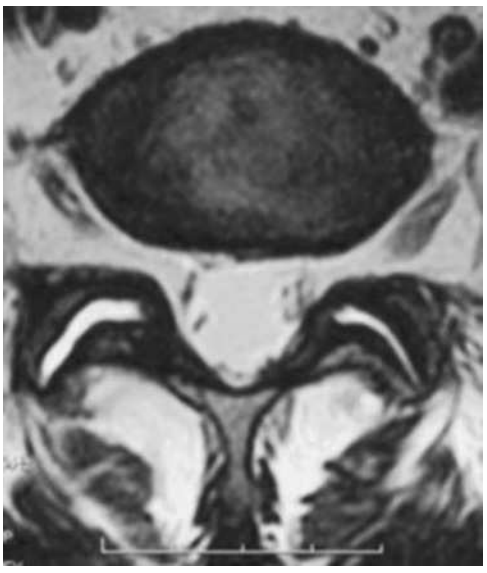

FIG. 16.5 L5–S1 axial T2-weighted magnetic resonance image showing zygapophyseal edema (right greater than left), suggestive of instability. In the upright weight-bearing position, anterolisthesis was noted; in the unloaded supine position, anterolisthesis reduced and zygapophyseal joints are gapped and filled with fluid. (Courtesy Richard Derby, MD.)

inversion recovery images. Radionuclide bone scintigraphy detects bone areas with synovial changes (inflammation or hyperemia) or increased osteoblast activity and degenerative regions with a high degree of remodeling. Osteophytes in the process of growing show a high degree of bone scan activity. As mentioned earlier, a positive lumbar SPECT scan predicts a statistically significant reduction in pain after zygapophyseal joint blocks.[33]

Zygapophyseal Joint Pain Referral Maps

Pain referral patterns have been studied using stimulation of patients during provocative diagnostic injections[120] by injection of hypertonic solutions into normal and abnormal subjects[121] or by electrical stimulation of medial branches.[120,121] Most studies showed distinct but overlapping referral areas; it is likely that the pain referral patterns obtained in normal volunteers are smaller because of less sensitization. There are also limits to the referral maps; Mooney and Robertson[121] reported on lumbar zygapophyseal joint referral maps in normal volunteers and subjects with a positive diagnostic zygapophyseal joint block (Fig. 16.6). Under fluoroscopic guidance, they injected contrast dye (unspecified volume) followed by 3 to 5 mL of hypertonic saline. Some of the distal extremity pain seen in the diagrams may be due to excessive volume of saline with irritation of the sciatic nerve roots. Given the lack of sensitivity and specificity of history, physical examination, and imaging and until more research is performed with finite injectant volumes (in patients with confirmed dual positive blocks), these referral maps can be used as a starting point to guide selection of levels to be injected.

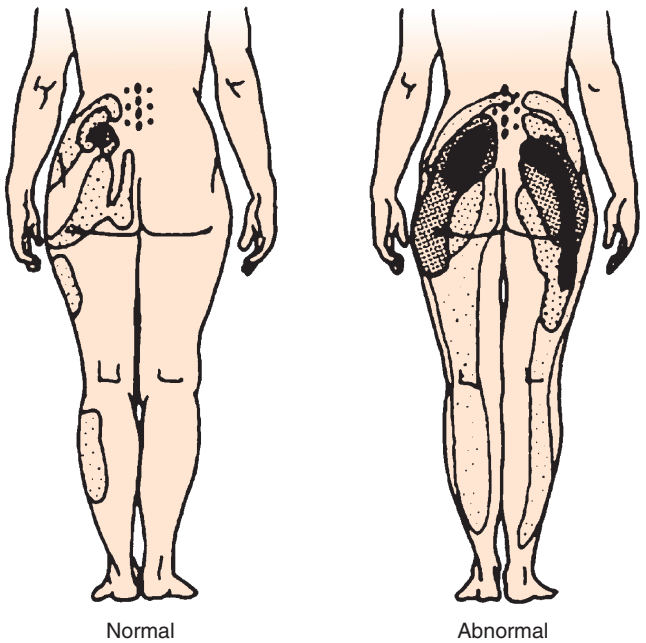

FIG. 16.6 Pain referral patterns for asymptomatic (normal) and symptomatic (abnormal) subjects obtained by intraarticular zygapophyseal joint injection of contrast dye followed by 3 to 5 mL of hypertonic saline. Predictive Value

How useful are diagnostic zygapophyseal joint injections? The predictive value of any spinal diagnostic test directly varies with the rigorousness of test standards and the inherent ability of that treatment to alleviate the source of pain without creating new sources unrelated to the original cause or causes. A positive test is valuable if it can guide treatment and obtain better outcomes than not using the diagnostic test at all. A systematic review of the evidence for treatment of zygapophyseal joint pain is beyond the scope of this chapter; however, a case is made for the therapeutic utility of zygapophyseal joint blocks.

Historically, lacking robust studies, guideline and systematic review articles have been relegated to quoting studies with methodologic flaws as implied evidence that one need not diagnose zygapophyseal joint–mediated pain before surgery.[24,98] There is no reason that a variable amount of relief after uncontrolled, variable volume, intraarticular zygapophyseal joint blocks should predict fusion outcomes using surgical fusion techniques from the 1980s in a group of patients being operated on for various unknown or unstated reasons. Jackson[122] correlated relief after spinal fusion in 36 patients from 1980 to 1988 to results of a single intraarticular zygapophyseal joint injection with 1.5 mL of local anesthetic and an unknown volume of contrast dye. Of the patients, 85% had "some improvement" with an average relief after injection of 29%. The authors found no relationship between fusion surgery performed for unstated reasons and a "favorable response" to zygapophyseal joint injection. The surgeries were presumably performed not because the authors believed the patients' symptoms were due to their zygapophyseal joints. The surgical results based on their "mean pain and functional assessment scores" also seemed to improve by significantly less than 50%, suggesting poor patient selection.

An important historical study, published by Esses and Moro in 1993,[123] is often quoted to refute the therapeutic utility of zygapophyseal joint blocks; however, it warrants a careful, critical review. These authors concluded that single intraarticular diagnostic zygapophyseal joint injections "should not be used in determining treatment because they are not predictive of either surgical or nonsurgical success." This study had significant methodologic shortcomings, which limit the validity of the authors' conclusions. First, the study was retrospective, with patients surveyed by telephone approximately 5 years after surgery. Second, 1.5 mL of local anesthetic was injected into the zygapophyseal joints, and no mention is made of the volume of contrast dye needed to confirm needle position; the injections likely were nonspecific because of zygapophyseal joint capsule rupture from excessive volume (>1.5 mL). Third, the patient population was markedly heterogeneous, with significant confounding factors: an average duration of back pain of 8 years and approximately 40% of patients with a history of prior surgeries, including failed fusions. More than 50% of patients underwent three-level, four-level, or five-level fusions, which are known to have a worse outcome than single-level or two-level fusions. Fourth, of the 82 patients who underwent surgery, 36 (44%) had 0%

relief from zygapophyseal joint injections. Almost half of the patients undergoing surgery had no relief from diagnostic blocks. Eight of 19 (42%) of the patients with complete relief after zygapophyseal joint injections declined surgery, leaving only 11 of 82 (13%) patients who underwent surgery who had 100% relief from zygapophyseal joint blocks. The remaining 35 of 82 patients (43%) had "partial but significant relief" (the exact percentage relief is not reported). Fifth, 30 of 82 (37%) patients had prior surgeries (laminectomy, discectomy, and fusion). It is well known that patients with failed back surgery syndrome often fare poorly with repeat surgery. Also, during the 1980s, diagnosis of the etiology of failed back surgery syndrome was elusive and might not be corrected by a posterior arthrodesis. For failed back surgery syndrome, zygapophyseal joint pain comprises only 3% of cases; the most common diagnoses are foraminal stenosis (25–29%), painful disc (20–22%), pseudarthrosis (14%), neuropathic pain (10%), recurrent disc herniation (7–12%), and sacroiliac joint pain (2%).[124]

Next, Esses and Moro[123] did not match the surgery to specific zygapophyseal joint levels blocked. Patients had either one-level or two-level zygapophyseal joint blocks, yet the following posterior fusions were performed: 20 single-level; three two-level; 10 three-level; four four-level; and 12 five-level or greater, including thoracic spine (wherein zygapophyseal joints were never blocked). Finally, significant questions arise regarding the efficacy of the surgical intervention because there was no significant difference between surgical and nonsurgical outcomes. As reported, only approximately one-third of patients in either the surgical or the nonsurgical group had a good outcome. Because of methodologic flaws and limitations of the Esses and Moro study,[123] zygapophyseal joint intraarticular injections cannot be impugned as either predictive or nonpredictive of surgical success.

In another observational study, Lovely and Rastogi[125] required a "positive response" to intraarticular injection of greater than 70% relief after bupivacaine zygapophyseal joint block for 6 hours and required a confirmatory response on two subsequent injections. Of 28 patients, 23 had a good to excellent outcome after fusion surgery; however, large volumes of 3 to 5 mL were used during the blocks, making interpretation difficult. At present, there is no research regarding the utility of cervical or thoracic zygapophyseal joint blocks as presurgical screening tests.

By comparison, when a specific treatment is directed at a cause of pain originating from the zygapophyseal joint, accurate diagnostic testing does matter. In a more recent study, researchers reported that when a putative inflammatory cause of lumbar zygapophyseal joint pain was confirmed using a positive SPECT scan, a positive response (a significant reduction in pain) was clearly predicted with intraarticular and pericapsular steroids at 1 and 3 months compared with subjects with negative scans or routine care.[33]

In contrast to diagnostic intraarticular zygapophyseal joint injections, evidence supports the use of diagnostic medial branch nerve blocks (MBBs) as the criterion standard to diagnose zygapophyseal mediated pain.[17,126] Using controlled blocks and progressively stringent pain relief requirements for a positive block incrementally decreases the potential false-positive rate and improves results for a well-validated treatment for zygapophyseal joint pain, medial branch neurotomy.[17,126–128]

Most consensus standards for diagnosis of zygapophyseal-mediated pain require at a minimum 70% to 80% reported pain relief for the duration of the local anesthetic obtained in two separate sessions.[17,126] In particular, Dreyfuss and colleagues,[129] studied patients who obtained greater than or equal to 80% relief from MBBs selected to undergo lumbar radiofrequency neurotomy. At 12 months, 60% of the patients obtained at least 90% relief of pain, and 87% obtained at least 60% relief. Dreyfuss and colleagues[129] concluded that lumbar medial branch neurotomy is an effective means of reducing pain in patients carefully selected on the basis of controlled diagnostic blocks. A high-quality study randomized controlled trial evaluating radiofrequency neurotomy in patients with chronic low back pain[130] used three positive blocks in the inclusion criteria and a "sham radiofrequency" procedure for comparison; statistically significant reduction in pain and improvement in various quality-of-life variables were obtained. In another study, when the diagnosis is confirmed by relief of pain for greater than 3 months after medial branch neurotomies, repeat neurotomies are successful in greater than 75% in the lumbar and cervical spine.[131,132] More recently, Derby et al. used percent pain relief following MBB in 10% increments, finding a statistically favorable outcome for medial branch neurotomy using an MBB protocol requiring 70% or greater reported pain relief for the duration of the local anesthetic recorded on two separate sessions (double-block protocol).[127] Using a single-session protocol, 80% or greater report of pain relief predicted favorable medial branch neurotomy outcome, albeit less favorable than the two-session protocol.[127,133]

In regard to newer surgical treatments, the development and perfection of procedures such as minimally invasive zygapophyseal joint fusions or various types of total and subtotal arthroplasties require accurate diagnosis along with stringent criteria for success. The many confounding variables and often-reported weak results of current spinal fusion and arthroplasty techniques make disproving these results relatively easy. The diagnosis of zygapophyseal joint pain employing strict double-block or placebo-controlled standards should perhaps be used to restrain a surgeon from offering a circumferential (360 or 280 degrees) segmental fusion or arthroplasty. The failure to confirm zygapophyseal joint pain is perhaps even more important because doing so leaves other sources of pain that may be better suited to a particular surgical technique or limits the number of levels needing stabilization.

Cervical Spine Zygapophyseal Joint Syndrome

History

The cervical zygapophyseal joints are known to be sources of persistent chronic pain and central sensitization.[134,135] In 1940, Hadden[136] described pain from zygapophyseal joints causing headache. In the 1970s, Macnab[137] described pain arising from the zygapophyseal joints after whiplash injury. Bogduk and Marsland[138] devised a technique to block the

third occipital nerve, which relieved neck pain and headache stemming from the C2–C3 zygapophyseal joint in 70% of patients. Headache arising from C0–C1 or C1–C2 joints has also been described.[139,140] Bogduk and Marsland[141] were also the first to describe medial branch blocks for all cervical spine levels. They studied patients presenting with idiopathic neck pain and reported that medial branch block and intraarticular blocks provided complete, temporary relief of pain for 70% of patients.

Cervical Zygapophyseal Joint Pain

Based on the confirmatory block paradigm, the cervical zygapophyseal joints are a common source of chronic neck pain; the prevalence of cervical zygapophyseal joint syndrome is greater than the prevalence of lumbar zygapophyseal joint syndrome. Cervical discogenic pain shares referral patterns with zygapophyseal joint pain, but it is far less common.[142] Based on comparative blocks of cervical zygapophyseal joints causing chronic neck pain with either associated headache or shoulder pain, the C2–C3 (36%) and C5–C6 zygapophyseal joints (35%) were the most common pain generators.[143] After whiplash injury, level I prospective clinical studies provide evidence that zygapophyseal joints are the most common source of chronic pain.[144,145] Cervicogenic headache stemming from the C2–C3 zygapophyseal joint after whiplash has a 53% prevalence.[144]

Often neglected are C0–C1 and C1–C2 joints in evaluation of upper neck pain and headache. Dreyfuss and colleagues[139] studied the referral patterns for the atlantoaxial and lateral atlantoaxial joints. In 2002, Aprill and colleagues[146] failed to confirm the null hypothesis that lateral atlantoaxial joints are *not* a common source of occipital headache. These investigators found that of 34 patients presenting with symptoms and signs of atlantoaxial joint pain, 21 obtained complete relief of headache after diagnostic injection of local anesthetic. Pain referral patterns have been defined in C2–C3 through C7–T1 zygapophyseal joints (Fig. 16.7).[147] Innervation of the cervical zygapophyseal joints is well described (Fig. 16.8).[147] The cervical zygapophyseal joints can be blocked either by MBBs or with intraarticular injections (Fig. 16.9).

Prevalence rates for neck pain originating from cervical zygapophyseal joints range from 36% to 60%. The false-positive rate for a single, uncontrolled block is 27% (95% CI, 15–38%).[148] The following prevalence rates (mean [95% CI]) are reported from studies using either a double-block or a triple-block paradigm (normal saline as a placebo): 54% (95% CI, 40–68%),[144] 36% (95% CI, 27–45%),[149] 60% (95% CI, 33–64%),[145] and 60% (95% CI, 50–70%).[150] Manchikanti and colleagues[151] restudied the prevalence of cervical zygapophyseal joint pain in a larger group of patients and found a similar 55% (95% CI, 49–61%) prevalence. In a study by Manchikanti's group in 2007,[85] of 438 patients requiring 80% relief of pain for 2-hour duration with lidocaine and 3-hour duration with bupivacaine, a 39% prevalence of zygapophyseal joint–mediated pain was demonstrated. Corroborating the high prevalence of cervical zygapophyseal joint pain, Yin and Bogduk[186] in a private practice clinic audit found a 55% prevalence of cervical zygapophyseal joint–mediated neck pain using a strict double-block comparative protocol. In a recent well-executed prospective outcome study, MacVicar et al.[152] further corroborated the diagnostic value of diagnostic MBBs. His study found that 100% pain relief following rigorously evaluated comparative MBBs predicted that between 61% to 74% of patients will obtain 80% or greater pain relief following cervical medial branch neurotomies for an average of 17 to 20 months after the primary procedure and an average of 15 months after repeat procedures.[152]

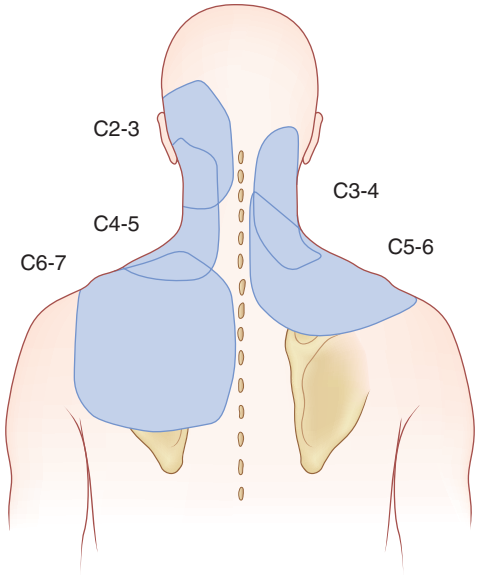

FIG. 16.7 Patterns of referred pain from cervical zygapophyseal joints in normal volunteers (From Dwyer A, Aprill C, Bogduk N. Cervical zygapophyseal joint pain patterns. Part 1: a study in normal volunteers. *Spine.* 1990;15:453–457.)

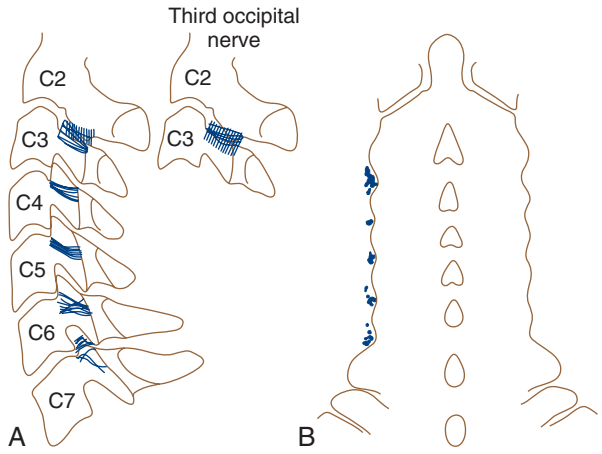

FIG. 16.8 (A) Lateral view of cervical spine showing variable locations of medial branches. At C3, the location of the C3 deep medial branch is shown. The *inset* shows the location of the third occipital nerve. The *shaded area* shows where the C3 deep branches and third occipital nerve overlap. The C5 medial branch is located in the middle of the articular pillar; at C6 and C7, medial branches are located progressively higher. (B) Anteroposterior view of the cervical medial branches. (From Bogduk N, ed. *Practice Guidelines for Spinal Diagnostic and Treatment Procedures*. San Francisco: International Spine Intervention Society; 2004.)

Similar to lumbar zygapophyseal joint pain, there are no high-quality studies showing a particular set of clinical features that can predict results of diagnostic cervical zygapophyseal joint blocks or MBBs.[153] With diagnosis by MBBs, one exceptionally skilled manipulative therapist was able to identify all 15 subjects with diagnostic block–proven symptomatic zygapophyseal joints and specify the correct symptomatic segment. None of the five patients with asymptomatic joints was misdiagnosed as having symptomatic zygapophyseal joints.[154] A later follow-up study by the same group failed to confirm the apparent high specificity and sensitivity, however, and reported a high sensitivity but low specificity and concluded that manual examination of the cervical spine lacks validity for the diagnosis of cervical zygapophyseal joint pain. In the study by Aprill and colleagues[146] of C1–C2 zygapophyseal joint pain as a source of occipital headache, only 60% of the patients shared clinical criteria that predicted a positive response to the block.

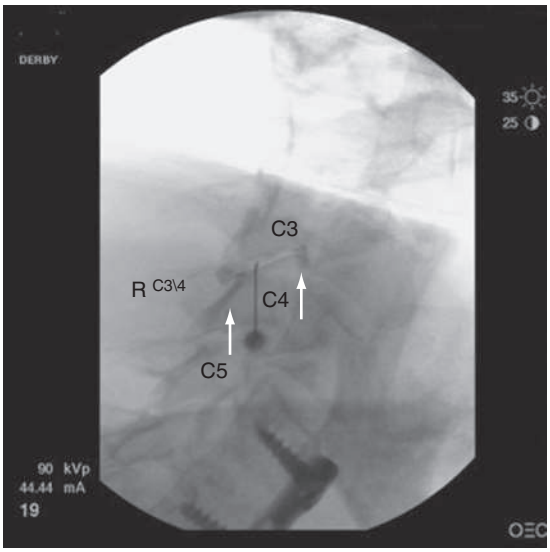

FIG. 16.9 Lateral fluoroscopic view of a C3–C4 zygapophyseal joint injection using a 3.5-inch, 25-gauge needle. Note contrast dye in posterior and anterior capsular folds (*arrows*). (Courtesy Richard Derby, MD.)

Advanced imaging has not been correlated with positive responses to diagnostic blocks. Hechelhammer and colleagues[155] found no relationship between short-term pain relief after cervical intraarticular and pericapsular injection of local anesthetic and corticosteroid and the degree of osteoarthritis graded on a CT scan.

Thoracic Spine

The prevalence of patients who complain of chronic upper back or mid-back pain ranges from 3% to 22%.[32,156,157] One survey study of 35- to 45-year-old patients estimated the prevalence of thoracic pain to be 15%.[158] Thoracic zygapophyseal joint pain referral patterns have been reported (Fig. 16.10).[159,160] Thoracic medial branch anatomy has also been described (Fig. 16.11).[161] However, it must be acknowledged that a "thoracic zygapophyseal joint syndrome" has not been described in detail relative to the cervical and lumbar zygapophyseal joint syndromes outlined earlier. Given the relative lack of mobility in the sagittal plane (i.e., flexion and extension) at the thoracic zygapophyseal joints due to their relatively coronal orientation, less loading stress occurs at these levels

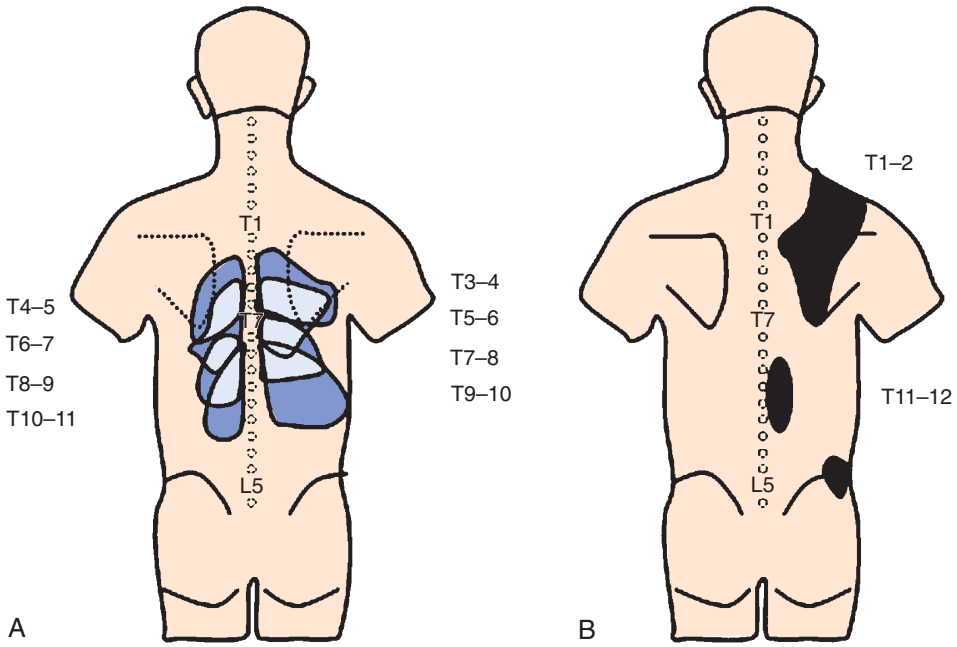

FIG. 16.10 Maps of referred pain patterns in segments indicated. (A) Based on Dreyfuss et al.[139] in normal volunteers. (B) Based on Fukui et al.[160] in patients with single positive zygapophyseal joint block. (From Bogduk N, ed. *Practice Guidelines for Spinal Diagnostic and Treatment Procedures.* San Francisco: International Spine Intervention Society; 2004.)

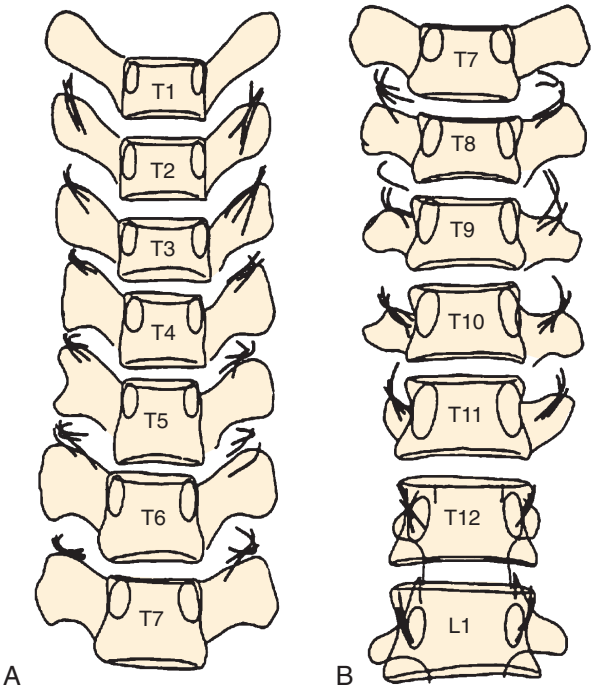

FIG. 16.11 (A–B) Composite sketch of work by Chua and Bogduk[161] with radiographs of cadaveric thoracic spines. Medial branches of thoracic dorsal rami marked with wires to depict location with respect to transverse processes. (From Bogduk N, ed. *Practice Guidelines for Spinal Diagnostic and Treatment Procedures.* San Francisco: International Spine Intervention Society; 2004.)

relative to the cervical and lumbar zygapophyseal joints during extension movements and postures.[162,163]

There are no pathognomonic clinical or radiographic findings by which thoracic zygapophyseal joint pain may be diagnosed.[164] As with the cervical and thoracic spine, diagnosis is by suspicion and, at a minimum, the pain pattern should correlate with established pain referral maps.[147] The methods that physicians apply clinically to the diagnosis and treatment of thoracic zygapophyseal joint pain rest largely on research done in the lumbar and cervical spine. This is not an entirely unreasonable approach based on what clinicians know in general regarding zygapophyseal joint anatomy and innervation; however, more research is needed.

Investigators have mapped out the referral patterns for the thoracic joints. These findings are often used as a starting point to select which thoracic zygapophyseal joints to block.[159,160] Dreyfuss and colleagues[159] mapped out thoracic zygapophyseal joint referral patterns in normal volunteers and found that capsular distention did not provoke pain in 27.5% of volunteers. Fukui and colleagues[160] mapped out referral patterns in patients with suspected thoracic zygapophyseal joint pain who had a positive response to local anesthetic in C7–T1 to T2–T3 and T11–T12 zygapophyseal joints. There was considerable overlap between the C7–T1 and T2–T3 thoracic joints; thus, pain maps from these joints are not considered reliable enough to identify the symptomatic segmental level. Dreyfuss and colleagues[159] studied nine asymptomatic volunteers who underwent 40 provocative thoracic

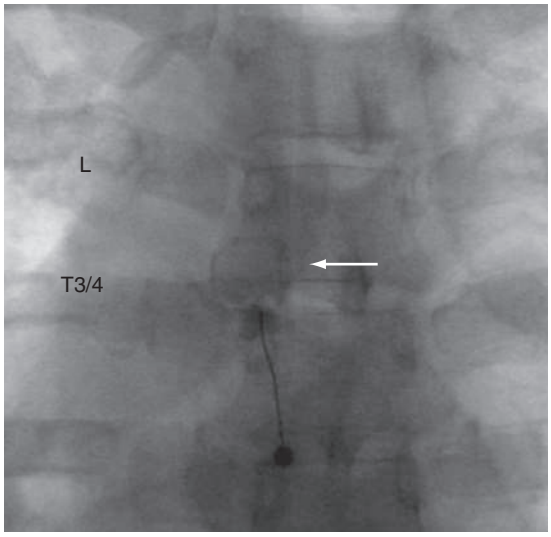

FIG. 16.12 Left T3–T4 zygapophyseal joint intraarticular injection. Note circular zygapophyseal joint arthrogram (*arrow*). (Courtesy Richard Derby, MD.)

zygapophyseal joint injections from T3–T4 to T10–T11. Referral patterns were consistently unilateral. The area of the most intense pain for segments from T2–T3 to T11–T12 was one level inferior and lateral. Significant overlap occurred over three to five levels. The researchers found that needle position can be confirmed with 0.1 to 0.3 mL of contrast dye, and adequate blocks can be achieved with a volume of 0.5 to 0.6 mL. Normally, thoracic zygapophyseal joints cannot hold more than 0.75 mL (Fig. 16.12 shows a typical thoracic zygapophyseal joint block).[17]

One research group has performed the three studies in the literature using a controlled, double-block paradigm, requiring 75% to 80% relief based on the duration of the local anesthetic used.[105,165,166] Combining all three studies with patients presenting with chronic middle or upper spinal pain (n = 183), using dual blocks obtains a 40% prevalence of thoracic zygapophyseal joint syndrome, with a false-positive rate of 42% if using a single-block paradigm.[28]

What is the predictive value of a positive dual block? In other words, how well do patients fare who have positive dual blocks and undergo therapeutic intervention? Research is limited in this regard. One systematic review[28] reported that only therapeutic thoracic MBBs received a 1A or 1B/strong recommendation. Manchikanti and colleagues[167,168] performed two studies. In the first study, 55 consecutive patients were studied; greater than 70% of patients had statistically significant relief (defined as >50% relief) at 3, 6, and 12 months. Most patients received four injections of bupivacaine with or without 1 mL of Sarapin and 1 mg of methylprednisolone per milliliter of solution with 1 to 1.5 mL of solution injected per nerve. In the second study of 48 patients with positive dual blocks, 24 patients received bupivacaine, and 20 patients received bupivacaine plus betamethasone. Statistically significant (>50%) pain relief was reported in both groups at all time points up to 1 year. In the systematic review of radiofrequency neurotomy, only two studies were on thoracic medial branch neurotomy; however, both were of low quality and failed to meet inclusion criteria for the review because of

lack of diagnosis by controlled blocks, small patient sample, and other methodologic shortcomings.[28] More research is needed in regard to diagnosis and treatment of thoracic pain so that the evidence can be graded and systematically reviewed, the caveat being that a lack of evidence is not equivalent to no evidence.

Summary

Chronic disabling spinal pain in a patient suggestive of "facet (zygapophyseal joint) syndrome" that is unresponsive to usual care may be considered for diagnostic comparative MBBs, with low-volume MBBs favored due to superior evidence for diagnostic specificity. The levels to be investigated are typically chosen by pain referral patterns described by the patient, which are correlated with validated zygapophyseal joint pain referral patterns. Upper neck pain and headache are most commonly caused by the C2–C3 zygapophyseal joint, and neck pain with shoulder girdle pain is most commonly caused by the C5–C6 zygapophyseal joint. The clinician should not neglect the C0–C1 and C1–C2 articulations as potential pain generators, in which case diagnostic intraarticular blocks would be used to help confirm or refute the diagnosis. Evaluation of the exact level of thoracic zygapophyseal joint pain can be more challenging because pain may be referred over more than three segments. Lumbar zygapophyseal joint referral patterns are also reported in the literature; zygapophyseal joint pain may be localized or referred to the buttocks and lower extremity.

Although comparative double blocks are considered the reference standard for diagnosis, routine history, physical examination, radiographs, and advanced imaging should be obtained for completeness. The clinician often finds elements that rule out zygapophyseal joint syndrome and are more suggestive of disc pathology, radiculopathy, or "red flag" conditions that require different diagnostic and treatment methods. There are also cases in which a history of trauma, particularly whiplash, is highly suggestive of pain of zygapophyseal joint origin, with a known greater than 50% prevalence in the cervical spine. Certain specific imaging findings, if present, also may suggest zygapophyseal joint syndrome, such as a positive SPECT scan, approximately 2 mm edema on axial MRI of lumbar zygapophyseal joints, or a single zygapophyseal joint with markedly deforming arthropathy compared with other joints.

With regard to testing protocol, whether to perform MBBs, intraarticular zygapophyseal joint injections, or both varies depending on the situation and preference of the physician. If one is confirming zygapophyseal joint–mediated pain in preparation for possible medial branch neurotomy, one could argue that MBB should be the method of choice due to improved specificity. If radiofrequency denervation of the zygapophyseal joint is not planned or SPECT scan imaging shows edema, intraarticular block is reasonable. In the case of C0–C1 and C1–C2, intraarticular injections are the only practical method of diagnosing zygapophyseal joint pain.

As noted earlier, preprocedural and postprocedural evaluation should be performed by unbiased personnel and checked by the physician using standardized instruments. Evaluation after the procedure includes VAS of standard provocative maneuvers and positions, as well as a report of subjective percent relief of pain. Ideally, the patient would be tested at approximately 30 minutes after lidocaine block and approximately 40 to 60 minutes after bupivacaine block. Ideally, a pain diary over the 6 to 8 hours following the block procedure is recorded by the patient and then reported the following day in order to decrease recall bias. However, retesting at 2 to 3 hours postinjection is a more reliable protocol. A subject should have at least 70% to 80% relief for a positive response to be considered; at least 80% relief is more convincing. Usually, two to three levels are evaluated per session. Depending on the importance of refuting or confirming whether a particular zygapophyseal joint is symptomatic, one may select fewer joints if needed.

Several technical parameters must be met to obtain useful diagnostic information. Diagnostic volumes must be appropriate. Contrast medium will confirm accurate target identification. For intraarticular zygapophyseal joint blocks, injection volumes should be limited to 0.3 mL, 0.75 mL, and 1 mL in the cervical, thoracic, and lumbar spine, respectively. For MBBs, needle position may be confirmed with injection of a small volume (0.3–0.5 mL) of contrast dye and the same volume of local anesthetic. The interventionalist should observe for venous uptake or undesirable flow patterns. If there is venous uptake, there is only a 50% chance of successfully anesthetizing the joint; thus, the interventionalist may consider bringing the patient back at a later date or interpreting the results of the block accordingly.

Infection may occur after any interventional procedure. Various infections are reported after zygapophyseal joint injections, including paraspinal abscess,[169] zygapophyseal joint abscess,[170] osteomyelitis,[171] and epidural abscess.[172] In addition to infections, subdural injections or injection into the spinal cord may occur. A case of transient tetraplegia[173] was reported during a cervical zygapophyseal joint injection performed without fluoroscopy and most likely was an accidental subdural injection of local anesthetic. Even when using fluoroscopy, there is a risk of accidental subdural injection or potential spinal cord injection. The danger is especially real when performing cervical intraarticular injection using a lateral technique. Using this technique, the needle is passed laterally using a lateral fluoroscopy view. If the anteroposterior view is not periodically checked, one may not recognize passage of the needle through the zygapophyseal joint and dura and then into the cord. In a thin individual, the cord may be reached with a 1-inch needle. Keeping the needle directly over the inferior or superior zygapophyseal joint and touching the bone before entering the joint helps the interventionalist avoid accidentally entering the spinal canal.

Sacroiliac Joint

With the gradual acceptance of local anesthetic block relief after fluoroscopy-guided sacroiliac joint blocks as the reference standard for diagnosis, there is a renewed interest in the sacroiliac joint as a legitimate source of chronic pain.[26] The degree of impact on health is the same as that of radiculopathy,

as evidenced by statistically similar scores in health-related quality-of-life testing instruments between patients with a diagnosis of sacroiliac joint pain and patients with a diagnosis of radiculopathy.[161]

Similar to zygapophyseal joint and discogenic pain, the diagnosis of sacroiliac joint pain depends on the reference standard used (and the particular population studied) to confirm the diagnosis. Society guidelines most often require a placebo control or differential blockade with 50% to 90% relief.[3,147,174] Typically, a differential duration of reported pain relief of lidocaine (approximately 2–3 hours) compared with bupivacaine (approximately 4–6 hours) is required. Although concordant provocation of pain during joint arthrography has been used as an additional requirement, the high percentage of asymptomatic patients reporting pain during sacroiliac joint injection implies that provocation has a high false-positive potential. Currently, using the dual-block paradigm, the best estimates of prevalence of sacroiliac joint–mediated pain in patients with low back symptoms range from 10% to 38%, but the lower end of this range is likely most accurate.[175,176] For single, uncontrolled sacroiliac joint injections, the false-positive rate is 20% to 54%.[177–181]

Pathophysiology

The sacroiliac joint has long been recognized as a synovial, fluid-filled diarthrodial joint between the sacrum and ilia with thick, 6-mm sacral cartilage and thinner, approximately 1-mm iliac cartilage (Fig. 16.13). The joint is auricular or C-shaped, with the convex side of the "C" facing anteriorly and inferiorly (Fig. 16.14).[182] Although the anterior portion is no more than a thickened capsule, the posterior capsule blends into the extensive, thick posterior ligamentous structures, which bind the sacrum to the spine and bilaterally to the ilia. After puberty, the iliac surface develops a convex ridge and the sacral surface develops a corresponding concave depression. These articular surfaces allow slight movement between the contiguous bony surfaces.

Although early in life gliding motions in all directions are permitted, by the middle of the second decade of life, the joints develop prominent ridges centrally along the entire length of the iliac surface and a corresponding groove along the sacral surface. Bowen and Cassidy[182] believed that this interdigitation of the joint surfaces restricts motion to a sagittal rotation or posterosuperior-anteroinferior "nodding" along the crest of the interdigitations. The motion is complex, however, and usually limited to less than 4 degrees of rotation and less than 1.6 mm of translation. Significant motion occurs only after severing the interosseous ligament.[183] It is unclear whether a type or degree of sacroiliac joint motion causes pain in older individuals. Beyond the sixth decade, cadaveric specimens commonly show a central region of ossification of the interosseous sacroiliac ligament and the presence of ridges and depressions, which likely result in little to no movement of the sacroiliac joint in these older individuals.[184] Although there is restriction by periarticular osteophyte formation, intraarticular bony ankylosis appears rare.[182]

Several investigators have studied the innervation of the sacroiliac joint. Nakagawa[185] reported innervation from the ventral rami of L4 and L5; the superior gluteal nerve; and the dorsal rami of L5, S1, and S2. An anatomic dissection of the innervation of the sacroiliac joint was performed by Yin and colleagues[186] for the purpose of defining the exact position of the nerves for "sensory stimulation–guided sacroiliac joint radiofrequency neurotomy." These authors dissected cadavers and placed small-gauge wires adjacent to the lateral branch nerves entering the joint and over the dorsal sacrum to the dorsal sacral foramen from S1 to S3. In 1988, Willard[187] reported dissection of 10 cadavers, which revealed that the S1 and S2 lateral branches provide the primary innervation of the sacroiliac joint and associated dorsal ligaments. An occasional contribution was found by S3 but not S4. Predominant

innervation from lateral branches of S1 was also reported by Grob and colleagues.[188] These authors found that dorsal nerves derived from S1–S4 exclusively innervated the sacroiliac joint and associated ligaments. Nerves were distributed to superficial and deep dorsal sacroiliac ligaments and to the sacrotuberous and sacrospinous ligaments. Emerging from the sacral foramen, the nerves course laterally, sandwiched between superficial and deep portions of the sacroiliac ligaments. There is a great variability in the location and number of lateral branch nerves side to side and between individuals.[186] Due to this variability, the current standard for blocking the posterior sacroiliac joint as associated dorsal ligaments is to block the L5 dorsal ramus and S1–S3 lateral branches using a multisite, multidepth technique described by Dreyfuss and colleagues.[189]

Berthelot and colleagues[190] used the term *sacroiliac joint lato-sensu* to describe pain from the sacroiliac joint that may be emanating from adjoining ligaments rather than simply the synovial joint. These ligaments include the iliolumbar ligaments, dorsal and ventral sacroiliac ligaments, and sacrospinous and sacrotuberous ligaments. The prevalence of pain originating from these structures has received little formal study, and there is no validated technique to diagnose ligamentous pain. Nevertheless, sacroiliac joint ligamentous pain is proclaimed as a frequent primary source of low back and buttock pain by orthopaedists.[191] More important, a negative response to a sacroiliac joint injection does not mean that pain does not originate from the iliolumbar ligament and sacroiliac joint ligaments. A more recent histologic study found calcitonin gene-related peptide and substance P immunoreactive nerve fibers in the normal sacroiliac joint anterior capsular ligament and interosseous ligament. The authors of the study opined that diagnostic infiltration techniques for sacroiliac joint pain should employ extraarticular and intraarticular approaches.[192]

In contrast to the zygapophyseal joints, the sacroiliac joint supporting ligaments are thick, and intraarticularly injected local anesthetic may not adequately diffuse into the sacroiliac ligaments. Using a single or comparative block protocol, one can investigate sacroiliac joint ligaments by fluoroscopically guided injections of local anesthetics into the ligaments. Ligamentous injections have not undergone rigorous academic inquiry, however, and because the injections are rarely or poorly reimbursed by third-party payers and treatment of ligamentous laxity typically involves unreimbursed "prolotherapy," there is little incentive for expensive investigations. The information is important, however, and differential pain arising from the sacroiliac joint versus sacroiliac joint ligaments is reported.

In a comparative study, Murakami and colleagues[193] performed periarticular injections in 25 patients and intraarticular injections in another 25 patients. Periarticular injections relieved, on average, 92% pain in 100% of the injected patients compared with only 9 of 25 patients receiving intraarticular injections. All 16 patients not receiving relief by intraarticular injections were improved after periarticular injections. The presence of other structural abnormalities does not rule out the sacroiliac joint as a primary source of pain. Weksler and colleagues[194] studied 55 patients with herniated discs with axial and referred leg pain, without objective neurologic deficits but with positive sacroiliac provocation tests. Using intraarticular injection of local anesthetic as the reference standard, the mean baseline VAS pain score decreased 30 minutes after injection, from 7.8 to 1.3. In 46 patients 8 weeks after injection, VAS scores ranged from 0 to 3.

The question of whether fusion surgery leads to increased stress on the sacroiliac joint and may be a cause of failed back surgery syndrome was first raised by Frymoyer and colleagues,[195] although their method of assessing sacroiliac joint pathology yielded a negative result. In 1978, Frymoyer and colleagues[195] evaluated patients with radiographs (no diagnostic blocks) 10 years after posterior fusion versus postdiscectomy and found no significant difference in radiographic abnormalities; they opined that sacroiliac pain was "noncontributory" to persistent low back pain after surgery. In their subject population, they believed that the graft donor site was a more common pain generator. Fusion to the sacrum might be expected to stress the sacroiliac joints and lead to late failures or to early failures owing to undiagnosed sacroiliac joint pain. Ha and colleagues[196] prospectively examined 37 patients undergoing posterolateral lumbar and lumbosacral fusions; 22 patients had a floating fusion, and 10 patients had a lumbosacral fusion. CT scans of the sacroiliac joint were performed before surgery and at 2 weeks, 1 year, and 5 years after surgery and compared with 34 matched controls. The incidence of sacroiliac joint degeneration was 75% in the fusion group versus 38.2% in the control group and greater in patients fused to the sacrum. Both groups reported significant improvements in VAS and Oswestry Disability Index scores, and there was no difference in scores between the two groups.

More recent research has shown that the sacroiliac joint can be a significant source of pain after fusion. Biomechanical models seem to support these conclusions. Ivanov and colleagues[197] performed a finite-element study with lumbosacral models and fusion constructs and found that fusion to the sacrum increased motion and stresses at the sacroiliac joint. Cadaveric studies show that disruption of the ventral band of the iliolumbar ligament significantly increases sacroiliac joint mobility.[198] Ebraheim and colleagues[199] evaluated the prevalence of sacroiliac joint disruption by CT scan in 24 patients after fusion with persistent "donor site pain" after posterior superior iliac crest graft harvesting. They found a high prevalence of persistent sacroiliac joint pain in patients with inner-table disruption. Patients with violation of the synovial portion of the sacroiliac joint had severe degenerative changes on CT versus mild to moderate degeneration with inner-table disruption only. It seems that the original hypothesis by Frymoyer and colleagues[195] that sacroiliac joint dysfunction was the cause of donor site pain may have been correct.

What is the evidence for using diagnostic blocks as the reference standard? Diagnosis of sacroiliac joint pain has been reported by researchers using single and dual blocks; with these methods, prevalence rates of sacroiliac joint pain after lumbar fusion range from 27% to 35%. Maigne and Planchon[200] studied 40 patients after fusion with continued pain using 75% pain relief after a single sacroiliac joint intraarticular

injection as the gold standard. They reported a 35% rate of positive blocks. The only characteristic that distinguished the positive from the negative responders was a different distribution of postoperative pain compared with preoperative pain. A pain-free interval of 3 months after surgery was significant; however, increased uptake in the sacroiliac joint on bone scintigraphy or posterior iliac bone graft harvesting was not significant.

Katz and colleagues[201] studied 34 patients after lumbosacral fusion with continued pain thought to be due to the sacroiliac joint with intraarticular injections of local anesthetic and corticosteroids. Eleven patients (32%) had greater than 75% pain relief with local anesthetic and a minimum of 10 days of continued pain relief (with steroid) and were considered to have definite sacroiliac joint pain. Another 10 patients (29%) had greater than 75% relief with local anesthetic but no long-term relief. There was no correlation between the donor site and pain side. Irwin and colleagues[177] used dual comparative sacroiliac joint blocks as the reference standard to define sacroiliac joint pain and found that the 27% of positive responders tended to be older. They found no statistical relationship between age, body mass index, and gender.

Diagnostic Accuracy of Clinical History and Physical Examination for Sacroiliac Pain

The diagnostic utility of history and accepted sacroiliac joint physical examination tests was first rigorously examined by Dreyfuss and colleagues in 1996.[202] Their study was designed to determine if any single or combination of 12 history and physical examination findings could predict intraarticular sacroiliac joint pain as judged against a single positive intraarticular sacroiliac joint block with greater than 90% pain relief. In 85 patients, there were 45 positive blocks. None of the 12 physical examination tests, the presence of 5 to 12 positive tests, or any combination of these 12 tests correlated with the presence of sacroiliac joint pain. One important historical feature was notable, however: only 2 of 45 patients drew pain above the L5 level, suggesting that pain below L5 is more likely to be of sacroiliac joint origin. Maigne and colleagues[176] reached a similar conclusion using dual comparative blocks: no single provocation test reached statistical significance in the 10 patients (18.5%) who had temporary pain relief on the confirmatory injection.

Although no single provocative maneuver has been shown to be of diagnostic value, using the dual-block paradigm, several studies have obtained highly acceptable sensitivity (85–91%) and specificity (78–79%) rates by combining three or more sacroiliac joint pain provocation tests for diagnosis by physical examination.[12,178,179,181,203] There is some slight variation in the tests used by various authors but, in summary, they include the following provocation tests: thigh thrust, distraction test, Gaenslen test, Patrick sign, compression test, midline sacral thrust test, and heel drop test. Specificity increased to 87% if the patient's pain did not centralize or could not be made to move toward the spinal midline (which is typical of discogenic pain).[204] When three or more provocation tests (distraction, compression, thigh thrust, Patrick sign, Gaenslen test) are negative, the likelihood of sacroiliac joint pain is very low (6–15%); when all provocation tests are negative, the sacroiliac joint was never the source of pain.[178,179,181,204]

With regard to pain referral maps, Slipman and colleagues[205] and Dreyfuss and colleagues[202] concluded that of all alleged signs of sacroiliac joint pain, maximum pain below L5 coupled with pointing to the posterior superior iliac spine or tenderness just medial to the posterior superior iliac spine (sacral sulcus tenderness) has the highest positive predictive value of 60% of true sacroiliac joint–mediated pain; if these do not exist, the likelihood of sacroiliac joint pain is less than 10%. It must be noted that sacroiliac joint pain can refer into various aspects of the lower extremity, with 94% of patients reporting buttock pain, 48% reporting thigh pain, and 28% reporting lower leg pain (Fig. 16.15).[175,176,206] However, referral to the lower extremity may not always be reliably distinguished from other pain sources (e.g., S1 radiculopathy).[175,207]

Last, although pain referral patterns between responders and nonresponders are similar, Fortin and colleagues[208] described an area of pain approximately 3 × 10 cm just inferior to the posterior superior iliac spine that was common in all subjects with sacroiliac joint pain. More recently, Murakami and colleagues[209] studied the specificity and sensitivity of the "Fortin" point with periarticular injections. Labeled the *one finger test,* 18 of 38 patients pointed to a location of pain at the posterior superior iliac spine or within 2 cm of the posterior superior iliac spine, which had a positive response to periarticular sacroiliac joint block. The authors recommended that sacroiliac joint pain should be considered in patients who can point to their pain using one finger in the vicinity of the posterior superior iliac spine.

Systematic reviews report various conclusions regarding the specificity of the physical examination and sacroiliac joint

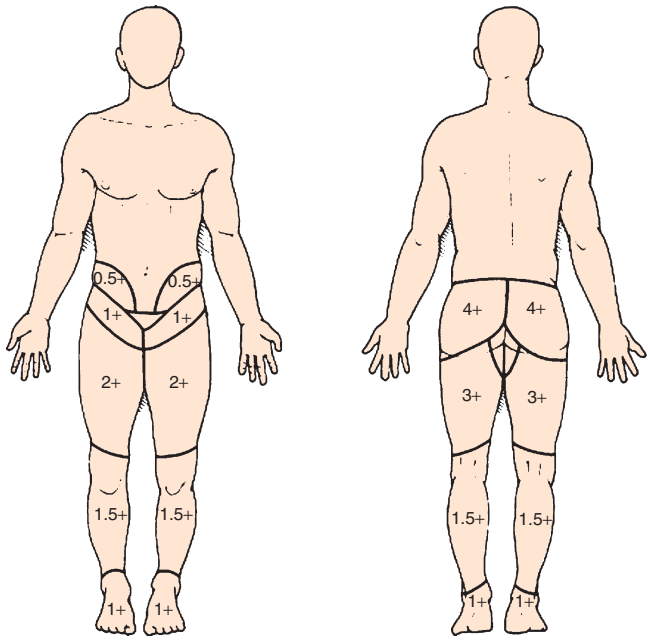

FIG. 16.15 Density of referral zones for sacroiliac joint pain. 0.5+ is the least common referral zone; 4+ is the most common referral zone. (From Dreyfuss P, Dreyer S. Sacroiliac joint pain. *J Am Acad Orthop Surg.* 2004;12:255–265.)

block to diagnose sacroiliac joint pain based on the authors' assessment of the diagnostic accuracy of sacroiliac joint blocks. The review by Berthelot and colleagues[190] concluded that sacroiliac joint blocks and sacroiliac joint maneuvers were unreliable for diagnosing sacroiliac joint pain. In contrast, Hansen and colleagues[210] concluded in their review that there was moderate evidence for the specificity and validity of diagnostic sacroiliac joint injection and limited evidence for the accuracy of provocative maneuvers. Using a comparative double-block reference standard, the most recent meta-analysis and systematic review concluded that the pooled data of the thigh thrust test, compression test, and three or more positive stress tests showed discriminative power for diagnosing sacroiliac joint pain.[211]

Diagnostic Accuracy of Imaging

No imaging studies consistently provide findings that are helpful to diagnose primary sacroiliac joint pain. CT, MRI, and bone scan are done predominantly to exclude other causes of pain rather than to diagnose mechanical sacroiliac joint pain. Among patients referred to a low back pain clinic with a variety of pathologies, Hodge and Bessette[212] found a high percentage (75%) of patients with sacroiliac joint arthritis shown on CT scan. Although these authors did not confirm the diagnosis with sacroiliac joint injections, they opined that sacroiliac joint arthritis should be considered a possible diagnosis.

There is limited diagnostic value of CT scan in mechanical sacroiliac joint disease as defined by pain relief after sacroiliac joint blocks under CT scan guidance. Comparing the CT scans of patients diagnosed with sacroiliac joint pain using image-guided analgesic sacroiliac joint blocks with a matched control group of asymptomatic patients, Elgafy and colleagues[213] reported that an abnormal sacroiliac joint CT scan had a sensitivity of 57% and a specificity of 69% for identifying sacroiliac joint pain. Although sacroiliac joint scintigraphy can detect early sacroiliitis,[214] stress fractures, infection, and tumors, the sensitivity of bone scans for detecting mechanical sacroiliac joint pain is poor (range, 12–46%),[215,216] Patients with a positive bone scan are likely to have mechanical or arthritic sacroiliac joint pain with a reported specificity of 90% to 100%.[205,217]

Diagnostic Accuracy of Sacroiliac Joint Injections

In a recent prospective case series of 1408 patients undergoing dual-session sacroiliac joint blocks, the authors found that the first sacroiliac joint block will be confirmed by the confirmatory injection in 87% of cases.[218] However, the current recommended standard for diagnosing sacroiliac joint pain is pain relief after dual controlled sacroiliac joint injections, owing to the high false-positive rate of single blocks reported in prior publications[17,177] When blocking the sacroiliac joint or lateral branches of the sacroiliac joint, imaging guidance must be used. The success of "blind" intraarticular injection is only 22%.[219] A positive response should include approximately 70% to 80% relief for 1 to 2 hours of relief after a lidocaine block and 3 to 4 hours of relief after a confirmatory block with bupivacaine. Although the reference standard is reasonable, there are several caveats for the diagnosis of mechanical pain originating within the sacroiliac joint. Patients may exhibit extraarticular or periarticular sacroiliac joint pain or perhaps both. As noted earlier, Murakami and colleagues[193] relieved a significant amount of sacroiliac joint pain with periarticular injections. In a retrospective review of 120 patients, subjects who received intraarticular and periarticular injections had superior pain relief compared with subjects receiving intraarticular injections alone.[220]

False-positive results may occur secondary to leak of local anesthetic through capsular tears, which may be present even in asymptomatic individuals. Extracapsular flow is present in 61% of sacroiliac joint intraarticular injections in patients.[221] Of sacroiliac joint intraarticular injections, 27% show extravasation that communicates with nearby neural structures, including dorsal sacral foramina extravasation, superior recess extravasation at the sacral ala level to the fifth lumbar epiradicular sheath, and ventral extravasation to the lumbosacral plexus.[221] Patients who have postblock extremity numbness are usually considered to have a leak, and the block is typically repeated at a different session. In such cases, it may also be reasonable to use multisite, multidepth blocks of the L5 dorsal ramus and S1–S3 lateral branches in order to avoid anesthesia of confounding anterior structures.

More important is the potentially significant false-negative response rate because of a failure to anesthetize extracapsular pain sources mentioned previously. Block of the sacroiliac joint dorsal innervations may offer a solution because the block would potentially denervate intraarticular and extraarticular pain sources. Because the sacroiliac joint and ligaments are innervated, similar to the zygapophyseal joint, the joint and capsules are regarded as the same structure. In contrast to the zygapophyseal joint, the sacroiliac joint is surrounded by thick supporting ligaments, and intraarticular injected local anesthetic may not anesthetize the ligaments.

Dreyfuss and colleagues[207] used a double-blind randomized controlled trial to assess ability of single-site, single-depth L5 dorsal ramus and S1–S3 lateral branch blocks to anesthetize the sacroiliac joint in 19 volunteers, using sacroiliac joint fluid distraction before and after blocks to determine effectiveness. The authors reported that only 40% of the volunteers did not feel distention after the blocks. The poor results prompted a cadaveric study of multisite,[189] multidepth blocks to anesthetize the joint. L5 dorsal ramus block was performed at the standard location of the S1 superior articular process and the sacral ala; S1–S2 lateral branches were blocked (right side) at these clock positions—2:30, 4:00, and 5:30; and S3 lateral branch was blocked at the right 2:30 and 4:00 positions. The lateral branch blocks were performed 8 to 10 mm lateral to the posterior sacral foramen. A 0.2 mL volume of green dye was injected on the dorsal sacral plate, and an additional 0.2 mL was injected 2 to 3 mm above the sacral plate.

Dissection revealed that the S1–S3 lateral branch nerves were stained in 91% (31 of 34) of cases. Employing the same protocol on 20 volunteer subjects using intraosseous ligament probing and capsular distention, Dreyfuss and colleagues[189]

found that 86% of the sham local anesthetic injection subjects retained the ability to feel capsular distention, leading the authors to conclude that lateral branch blocks do not reliably block the intraarticular portion of the joint and that intraarticular blocks do not reliably block the extraarticular ligaments. One may conclude that to evaluate fully intraarticular and extraarticular pain sources, dorsal ramus and lateral branch blocks and intraarticular injections should be done. The caveat is that the nerve blocks were successful in 70% of cases, leaving a potential 30% false-negative cases. Injecting larger volumes or injecting the ligaments directly may potentially reduce the false-negative results with the risk of increasing false-positive results secondary to leak of local anesthetic through the posterior foramen.

Predictive Value

Surgical fusion outcomes for mechanical sacroiliac joint pain are reported for only a few small case series audits of initial outcomes after several "new" techniques for fusing the sacroiliac joint.[222–225] Published case series use pain relief after image-guided analgesic sacroiliac joint injections as the reference standard for diagnosing sacroiliac joint pain. Although Schutz and Grob[223] reported an 82% unacceptable outcome after bilateral sacroiliac joint fusion in 17 patients based on results from sacroiliac joint anesthetic block, three other studies using novel techniques reported more favorable results for mostly unilateral fusions. Al-Khayer and colleagues[224] reported an approximate 50% decrease in VAS and a 14-point decrease in Oswestry Disability Index in nine patients at 2 years after percutaneous sacroiliac joint arthrodesis using a Hollow Modular Anchorage screw (Aesculap). Using percutaneously inserted fusion cages and bone morphogenetic protein, Wise and Dall[222] reported an average back pain VAS improvement of 4.9 and leg pain VAS improvement of 2.4 in 13 patients at 6 months. Finally, Ziran and colleagues,[225] using CT-guided sacroiliac joint blocks as a reference standard, percutaneously fused 17 patients with recalcitrant sacroiliac joint pain and found a statistically significant correlation ($P < .02$) between final postoperative pain scores and preinjection as well as postinjection pain scores.

Evidence is limited to a small body of literature, including mostly observational studies assessing the outcome of various treatments for sacroiliac joint pain. Cohen and colleagues[226] performed a randomized sham-controlled trial, selecting patients for various types of radiofrequency neurotomy of the L4 medial branch, L5 dorsal branch, and S1–S3 lateral branches using the reference standard of a single sacroiliac joint intraarticular block with greater than or equal to 75% relief of pain for 2 hours after injection of 2 mL of bupivacaine. Of 18 patients, 13 obtained satisfactory relief of pain with average scores reduced by 60%, 50%, and 57% at 1 month, 3 months, and 6 months, respectively. Only two patients in the placebo group obtained relief; pain scores of the placebo subjects were unchanged from baseline. Yin and colleagues[186] used dual injection into the sacroiliac joint intraosseous ligament to diagnose sacroiliac joint pain. Of patients, 64% reported a minimum of 60% subjective pain relief for a minimum of 6 months after sensory stimulation–guided sacral lateral branch radiofrequency neurotomy. The remainder of this clinical outcome literature is reviewed elsewhere.[227]

Summary

Sacroiliac joint pain is a significant cause of chronic low back pain that is diagnosable and treatable with precision injection techniques. The prevalence of sacroiliac joint pain, based on a dual differential block protocol, ranges from 10% to 38%; for single, uncontrolled blocks, the false-positive rate is 54%.[177–181] The sacroiliac joint as a pain generator is no longer disputed. Current research also suggests that the sacroiliac joint is a significant source of persistent pain after lumbar fusion and may be a cause of graft donor site pain.[199–201] Although motion is limited and complex, the joint is known to rotate less than 4 degrees and to translate less than 1.6 mm. Anatomic studies have elucidated the innervation to the joint, with most practitioners directing diagnostic and therapeutic interventions to the L5 dorsal ramus and S1–S3 lateral branches.[185,187] Sacroiliac joint pain is now thought to emanate from the joint itself but also from extraarticular dorsal ligamentous sources. Interventionalists are just beginning to diagnose and treat putative extraarticular pain generators.

In contrast to the history and physical examination for zygapophyseal joint pain, certain diagnostic features for sacroiliac joint pain have been validated by controlled blocks. Maximal pain below L5 coupled with pointing to the posterior superior iliac spine has a predictive value of 60%.[202,205] Although no single physical examination test has been shown to be of satisfactory diagnostic value in isolation, using the dual-block paradigm, several studies have shown high sensitivity (85–91%) and specificity (78–79%) for accurately identifying the sacroiliac joint as the source of pain by combining three or more provocative maneuvers.[179,181] Specificity increases to 87% if the patient's pain cannot be centralized.[204] Diagnostic imaging of sacroiliac joint pain has not been shown to be helpful other than excluding nonmechanical causes of sacroiliac joint pain. The sensitivity of bone scans for detecting sacroiliac joint pain is poor (range 12–46%).[215,217] CT scan of the sacrum in a patient with persistent low back or buttock pain after lumbar fusion may be useful, particularly if the synovial joint has been violated. In these patients, severe degenerative changes were found on CT scan.[199]

The current standard for diagnosis of sacroiliac joint pain is approximately 70% relief of pain for 1 to 2 hours after lidocaine block and 3 to 4 hours after bupivacaine block. Total volume should be limited to 1.5 mL. The interventionalist should carefully study the joint arthrogram for any evidence of extravasation via the dorsal sacral foramina, superior joint recess and fifth lumbar epiradicular sheath, or ventral capsule to the lumbosacral plexus because this can cause false-positive responses. Not all patients obtain relief from intraarticular joint injections, and extraarticular sources of pain must be evaluated as well. Other techniques for diagnosis and treatment of the sacroiliac joint include targeting the L5 dorsal ramus and S1–S3 lateral branches.

If pain persists, new techniques have also been described for blocking the interosseous sacral ligaments.[220] Regarding the predictive value of diagnostic sacroiliac joint injection for sacroiliac joint arthrodesis, some case studies show poor results for arthrodesis; other studies using novel techniques report better results.[222–225] Evidence exists for the effectiveness of neurotomy of sacroiliac joint lateral branches after diagnostic block.[227] Other researchers have also shown promising results with periarticular blockade.[193]

Middle Compartment: Selective Nerve Root Blocks

Radicular Pain and the Role of Selective Nerve Root Blocks

Patients with clinically significant radicular pain unresponsive to conservative care and medications may be offered a therapeutic injection, including local anesthetic and corticosteroids. The injection can be performed using an interlaminar, transforaminal, or combined approach and can be performed at all suspected levels using volumes of injectant that cover all suspected symptomatic levels. If the patient has convincing pain relief for 1 week or longer, it is likely that the cause of pain is reversible and secondary to inflammation.[34] More important, if the patient reports minimal or very short-term relief of extremity pain, the pain has been present for greater than 1 year, and the offending pathology is unconvincing, the pain may be neuropathic or referred somatic pain.[34] If pain relief is satisfactory and lasts several weeks or longer, one may use additional therapeutic injections to facilitate conservative care, and there may be no need to proceed with exactly identifying the symptomatic level. When pain recurs or is poorly responsive to therapeutic injections and the clinical and imaging studies are inconclusive or indicate more than one potential pain level, diagnostic transforaminal injections may be considered. Box 16.1 summarizes indications for diagnostic selective nerve root blocks.

Despite the growing sophistication of modern imaging, the source of extremity pain is not always clearly apparent. Extremity pain may also be referred from the hip, buttock, or shoulder secondary to intrinsic pathology in these structures. Radicular pain can be secondary to entrapment by bone, ligament, or disc or result from leakage of noxious cytokines from either the disc or an inflamed zygapophyseal joint without evidence of compression. *Segmental instability,* albeit difficult to detect or prove, may cause repetitive dynamic irritation of the dorsal root ganglion leading to chronic dorsal root ganglion hypersensitivity. Advanced MRI often shows multilevel degenerative pathology, abnormalities on the side opposite the patient's symptoms, or abnormalities that are asymptomatic.[228–230] Except for the most profound structural abnormalities, MRI provides morphologic information only; correlations must be made with clinical presentation in order to establish the significance of imaging findings.[231] Confounding the diagnosis further, pain patterns may not follow classic referral distributions.[232,233]

Before considering surgical interventions, one should have a clear diagnosis with concordant imaging studies that show a surgically correctable lesion compressing the spinal nerve root, dorsal root ganglion, or ventral ramus. Pain referral patterns and physical examination findings should also be consistent with the suspected level of pathology. Most single-level entrapments are obvious. If not, further diagnostic information may be considered, such as selective nerve root blocks. Some interventionalists and surgeons still find myelography useful because MRI may miss a sequestered fragment or the MRI cuts may not be fine enough to detect the pathologic lesion.

Selective injection of local anesthetic around the spinal nerve within or near the intervertebral foramen has long been used to help surgeons confirm or refute a hypothesis that a particular spinal nerve root is the source of pain. Selective nerve root blocks are distinguished from transforaminal epidural steroid injections. With a selective nerve root block, a small volume of contrast medium, approximately 0.5 mL, is injected with the goal of outlining the exiting spinal nerve and ventral and dorsal roots (Figs. 16.16 to 16.18); then, the same volume of local anesthetic is injected such that epidural flow

BOX 16.1 Indications for diagnostic selective nerve root blocks

1. Patients with radicular pain without localizing signs to indicate which level is involved
2. Patients without obvious nerve root entrapment on high-quality imaging studies
3. Patients with chronic radicular pain present for ≥1 year, resistant to usual care and being considered for surgery
4. Patients with persistent pain after surgery or status following multiple surgeries
5. Patients with radicular symptoms in more than one distribution with multilevel structure impingement
6. Patients with atypical extremity pain
7. Nondiagnostic or conflicting results of imaging studies, discography, or electromyography

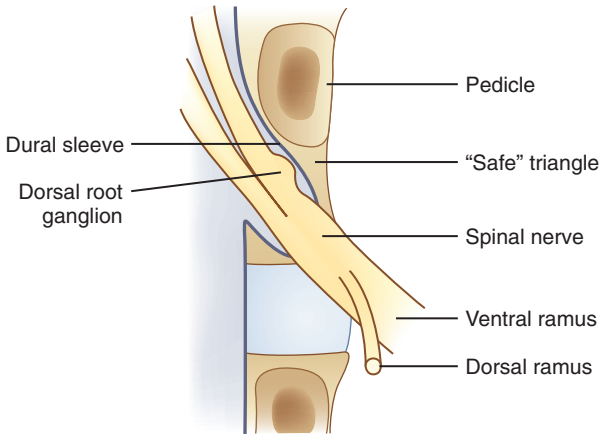

FIG. 16.16 Spinal nerve within the intervertebral foramen. The spinal nerve is a short segmental structure that quickly divides into ventral and dorsal rami. A selective nerve root block places local anesthetic no further than the 6 o'clock position on the pedicle. (From Bogduk N, Aprill C, Derby R. Epidural steroid injections. In: White AH, ed. *Spine Care. Vol. 1: Diagnosis and Conservative Treatment*. St. Louis: Mosby; 1995:322–343.)

A 1.5-inch, 25-gauge needle was used to inject 0.3 mL of contrast dye. There is no spread of contrast dye around the pedicle and into the epidural space. (Courtesy Richard Derby, MD.)

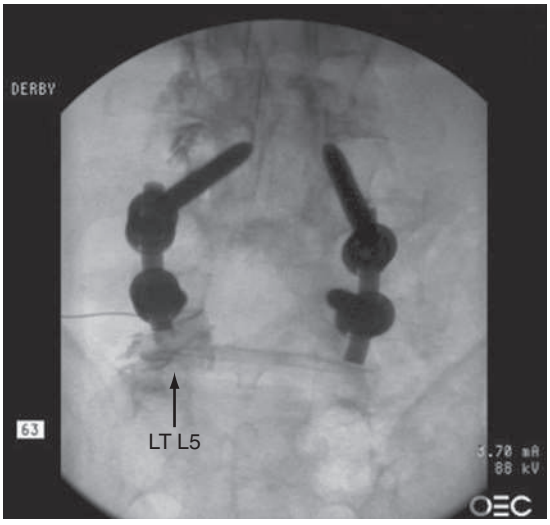

FIG. 16.18 Left L5 selective nerve root block. Note how 0.5 mL of injected contrast dye surrounds and outlines the root and dorsal root ganglion. There is a cutoff of contrast dye at the lower and medial border of the pedicle because of scar tissue from prior surgery (*arrow*).

to adjacent nerve root levels does not occur[234] in order to maintain specificity to the single nerve root in question. With selective nerve root blocks, relief of pain does not determine the cause of pain. Greater or lesser relief of pain may occur even if the cause of pain is peripheral entrapment or if the blocked nerve innervates a painful structure, such as the hip. Relief of pain for the duration of the local anesthetic may occur even if the root has irreversible damage.

History

Spine surgeons began using diagnostic root blocks in the late 1960s to help locate sources of radicular pain not well visualized with myelography.[233,235–238] Provocation of symptoms, pattern of the neurogram, and relief of pain were used to identify hidden pathology that was later confirmed or refuted during surgical exploration. A high degree of correlation was found between "positive" blocks and surgical findings. In addition, some early studies began reporting the surgical outcome based on selective nerve root block findings.[236] The routine use of CT and MRI improved the identification of structural causes of root compression, and some surgeons began using root blocks in difficult cases in which provocation and relief of pain helped to determine the operated level.[239–242] Surgeons noted that although MRI and CT improved visualization of pathology, imaging did not correlate with cause of pain and it did not correlate the abnormal anatomy with actual symptoms.[239]

Structural confirmation of suspected pathology and subsequent pain relief after surgery were reported in mostly retrospective case series. These studies also reported that selective nerve root blocks were better able to identify a symptomatic root compared with CT and MRI in "difficult" cases.[231,240,241,243,244] Of particular note was a finding that although outcome of patients diagnosed with various nerve root entrapment syndromes was excellent, patients diagnosed with scarring or arachnoiditis had very poor outcomes.[239,241] All studies reported "successful" surgery to a greater or lesser extent in approximately 90% to 95% of patients following pain relief after selective nerve injections if patients having prior surgery, scarring, and arachnoiditis were excluded. In the two studies that evaluated surgical outcome on patients with less than approximately 95% relief after injection, surgical results were modest to poor.[239,243]

In an observational study in 1971, Macnab[235] analyzed the causes of nerve root involvement in 68 patients who had undergone a "negative exploration" for presumed radicular pain caused by a herniated disc. Various pathologies were described, including migration of a disc fragment into the intervertebral foramen, nerve root kinking by the pedicle, articular process impingement, and extraforaminal lateral disc herniation. In the case of pedicular kinking, Macnab[235] described a technique of placing a 25-gauge needle into the intervertebral foramen and injecting 0.5 to 1 mL of oil-soluble contrast material. The provocation of concordant pain by striking the nerve with the needle, the characteristic contrast outline of the "kinked" nerve root within the foramen, and subsequent relief of pain after injection of 1 mL of 2% lidocaine were used to establish the diagnosis and led to "excellent results" in the six studied patients. Macnab[235] also described two patients with an undiscovered extraforaminal lateral disc herniation who underwent successful operation after relief of pain with a selective nerve root block. Likewise, Schutz and colleagues[237] in 1973 described the use of selective root blocks in 23 patients. In 13 of 15 patients who underwent surgery, the positive results of the selective nerve root blocks were confirmed.

Using a selective nerve root block technique similar to Macnab, Tajima and colleagues[238] in 1977 described various contrast patterns after injection of 2 mL of water-soluble contrast media, including cutoff patterns of contrast flow within

the foramen and lateral recess indicating stenosis or block by a herniated disc. Provocation and pain relief after injection of 3 mL of 1% lidocaine confirmed the diagnosis, which was later proven during surgical exploration in this small case series. Kikuchi and colleagues[233] published a larger case series comprised of 332 patients in 1984, in which they performed nerve root infiltration in all patients and correlated the resulting neurogram with anatomic findings of cadaveric dissections. In most patients, pain was relieved by injection at a single level. The cadaveric studies revealed the following causes of atypical pain: congenital or acquired abnormalities of nerve and nerve roots, sensory rootlets communicating with adjacent nerves, conjoined nerves, and the common occurrence of the nerve exiting much more commonly at the L4 than L5 level and giving branches to the lumbosacral trunk and femoral and obturator nerves. Kikuchi and colleagues[233] also described the descent of the vertebral pedicle associated with disc collapse, degenerative changes of the articular zygapophyseal joint, and compression of the nerve at different sites.

Krempen and Smith[236] in 1974 were the first to report surgical outcomes based on provocation and pain relief after injection of the nerve root with 1 mL of 1% lidocaine. They also described and included radiographs of neurogram patterns of extraforaminal disc herniations, pedicle kinking, articular process impingement, and scar tissue. These authors used the injections to diagnose pain in 21 patients with prior lumbar laminectomies and commented that most patients were able to pinpoint the level of the lesion to either of two injected levels. Of the 16 operated patients, three had excellent results, nine had good results, and four had moderate results. The technique involved inserting an 18-gauge spinal needle 4 cm above the transverse process and approximately 6 cm from midline, directed downward and medially to strike the nerve. In the 1980s, Haueisen and colleagues[244] used Krempen and Smith's technique of spinal nerve injections to diagnose pain in difficult-to-diagnose patients, including 57% who had previous lumbar surgery. Of 63 operated patients, Haueisen and colleagues[244] confirmed compression of the suspected nerve root in 93% of the cases; at an average follow-up of 20 months, 73% of patients had no pain, slight pain, or some pain. Myelography and electromyelography aided in correct diagnosis of the lesion in only 24% and 38% of the cases.

Dooley and colleagues[239] used provocation and relief of pain after selective nerve root block to review retrospectively the results of 63 patients undergoing operations based on positive pain reproduction and pain relief after injection of 1 mL of 1% lidocaine correlated with surgical findings and outcome. The authors presented results according to whether the patients had full or incomplete pain relief and whether pain was reproduced. Of patients with reproduction and full pain relief, 45 of 46 had an anatomic diagnosis made at the time of surgery. Eight patients had herniated nucleus pulposus and all were relieved of leg pain at follow-up. At follow-up, 17 patients had bony entrapment and 14 (82%) were asymptomatic. Only one of 11 patients found to have arachnoiditis was pain free at follow-up, although five of seven patients found to have periradicular adhesions but without intraneural scarring were asymptomatic at follow-up. Patients with reproduction but incomplete relief included one patient who was diabetic with probable neuropathy causing failed surgery; the other three patients had pathology at other levels, and only one of the three had a satisfactory surgical outcome. In patients who had no reproduction and incomplete relief, only five of 14 cases were relieved of symptoms, and the authors recommended that patients with this group of responses should undergo careful reevaluation.

In 1988, Jonsson and colleagues[245] reported total relief of pain in 51% of patients undergoing diagnostic lumbar "root anesthesia" in 100 cases of sciatic pain with normal findings on myelography, CT, or MRI. The patients experiencing pain relief underwent surgical root decompression with short-term surgical outcome comparable to conventional surgery in more obvious cases.

In 1990, Stanley and colleagues[240] likewise reported outcomes based on response to injection in which they included only positive and negative responses. Positive responses required pain provocation and relief of pain with 1 mL of 1% lidocaine; a negative response was defined as nonconcordant pain provocation immediately and only partial relief or no relief of pain after the expected duration of onset of lidocaine. At least two roots were studied in each patient. Of 20 patients with positive responses, 19 underwent operation, and Stanley and colleagues[240] found that "nerve root infiltration" identified the symptomatic level in 18 of 19 cases. CT scan and myelogram identified the correct level in only 14 of 19 cases and 12 of 19 cases, respectively.

In 1989, Herron[241] reported the use of spinal nerve root blocks with pain provocation immediately and pain relief after 1 mL of 0.5% bupivacaine. A positive response included reproduction of pain and at least 75% pain relief. Herron[241] divided outcomes into good, fair, and poor. A good outcome was defined as 75% pain relief and return to previous work status with minimal medications and minimal or no restrictions of physical activities. In the previously unoperated disc herniation group, 15 of 18 patients had good results, and three had fair results. In nine patients, the imaging studies were positive at two levels, but surgery was performed only at one symptomatic level identified with a root block. There were seven good results and two fair results. In patients with previous unoperated spinal stenosis, 19% had a poor outcome versus 52% poor outcomes in patients with prior stenosis surgery. Herron[241] noted that in most patients with radiculopathy, selective nerve root blocks are not needed because the level was readily apparent on clinical examination and imaging studies; however, root blocks were useful for patients with equivocal findings, previous surgery, and multilevel structural pathology.

Porter and colleagues[242] used CT-guided root blocks, employing a two-needle technique to place an inner needle adjacent to the target nerve. In contrast to previous authors, these authors did not include provocation and injected 1.5 mL of 0.5% bupivacaine. Porter and colleagues[242] reported that, of the 18 patients undergoing surgery, 78% had a good outcome; two patients had unsuccessful surgeries.

The study in 2005 by Sasso and colleagues[243] is the most comprehensive, albeit retrospective, evaluation of the value of

selective nerve root injections to predict lumbar and cervical surgical outcomes. These authors studied 101 patients culled from an institutional database from 1996 to 1999. Injections were performed by placing the needle tip just below the superior pedicle without intentional pain provocation. Additionally, a stimulating electrode to locate the needle close to the exiting nerve was employed. A neurogram was obtained, and a volume of 0.5 to 0.75 mL of 2% lidocaine was injected with the requirement of greater than 95% pain relief during postblock provocative testing in order to be considered "positive." Confirmatory injections were performed when pain relief was rated as 80% to 95%. Surgical follow-up occurred at a mean of 16 months, with 18 patients undergoing cervical surgery and 83 patients undergoing lumbar surgery. Of patients with positive selective nerve root injections, 91% had a good surgical outcome defined as a follow-up VAS of 2 or less and a positive patient satisfaction score. In 10 patients with negative selective nerve root injections, only 60% obtained a good surgical outcome. Patients undergoing surgery at a level with a positive block were 9.1 times more likely to have good outcomes than patients who had surgery at negative selective nerve root injection levels. When the findings between selective nerve root injection and MRI differed (n = 20), surgery at a level consistent with the selective nerve root injection was more strongly associated with a good surgical outcome than surgery based on MRI. For selective nerve root injection, the positive predictive value was 91.2% with a negative predictive value of 40% compared with 88.4% positive predictive value of MRI. Subgroup analysis of lumbar and cervical results was not reported.

Finally, Derby and colleagues[34] in 1992 reported the correlation between immediate leg pain relief after lumbar block and 1-year surgical outcomes. The authors segregated 78 patients undergoing epidural injections with a minimum of 80% immediate postblock leg pain relief into two dichotomous groups: patients with 50% or greater subjective leg pain relief lasting for 1 week or longer and patients with duration of extremity pain lasting 1 year or longer. Regardless of immediate pain relief, 85% of patients who had pain for less than 1 year had a positive surgical result defined as 50% or greater pain relief at 1 year. More important, 95% of the patients who did not respond to the block had a poor surgical outcome. Derby and colleagues[34] opined that the poor outcome might be explained in some cases by an inadequate structural correction, inadequate stabilization, or functional reasons, but most failures probably represented irreversible changes in the neural structures. Although unstudied, thus unconfirmed, the results by Derby and colleagues[34] are consistent with findings reported by Kumar and colleagues[246] that outcome after spinal cord stimulation in patients with failed back surgery syndrome was superior to revision surgery.

Diagnostic Accuracy of Selective Nerve Root Blocks

Diagnostic accuracy and ultimately utility depend on the degree to which a selective nerve root block relieves pain caused by any lesion within the nerve at or distal to the injection site. A greater or lesser degree of pain relief caused by a lesion affecting the nerve proximal to the injection site should also be taken into account when determining value.[99] Ideally, blocking an unaffected nerve would not relieve any pain. The degree to which these goals are accomplished constitutes the diagnostic accuracy as measured by sensitivity, specificity, and predictive value. Understanding these variables guides the clinician in terms of either accepting or discarding the block results or whether even to consider obtaining the information.

To study the diagnostic accuracy, one would select cases of acute or subacute monoradiculopathy caused by an obvious single-level lesion verified by imaging studies, intraoperative findings, and relief after surgical intervention. The most common gold standard lesion would be L4–L5 paracentral herniation irritating the traversing L5 root.[243] Blinding the patient, the symptomatic root and presumably at least one unaffected root would be blocked at different sessions, and the data would be prospectively collected. The lesion would be confirmed at surgery and by postsurgical pain relief.

Although many prior studies retrospectively studied the ability of provocation and relief of pain to predict structural nerve entrapment and surgical outcome, only two studies examined injections performed on symptomatic roots and presumed asymptomatic roots with the expressed goal of defining sensitivity and specificity, and both studied only the value of lumbar injections.[247,248] From these two studies, particularly the more recent study by Yeom and colleagues,[247] one may estimate the diagnostic value of lumbar diagnostic root blocks. An additional study evaluated the effect of needle tip position on the accuracy of selective nerve root block (with lack of epidural spread), and found that a needle tip position lateral to the middle third of the pedicle produced an accurate contrast pattern in 92% of cases, which fell to 70% when the needle was advanced beyond the lateral third of the pedicle[249]

Assessment of Effect

Only the study by Yeom and colleagues[247] determined the optimal cutoff level in the percent relief of pain reported by a patient after a procedure needed to qualify for a positive response. Using receiver operator curves, these authors chose a cutoff of 70% subjective relief of pain after a lumbar transforaminal block as the best value to provide optimal accuracy but stated that this level could be adjusted depending on the importance of avoiding false-negative versus false-positive results.

We recommend adjusting the cutoff criteria between 50% and 90% depending on the importance of avoiding false-negative versus false-positive blocks. In our opinion, it is probably best not to treat results as a dichotomous variable but rather as a data point that is more or less likely to indicate the root is a source of pain. If a discrete cutoff is required, 70% is a good compromise. One might also consider requiring a similar degree in change of VAS improvement or, if inconsistent with the patient's subjective report of pain relief, asking the patient why the discrepancy exists or performing a confirmatory injection. The patient often reports a global relief of pain, whereas diagnostically one is interested only in the

degree of pain relief of the particular extremity distribution being evaluated. Relief or nonrelief of axial pain is important information but not pertinent to the location of the patient's extremity pain and to surgical outcomes.

Although provocation of concordant pain was frequently used in the past and perhaps is useful information, more recent studies use techniques to avoid creating pain during injection.[243,247] Pain referral patterns obtained by electrical stimulation may be considered as supplementary proof or nonproof.[243]

Sensitivity

The most likely causes of low sensitivity or a high rate of false-negative injections are inadequate blocks owing to poor spread around the root, failure to reach the pathologic site, dilutional effects with inadequate mass of anesthetic reaching the root, or poor diffusion because of scarring.[247] van Akkerveeken[248] found 100% sensitivity in 46 patients using 0.2 to 0.5 mL of 0.5% bupivacaine (with provocation) and reported 100% pain relief at 1 hour. Yeom and colleagues,[247] using 1 mL of 2% lidocaine without considering provocation, calculated a lower sensitivity of 57% (27 of 47) in all patients, increasing to 71% (25 of 35) when injections with inadequate spread were excluded. The causes of the inadequate blocks were spread of injectant into adjacent tissues in 4 of 10 patients, block by large disc herniation in 4 of 10 patients, and intraepiradicular sheath injection in 2 of 10 patients. Although Yeom and colleagues[247] had no explanation in the remaining 10 cases, these false-negative results might be explained by a paracentral herniated disc, which, although affecting primarily the traversing root, may also cause chemical irritation of the exiting root.

In addition, Dooley and colleagues[239] found that the most common reason for typical pain provocation during lumbar block with incomplete pain relief is multilevel pathology. The most probable cause in obvious cases is an inadequate block performed at a location distal to the structural entrapment. Diagnostic injections are often performed in patients with long-standing chronic pain and patients with prior surgery who may have intraneural and extraneural scarring. In such cases, local anesthetic may not penetrate the nerve effectively, and incomplete relief would be expected. Using a more concentrated anesthetic or an anesthetic that preferentially blocks nociceptors (e.g., bupivacaine) may reduce these false-negative responses.

Specificity

Because surgery is often less effective in patients with equivocal structural pathology, in patients with atypical, long-standing pain or prior surgery, one would ideally want to have minimal or no pain relief after the block of an asymptomatic root. van Akkerveeken[248] used a 0.2- to 0.5-mL volume of 0.5% bupivacaine and required 100% pain relief for 1 hour. He reported a specificity of "around" 90%.[248] In the lumbar spine, using 1 mL of 2% lidocaine and a cutoff value of greater than or equal to 70% pain relief, Yeom and colleagues[247] calculated 86% (50 of 58) specificity, which increased to 91% (43 of 47) specificity after excluding seven patients with overflow of local anesthetic. Although this overflow was thought to be a probable cause of false-positive blocks in 4 of 11 cases, 7 of 11 cases were true negatives, indicating that the estimated overflow when using 1 mL is about 20% (10 of 47) and with a potentially clinically observable effect in less than 10%.

Furman and colleagues[234] showed that even after injecting only 0.5 mL, the contrast pattern indicated nonselective flow in 30% of lumbar injections. The mass of drug overflowing at these low volumes may not be significant and is consistent with van Akkerveeken's higher, approximately 90% specificity. North and colleagues[99] reported an average 50% relief of sciatic pain when blocking the medial branches at several levels using a 3-mL volume, which would spread into the neuroforamen and epidural space, making the putative medial branch block nonspecific.[93] Nevertheless, sensory pathway convergence may be an alternative explanation of less than 50% pain relief in some cases, and a nonspecific "placebo" response may explain some or most false-positive responses.

Predictive Value

Many, mostly retrospective, observational studies describe in variable levels of detail the predictive value of lumbar spinal nerve root blocks. One retrospective study included the surgical predictive value of cervical and lumbar spinal nerve root injections.[243] Another prospective, diagnostic cervical selective root block study compared the diagnostic value of imaging with the short-term surgical predictive value of the test.[243] No studies to date support the use of diagnostic thoracic selective root injections, although this is primarily because the thoracic spine is not often studied because of the low prevalence of herniated thoracic discs.

In the only prospective outcome study, van Akkerveeken,[248] in his doctoral thesis, presented a series of studies correlating the value of selective root blocks to diagnosis of various lumbar entrapment syndromes and later summarized the data in a journal publication in 1993. A positive response was provocation of concordant pain and "disappearance" of leg pain after 0.2 to 0.5 mL of 0.5% bupivacaine. He studied patients with radiologic signs of nerve root entrapment but without localizing neurologic signs who subsequently underwent surgical decompression. Excluding the patients who had positive blocks and refused surgery, van Akkerveeken[248] reported a positive predictive value of 95% with a 95% confidence interval of 77% to 100%.

Technical Considerations and Potential Pitfalls

Techniques used by diagnostic lumbar studies place a needle varying in size from 22-gauge to 25-gauge into the foramen. Although older studies located the root by producing paresthesias,[233,235,238,239,241,242,244] more recent studies use a standard Spine Intervention Society technique of placing the needle tip just below the pedicle at the approximate 6 o'clock position viewed in and oblique plane (approximately 25–35 degrees) without purposefully provoking pain.[17,147] The transforaminal lumbar technique used by Macnab in the 1960s is similar to

the current technique and the technique often used by many longer-term interventionalists, including the senior author (R.D.).[34,250] The needle is first advanced to contact the transverse process beginning approximately 6 cm from the midline, parallel to the transverse process and at an angle of approximately 30 degrees. The needle is advanced into the foramen at a position that would be approximately 6 o'clock below the pedicle.[235,239]

Another older described selective nerve root block technique used in the lumbar spine begins with needle insertion approximately 6 cm from the midline and approximately 2 to 3 cm above the transverse process with needle advancement into the foramen at a cephalad-caudad angle to contact the ventral root at approximately the midpoint between the upper and lower pedicles and slightly lateral to the foramen.[233,238,244] A stimulating electrode can also be used to verify close proximity of the needle tip to the nerve.[243] Although this technique has been referred to as a selective nerve root block, it is actually a selective ventral ramus block or, if the dorsal root ganglion is outside the foramen, additionally a dorsal root ganglion block. A standard needle, blunt tip needle, or a polytef (Teflon)-coated (e.g., approximately 3.5-inch, 22-gauge) radiofrequency needle may be used to position the needle tip within approximately 1 to 2 mm of the nerve, which in many cases is adjacent to the dorsal root ganglion. If a stimulating needle is used, observing motor stimulation at 2 Hz and approximately 2 V helps position the needle, and pain referral patterns can be noted using sensory stimulation at 50 Hz at approximately 0.2 to 0.5 V. Using live fluoroscopic monitoring, a volume of contrast medium equal to that used for local anesthesia is injected. The presence or absence of axial, buttock–hip, and extremity provocation and the location of contrast dye when provocation occurs should be recorded (e.g., within the foramen or more proximal or distal to the foramen). The pattern and extent of contrast flow is recorded via digital copy. Flow of contrast dye should show a negative outline of the dorsal root ganglion, spinal nerve, and ventral ramus. If spread of contrast dye is clearly outside the foramen and does not surround the nerve, the needle can be repositioned and reinjected.

All prior lumbar studies except one[242] used approximately 1 mL of contrast dye to outline the nerve. Most studies and guidelines recommend visualizing contrast spread using live fluoroscopy during injection. In the cervical spine, some authors advocate observing contrast flow in an anteroposterior view using digital subtraction fluoroscopy to better recognize potential injection into an artery coursing medially toward the spinal cord.[251,252]

Some prior studies used a volume varying from 0.3 to 0.5 mL of 0.5% bupivacaine[248] to 1.5 mL of 0.5% bupivacaine in the lumbar spine,[242] but most injected 1 mL of either 1% or 2% lidocaine. In the only diagnostic article that evaluated cervical injections, Sasso and colleagues[243] used 0.5 to 0.75 mL of 2% lidocaine but varied volume depending on the observed contrast dye distribution. No studies have evaluated the diagnostic value of thoracic injections.

We recommend limiting the volume to 0.5 to 1 mL in the lumbar spine and 0.3 to 0.5 mL in cervical and thoracic spine. Although many prior studies used 1% to 2% lidocaine, we recommend a higher concentration to ensure adequate block.[243,247] At a minimum, 2% lidocaine should be used; however, an equal combination of 4% lidocaine and 0.5% bupivacaine can be used. The volume can be adjusted between the lower and upper limit depending on the contrast flow pattern. Higher concentrations must, however, be used with caution as seizure is a reported complication of local anesthetic injection in the cervical transforaminal space using a subpedicular approach.[253]

Pitfalls regarding selective nerve root blocks include complications of the procedure. Although complications after transforaminal injections are mostly minor,[254–256] there are growing concerns regarding the safety of cervical transforaminal injections[257,258] and to a lesser extent thoracic and lumbar injections based on published and unpublished cases of neurologic damage after the injection of local anesthetic and corticosteroids into the neuroforamen.[259–263] Reported and unreported complications all involve the use of particulate corticosteroids that are alleged to have been injected into the vertebral or radicular artery. Some unpublished legal cases are, however, consistent with direct injection into the cord. Although legal cases claim that injury was secondary to injection of particulate corticosteroids into a lumbar or thoracic radicular artery, to our knowledge, there has been no reported case of neurologic damage secondary to arterial injection using nonparticulate corticosteroids. Nonparticulate corticosteroids are now recommended when performing cervical transforaminal injections.[264] Furthermore, as studies[265,266] show little difference in therapeutic efficacy between particulate and nonparticulate steroids, there is a growing consensus for the use of nonparticulate steroids for all transforaminal injections. On the other hand, if steroid is not added to the injectate for selective nerve root block, there should be no risk of spinal cord infarction due to intravascular injection of local anesthetic. Direct spinal cord injection is rare and in cervical transforaminal injections is likely preventable by using a shorter needle, always advancing the needle over bone (superior articular process), checking an anteroposterior fluoroscopy view before injection, and titrating patient sedation appropriately.

Although current techniques strive to avoid contacting the nerve, contact does occasionally occur, and probing for paresthesias was a common technique in the past. Lasting effects are probably uncommon, and none of the prior reviewed diagnostic block studies reported any complications. Injecting local anesthetic or contrast dye directly into the dorsal root ganglion, nerve, or epiradicular sheath may cause a flare in pain, however, lasting several days to several weeks.[247] Permanent injury is probably rare and to our knowledge unreported.

A needle placed too far medially can pierce the nerve root sleeve surrounded by the dura contiguous with the subarachnoid space. Injection may cause a high spinal block, which may necessitate resuscitation if injected in the cervical spine and may potentially lead to some degree of cord or root irritation secondary to added preservatives if depot steroids are injected. Puncture of the dura may also cause a low-pressure cerebrospinal fluid headache, which usually

resolves spontaneously or can be treated with a routine blood patch. Slipman and colleagues[232] reported a case of recalcitrant headache cured after transforaminal blood patch. Infection may occur, but is rare. If the patient has a foraminal disc protrusion, inadvertently passing a needle into the disc may occasionally occur and could lead to a disc space infection.[267] If the operator knows that disc injection has occurred, use of a small amount of intradiscal and intravenous antibiotics may be considered (as would be the routine with discography).

Confounding Factors

Blocking the exiting spinal nerve anesthetizes several important neural elements. Receiving branches from the sympathetic system, the sinuvertebral nerve emerges lateral to the foramen and courses back through the foramen to innervate the posterior longitudinal ligament, the disc anulus at that level and one or two levels above. The sinuvertebral nerve can also innervate the contralateral side. In addition, lateral to the dorsal root ganglion, the dorsal root branches innervate posterior structures, including branches to the zygapophyseal joint at the same level and level below as well as the interspinous and supraspinous ligaments. Relief of pain may be due to anesthesia of these structures, which are not typically considered. Additionally, the furcal nerve, which typically exits the L4 foramen, is a separate nerve with its own dorsal root ganglion; it sends branches to the lumbosacral trunk, femoral, and obturator nerves. Irritation of this nerve causes seemingly aberrant pain distribution to the hip, groin, and inner thigh.

Summary

When pain recurs or is poorly responsive to therapeutic injections and the clinical and imaging studies are inconclusive or indicate more than one potential pain level, diagnostic transforaminal injections may be considered. As with all diagnostic spine injections, preprocedural and postprocedural evaluation should be performed with a standardized protocol by unbiased personnel and confirmation by the physician. Using the same testing protocol, the patient is tested at approximately 20 to 40 minutes after block with lidocaine and approximately 40 to 60 minutes after block with bupivacaine or ropivacaine. Additional testing at 1 to 3 hours postblock may help reduce both false-positive and false-negative results. The block should last for 2 hours if lidocaine is used and about 2 to 4 hours if bupivacaine or ropivacaine is used. If the pain relief is less than 70%, one can return the patient to the interventional suite and block one more additional suspected level. Diagnostic injection should be performed using one of the standard transforaminal approaches, preferably performed by an experienced interventionalist or surgeon. The patient should be no more than lightly sedated or sedated with a low dose of propofol that has a very short half-life.

A low volume of a concentrated anesthetic solution should be used that is limited to 0.3 mL or less in the cervical spine, 0.5 mL or less in the thoracic spine, and 1 mL or less in the lumbar spine.[234] One might consider using an equal mixture of 1% and 4% lidocaine or 0.5% bupivacaine. If performing a therapeutic injection, 0.5 mL of nonparticulate corticosteroid (e.g., 5 mg dexamethasone) may be injected in the cervical and thoracic spine approximately 1 to 2 minutes after local anesthetic injection, and either nonparticulate or a longer-acting depot preparation may be injected in the lumbar spine (e.g., approximately 20 mg of triamcinolone acetonide or 5–10 mg of betamethasone).

The immediate results and patients' longer-term pain relief are used to counsel them on their chances of obtaining relief of extremity pain after a surgical procedure. Patients who have immediate pain relief after one-level block of approximately 70% or greater and pain less than 1 year's duration have an 85% or greater chance of a satisfactory result.[239,240,243,247,248,250] If the patient has had prior surgery, one might want to lower the patient's expectation from 85% to perhaps approximately 70% or less depending on how convincing the structural pathology appears on MRI or CT.[241,244] Patients who have unconvincing structural pathology, radicular pain greater than 1 year's duration, relief of less than approximately 70% of pain after block, less than approximately 1 week of therapeutic pain relief, and especially evidence of intraradicular or extraradicular scarring should be referred for possible spinal cord stimulation or other nonoperative treatment.[34,239,241,247,248]

Patients with clear structural nerve entrapment with radicular pain less than approximately 1 year's duration, with no immediate or delayed longer-duration relief, may be offered surgery, but the patient should be counseled that there is an approximately 60% chance of a good outcome.[243] If the duration of the patient's pain is greater than 1 year, perhaps the patient should be told that there is an approximately 60% chance of having partial pain relief but that the pain relief would likely be less than 50%.[34,243] Even if the same patient with more chronic radicular pain had immediate pain relief but no longer-term relief, and especially if there was suspected neuropathic pain and a prior surgery, the patient should be counseled that the chances of a good outcome are no greater than approximately 50%.[241] Finally, we emphasize that relief of pain does not determine the cause of the pain, and if a patient's spinal nerve root pain is neuropathic, decompression with or without stabilization would most likely not provide satisfactory relief of pain.[268]

PEARLS AND PITFALLS

1. Much is learned during the process of diagnosis, especially if the process includes unpleasant diagnostic interventional procedures.
2. Diagnosis is the process of elimination. Patients should be counseled that negative responses are useful and important information.
3. Beware of patients with chronic pain without convincing structural pathology who consistently complain that they are no better or worse after appropriate therapeutic interventional procedures. Your reconstructive spine surgery may suffer the same fate.
4. Indeterminate and negative diagnostic block results are more common than clearly positive results.

5. Chronic spinal pain is often caused by structures in different columns and levels. Treating one source of pain often unmasks pain from a different source. Failure to relieve other sources of pain does not necessarily mean one's surgery failed, but the possibility of failure due to other sources is best identified before surgery.
6. When the diagnosis is not obvious and most of the pain is axial and referred extremity pain, consider first evaluating the posterior elements. Blocking the medial and/or lateral branches of the dorsal ramus will denervate most structures in the posterior column.
7. Do not neglect to rule out shoulder and hip pathology.
8. Convincing relief of pain for several weeks or longer is consistent with a reversible cause of pain.
9. Fusing to a painful sacroiliac joint is best avoided. Investigate and discuss the possibility before surgery rather than after.
10. Chronic dynamic irritation of neuraxial structures can cause buttock and axial pain in addition to referred extremity pain. Relief of axial pain following selective epidural block(s) that lasts several weeks or longer is consistent with pain due to static or dynamic stenosis. If in doubt, diagnosis can be confirmed by a *negative* response to medial branch block and a *negative* response to pressure-controlled discography, analgesic discography, or both.

KEY POINTS

1. Image-guided, precision injections (with local anesthetic and a dual-block paradigm) are the current reference standard for diagnosis of chronic spinal pain emanating from the middle and posterior column. Current research shows that history, physical examination, and advanced imaging findings have insufficient sensitivity and specificity for identifying the pain generator. Ideally, as with sacroiliac pain, the reference standard will evolve to include validated and accurate historical and physical examination features; however, with radicular pain and zygapophyseal joint pain, this is not yet the case.
2. Diagnostic injections are typically reserved as a tertiary intervention for patients with chronic, disabling spinal pain that is nonresponsive to conservative care and for patients with atypical presentations in whom the history, physical examination, and electrodiagnostic and imaging studies are unrevealing or nondiagnostic.
3. During a diagnostic block, relief of pain is more convincing than provocation of pain. The standard for percent relief is, at a minimum, greater than 50%; however, greater than 70% is more convincing.
4. Patients with psychosocial distress can have legitimate pain. Often, the psychosocial distress resolves with appropriate diagnosis and treatment of the pain generator.
5. Negative diagnostic blocks also provide useful information. A negative response suggests alternate explanations: first, the structure evaluated may not be the source of pain and therefore additional structures must be evaluated. Lack of relief may also be due to the development of irreversible local damage (e.g., intraneural fibrosis) or neuropathic pain with significant peripheral and central sensitization.
6. If rigorous technical and procedural performance standards are adhered to, the response to diagnostic blocks has been shown to predict good to excellent surgical and interventional treatment outcomes. Fair or poor response to diagnostic blocks can be used to counsel patients appropriately in terms of surgical outcomes.

17 CHAPTER Discography

Eugene Carragee
Michael Stauff

Provocative discography is a diagnostic test sometimes used to evaluate the disc as a potential source of persistent back and neck pain syndromes. In its simplest form, provocative discography is an injection into the nucleus of an intervertebral disc; the test result is determined by the pain response to this injection. If the injection reproduces the patient's usual pain, some authors have proposed that the "cause" of the axial pain syndrome can be ascribed to that disc—that is, *primary discogenic pain*.

In 1948, Lindblom[1] originally reported discography as a method to identify herniated discs in the lumbar spine by injecting contrast medium into the disc and following the outline of contrast medium into the spinal canal. It was noted as only a secondary consideration of the test that reproduction of the patient's usual sciatica sometimes occurred during the disc injection. It was observed later that back pain was sometimes reproduced during the injection as opposed to sciatica. Eventually, some clinicians began using the test to evaluate discs as the source of axial pain in patients without radicular symptoms.

Since the early use of discography, it has been unclear whether reproduction of pain with injection indicated that the injected disc is the true primary source of clinical back pain, or whether the injection had simulated the usual pain in an artificial manner. Over time, attempts have been made to determine the specificity of the test and to refine the technique to reduce the risk of false-positive or false-negative results. Currently, this test remains highly controversial. Even the staunchest proponents of the procedure state that "discography is a test that is easily abused."[2] Assessment of provocative discography as a basic diagnostic test has found fundamental problems with test reliability (i.e., does the test give the same result on repeated testing?) and validity (i.e., does the test prove what it purports to prove?). Also, it has not been shown that using the test improves the outcomes in patients receiving the test compared with patients not receiving the test. More recently, the long-term safety of disc puncture and injection has also been questioned. This chapter discusses the rationale, technique, utility, and clinical effects of provocative discography when used in patients with primary axial pain syndromes.

Clinical Context

Back and neck pain are very common, and in most cases determining the "cause" of a specific episode of back or neck pain is unimportant because these symptoms frequently resolve in a short time or do not seriously interfere with function.[1] Provocative discography may be described as representing a *tertiary diagnostic* evaluation, which should be considered only in a select group of patients.

A *primary diagnostic* evaluation usually involves screening for serious underlying disease ("red flags") by history and physical examination aimed at detecting systemic disease, spinal deformity, and neurologic loss. In most patients, these examinations are negative, and nonspecific treatment alone is recommended. In a patient who does not recover good function in 6 to 12 weeks, a *secondary diagnostic* survey may be indicated. This follow-up evaluation should identify serious psychosocial barriers to recovery ("yellow flags") and definitively rule out serious conditions that may result in neurologic injury; structural failure; or progression of a visceral disease, systemic infection, or malignant process. Diagnostic tests for serious structural disease, including blood tests and imaging studies, have become so sensitive that these serious conditions are usually identified in the early stages.

Establishing a more specific pathoanatomic diagnosis than "nonspecific back pain syndrome" or "persistent back pain illness" becomes important only if specific therapy directed to common age-related structural changes is considered because of continued serious symptoms and functional loss. At this point, if the primary and secondary evaluations have revealed neither serious structural pathology nor significant confounding psychosocial or neurophysiologic factors, a tertiary diagnostic evaluation may be undertaken. This evaluation may occasionally uncover a clear degenerative cause of symptoms, such as unstable spondylolisthesis or progressive degenerative deformity, such as degenerative scoliosis.

The most common structural degenerative changes (e.g., loss of disc height, loss of nuclear signal, minor facet arthrosis, anular fissures) may be very difficult to reconcile with the severity of apparent symptoms and pain behavior, however,

because many people with minimal or no spinal symptoms have similar mild degenerative findings. The question is why do individuals with such benign findings sometimes report severe and persistent pain and impairment? The rationale of provocative discography in the tertiary evaluation is to separate anatomic spinal changes causing serious primary pain illnesses from similarly appearing common degenerative changes that do not cause serious illness. As this chapter shows, it is unclear that this goal is routinely achievable with provocative discography.

Discography Technique

Discography is performed using local anesthetic and mild sedation. The objective is percutaneous injection of a nonirritating radiopaque dye, under fluoroscopic guidance, into one or more intervertebral discs. The technique involves using a long, fine-gauge needle to penetrate the nucleus from a posterolateral approach in the thoracolumbar spine and anterolaterally in the cervical spine. In the lumbar spine, the needle passes posterior to the exiting nerve root and anterolateral to the traversing root. Sometimes a bend of the needle or introducer is required to place the needle accurately, especially at L5–S1.

The passage of the needle in skilled hands should be quick and atraumatic. When the position is verified in two planes using fluoroscopy, the dye is slowly injected into the nucleus of several lumbar discs with the patient blinded to the timing and site of injection. The spread of the dye in the disc is noted on the images, and the patient's response to the injection is documented. The patient is queried at each injection or at random intervals as to whether or not the procedure is painful and is asked to rate the pain against a standardized scale (e.g., 0–5, 0–10, none to unbearable). If the injection is painful, the patient is asked to describe the discomfort provoked qualitatively. The injection is usually rated as exactly the same as, similar to (concordant), or dissimilar to the patient's usual back or neck pain.

Criteria for Positive Test

In an effort to improve the specificity of discography in diagnosing so-called discogenic pain, some investigators have used additional criteria beyond pain reproduction on injection. The criteria for establishing a positive discogram are controversial. The primary criteria for a "positive" disc injection are pain of "significant" intensity on disc injections (usually defined as ≥6 out of 10 pain scale) and a reported similarity of that pain to the patient's usual, clinical discomfort (concordant pain). Walsh and colleagues proposed these basic criteria in their experimental work in 1990.[3] In this study, "significant pain" was defined as 3 out of 5 (or 6 out of 10) on an arbitrary pain thermometer. "Bad pain" was defined as 3 out of 5 pain, and "moderate pain" was described as 2 out of 5 pain. The authors did not stringently define concordance of pain reproduction. Some investigators have proposed additional and sometimes idiosyncratic criteria for positive injections (Table 17.1).

Pain Generator Concept and Provocative Discography

The diagnosis made by a "positive provocative discogram" should indicate that the disc identified is the primary or only cause of the patient's back pain illness, or the *pain generator*. The idea of a pain generator, however, has proven to be problematic. In a patient with persistent symptoms and a secondary workup with only degenerative findings, the task of identifying a specific isolated pain generator can be formidable. Most patients have multiple findings of disc changes and facet arthrosis, often at multiple levels. To determine which degenerative finding is associated with a patient's severe axial back pain can be difficult. Many people have occasional back or neck ache with common activities or episodic axial pain without impairment. The question is not whether any previous or possible future back or neck pain may be coming from a certain spinal structure because it may be assumed that most people with degenerative change of the axial skeleton may have occasional discomfort from several sites alone or at the same time.

The pertinent question is whether or not a suspected local anatomic structure (e.g., disc, facet, sacroiliac joint) is causing serious, disabling axial pain illness or is only a minor contributor to a generalized pain-sensitivity syndrome (e.g., fibromyalgia), a central pain-processing syndrome, an overuse syndrome related to posture or activity, or other conditions. It is hoped that some diagnostic test can identify whether or not a specific *local* spinal pathoanatomic structure adequately explains the severity of clinical symptoms. As a matter of practical definition, for a pathoanatomic diagnosis to be clinically relevant requires that the identified pain generator not only be capable of causing some discomfort under any circumstances (e.g., puncture and injection of a disc) but also that this structure is a primary independent cause of the patient's apparent severe illness.

When only degenerative changes are found, it is controversial that a discrete local pain generator can be identified as the cause of serious back pain illness. Some clinicians believe that serious axial pain and disability can be so multifactorial (mechanical, psychological, social, and neurophysiologic contributors) that it is unreasonable to expect specific diagnostic studies to confirm an anatomic "diagnosis" for axial pain illness in every patient.[4–6] Even if a pain generator is suspected, it is unclear how this can be reliably confirmed as the cause of the patient's perceived pain, impairment, and disability in the face of complex social, emotional, and neurophysiologic confounders.

Other clinicians believe that identifying a pain generator is central to spine evaluations because it meets patients' expectations and leads to an optimal treatment that focuses on an anatomic structure. In this model, social issues such as disability, litigation, psychological distress, and pain intolerance are believed to be *secondary* issues to the structural pathology.[1,7–13] These clinicians generally believe that although the history and physical examination may be helpful in suggesting serious underlying pathology, such as infection and tumor,

TABLE 17.1 Suggested Criteria for Positive Provocative Discographic Injection

Test Criteria for Positive Result	Positive Test Threshold	Comments
Pain response (intensity)	≥6/10 or 3/5 "Bad" pain or worse on pain thermometer ≥7/10	Subjective and arbitrary scale. No data on reliability. Data on validity in small groups of asymptomatic subjects without psychosocial comorbidity are good (specificity >90%). Data in several studies of subjects with increased psychosocial or chronic pain comorbidity indicate validity in these subgroups is poor (specificity 20–60%).
Qualitative pain assessment (concordant pain)	"Concordant pain" usually including "similar" but not exact pain "Exact" pain only	Subjective response. Data on reliability are unknown. Data on validity in small study of experimental nondiscogenic low back pain indicate that validity is questionable.
Anular disruption	Dye must show fissure to or through outer anulus	Tested only in clinical studies without follow-up to confirm outcome or other gold standard. Radiologic reliability best with computed tomography scan after disc injection compared with radiograph alone. Validity of additional criteria as confirming true-positive test unknown; positive injection in discs without anular disruption more common in psychologically disturbed subjects.
Control disc injections	"Negative" injection (minimal or discordant pain) required adjacent to proposed "positive" disc "Normal" injection (i.e., no pain) Some authors insist that adjacent "control disc" must also have grade 3 anular fissure, which is "relatively painless" at equal or higher pressures than "positive disc"	Injections in morphologically normal discs seem to be reliably negative even in subjects with serious psychological distress and no back pain. Reliability in other disc morphology unknown. Validity of this additional criterion as confirming true-positive test unknown.
Demonstration of pain behavior	Facial expressions of pain must be observed to confirm verbal pain report	Reliability and validity of this criterion as confirming true-positive test unknown.
Pressure-controlled injection	Disc injections should be classified into low (<15 or <20 psi) or high (>50 psi) pressures at time of significant pain response; responses at pressures in between are indeterminate	Small outcomes series suggest that low-pressure sensitive discs are better treated with interbody fusion techniques. Reliability and validity unknown.
Volume-controlled injections	"Excessive volume" or speed to injection invalidates injection	Unvalidated concept based on anecdotal evidence. Primary data unavailable to analyze.
Maximum one or two positive disc injections	More than one or two positive disc injections invalidates study (all are indeterminate)	Assumption is made that generalized hyperalgesic effect may lead to multiple positive discs around single pain generator.
Quantify pain tolerance by response to buffered anesthetic injection	Subjects with poor pain tolerance may not be "ideal" candidates for discography; needs to be detected	It is unclear that pain tolerance to intradermal anesthetic injection is valid test to determine "pain tolerance" in patients with long-standing axial pain.
Needles should be inserted from asymptomatic or least symptomatic side	Theoretically may decrease confusion between injection and insertion pain	Some data suggest this is not an important technique. No gold standard confirmation was applied.
Any positive disc injection must be repeated with similar outcomes before accepting result as "positive"	Intraprocedure reliability test	No data available on whether this improved or decreased test accuracy.

these methods are not helpful in determining the true pain generator among many degenerative structures.

Diagnostic Injections and Modulation of Pain Perception in Axial Pain Syndromes

Provocative discography relies on a patient's subjective perception and report of pain after a progressive pressurization injection of a disc. Alternatively, a disc may be injected with an anesthetic agent with subsequent documentation of the patient's subjective pain relief after activities that usually provoke pain. These diagnostic injections seek to identify a primary pain generator by provocative testing (stimulating a potential site of pain, as in discography) or by temporary local anesthetic relief. These are subjective tests of pain perception and are subject to the effects of volitional and neurophysiologic modulation at multiple points along the neuraxis. Many common factors are known to have potential dampening or amplifying effects on the perception of back and neck pain. These factors must be considered when evaluating the validity of diagnoses determined by diagnostic injections.[14–19]

Adjacent Tissue Injury

Injury to adjacent tissues may increase the perception of pain in surrounding structures by a local *hyperalgesic effect*. This is a well-known phenomenon that occurs with any tissue damage; it may amplify pain perception by increasing local inflammatory processes with secondary neurologic sensitization in areas not directly injured, such as the area surrounding a burn or a fracture that is sensitive but without any thermal or mechanical injury. This is an important phenomenon in patients with low back pain and significant disease at one or more levels, which may sensitize the adjacent segments to provocative testing (e.g., a spine that has undergone multiple operations).[14,20]

Local Anesthetic

Local anesthetic injections may decrease the perception of pain at a local site. This is the specific, active effect used in diagnostic blocks. This decrease in pain perception can also be a source of confounding effects if the exact placement of the agent is not well controlled. In addition to this direct local effect, a nonspecific placebo effect and a neurophysiologic modulation effect may occur. A relevant example is the effect of local anesthetic blockade on the perception of painful stimulus along the neuraxis proximal to the injection. A local anesthetic injection in the lower extremity may be perceived as relieving sciatica owing to disc herniation.[21] This is not a placebo effect (i.e., the phenomenon is seen only with an active anesthetic agent) but rather an effect on neuromodulation. This effect is important in diagnostic anesthetic blockade as a source of false-positive and false-negative findings.[22]

Tissue Injury and Nociception in Adjacent or Same Sclerotome

Tissue injury having the same or adjacent sclerotomal afferents as lower spinal elements may increase pain sensitivity at any given site. This effect is thought to be due to physiologic and anatomic changes at the level of the dorsal root ganglion or spinal cord ascending tracts. In animal models, single afferent neurons from a dorsal root ganglion may innervate three adjacent discs and a wide range of adjacent structures. This effect is important in considering the specificity of discography at sites of similar embryonic derivation to a known pathologic structure (e.g., nonunion, spondylolisthesis, painful iliac crest bone graft site). The confounding effect of this phenomenon in discography has been experimentally and empirically shown (discussed later).[14,23]

Chronic Pain Syndromes

Chronic pain syndromes may complicate the evaluation of low back pain. Chronic pain from regional sites that are near the lumbar spine (chronic pelvic pain, irritable bowel syndrome, failed hip arthroplasty) or distant to the lumbar spine (chronic neck pain, chronic headache, temporomandibular joint syndrome) may increase pain sensitivity at lower spinal elements. This effect may be regional or global and may be related to neurophysiologic changes at multiple levels along the neuraxis. Preexisting chronic pain syndromes are also associated with depression, narcotic use, and habituation, which have independent pain perception effects. This effect has been shown to have an impact on the pain intensity from discography in experimental subjects.[14,23]

Narcotic Analgesia and Habituation

Narcotic medications act at multiple levels to decrease pain sensitivity thresholds, intensity, and affective response. Administration of a narcotic medication may act as a common confounder for diagnostic techniques that require accurate feedback of pain perception from a patient.[14,24,25] Chronic narcotic habituation may act to decrease pain tolerance in the absence of increased narcotic intake. Narcotic habituation decreases endogenous abilities to modulate peripheral nociceptive input. This effect is multifactorial. Chronic narcotic habituation is also associated with depression and sleep disturbances.

Depression, Anxiety, and Somatic Distress

Clinical depression, anxiety disorders, and increased somatic awareness may be seen as predisposing factors to chronic low back pain syndromes or reactions to the pain and disability of chronic low back pain illness, or both. In either event, psychological distress usually decreases the pain threshold perception and increases perceived pain intensity and affective response.[5,24,26] These effects are likely due to central neurochemical changes and systemic effects and have been shown to affect pain responses in discographic evaluation.

Social Imperatives

Overriding social imperatives may result in a decreased pain perception or a dissociation of pain perception and functional loss. A decreased pain perception or even an absence of pain perception despite injury can be seen during some short-term stressful events, such as in accident victims, soldiers in combat, or individuals in certain training environments. Even over long periods, social and cultural factors reinforce low pain-perception reporting and muted or absent pain behaviors.

Social Disincentive

Secondary gain issues may exaggerate pain responses of all types. When the intensity of pain behavior and report is correlated with a real or perceived social benefit or monetary compensation, the reported pain perception and pain behavior may be increased. This situation can have direct effects on provocative testing (e.g., discography) and the need for a specific anatomic diagnosis to establish social validity of an ongoing "sick role." A real-world example of social disincentive exists in patients who have sustained a work-related injury that requires an extended course of evaluation and treatment.

Summary

When considering the diagnostic certainty of a possible pain generator in chronic axial pain illness, it is necessary to view the aforementioned confounding factors for contribution to the illness behavior observed (Table 17.2). An injured soldier with facial trauma, after narcotic administration and in the heat of combat, may mask the perception of a significant low back pain injury that otherwise could be clearly symptomatic. In this case, a bona fide local pain generator results in little pain perception. Conversely, a very minor nociceptive input (common backache) from a disc can be amplified in the case of a patient with multiple chronic pain syndromes, narcotic habituation, depression, and compensation issues (social disincentives). In this case, a common mild backache pain generator is amplified to become a catastrophic illness.

Evidence for Validity and Usefulness of Provocative Discography

Sackett and Haynes have described the criteria for an evidence-based evaluation of diagnostic test validity.[27] Four phases of scientific scrutiny and evidence in discography research are shown in Table 17.3. These phases of evidence progress from the simple comparison of testing in subjects known to have

TABLE 17.2 Neurophysiologic Factors Influencing Result of Diagnostic Injections

Modulator of Diagnostic Injection Effect	Type of Effect on Pain Perception at Site of Injection	Diagnostic Effect
Adjacent tissue injury	Increased regional pain perception	Decreased specificity in provocative injection
Local anesthetic	Decreased pain perception at depot site and sometimes in sclerotomal or referral pattern	Decreased specificity in provocative injection
Tissue injury in adjacent or same sclerotome	Increased regional pain perception	Decreased specificity in provocative injection
Chronic pain syndrome	Increased generalized pain perception	Decreased specificity in provocative injection
Narcotic analgesia	Decreased generalized pain perception and affective response	Decreased sensitivity and increased specificity of provocative injections
Narcotic habituation	Increased pain perception and exaggerated affective response	Decreased specificity in provocative injection
Depression, anxiety, and somatic distress	Decreased generalized pain perception and unpredictable affective response	Decreased specificity in provocative injection
Social imperatives	Decreased pain perception, suppressed affective response	Decreased sensitivity and increased specificity of provocative injections
Social disincentives	Specific increased pain reporting and demonstration of pain behavior	Decreased specificity in provocative injection

TABLE 17.3 Four Phases of Evidence-Based Criteria for Evaluation Diagnostic Tests

Phase of Study	Strategy	Discography Evidence
Phase I	Diagnostic test compared in subjects with index disease vs. results in complete normals (experimental setting)	Few painful disc injections in completely normal asymptomatic subjects (e.g., normal psychometric testing, normal disc morphology, no chronic pain issues, no compensation issues) Examples: Walsh et al., 1990[3]; Carragee et al., 2000[16]
Phase II	Evaluation of range of test results in subjects with disease (establishes positive result guidelines) compared with known normals	Wide range of pain reactions to injections in asymptomatic subjects depending on psychological status, disc morphology, chronic pain issues, compensation issues. Wide overlap between asymptomatic subjects and patients with presumed discogenic pain. Examples: Carragee et al., 2000[16]; O'Neill and Kurgansky, 2004[23]; Carragee et al., 2006[38]
Phase III	Diagnostic test applied in clinical subjects likely to have disease (clinical setting of test application in subjects with similar presentation, signs, symptoms, and risk factors)	Poor validity testing subjects with persistent low back pain with known nondiscogenic pain syndromes (e.g., iliac crest pain) or asymptomatic disc pathology (i.e., previous disc surgery). PPV approximately 50% in ideal patient, PPV <50% in typical discography patient (outcome findings). Examples: Carragee et al., 1999[15]; Carragee et al., 2000[35]; Derby et al., 2005[36]; Carragee et al., 2002[37]; Carragee et al., 2006[43]
Phase IV	Does having the diagnostic test result improve outcomes compared with management without test result (controlled trial)?	Little to no evidence of provocative discography improving outcomes compared with modern diagnostic techniques.[40] Substantial evidence provocative discography is worse than anesthetic injection alone.[42] Substantial evidence discography may worsen outcomes in certain at-risk groups.[44–46]

Data from Sackett D, Haynes R. Evidence base of clinical diagnosis: The architecture of diagnostic research. *BMJ*. 2002;324:539–541.
PPV, positive predictive value.

a disease with subjects who are completely normal without any signs, symptoms, or morbidity associated with the disease (phase I) to the blinded study of a diagnostic test in determining outcomes in actual clinical therapeutic intervention (phase IV).

An example of a phase I diagnostic study is the classic study of discography by Walsh and colleagues[3] in asymptomatic healthy young men without significant degenerative disease or comorbidities associated with chronic low back pain illness (e.g., depression, chronic pain behavior, compensation issues). Discography seemed to perform well in this phase I study, with little pain provocation in the subjects with a lack of disease (one of 10 subjects [10%; 95% confidence interval, 0–40%] had pain intensity rated "bad"). In phase II and III studies, comparing subjects without low back pain illness but with significant comorbidities, discography did not perform as well.[15,16]

Generally, there has been limited high-quality evidence supporting provocative disc injections. Despite the limited evidence, some authors believe that primary discogenic pain is the most common cause of chronic low back pain illness.[12,13,28,29] As is shown subsequently, a major constraint in this research has been a failure to use a bona fide gold standard for primary discogenic pain causing low back pain illness against which investigators document that the diagnosis suggested by discography is correct.

Validity of Discography

Discography purports to diagnose the presence or absence of a disc lesion responsible for the syndrome of chronic low back pain illness caused by primary discogenic pain. There is no commonly used gold standard or criterion to determine who actually has chronic low back pain illness from primary discogenic pain. There are well-accepted standards, however, for who does not—someone with no evidence of significant low back pain. Similarly, someone with new pain resulting from another process (pelvic fracture) does not have "chronic low back pain illness caused by primary discogenic pain." Provocative discography can be assessed by the results of disc injections in subjects who definitively do not have chronic low back pain illness caused by primary discogenic pain.

Alternatively, a patient's response to treatment may be considered a surrogate gold standard if the treatment definitively removes the pain generator (the disc) and adjustments can be made for surgical and nonspecific limitations of the treatment. The following section describes a series of clinical and experimental studies that have attempted to define the specificity of discography in different at-risk subgroups.

Specificity of Positive Discography: Testing on Subjects With No Axial Pain History

Careful technique and the standardization of discography were believed by many discographers to have reduced the false-positive rate to a negligible level in experienced hands. In 1990, Walsh and colleagues[3] performed a carefully controlled set of discographic lumbar injections in 10 paid volunteers, all asymptomatic young men (mean age, 22 years) with little disc degeneration. Of 30 discs injected in this asymptomatic group, five produced "minimum" pain (16.7%), two produced "moderate" pain (6.7%), and one produced "bad" pain (3.3%). Based on these data, the authors believed that the risk of false-positive injections was very low. This study is frequently, and incorrectly, cited to confirm a 0% false-positive rate.

In 1997, a review of one discography practice[26] found cases that seemed to be clinically apparent false-positive cases. These injections were believed to meet full criteria for discogenic pain, with concordant, painful injections and negative control injections. Clinical follow-up revealed other causes of the patients' back pain illness, however, including spinal tumor, sacroiliac joint disease, and emotional problems. Block and colleagues[30] related abnormal Minnesota Multiphasic Personality Inventory (MMPI) testing and Ohnmeiss and colleagues[31] related abnormal pain drawings with "nonorganic" features, suggesting possible false-positive discographic injections. Other authors performed thoracic[32] and cervical[33] injections in subjects asymptomatic for pain in those areas. Significantly painful injections were found to occur in approximately 30% of these volunteers.

Following the Walsh protocol, Carragee and colleagues[16] examined 30 volunteer subjects with no history of low back pain who were recruited to undergo a physical examination, magnetic resonance imaging (MRI), psychometric testing, and provocative discography. The results showed that little pain was elicited by injection of any anatomically normal disc. Discs with advanced degenerative anular fissuring with dye leakage to the outer (innervated) anular margins were more commonly painful after discography than less degenerative or normal discs. The intensity of the pain reported by the subjects with anular disruption was predicted by the presence of chronic nonlumbar pain and abnormal psychological scores. Only 10% of subjects without any other pain processes had a positive disc injection by the Walsh criteria, but 50% of subjects with nonlumbar chronic pain had at least one positive disc injection.

The interaction between pending compensation claims and discographic pain was also significant in this select group of volunteers. Of the 10 subjects with positive injections, 8 had contested workers' compensation or personal injury claims, with resulting litigation. Conversely, of 9 subjects with disputed litigation claims, 8 had positive injections ($P < .0001$).[16] It was not found, however, that all subjects involved in previous work injury claims had similar rates of positive disc injection. A history of an uncontested claim from a past compensation injury and no pending legal action did not predict significant pain on disc injection. Given that no subject in this study stood to have any secondary gain from positive discography, the increased pain reporting in subjects with unrelated but contested compensation claims is intriguing. It is possible that the effect of the prolonged social turmoil associated with a litigation dispute has the effect of diminishing one's resilience to irritative stimuli. Another explanation could be that persons with abnormally low pain tolerance are more likely to have a legal dispute regarding the significance and damages associated with previous minor injury.

Discographic Injections in Previously Operated Discs

Provocative discography is frequently used to evaluate persistent or recurrent low back pain syndromes in patients who have had a posterior discectomy. The validity of interpreting painful injections after herniation is unknown despite its common usage. Heggeness and colleagues[34] reported on 83 postdiscectomy patients and found that 72% had a positive concordant pain response on injection of the previously operated disc. This study did not address the possibility of false-positive injections. All positive injections were assumed to be true-positive injections for identifying the source of the patient's pain.

Using the same methodology developed by Walsh and colleagues,[3] a large study of discography in asymptomatic patients after discectomy for sciatica was performed.[35] Painful disc injections were frequently seen in the asymptomatic postdiscectomy group. As in previous studies, a higher rate of painful injections was seen in patients with abnormal psychological profiles.

Validity of Concordance Report

Provocative discography is considered positive only when the injection elicits the patient's usual pain in quality and in location. The reliability of the test would be substantially supported *if* patients could identify the quality of pain coming from a particular disc and differentially compare that sensation with their usual pain. It is unclear to what extent similar neurologic and behavioral factors may influence the results in provocative discography. It is possible that the disc stimulation in discography may also provoke a "concordant" pain response without actually having located a true pain source. As discussed earlier, there have been reported cases of individuals undergoing discography who were diagnosed as having discogenic pain as the source of their illness on the basis of positive concordant disc injections, but who were subsequently shown to have nonspinal sources for their pain.[26]

This issue was investigated using an experimental model to determine the response to disc injection in patients known to have nonspinal back pain.[15] Subjects were recruited to participate in this study if they had no history of back pain and were scheduled to undergo posterior iliac crest bone graft harvesting for nonspinal problems, including appendicular fracture nonunions or bone tumors. Most of these patients experienced low back and buttock pain from bone grafting for several months postoperatively; this pain was in a similar distribution to what is normally considered discogenic lumbar pain. Discography was performed several months after bone graft harvesting; subjects were asked to compare the quality and location of the disc injection pain with their usual iliac crest pain.

Eight volunteer subjects were studied using the same protocol as the Walsh and colleagues study.[3] All subjects had some disc degeneration on MRI, and 24 of the discs were injected. Of the 14 disc injections causing some pain response, five were believed to be "different" (nonconcordant) pains (35.7%), seven were "similar" (50%), and two were "exact" pain reproductions (14.3%). The presence of anular disruption was correlated with concordant pain reproduction ($P < .05$). Of 10 discs with anular tears, injection of seven elicited "similar" or "exact" pain reproduction to the pain at iliac crest bone graft harvest sites. By the strict criteria for positive discography, four of the eight patients (50%) had positive injections: The pain on a single disc injection was "bad" or "very bad," and the pain quality was noted to be exact or similar to the usual discomfort. All subjects had a negative control disc. All positive disc injections had anular fissures. Half of the positive disc injections occurred at low pressures (< 20 psi).[15]

Discography in Subjects With Minimal Low Back Symptoms

The ability of a test such as discography to discriminate a true pain generator disc responsible for causing serious disabling low back pain illness from another disc that causes only trivial or clinically inconsequential backache is critical to the test's validity in clinical practice. Derby and colleagues[36] performed discography in a group of 16 subjects with occasional or minimal low back pain, none of whom required current medical care or were experiencing disability because of low back pain. Of the 16 subjects, five (31%) had a pain response of 5 out of 10 or greater, and two (12.5%) had a pain response of 6 out of 10 or greater. The subjects with more frequent benign low back pain had more painful injections. None of these subjects had abnormal psychological profiles, compensation issues, or chronic pain syndromes or had significant secondary gain motivation to underreport pain. In this study, there were significant confounding methodologic issues that made the results open to criticism. These issues include using the investigators' employees and staff as the subjects of the study.

In another study, the Stanford group performed experimental discography on 25 volunteer subjects with no clinical back pain illness; these volunteers had persistent low backache unassociated with any physical restrictions that was not bad enough to seek medical care.[37] All subjects had normal psychological profiles, but half had other chronic pain syndromes that are risk factors for positive injections. In 36% of these subjects with common backache, discographic injection of one or more discs was significantly painful and concordant. All positive discs had anular disruption, and all had negative control discs. By the usual proposed criteria, these were positive disc injections for clinically significant discogenic pain illness. Discs sensitive to low-pressure injections were found in 28% of subjects.

Pressure-Sensitive Injections and Discography Validity

In some cases, dye injected at low pressures may cause significant pain. Derby and colleagues[9] labeled these "chemically" sensitive discs as opposed to discs that are painful only on injection with high pressures. These authors theorized that "chemically" sensitive discs are painful because of the exposure of anular nerve endings or nearby neural structures to the

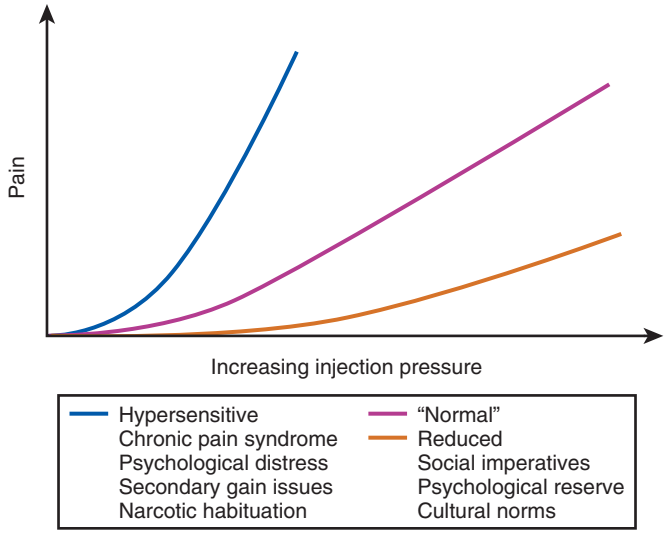

FIG. 17.1 Hypothetical responses to pressurization of degenerative disc depending on pain sensitivity and reporting biases of the patient.

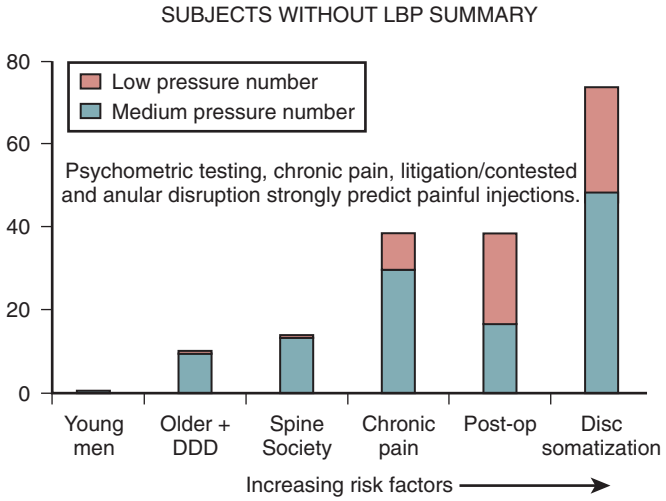

FIG. 17.2 Discography testing in asymptomatic subjects with varying risk factors. Proportion of painful disc injections and painful injections at low pressures seems to increase with increasing risk factors. DDD, degenerative disc disease; LBP, low back pain; Post-op, postoperative. (Data from references 15, 20, 29, and 36.)

leakage of irritating substances. It is postulated that this pain is incited by chemical leakage from the disc during daily activities. Some theorize that the disc injections simulate this chemical leakage. Low-pressure–positive discs are arbitrarily defined as discs found to be painful at pressures less than 15 or 22 psi greater than opening pressures.[9,23] Derby and colleagues[9] postulated further that disc injections eliciting pain at higher pressures (> 50 psi), called "mechanically" sensitive discs, physically distend the anulus and simulate mechanical loading. In these discs, it is presumed that a mechanical deformation of the anulus is the inciting painful event.

The use of pressure measurements has been postulated as a means to decrease the risk of false-positive injections. This assertion would be true if injections were rarely, if ever, positive at low pressures in subjects without true low back pain illness. Previous neurophysiologic considerations suggest that a pain and pressure profile for a given disc lesion may depend on individual pain sensitivity and local pain processes not related to the disc. Hypothetically, the pain and pressure profile may be depicted as shown in Fig. 17.1. The presence of the factors enumerated in Table 17.2 thought to have a desensitizing effect would move the curve down and to the right, whereas factors that increase pain sensitivity may move the pain and pressure curve up and to the left.

Experimental work has corroborated this hypothetical pain response. Discographic injections have been performed with pressure measurements in asymptomatic or minimally symptomatic volunteers.[3,16,35–37] Fig. 17.2 shows the proportion of painful injections at low pressures in volunteers with varying risk factors for increased pain sensitization. It seems from these and other data[38] that low-pressure injections are more likely positive in subjects with some type of chronic pain state, psychological distress, and, presumably, a generalized sensitization to irritable stimuli. An increased perception of pain at low-pressure injections seems to affect the pain response even when the chronic pain state is not in the low back region.

Evidence That Discography in Clinical Practice May Improve Outcomes

Many case series report that provocative discography is helpful in management of patients with chronic low back pain illness. These are uncontrolled studies, however, and the relationship of discography findings to clinical outcome after surgery is speculative. When encountered, good outcomes may be the result of nonspecific effects, natural history of the condition independent of diagnosis or treatment, scrupulous patient selection, or confounding findings on standard imaging studies. In a retrospective literature review, Cohen and Hurley[39] compared outcomes of spinal fusions in studies that included patients who had preoperative discography versus those who did not have preoperative discography. The outcomes were not significantly different.

In the era before routine MRI use, Colhoun and colleagues[40] retrospectively compared a series of fusions planned with and without preoperative discography. In this study on patients having surgery in the 1970s and early 1980s, there were no preoperative dynamic radiographs, MRI, or computed tomography (CT). The authors reported better results in the discography group. The two groups were not similar at baseline, however, and the authors did not examine or account for potential biases. One important bias in the study population is the fact that some patients had preoperative discography, whereas some did not. In the era before contemporary imaging techniques, this study suggested that discography might assist in the evaluation of patients before surgery. Even if this conclusion was true, this paradigm is currently unusual given the widespread availability of advanced imaging modalities in modern medicine.

Madan and colleagues[41] did a retrospective review of consecutive patients undergoing spinal fusion performed by the same surgeons, with and without preoperative discography. The two groups seemed well matched for demographic, psychometric, and radiographic features. At a minimum of 2-year

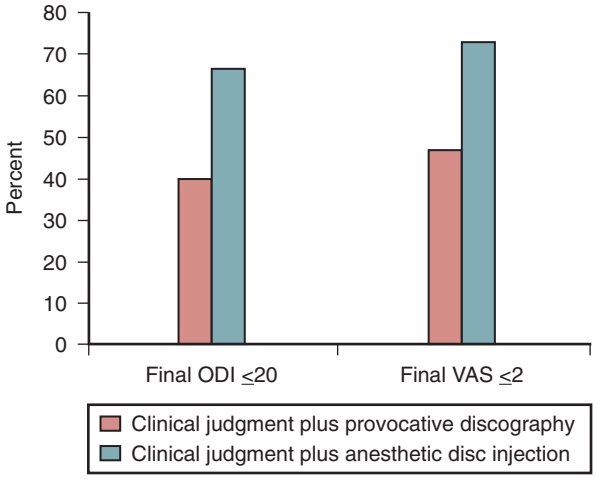

FIG. 17.3 Randomized clinical trial by Ohtori and colleagues comparing the proportion of good outcomes for pain and function after single-level spinal fusion in patients selected by best clinical judgment and provocative discography with best clinical judgment plus anesthetic disc injection. These were best-case scenario subjects in many respects: no worker's compensation cases, no road traffic accident litigation cases, no high somatic distress cases, no depression cases, all selected by very experienced spinal surgeons in Japan. Outcomes are clearly inferior when discography is used to select patients for fusion. ODI, Oswestry Disability Index, VAS, visual analog scale. (Data from Ohtori S, Kinoshita T, Yamashita M, et al: Results of surgery for discogenic low back pain: a randomized study using discography versus discoblock for diagnosis. *Spine.* 2009;34:1345–1348.)

follow-up, there was no significant difference in outcome between the two groups. The addition of discography to radiographs and MRI did not improve outcomes compared with radiographs and MRI alone.

A more recent randomized clinical trial compared outcomes of subjects having single-level fusion based on preoperative evaluation using provocative discography with subjects having an anesthetic disc injection.[42] In many ways, these subjects were the best-case scenarios given the lack of psychological distress, depression, workers' compensation cases, or traffic accident litigants. The discography was performed using low-pressure injections. The outcomes in the discography group were uniformly worse than the group using an anesthetic block to diagnose discogenic pain (Fig. 17.3). Despite the number of different studies on provocative discography, a phase IV evaluation (based on evidence-based criteria as described by Sackett and Haynes[27]) of discography has not been performed to date (see Table 17.3).

Clinical Outcome as a Gold Standard in Provocative Discography

From the evidence reviewed in this chapter, discography has been shown to be frequently positive in asymptomatic subjects and in subjects with pelvic pain owing to iliac crest harvesting. It has also been shown to be frequently fully concordant in subjects with clinically insignificant backache. These findings suggest that there is limited experimental evidence to support the premise that discography can accurately identify clinically significant lesions responsible for a patient's chronic low back pain illness. Direct assessment of a positive test against an accepted gold standard, confirming a true-positive result, has not been performed.

A common empirical gold standard would involve comparing the test results with clinical surgical outcomes, assuming that an excellent clinical outcome would confirm a true-positive test. There is concern, however, that an excellent clinical result may overestimate the number of true-positive results because of a placebo or nonspecific effect of spinal fusion or other intervention. There is also concern that clinical outcomes may underestimate the number of true-positive tests because the ability to achieve outstanding results is limited by patient-specific variables (psychological distress or social issues preventing recovery despite surgical cure of the lesion). Other concerns include results tempered by operative morbidity or technical limitations, which, in the best of cases, cannot achieve 100% success in the ideal situation of an accurate diagnosis.

An attempt was made to control these variables (patient-specific variables and operative comorbidities) in a prospective controlled study of spinal fusion for presumed diagnoses of unstable spondylolisthesis versus discogenic pain diagnosed by discography. Identical operative techniques were used, and patients had no psychosocial comorbidities.[43] Both groups included only highly selected patients with 6 to 18 months of severe low back pain, normal psychological testing, no previous or concomitant pain syndromes, and no workers' compensation or personal injury claims. All patients had either positive discography at one level only and at low pressures (< 20 psi) or unstable spondylolisthesis by strict radiographic criteria. All patients were working full time before their low back problem, and no patient was taking daily narcotic medications.

Both groups underwent an anterior spinal fusion with posterior instrumentation and fusion. Two years after surgery, only 27% of patients in the discography group met stringent criteria for clinical success compared with 71% of the spondylolisthesis group. Success was defined as full return to work and recreational activities, pain scores on a visual analog pain scale less than 2, Oswestry Disability Index score less than 15, and no daily medications for back pain. Even using less rigorous outcome measures, 43% of the discography group compared with 91% of the spondylolisthesis group reported at least moderate improvement. Even after controlling for operative morbidity, the maximum proportion of true-positive discograms in a best-case scenario (i.e., assuming normal psychometric testing, no other chronic pain history, no compensation issues or litigation, and single-level degeneration) was 40% to 60%, with a false-positive rate of approximately 50%.

For less "ideal" patients, provocative discography may be an extremely poor tool to select appropriate operative candidates. Freeman and colleagues,[44] used CT and provocative discography to select a wide range of typical low back pain subjects for an intradiscal electrothermal therapy trial, including patients with psychometric distress and compensation claims. These investigators found no improvement compared with control subjects. In a similarly designed trial, Pauza and colleagues[45] reported only slightly better outcomes even though they excluded patients with psychological abnormality, workers' compensation claims, or litigation claims.

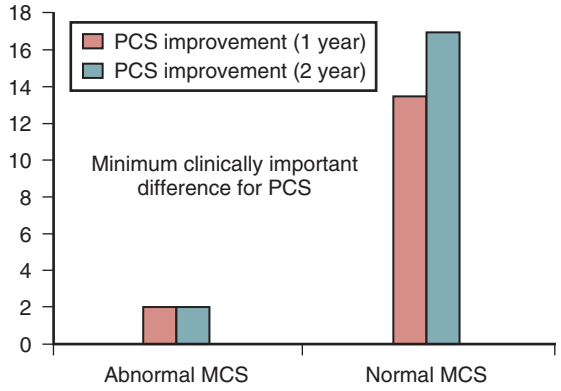

FIG. 17.4 Outcomes of spinal fusion when discography was used in patient selection. Subjects with a positive discogram in the setting of abnormal mental component scores (MCS) in the 36-Item Short Form Health Survey were highly unlikely to improve or reach even minimum clinically important change in physical outcomes. In contrast, subjects with more normalized mental component scores had significantly better improvement in outcomes ($P < .005$). In this study, positive provocative discography result in clinical subset of psychologically distressed patients seems to select patients unlikely to improve with surgical treatment. PCS, pain catastrophizing scale.

Even more striking, Derby and colleagues[46] found such poor outcomes for spinal fusion after provocative discography in patients with abnormal mental component scores on the 36-Item Short Form Health Survey that the discography seemed to *preselect* patients who were extremely unlikely to have a satisfactory outcome. These results, illustrated in Fig. 17.4, may be substantially worse than using alternative patient selection strategies without discography (e.g., radiographs, MRI, patient interview, or psychological screening).

Complications

Although there are many potential complications of any invasive procedure, several potential complications of discography warrant specific discussion:

1. *Infection*: There is a small but definite risk of discitis after percutaneous puncture and injection. The absolute risk is difficult to calculate, but modern methods likely limit this risk to much less than 1%. Double-needle techniques for insertion, less irritating dye, and intravenous or injectable antibiotics all have been postulated to decrease the infection risk.
2. *Prolonged pain episode*: Occasionally, patients may experience a prolonged episode of pain after a disc injection. One reason given for this phenomenon is the hypothetical displacement of fibrous repair over anular fissures owing to disc pressurization.[2] Other work has shown that 40% of subjects with psychological distress at the time of injection can have markedly increased back pain for 1 year after discography. This effect was not seen in subjects with normal psychological profiles.[47]
3. *Misleading diagnosis resulting in inappropriate or ineffective invasive treatments*: As discussed previously, subjects with one or more risk factors for false-positive testing may be misdiagnosed as having primary discogenic pain as the cause of their persistent low back pain illness. Patients with abnormal psychometric testing undergoing surgery based on this test are extremely unlikely to have substantial benefit from disc-directed interventions (see Fig. 17.4) and are exposed to the hazards and morbidity of these procedures.[46]
4. *Accelerated disc degeneration*: In animal models, disc puncture with a needle has provided a reliable model to initiate rapid disc injury with structural changes similar in some respects to naturally occurring disc degeneration. Working with a large animal model, Korecki and colleagues[48] showed that relatively minor disruption in the disc from even a 25-gauge needle puncture injury had "immediate and progressive mechanical and biologic consequences with important implications for the use of discography…." Similarly, Nassr and colleagues[49] showed that needle puncture in cervical discs during cervical spinal surgery localization radiographs was apparently associated with a threefold risk of rapid disc degeneration. Carragee and colleagues[50] performed a prospective, matched-cohort study of disc degeneration progression over 10 years with and without baseline discography. The investigators performed a protocol MRI and L3–L4, L4–L5, and L5–S1 provocative discography at baseline in 75 subjects without serious low back pain illness. The investigators enrolled a matched group at the same time and performed the same protocol MRI examination. Subjects were followed for 10 years. At 7 to 10 years after baseline assessment, eligible discography and control subjects underwent another protocol MRI examination. MRI examinations were scored for qualitative findings (Pfirrmann grade, herniations, endplate changes, and high-intensity zone). Loss of disc height and loss of disc signal were measured by quantitative methods (Fig. 17.5). The investigators found that modern discography techniques with small-gauge needle and limited pressurization resulted in accelerated disc degeneration, disc herniation, loss of disc height and signal, and development of reactive endplate changes compared with matched controls. The clinical follow-up of these patients demonstrated even more concerning findings in the study subjects through 10 years.[51] Despite some attrition related to a 10-year study, 110 of 150 subjects were available for all interval assessments. In these subjects, there was a statistically significant increase in the number of medical visits, lumbar CT/MRI tests, and lumbar spine surgery in the cohort exposed to provocative discography compared to the control cohort (Fig. 17.6). These data suggest that lumbar provocative discography leads to an increased risk of harm to exposed subjects.

Conclusions Regarding Provocative Discography

As for most diagnostic tests, the usefulness of discography is affected by the characteristics of the population being studied. As a provocative test depending on the subjective reporting of

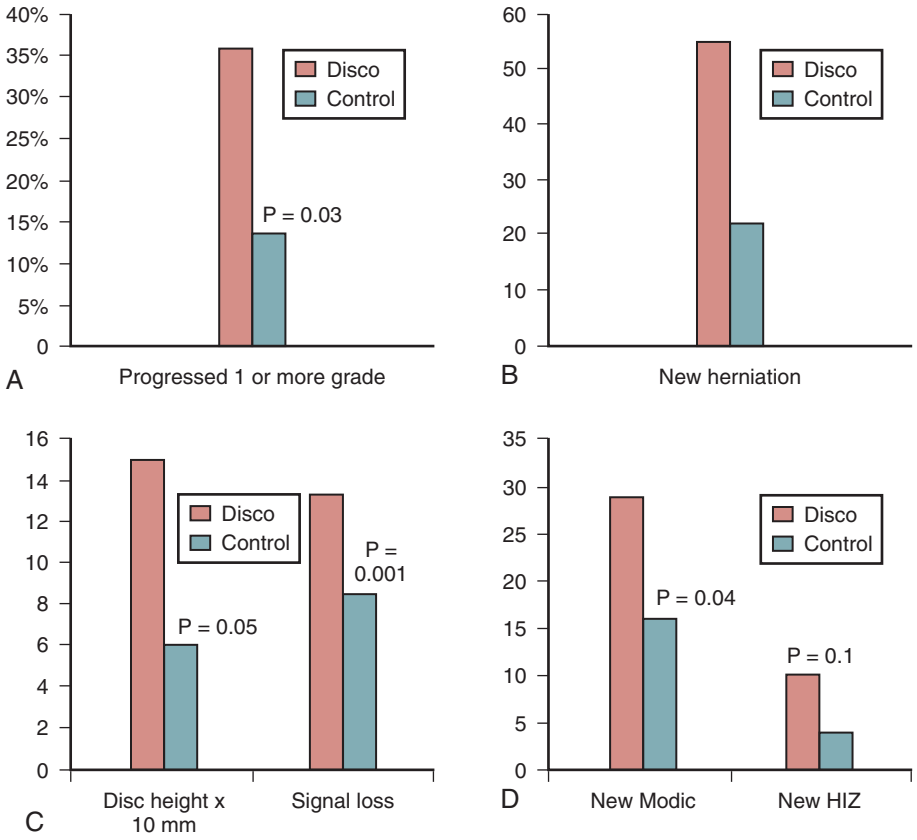

FIG. 17.5 Progression of disc degeneration in matched cohorts of subjects, discography (Disco) versus nondiscography controls. Baseline versus 10-year follow-up magnetic resonance imaging studies were compared for (A) progression of Pfirrmann grade, (B) development of new disc herniations, (C) loss of disc height and nuclear signal, and (D) development of new Modic findings or high-intensity zones (HIZ). In all parameters, degeneration was greater in discography group. (Data from Carragee EJ, Don AS, Hurwitz EL, et al: Does discography cause accelerated progression of degeneration changes in the lumbar disc: a ten-year matched cohort study. *Spine*. 2009;34:2338–2345.)

pain with injection, the central factors influencing reliability and validity of discography have to do with the neurophysiologic, psychological, and social factors that affect pain perception and expression. In the subset of patients without significant confounding factors, the test may be more likely to identify accurately a local pain generator as a primary cause of disabling axial pain illness. In subjects with significant psychosocial risk factors or confounding neurophysiologic factors, even the theoretical basis of the test is in doubt. Finally, the ability of the test to improve clinical outcomes has not been proven, and studies so far have been disappointing. Serious risks of accelerated disc degeneration are also suspected after disc puncture/injection and more recent clinical data have corroborated this concern. The risk and benefits of this procedure must be carefully weighed.

PEARLS

1. Patient selection for discography is of primary importance in determining the accuracy and utility of the test.
2. Results need to be interpreted in the context of the patient's entire medical history, including other chronic pain issues.
3. It is extremely unlikely that a disc with a negative injection, normal morphology, and no pain with the injection would be a primary cause of serious low back pain illness.
4. In the best-case scenario of a patient with no known risk factors for a false-positive test, the positive predictive value of the test is not greater than 50%.
5. Most low back pain syndromes are multifactorial.

PITFALLS

1. During injection, it is important to avoid high-pressure injections (> 100 psi) because these may cause gross mechanical motion of the segment or injure the endplate directly.
2. In patients with psychological distress, disputed compensation claims, or multiple chronic pain syndromes, the reported pain responses to disc injection have not been shown to be reliable or valid.
3. There is clear risk of accelerated disc degeneration with discographic injections and this disc degeneration may lead to clinically significant sequelae.
4. Disc injections in patients with psychological distress may result in an increase in back pain for weeks or months.

KEY POINTS

1. Provocative discography is a diagnostic test that may identify primary "discogenic" pain if present in psychologically normal patients without confounding pain or compensation issues.
2. Patient responses to disc injection are subjective and strongly influenced by pain sensitivity and reporting variables, including

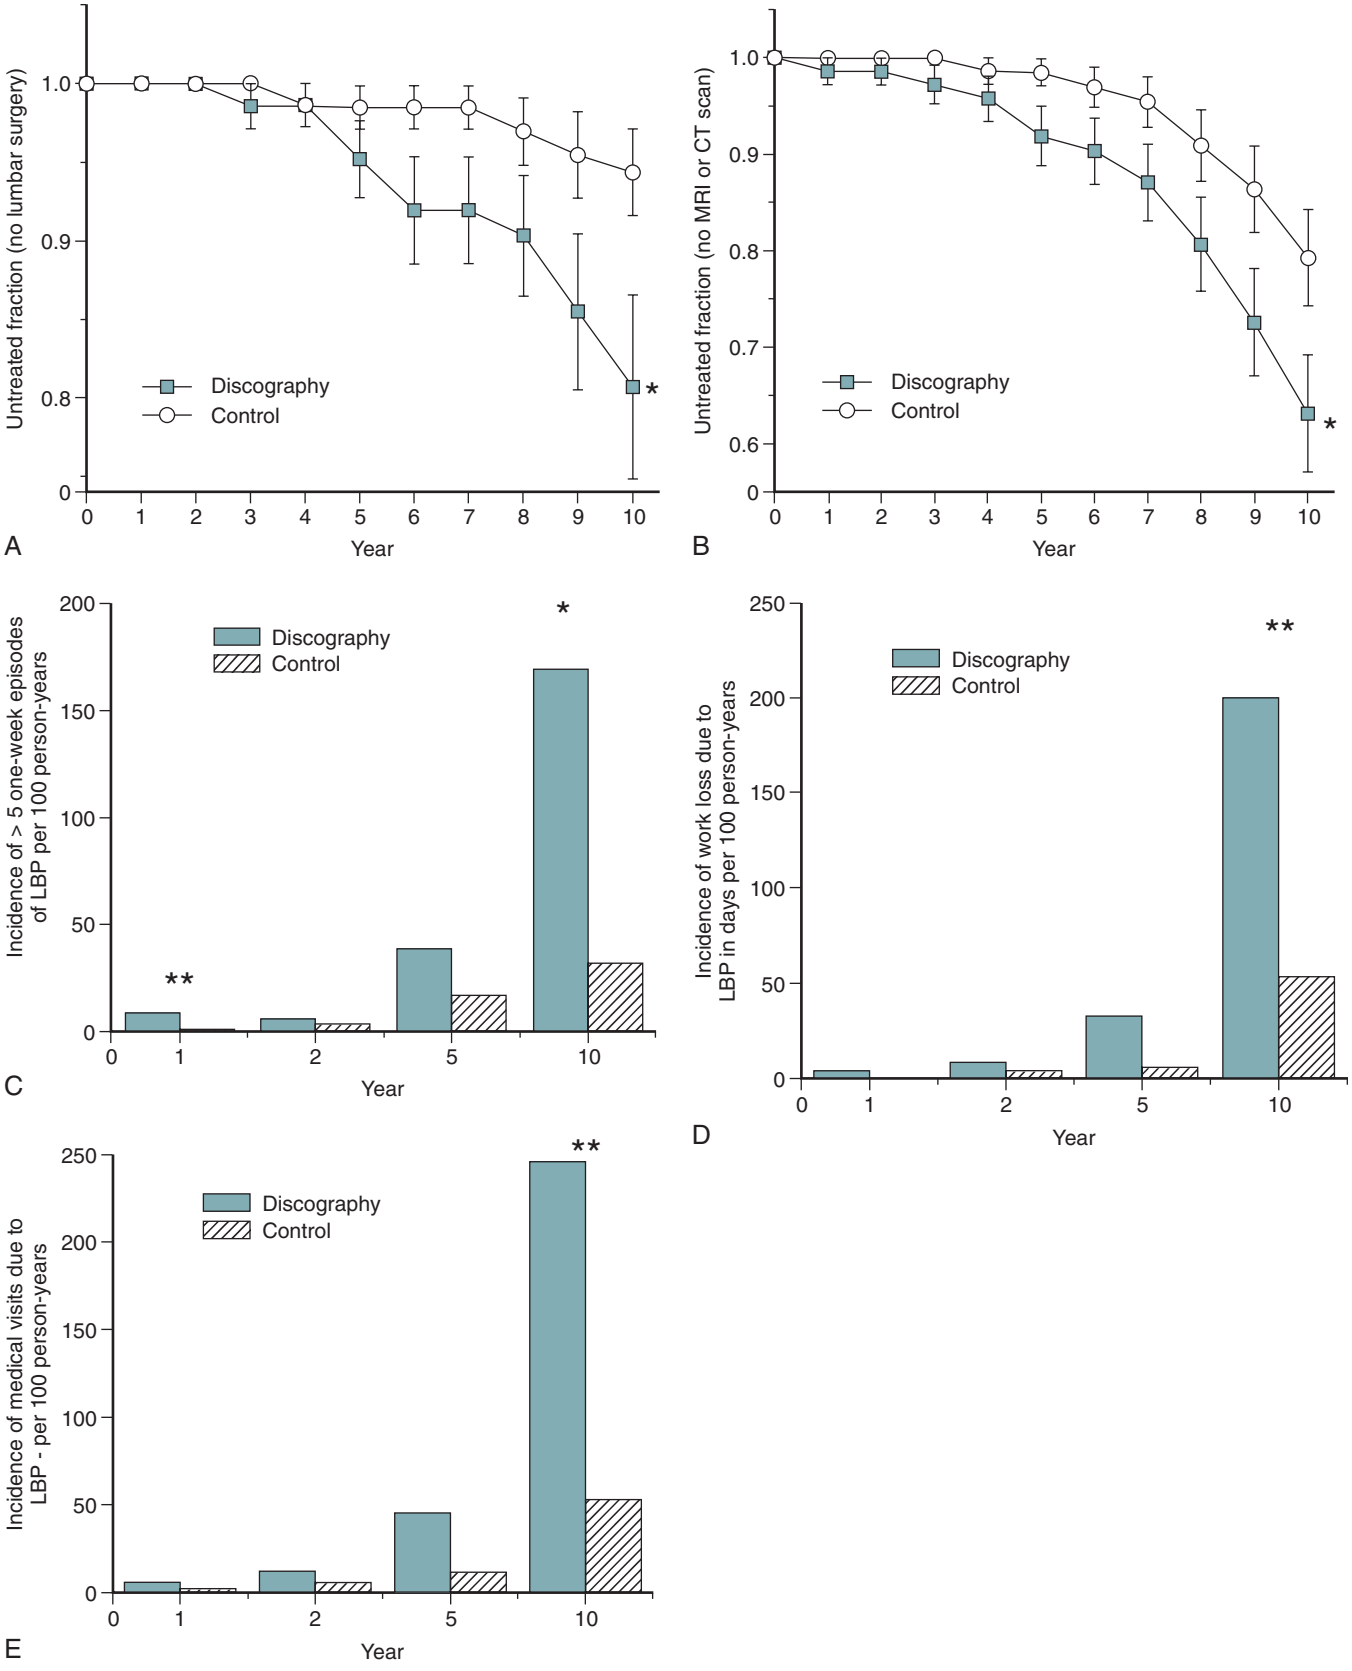

FIG. 17.6 The comparative incidence of clinical variables in patients exposed to lumbar provocative discography and controls over 10 years. Asterisks indicate statistically significant difference. (A) Surgery-free survivorship ($P = .016$). (B) Imaging-free survivorship ($P = .044$). (C) Serious low back pain episodes (**$P = .008$ and *$P = .016$). (D) Work loss ($P = .009$). (E) Medical visits for low back pain ($P = .002$). CT, computed tomography; LBP, low back pain; MRI, magnetic resonance imaging.

psychological factors, chronic pain behavior, regional or central pain syndromes, and compensation issues.

3. Provocative discography has not been proven to improve outcomes of treatment for low back pain syndromes. In patients with emotional distress issues or compensation issues, there is some evidence that using discography may result in poorer outcomes and inappropriate invasive procedures.
4. Risks of provocative discography include false and misleading diagnoses in patients with high pain-sensitive risk factors, increased axial pain for weeks or months after injection, pyogenic discitis, and accelerated disc degeneration after long-term follow-up.

SECTION III

SURGICAL ANATOMY AND APPROACHES

This page intentionally left blank

18 CHAPTER Cervical Spine: Surgical Approaches

Hamid Hassanzadeh
Varun Puvanesarajah
Howard S. An

The cervical spine is a complex structure with many sensitive anatomic elements. Successful surgical manipulation of the cervical spine requires an in-depth understanding of how vascular, neural, and musculoskeletal elements interweave in order to prevent dire complications. This chapter first examines the anatomy of the cervical spine, focusing on surface anatomy, osseous anatomy, bony articulations, ligaments, intervertebral discs, neurovascular structures, musculature, and triangles of the cervical spine. In the second section, the applied surgical anatomy is explored, with descriptions of both anterior and posterior approaches to the cervical spine.

Surgical Anatomy

Surface Anatomy and Skin

Surface landmarks are the key to successful localization of specific vertebral levels. For example, prominent musculoskeletal structures—namely, the hyoid bone, thyroid cartilage, and cricoid cartilage—delineate C3, C4, and C6, respectively.[1] The transverse processes can generally be palpated, with the transverse process of the atlas prominently featured anterior and inferior to the mastoid process. The Chassaignac tubercle, the anterior prominence of the transverse process of C6, is another important landmark that can be palpated. When palpating in a cranial-to-caudal direction along the posterior midline, the spinous process of the second vertebra is the first bony prominence that can be felt. Due to the natural lordosis of the cervical spine, the next palpable spinous process is typically of the sixth or seventh vertebra, with the seventh vertebra being particularly prominent.

When considering anterior approaches, surgical incisions should fall in line with skin creases to facilitate healing and prevent more noticeable scarring. In the lower neck, skin creases are transverse. Moving cranially, skin creases become more oblique in orientation. Skin on the front of the neck is generally softer, more mobile, and well vascularized, in contrast to skin on the back of the neck. As such, the typical longitudinal midline skin incision used on the posterior neck results in increased scar formation because of trapezius muscle tension.

Osseous Anatomy and Bony Articulation

The cervical spine comprises the first seven vertebrae in the spinal column. The bony anatomy and articulations of the upper cervical spine (occiput–C1–C2) are unique and distinct from the remaining lower five cervical vertebrae (C3–C7).

The atlas, or C1, is a ringlike structure lacking a body and a spinous process. It consists of two thick lateral masses plus an anterior and posterior arch. The longus colli muscle and anterior longitudinal ligament attach to the anterior tubercle of the atlas, whereas the posterior tubercle serves as the bony attachments for the rectus minor muscle and suboccipital membrane. The superior and inferior oblique muscles attach to the large transverse processes. The vertebral artery passes through the foramen transversarium located within the transverse process and courses posteriorly within a sulcus on the superior aspect of the posterior arch of the atlas. In 15% of the population, the sulcus for the vertebral artery can be completely covered by an anomalous ossification, which has been called the *ponticulus posticus* and may have surgical implications when identifying anatomic landmarks for bony fixation of C1.[2]

The axis, or C2, is characterized by an odontoid process, or dens, that projects upward anteriorly, articulating with the posterior aspect of the anterior arch of the atlas as a synovial joint. At its narrowest portion, at the base of the dens, the coronal and sagittal plane diameters are 8 to 10 mm and 10 to 11 mm.[3,4] Posteriorly, the axis has a large lamina and a bifid spinous process, which serve as attachments for the rectus major and inferior oblique muscles. The zone between the lamina and the lateral mass of the axis is indistinct, and posteriorly the neural arch connects to the body by large pedicles that are 8 mm wide and 10 mm long.[5] Lying directly anterolateral to the pedicle is the vertebral artery, which runs through the foramen transversarium. The pedicle of the axis projects 30 degrees medially and 20 degrees superiorly from a posterior-to-anterior direction.[4]

The bony articulations of the upper cervical spine (occiput–C1–C2) are unique and warrant special attention (Fig. 18.1). The atlanto-occipital articulation is a shallow ball-and-socket joint allowing for considerable motion mostly in flexion, extension, and lateral bending. The greatest degree of flexion

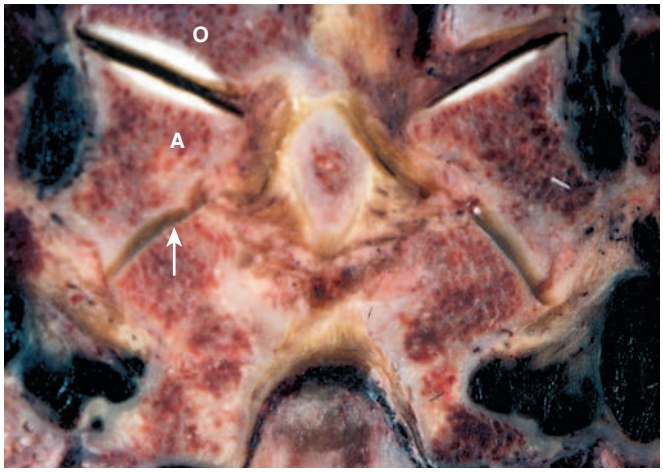

FIG. 18.1 Coronal cryomicrotome section of the upper cervical spine. Note articulation between occiput (O) and atlas (A). The atlantoaxial joint is identified by the arrow.

and extension of any cervical articulation occurs at this level (25 degrees).[6] Lateral displacement is minimized because the lateral wall of the cup-shaped articulation of the atlas is higher than the medial wall. The superior articular surface of the atlas projects cephalad and medially, articulating with the occipital condyle, which projects caudad and laterally. Conversely, the inferior articular surface of the atlas projects caudad and medially and articulates with the laterally projecting superior facet of the axis. As a result of this bony configuration, axial loads on the atlas tend to result in horizontal displacement of the lateral masses.[7]

The atlantoaxial articulation provides about 50% of rotatory motion of the cervical spine.[6,8] The transverse ligament, which spans across the arch of the atlas, holds the odontoid process against the anterior arch of the atlas, creating a pivot joint with a synovial membrane and capsular ligaments anteriorly and posteriorly to the dens. This transverse ligament is the principal stabilizing structure for the atlantoaxial articulation and averages 21.9 mm in length.[9] The transverse ligament has superior and inferior extensions, which form the cruciform ligament of the atlas, connecting it to the anterior edge of the foramen magnum and posterior aspect of the C2 body. To allow more rotatory motion, the inferior facets of the atlas are flatter and more circular than the superior facets, and face inferiorly to articulate with the axis.

The lower cervical vertebrae are morphologically similar and increase in dimension as they proceed inferiorly from C3 to C6, with C7 as the transitional vertebra into the thoracic spine. The vertebral bodies are small and oval, with the mediolateral diameter greater than the anteroposterior diameter.

The inferior surface of the vertebral body is convex in the coronal plane and concave in the sagittal plane, with the anterior lip occasionally overlapping the inferior vertebra.[9] Conversely, the superior surface of the vertebral body is convex or straight in the sagittal plane and concave in the coronal plane, creating projections on either side of the lateral superior surface, called the *uncus,* or hook. These processes project upward and conform to small grooves in the inferolateral border of the cephalad vertebra, forming the uncovertebral joints, or joints of Luschka. The width and depth of the vertebral surfaces average 17 mm and 15 mm from C2 to C6 and increase to about 20 mm and 17 mm at C7. Vertebral heights on the posterior wall in the mid-sagittal plane range from 11 to 13 mm.[10]

The pedicles project posterolaterally from the vertebral body and join the lamina to form the vertebral arch. From C3 to C7, the angulation of the pedicles varies from 8 degrees below to 11 degrees above the transverse plane, and decreases from 45 degrees to 30 degrees in relation to the sagittal plane.[10] The width and height of the pedicles increase slightly in size from C3 to C7, and average diameters are 5 to 6 mm and 7 mm. The lateral wall of the pedicle is thinner than the medial wall and should be taken into consideration if attempts at pedicle fixation are considered in this region.[11–13]

At the junction of the pedicle and lamina, the anterior tubercle of the transverse process projects laterally and is connected to the posterior tubercle by the costotransverse lamella (bar), creating the foramen transversarium. Passing through the foramen transversarium is the vertebral artery and venous system.

In the lower cervical spine, the neural foramina are bounded anteriorly by the uncinate process, the posterolateral aspect of the intervertebral disc, and the inferior portion of the vertebral body; posteriorly by the facet joint and superior articular process of the vertebral body below; and superiorly and inferiorly by adjacent pedicles. Vertebral notches located on the superior and inferior aspect of each pedicle contribute to the size of the neural foramina, which are 9 to 12 mm in height, 4 to 6 mm in width, and 4 to 6 mm in length, and are aligned 45 degrees to the sagittal plane.[14,15] They can be visualized radiographically with oblique views, with the right neural foramina outlined on the left posterior oblique view and the left neural foramina outlined on the right posterior oblique view.

The spinal canal is triangular and at all levels in the cervical spine is significantly greater in the medial-to-lateral dimension than in the anterior-to-posterior dimension. The cross-sectional area of the spinal canal is largest at C2 and smallest at C7, with a sagittal diameter of about 23 mm at C1 and 20 mm at C2, decreasing to 17 to 18 mm at C3–C6 and to 15 mm at C7.[8] This is one reason that the passage of sublaminar wires is safer in the upper cervical spine than in the lower cervical spine.

The lateral mass, an important structure for posterior cervical plate-screw systems, forms at the junction of the lamina and the pedicle and gives rise to the superior and inferior articular processes. These processes project upward and downward and are angled approximately 45 degrees cephalad from the transverse plane, gradually assuming a more vertical position as they descend into the thoracic region (Fig. 18.2). The articular process of the superior facet faces posteriorly, whereas the inferior facet of the upper vertebra faces anteriorly; the facets oppose one another to form a zygapophyseal joint. The facet joints are true diarthrodial

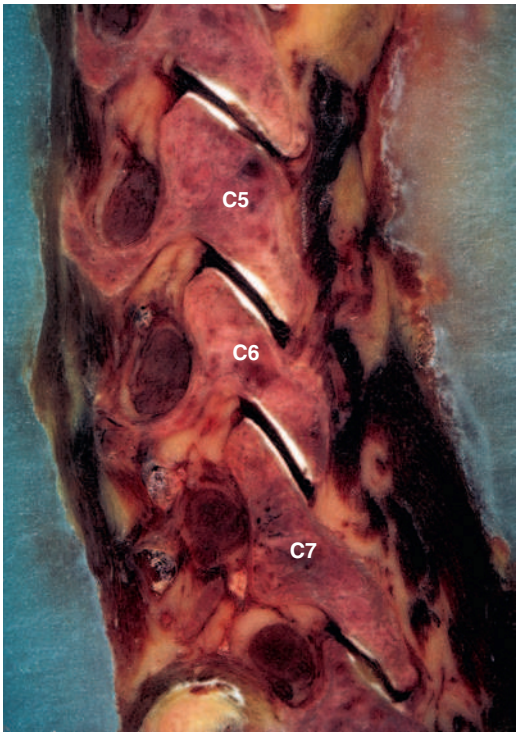

FIG. 18.2 Parasagittal cryomicrotome section of facet joints. The lateral mass of C7 is more elongated from superior to inferior and thinner from anterior to posterior. The facet joint angle is roughly 45 degrees from the transverse plane and assumes a more vertical position distally.

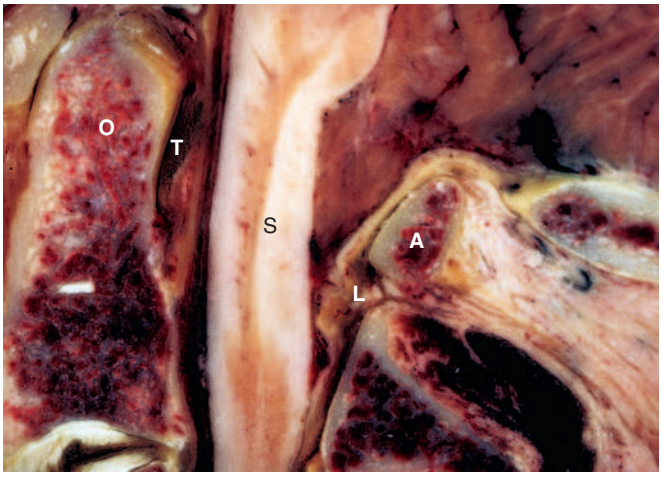

FIG. 18.3 Midsagittal microtome section at the upper cervical spine. The transverse ligament (T) acts as a stabilizer of the atlantoaxial joint by helping to restrain the odontoid (O) from posterior translation. The spinal cord (S), ligamentum flavum (L), and posterior arch of atlas (A) are also identified.

joints, with articular cartilage and menisci surrounded by a fibrous capsule lined by a synovial membrane. The interfacet distances are relatively constant between levels, with individual variations ranging from 9 to 16 mm (average, 13 mm).[5,16]

Posteriorly, the spinous processes project inferiorly and are bifid from C3 to C6; the C7 spinous process is large and not bifid, and is often called the *vertebra prominens*. The junction between the spinous process and lamina, the spinolaminar line, is an important anatomic landmark during spinous process wiring. Inadvertent penetration of the wire anterior to this line may result in spinal cord impingement.

The cervicothoracic junction is a transition region, with C7 having similar anatomic characteristics as T1 and T2. The dimensions of the vertebral body and the sizes of the transverse processes and spinous processes are larger at C6 and C7. Additionally, dimensions of the spinal canal decrease at C6 and C7, representing a distinct transition to the thoracic region. The articulating facet joint between C7 and T1 resembles the thoracic facet joint, and the lateral mass of C7 is thinner than that of upper levels. Morphologic characteristics of pedicles of C7, T1, and T2 were obtained with respect to diameters, depths, and medial angulations. Inner diameters of the pedicles at C7, T1, and T2 from medial to lateral plane averaged 5.2, 6.3, and 5.5 mm. Medial angulations were 34, 30, and 26 degrees at C7, T1, and T2, respectively.[10,17] These morphologic characteristics should be remembered when performing transpedicular procedures in the cervicothoracic region.

Ligaments

In addition to the bony anatomy, the ligamentous attachments provide support to the cervical spine and associated articulations. In the atlanto-occipital complex, two membranous attachments, the anterior and posterior atlanto-occipital membranes, connect the anterior and posterior arch of C1 to the margins of the foramen magnum. The anterior atlanto-occipital membrane is the superior continuation of the anterior longitudinal ligament, whereas the posterior membrane is the superior continuation of the ligamentum flavum.

The transverse ligament is the major stabilizer of the atlantoaxial complex (Fig. 18.3). It attaches laterally to tubercles located on the posterior aspect of the anterior arch of C1, where it blends with the lateral mass. Secondary stabilizers include the thick alar ligament, which arises from the sides of the dens to the medial aspects of the condyles of the occipital bone, and the apical ligament, which arises from the apex of the dens to the anterior edge of the foramen magnum. In some individuals, an anterior atlantodental ligament exists connecting the base of the dens to the anterior arch of the atlas.[18] The tectorial membrane, the superior continuation of the posterior longitudinal ligament, covers the dens and all the occipitoaxial ligaments and extends from the posterior body of C2 to the basilar portion of the occipital bone and the anterior aspect of the foramen magnum.

The bodies of the lower cervical vertebrae (C3–C7) are connected by two longitudinal ligaments and the intervertebral discs. The anterior longitudinal ligament is a strong band that attaches from the skull, as the anterior atlanto-occipital membrane, and continues caudad over the entire length of the spine down to the sacrum. The anterior longitudinal ligament is thinner and more closely attached at the intervertebral disc margins than at the anterior vertebral surfaces.[19] The anterior longitudinal ligament also sweeps around and envelops the lateral aspect of the vertebral bodies under the longus colli

muscle, and the lateral extension is continuous with the deep layer of the posterior longitudinal ligament in the region of the intervertebral foramina.

The posterior longitudinal ligament, lying within the vertebral canal on the posterior aspect of the vertebral body and intervertebral disc, is wider in the upper cervical spine than the lower cervical spine.[19] Superiorly, it is continuous with the tectorial membrane; as it descends, it widens over the intervertebral discs and narrows behind each vertebral body. The posterior longitudinal ligament supplies additional strength and stability to the posteromedial fibers of the anulus. There is an area of relative weakness in the posterolateral corners of the disc, however, at the junction of the posterior longitudinal ligament and uncinate process. As a result, it is the site of most cervical disc herniations.[20] According to Hayashi and colleagues,[21] the posterior longitudinal ligament is double-layered, and the deep layer sends fibers to the anulus fibrosus and continues laterally to the region of the intervertebral foramina. The superficial or more dorsal layer of the posterior longitudinal ligament is adjacent to the dura mater and continues as a connective tissue membrane, which envelops the dura mater, nerve roots, and vertebral artery, suggesting that this membrane may serve as a protective barrier.

The ligamentum flavum of the cervical spine attaches to the anterior surface of the lamina above and to the superior margin of the lamina below and extends laterally to the articular processes, contributing to the boundary of the intervertebral foramen. The ligamentum flavum consists primarily of elastic fibers, whose numbers lessen with aging, resulting in anterior buckling that can contribute to symptoms of spinal cord compression. A gap in the midline of the ligamentum flavum allows for the exit of veins.

The interspinous ligament of the cervical spine is thin and less well developed than in the lumbar region. It attaches in an oblique orientation from the posterosuperior aspect to the anteroinferior aspect of the spinous process. There is no separate supraspinous ligament in the cervical region. The ligamentum nuchae, a fibroelastic septum, is the superior continuation of the supraspinous ligament of the thoracolumbar spine and extends from the external occipital protuberance to C7.

Intervertebral Discs

Intervertebral discs are present between all vertebrae except at the atlantoaxial level. Each intervertebral disc is an avascular structure that consists of the nucleus pulposus at the interior of the disc, the outer anulus fibrosus, and the cartilaginous endplates adjacent to the vertebral surfaces. The nucleus pulposus functions as a shock absorber, and the anulus fibrosus maintains the stability of the motion segment. With increasing age, the margin between the nucleus pulposus and anulus fibrosus becomes less distinct. Often, by age 50 years, the nucleus pulposus has become a fibrocartilaginous mass similar to the inner zone of the anulus fibrosus.[22]

The anulus has an outer collagenous layer, in which the fibers are arranged in oblique layers of lamellae. The outermost fibers of the anulus fibrosus are contiguous with the anterior and posterior longitudinal ligaments and are firmly attached to the adjacent vertebral endplates. The fibers of the lamella run perpendicular to the fibers of the adjacent lamella. The collagen fibers in the posterior portion of the disc run more vertical than oblique; this may account for the relative frequency of radial tears seen clinically. The discs are shaped to conform to the surface of the bodies; the superior surface of the disc is concave, and the inferior surface of the disc is correspondingly convex in the coronal plane. The discs are also slightly thicker anteriorly than posteriorly, which contributes to the lordotic posture of the cervical spine. The cervical intervertebral discs allow some translational movement in the sagittal plane, but the uncinate processes resist lateral movement. The uncinate process, located in the posterolateral aspect of the disc, also helps prevent disc herniations in this area. Degeneration of the anulus fibrosus (Fig. 18.4) in the cervical region is similar to the lumbar region in that concentric, transverse, and radial tears of the anulus occur, and the radial tear in the posterior aspect of the disc may be more clinically significant.

The cartilaginous endplate is a layer of hyaline cartilage resting on the subchondral bone and serves as a barrier between the pressure of the nucleus pulposus and the adjacent vertebral bodies. This cartilage is a growth plate and responsible for endochondral ossification during growth (Fig. 18.5). The cartilaginous endplates also allow the insertion of the inner fibers of the anulus fibrosus and the diffusion of nutrients from the subchondral bone to the disc.

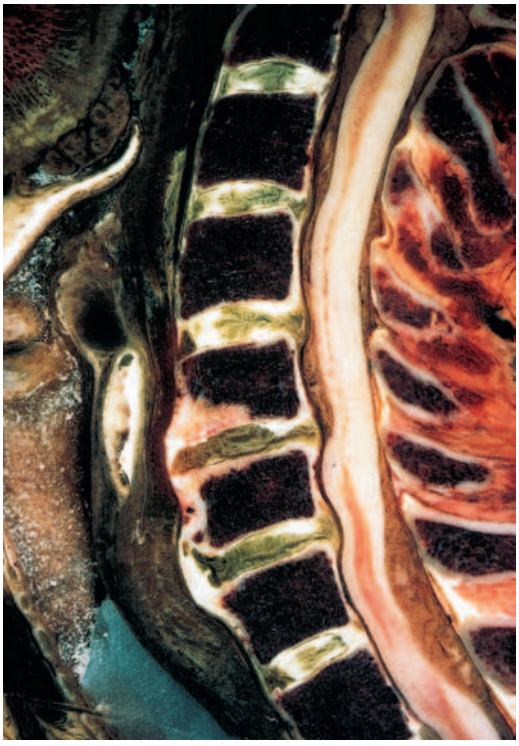

FIG. 18.4 Midsagittal cryomicrotome section of a degenerative cervical spine showing degeneration of anulus fibrosus and herniation of nucleus pulposus posteriorly with impingement of the spinal cord.

FIG. 18.5 Midsagittal microtome section of the cervical spine showing nucleus pulposus (n) and outer anulus fibrosus (a) of the intervertebral disc. Arrows identify a cartilaginous endplate.

Neural Elements

The cervical cord emerges from the foramen magnum as a continuation of the medulla oblongata. There is considerable variation in size of the spinal cord; however, in general, owing to the increased nerve supply to the upper limbs, the cervical cord enlarges from C3 and becomes maximal at C6. Maximal transverse diameters of 13 to 14 mm have been reported,[23] with transverse areas ranging from 58.3 ± 6.7 mm^3 at C6[24] to 85.8 ± 7.2 mm^3 at C4–C5.[25]

The spinal cord includes the outer white matter and the inner gray matter. The white matter of the spinal cord contains nerve fibers and glia, and is divided into the posterior, lateral, and anterior columns. The posterior column includes the fasciculus cuneatus laterally and fasciculus gracilis medially, mediating proprioceptive, vibratory, and tactile sensations. The lateral column contains the descending motor lateral corticospinal and lateral spinothalamic fasciculi. The anterior funiculus contains the ascending anterior spinothalamic tract and other descending tracts. The lateral spinothalamic tracts cross through the ventral commissure to the contralateral side of the cord, conveying pain and temperature sensations. The anterior spinothalamic tract conveys the crude touch sensation.

The gray matter of the spinal cord contains cell bodies of efferent and internuncial neurons. The somatosensory neurons are located in the posterior horn, and the somatomotor neurons are found in the anterior horn of the gray matter. The visceral center of the gray matter is found in the intermediolateral horn. In the center of the spinal cord is the central ependymal canal for the passage of cerebrospinal fluid.

The spinal cord is covered by the pia mater, which is the outer lining of the cord, and transparent arachnoid membrane that contains the cerebrospinal fluid. The dura mater is the outer covering of the spinal cord, which becomes the inner layer of the cranial dura at the level of the foramen magnum. The cervical cord is anchored to the dura by the dentate ligaments that project laterally from the lateral side of the cord to the arachnoid and dura at points midway between exiting spinal nerves. By suspending the spinal cord in the cerebrospinal fluid, the dentate ligaments cushion and protect the cord, while minimizing the movement of the cord during range of motion (ROM). The epidural space contains fat, internal vertebral venous plexus, and loose connective tissue. This venous plexus may be involved in spreading infection or neoplasm. There is a potential space between the dura and the arachnoid, and the subarachnoid space is between the arachnoid and the pia. The subarachnoid space contains the cerebrospinal fluid (CSF), spinal blood vessels, and nerve rootlets from the spinal cord.

The dorsal sensory rootlets enter the cord through the lateral longitudinal sulcus, and the ventral motor rootlets exit the cord through the ventral lateral sulcus. The six or eight rootlets at each level leave the spinal cord laterally to lie in the lateral subarachnoid space bathed in the CSF. The rootlets join to form the dorsal and ventral root, which together enter a narrow sleeve of arachnoid and pass through the dura to become a nerve root at each level. The cervical nerve roots that form from the ventral and dorsal nerve rootlet extend anterolaterally at a 45-degree angle to the coronal plane and inferiorly at about 10 degrees to the axial plane.[15] The nerve roots enter the intervertebral foramina by passing directly laterally from the spinal canal adjacent to the corresponding disc and over the top of the corresponding pedicle. The anterior root lies anteroinferiorly adjacent to the uncovertebral joint; the posterior root is close to the superior articular process. The nerve root is positioned at the tip of the superior articular process in the medial aspect of the neural foramen; it courses more inferiorly to position over the pedicle in the lateral aspect of the neural foramen (Fig. 18.6).

The roots occupy about one-third of the foraminal space in the normal spine but much more in the degenerative spine. The roots are located in the inferior half of the neural foramen normally, but the nerve roots occupy a more cranial part of the foramina, and the size of the foramen is diminished if the neck is fully extended.[26] The upper half of the neural foramen contains fat and small veins.[27] The nerve root is enlarged in the distal aspect of the intervertebral foramen, and the dorsal root ganglion is located just distal to the foramen.[28] The dorsal root ganglion is located between the vertebral artery and a small concavity in the superior articular process. Just distal to the ganglion and outside the intervertebral foramen, the anterior and posterior roots join to form the spinal nerve. The spinal nerve divides into dorsal and ventral primary rami branches.

The gray rami from the sympathetic cervical ganglion join the ventral primary rami. There are interconnections between gray rami, the perivascular plexus around the vertebral artery, and the sympathetic trunk, all of which give contributions

FIG. 18.6 Parasagittal cryomicrotome section of the lateral aspect of the neural foramen shows a nerve root coursing more inferiorly lying over a pedicle as it begins to exit the foramen.

to the ventral nerve plexus to innervate the anterior longitudinal ligament, outer anulus fibrosus, and anterior vertebral body.[29,30] The dorsal nerve plexus receives contributions from the sinuvertebral nerves, which originate from the gray rami and perivascular plexus of the vertebral artery. The dorsal nerve plexus innervates the posterior longitudinal ligament, and the sinuvertebral nerves give branches to the posterior part of the anulus and the ventral part of the dura. The sinuvertebral nerves innervate two or more discs or motion segments.

The first cervical nerve or suboccipital nerve exits the vertebral canal above the posterior arch of the atlas and posteromedial to the lateral mass, and lies between the vertebral artery and the posterior arch. The posterior primary ramus of the first cervical nerve enters the suboccipital triangle and sends motor fibers to the deep muscles. The anterior primary ramus of the first cervical nerve forms a loop with the second anterior primary ramus and sends fibers to the hypoglossal nerve. The cervical plexus receives fibers from anterior primary rami of C1–C4. The cervical plexus is located opposite C1–C3, ventral and lateral to the levator scapulae and middle scalene muscles. The cervical plexus has distributions to the skin and muscles, such as the rectus capitis anterior and lateralis, longus capitis and cervicis, levator scapulae, and middle scalene. The cervical plexus forms loops and branches to supply the sternocleidomastoid and trapezius muscles. It has communications with the hypoglossal nerve from C1 and C2, and leaves this trunk as the superior root of the *ansa cervicalis*, which is a nerve loop that is formed with the inferior root from C2 and C3.

The second cervical nerve lies on the lamina of the axis posterior to the lateral mass; the posterior primary ramus or the greater occipital nerve pierces the trapezius about 2 cm below the external occipital protuberance and 2 to 4 cm from the midline. Trauma or irritation to any of the three terminal nerves (the greater and lesser occipital nerve and the greater auricular nerve) can produce pain, headache, or hyperesthesia in their dermal distribution over the occiput and around the ear.

Cutaneous branches of the posterior primary rami of C2–C5 are consistently present in the skin of the nuchal region; the largest cutaneous nerve in this region is the greater occipital nerve. The lesser occipital nerve is a branch from the anterior cervical plexus, running upward and lateral to the greater occipital nerve. The posterior primary ramus of C3, or the third occipital nerve, pierces the trapezius more inferiorly and about 1 cm medial from the midline. The cervical nerve exits over the pedicle that bears the same number except the C8 cervical nerve lies between the C7 and T1 vertebrae. The posterior primary rami of cervical nerves send motor fibers to the deep muscles and sensory fibers to the skin, but the first cervical nerve has no cutaneous branches. The anterior primary rami of C1–C4 form the cervical plexus, and the rami of C5–T1 form the brachial plexus.

Vascular Structures

The major blood supply of the cervical cord and cervical spine is the vertebral artery. Variations of the course of the vertebral artery have been reported.[31] In most cases, the vertebral artery originates from the first part of the subclavian artery and begins its ascent behind the common carotid artery between the longus colli and the anterior scalene. In the lower cervical spine, the vertebral arteries are crossed by the inferior thyroid artery and on the left by the thoracic duct. The vertebral arteries course anterior to the ventral rami of the seventh and eighth cervical nerves and the C7 transverse process before entering the C6 transverse foramen, where they ascend within the transverse foramen of C6–C2.

The surgeon should remember that the vertebral artery is located lateral to the uncinate process and in line with the middle one-third of the vertebral body just anterior to the nerve root. During anterior exposure of the vertebral body and intervertebral discs, too far lateral dissection on the inferior half of the vertebral body and uncovertebral joints would endanger the vertebral artery and spinal nerve around the intervertebral foramen. The vertebral artery may also be involved in patients with severe cervical spondylosis when it may be impinged by the osteophyte. At the level of the atlas, the artery winds posteromedially around the lateral mass and over the posterior arch of the atlas before passing through the posterior atlanto-occipital membrane into the foramen magnum, joining the other vertebral artery to form the basilar artery.

In the foramen magnum region, the vertebral artery gives branches anteriorly that join to form the single anterior spinal artery, whereas the paired posterior spinal arteries are branches from the posterior inferior cerebellar arteries. The anterior

and posterior spinal arteries are the major blood supplies of the spinal cord. The posterior spinal arteries give rise to plexiform channels that are arranged transversely on the dorsum of the cord. The anterior spinal artery supplies most of the spinal cord, except the posterior columns.[32] The spinal cord also receives blood supplies from radicular arteries or medullary feeders from the vertebral arteries and ascending cervical arteries.[32] The segmental arteries that are branches of the vertebral artery are present at each level to supply the vertebrae and surrounding tissues, but only a few segmental vessels give rise to radicular arteries or medullary feeders to the spinal cord. These vessels have a variable distribution, but medullary feeders are more commonly present at C6 and C3 from the left and C5 and T1 from the right.[19]

Venous blood returns from the cord through three veins posteriorly and three veins anteriorly. The venous system within the spinal canal consists of valveless sinuses in the epidural space. The venous plexus is most apparent anteriorly just medial to the pedicles over the mid-portion of the vertebral bodies and anastomoses with the veins from the opposite side and with the basivertebral sinus, which is located in the space between the posterior longitudinal ligament and the posterior aspect of the vertebral body.

Musculature

The musculature of the cervical spine can be grouped into the anterolateral and posterior muscle groups. The anterolateral muscles of the neck include the platysma muscle, sternocleidomastoid muscle, hyoid muscles, strap muscles of the larynx, scalene muscles, longus colli muscle, and longus capitis muscle. The posterior musculature is subdivided into superficial, intermediate, and deep muscle groups.[33]

The platysma is a thin muscle underneath the subcutaneous tissue that spans from the deltoid and upper pectoral fascia and crosses over the clavicle and passes obliquely upward and medially to insert to the mandible, muscles of the lip, and skin of the lower part of the face. The platysma depresses the lower jaw and the lip, and tenses and ridges the skin of the neck.

The sternocleidomastoid originates from the sternum and the medial clavicle to the mastoid process and the lateral half of the superior nuchal line of the occipital bone. The second cervical nerve and the spinal accessory nerve innervate the sternocleidomastoid, which functions to draw the head toward the ipsilateral shoulder and rotate it and point the chin craniad toward the contralateral side. The sternocleidomastoid muscles together flex the head and raise the thorax when the head is fixed.

Muscles that attach to the hyoid bone include the digastric, stylohyoid, mylohyoid, geniohyoid, and omohyoid muscles; the strap muscles of the larynx include the sternohyoid and sternothyroid muscles. These muscles do not control the cervical spine but are important in controlling the movement of the hyoid and larynx, and are important landmarks in the anterior approach to the cervical spine.

The longus colli and longus capitis are the prevertebral muscles of the neck. The longus colli spans from C1 to T3 and extends laterally to attach to the anterior tubercles of the transverse processes of C3–C6. The longus capitis originates from the anterior tubercles of the transverse processes of C3–C6 and attaches on the inferior surface of the basilar part of the occipital bone. Underneath the longus capitis, the rectus capitis anterior spans from the lateral mass of the atlas to the base of the occipital bone. The rectus capitis lateralis runs laterally from the transverse process of the atlas to the inferior surface of the jugular process of the occipital bone.

The scalenus anterior originates from the anterior tubercles of the transverse processes of C3–C6 and inserts on the first rib. The scalenus medius originates from the posterior tubercles of the transverse processes of C2–C7 and inserts on the first rib. A vascular impingement of the subclavian artery may occur as it runs between the scalenus anterior and scalenus medius, as seen in the thoracic outlet syndrome. The scalenus posterior originates from the posterior tubercles of the transverse processes of C4–C6 and inserts on the second rib.

The posterior muscles of the neck are divided into superficial, intermediate, and deep groups.[33] The most superficial muscle is the trapezius, which originates from the external occipital protuberance and the medial nuchal line of C7–T12 spinous processes and inserts on the spine of the scapula, the acromion, and the lateral aspect of the clavicle. The trapezius is innervated by the 11th cranial nerve and functions to extend the head. The intermediate muscles beneath the trapezius muscle are the splenius capitis and splenius cervicis, which originate from the spinous processes of the lower cervical and upper thoracic spines and insert on the transverse processes of the upper cervical spine and the mastoid process. In the deep layer, the erector spinal muscles continue into the cervical region, which includes the iliocostalis laterally; the longissimus cervicis and longissimus capitis centrally; and the spinalis cervicis, semispinalis capitis, and semispinalis cervicis medially. Beneath the semispinalis muscles lie the multifidus from C4–C7 and rotatores muscles, which cross only one segment from the transverse processes to the spinous processes.

In the upper cervical spine, suboccipital muscles attach at the occiput to the second vertebra. The rectus capitis posterior major originates from the C2 spinous process and inserts to the inferior nuchal line of the occiput, and the rectus capitis posterior minor originates from the posterior tubercle of the atlas and inserts to the occiput. The obliquus capitis inferior originates from the C2 spinous process and inserts on the transverse process of the atlas, and the obliquus capitis superior originates from the transverse process of the atlas and inserts on the occiput between the superior and inferior nuchal lines. Most posterior muscles are involved in producing extension of the neck and head, and some muscles produce rotation and lateral flexion. The posterior deep muscles are innervated by the posterior primary rami, and the blood supply is by the deep cervical vessels.

Fascial Layers

The key to understanding the anterior approach to the cervical spine lies in recognizing the fascial layers of the neck, which invest the muscles and viscera and separate them into different compartments.[20] Anteriorly, the cervical fascia is divided into

one superficial and four deep layers. The superficial fascia contains fat and areolar tissue, including the platysma muscle, external jugular vein, and cutaneous sensory nerves. The deep cervical fascia, including the outer investing layer of deep fascia, middle cervical fascia, and prevertebral fascia, compartmentalizes the structures deep to the superficial fascia. The superficial layer of the deep fascia extends from the trapezius muscle over the posterior triangle and splits to enclose the sternocleidomastoid muscle. The middle layers of the deep cervical fascia enclose the strap muscles and omohyoid and extend as far laterally as the scapula. The deeper middle layer is the visceral fascia that surrounds the thyroid gland, larynx, trachea, pharynx, and esophagus. The alar fascia spreads behind the esophagus and surrounds the carotid sheath structures laterally. The carotid sheath encloses the carotid artery, internal jugular vein, and vagus nerve. The deepest layer of the deep fascia is the prevertebral fascia, which covers the scaleni muscles, longus colli muscles, and anterior longitudinal ligament.

Understanding these fascial planes also helps localize the source of cervical infections. Abscesses originating from either the vertebral body or the intervertebral disc generally start in the midline, whereas abscesses that are pharyngeal in origin tend to occur lateral to the midline. This is because the prevertebral fascia and alar fascia are fused laterally over the transverse processes, but not in the midline. If this infection breaks through the prevertebral fascia, it can spread inferiorly between the alar fascia and prevertebral fascia into the posterior mediastinum. With pharyngeal infections, the opposite occurs because the visceral fascia and alar fascia are fused in the midline; these abscesses tend to occur laterally, on either side of the midline.

Triangles of the Neck

The cervical region is divided into two anatomic compartments, the anterior and posterior triangles, by the sternocleidomastoid. The anterior triangle is formed by the midline anteriorly, the anterior border of the sternocleidomastoid posteriorly, and the inferior border of the mandible superiorly. The posterior triangle is bound anteriorly by the posterior border of the sternocleidomastoid, posteriorly by the anterior border of the trapezius, and inferiorly by the middle third of the clavicle. Understanding the structures within the triangles and their complex relationship helps the surgeon to learn these important landmarks during surgical approaches to the neck.[6]

The anterior triangle is subdivided further into the digastric (submandibular), carotid, and muscular triangles. The digastric triangle, so called because it is bound by the two bellies of the digastric muscle as well as the inferior border of the mandible, contains the submandibular gland; facial artery and vein; mylohyoid artery and nerve; and, posteriorly, a portion of the parotid gland and external carotid artery. Lying deeper in the digastric triangle is the internal carotid artery, jugular vein, and glossopharyngeal and vagus nerves. The carotid and muscular triangles are separated by the superior belly of the omohyoid muscle. The carotid triangle contains the carotid artery and its bifurcation; the superior thyroid, lingual, and facial branches of the external carotid artery; and the internal jugular vein. It also contains the ansa cervicalis; portions of cranial nerves X, XI, and XII; and the larynx, pharynx, and superior laryngeal nerve.

The posterior triangle is subdivided into the occipital and supraclavicular triangles by the inferior belly of the omohyoid muscle. The posterior triangle contains the accessory nerve, the brachial plexus, the third part of the subclavian artery, the dorsal scapular nerve, the long thoracic nerve, the nerve to the subclavius, the suprascapular nerve, and the transverse cervical artery.[19]

The brachial plexus travels behind the inferior belly of the omohyoid, crossing between the anterior and middle scalene muscles and over the first rib and beneath the clavicle. Its location in the posterior triangle can be identified by drawing a line from the posterior margin of the sternocleidomastoid at the level of the cricoid cartilage to the midpoint of the clavicle. The accessory nerve lies on the levator scapula on the floor of the posterior triangle. Emerging from behind the posterior border of the sternocleidomastoid muscle are the lesser occipital, greater auricular, and supraclavicular nerves. The subclavian artery lies inferior to the inferior belly of the omohyoid in the subclavian triangle and courses behind the anterior scalene laterally toward the border of the first rib.

Surgical Approaches

Although surgical approaches to the cervical spine are well described in the literature, certain approaches are more commonly used than others. A decision to use a particular approach should take into account the site of the pathologic process, the health of the patient, and the skill and comfort level of the surgeon with that specific exposure. An understanding of the advantages and limitations of each surgical exposure can help improve patient outcome and reduce complications. In this section, anterior and posterior operative approaches from the occiput to the cervicothoracic junction are described with their associated complications.

Anterior Approaches to Upper Cervical Spine

The complex anatomy of the upper neck makes adequate and safe exposure of the upper cervical spine challenging. The two main techniques are transoral and retropharyngeal exposures. If necessary, both techniques can be combined with a mandibulotomy or dislocation of the temporomandibular joint to gain additional local exposure.

The transoral approach provides anterior exposure to the atlantoaxial complex. Inferior exposure down to C3–C4 can be obtained with the addition of a lip-splitting approach with mandibulotomy, whereas superior exposure up to the clivus of the occiput can be obtained by splitting the uvula, soft palate, and posterior pharyngeal wall.[34,35] If necessary, a portion of the hard palate can also be cut with a rongeur. Thoughtful placement of a self-retaining retractor system also facilitates exposure by retraction of the hard and soft palate and tongue.

Several variations to the retropharyngeal exposure have been described, which can be divided into anteromedial and anterolateral approaches depending on the relationship of the dissection to the carotid sheath.[36–38] The anteromedial retropharyngeal approach uses the interval medial (anterior) to the carotid sheath, whereas the anterolateral approach uses the plane lateral (posterior) to the carotid sheath. In both cases, a thorough understanding of the local anatomy is imperative. For right-handed surgeons, the approach is typically from the patient's right side. At this level, above C5, the recurrent laryngeal nerve has already crossed the surgical field from lateral to medial and runs safely within the tracheoesophageal groove.

Transoral Technique

The transoral technique requires broad-spectrum antibiotic administration prior to incision. Antibiotics should cover both gram-positive and gram-negative bacteria.[39] It is further recommended to continue antibiotics for 3 days following surgery. Care must be exercised during this approach to stay in the midline and develop full-thickness pharyngomucosal flaps. A vertical incision is made through the posterior pharyngeal mucosa, the constrictors, and the longus colli muscle with the anterior arch of the atlas as the landmark. The incision should be directly down to bone. In total, the incision should be 3 to 5 cm in length, with its midpoint approximately 1 cm caudal to the anterior tubercle of C1. After adequate superior and inferior exposure is obtained, subperiosteal lateral dissection is done to expose the medial edge of the C1–C2 facet joint and can extend as far laterally as the lateral masses. Dissection beyond the lateral edge of the C1–C2 facet risks injury to the vertebral artery, which usually lies at a minimum of 20 mm from the midline.[40]

In a pure transoral approach, exposure is limited by the interdental distance and the degree of neck extension. Recommended interdental distances to allow an appropriate surgical corridor should be at least 25 mm. Associated pathologies, including temporomandibular joint stiffness, cervical kyphosis, and basilar invagination, can hinder the surgical approach. Use of a Mayfield retractor and a roll beneath the shoulder blades can allow appropriate neck hyperextension to facilitate the approach. The addition of a mandibulotomy can further increase exposure. The mandibulotomy is achieved with a midline incision of the lower lip around the chin in a C-shaped fashion and then straight down to the hyoid bone to expose the mandible subperiosteally.[41] Titanium plates are then fit for later closure; screw holes should be drilled before the actual osteotomy is performed, as this all decreases the risk of postoperative malocclusion. The mandible is then osteotomized between the central incisors, without overt removal of an incisor. Another incision is then made to divide the inferior mouth mucosa, with the incision falling between the submaxillary duct orifices and beneath the tongue. The divided mandible is then retracted laterally. If the decision is made to split the tongue as well, this should be done in the midline, with care taken not to injure the epiglottis.[41]

Complications

Reported results with this exposure are variable. Although access to the upper cervical vertebra through this approach is relatively direct, the potential for significant morbidity and mortality exists owing to the risk of infection by pharyngeal flora, the confined working area, and the lack of extensile exposure.[42] Complications can be minimized with careful patient selection and proper surgical technique.

Infection is a frequently reported complication with the transoral approach,[43] particularly with extensive resections and use of bone graft. Direct contamination and septic encephalomeningitis can occur through direct exposure or opening of the dura. In a series reported by Fang and Ong[43] in six patients who underwent extensive vertebral body resection and bone grafting, four developed wound infections, and one developed encephalomeningitis. In a separate study of 10 patients in whom the transoral approach was used to treat irreducible craniovertebral junction anomalies, one patient had a retropharyngeal infection, which was ultimately treated with saline irrigation, reclosure, and antibiotics.[44] Using perioperative antibiotics, limiting the use of bone graft when possible, and minimizing the exposure and resection can help decrease these risks. The use of a nasogastric tube postoperatively for 5 days until evidence of mucosal healing may decrease wound contamination.

Difficulty with wound closure may also occur. In the Lee et al series,[44] two patients were noted to have wound dehiscence that required resuturing. Dehiscence is a particular risk if the incision extends down to C3, where the overlying tissues can be thin and intimately adherent to the underlying vertebral body. Difficulty with wound closure can also occur if bone grafting is excessive or placed improperly. This difficulty can be managed by ensuring that the grafts are recessed beyond the anterior margin of the vertebral body or by creating lateral flaps to help provide additional tissue length to assist in coverage.

Vascular complications are also an inherent risk of this procedure. Venous hemorrhage from epidural veins can typically be controlled with the use of cellulose and cottonoid patties. Arterial hemorrhage owing to injury to the vertebral artery or its branches can be more problematic. Excessive or uncontrolled bleeding can occur if the dissection is not performed subperiosteally or strays too lateral into the vertebral arteries. Life-threatening hemorrhage or basilar artery ischemia can result, especially in elderly patients. Tamponade of the bleeding with hemostatic agents and bone wax may result in a false aneurysm or late bleeding, requiring urgent surgery or balloon embolization.[40] Uncontrolled bleeding often requires emergent balloon embolization or immediate surgical exposure of the vertebral artery in the foramen transversarium for ligation.

After surgery, the airway remains at risk from edema, hemorrhage, or continued drainage. Due to this risk, some patients may require endotracheal (ET) tube retention for a full day following surgery. ET tube retention is often determined by assessment of soft tissue swelling on postoperative lateral cervical radiographs. A nasogastric tube is also placed and retained for 5 to 7 days to prevent reflux.[45] Careful

intraoperative placement of retractors to ensure that the tongue and lips are not trapped and the application of topical hydrocortisone can help decrease postoperative oropharyngeal edema. If a tongue-splitting approach is planned, a tracheotomy should be considered.

Anteromedial Retropharyngeal Technique

Described by deAndrade and McNab in 1969[37] and later by McAfee and colleagues in 1987,[36] the anteromedial retropharyngeal approach is the superior extension of the anteromedial approach to the lower cervical spine, as described by Southwick and Robinson.[46] Similar to the anteromedial approach to the lower cervical spine, familiarity with the fascial planes is vital to understanding the approach. These planes include (1) the superficial fascia containing the platysma; (2) the superficial layer of the deep fascia extending from the sternocleidomastoid anteriorly and enclosing the trapezius posteriorly; (3) the middle layer of the deep fascia covering the strap muscles and omohyoid and visceral fascia surrounding the thyroid gland, larynx, trachea, pharynx, and esophagus; and (4) the deep layer of the cervical fascia, which includes the alar fascia connecting the two carotid sheaths laterally and fusing in the midline to the visceral fascia and the prevertebral fascia covering the scaleni and longus colli muscles and the anterior longitudinal ligament (Fig. 18.7).

A transverse submandibular incision is used in this approach, extending from the mastoid process and extending to the midline at the level of the hyoid. To complete a T-shaped incision, the opening is extended along the anterior aspect of the sternocleidomastoid muscle (Fig. 18.8A). The platysma and the superficial layer of the deep cervical fascia are divided in line with the incision to expose the anterior border of the sternocleidomastoid (Fig. 18.8B). With the help of a nerve stimulator, the marginal mandibular branch of the facial nerve (cranial nerve VII) is isolated and protected. Because the branches of the mandibular nerve are superficial to the lateral crossing veins, ligating the retromandibular vein as it joins the internal jugular vein and keeping the dissection deep and inferior to the vein during the exposure help protect the superficial branch of the facial nerve.

Next, the superficial layer of the deep cervical fascia is incised anterior to the sternocleidomastoid, and the carotid sheath is identified by palpating for the carotid pulse. The digastric lymph nodes and submandibular gland are resected, and the salivary duct is sutured to prevent a fistula. The stylohyoid and digastric muscle are identified and ligated to help mobilize the hyoid bone to improve exposure. Injury to the facial nerve may occur with excessive superior traction of the stylohyoid muscle. The nerve stimulator is used to identify and completely mobilize the hypoglossal nerve, which is retracted superiorly.

The retropharyngeal space is entered by using blunt dissection to develop the plane between the carotid sheath laterally and the visceral fascia containing the larynx and pharynx medially. Exposure can be improved by sequentially ligating tethering branches of the carotid artery and jugular vein, which may include the superior thyroid artery and vein, lingual artery and vein, ascending pharyngeal artery and vein, and facial artery and vein (Fig. 18.8C). The superior laryngeal nerve is identified, protected, and mobilized as it travels from its origin near the nodose ganglion into the larynx.

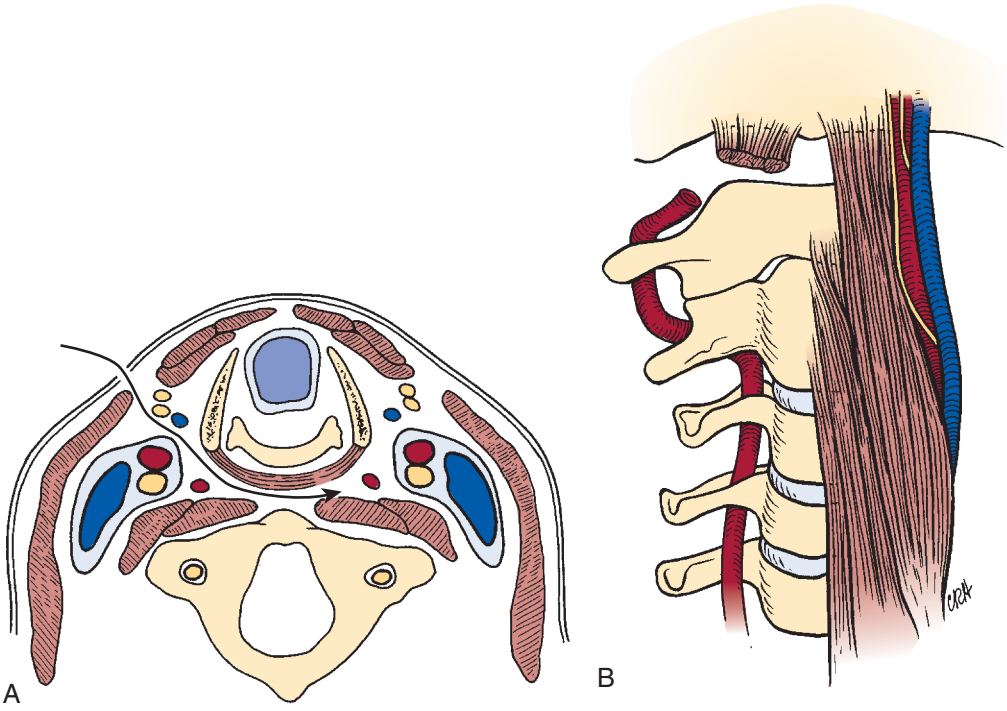

FIG. 18.7 Anteromedial approach to the upper cervical spine. (A) Dissection is done through a retropharyngeal approach as an extension of the Southwick-Robinson approach to the lower cervical spine. (B) The longus colli muscle is retracted to expose the anterior tubercle of the atlas and body of axis.

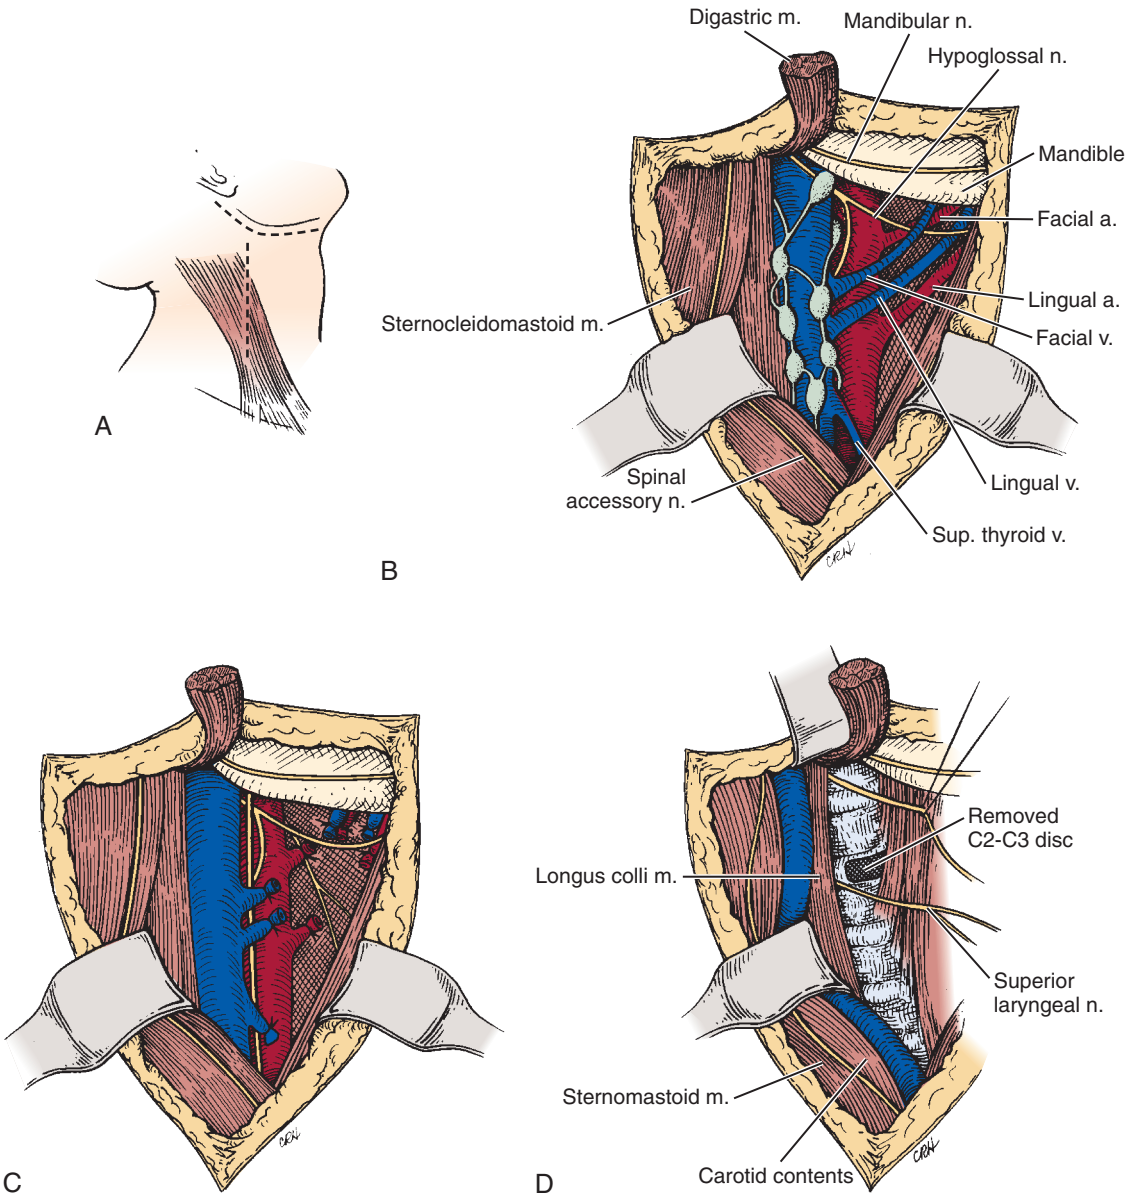

FIG. 18.8 (A) Right-sided submandibular transverse incision. (B) The anterior border of the sternocleidomastoid muscle is mobilized, and the digastric tendon is divided. The submandibular salivary gland and jugular digastric lymph nodes are resected. The hypoglossal nerve is identified and mobilized. (C) The carotid sheath is opened, and the arterial and venous branches are ligated. (D) The superior laryngeal nerve is identified and protected.

The prevertebral fascia overlying the vertebral body, intervertebral disc, and longus colli are now visible (Fig. 18.8D). The two longus colli converge in the midline on the anterior tubercle of the atlas. Because the hypoglossal, glossopharyngeal, vagus, and accessory nerves and the internal carotid artery and jugular vein are tethered to the occiput as they exit their respective foramina, they can be injured with vigorous retraction or greater than 2 cm lateral dissection from the midline. Additionally, excess anterior retraction of the pharynx can result in injury to the pharyngeal and laryngeal branches of the vagus nerve. At this point, a midline incision over the basiocciput, atlas, and axis can be performed, and the anterior longitudinal ligament and longus colli muscle can be dissected subperiosteally to obtain lateral exposure to the cervical spine.

Anterolateral Retropharyngeal Technique

Described by Whitesides and Kelly,[47] the anterolateral retropharyngeal approach provides exposure of the upper cervical spine by partially transecting the sternocleidomastoid and proceeding laterally and posterior to the carotid sheath (Fig. 18.9). As a result, the major branches of the external carotid and laryngeal nerves are not disturbed. Although this exposure allows for distal extension to include T1, its superior extension is limited to the ring of the atlas. Because the internal carotid artery; jugular vein; and vagus, accessory, and hypoglossal nerves are tethered to the skull, adequate retraction necessary to expose the basiocciput would result in injury to these structures.

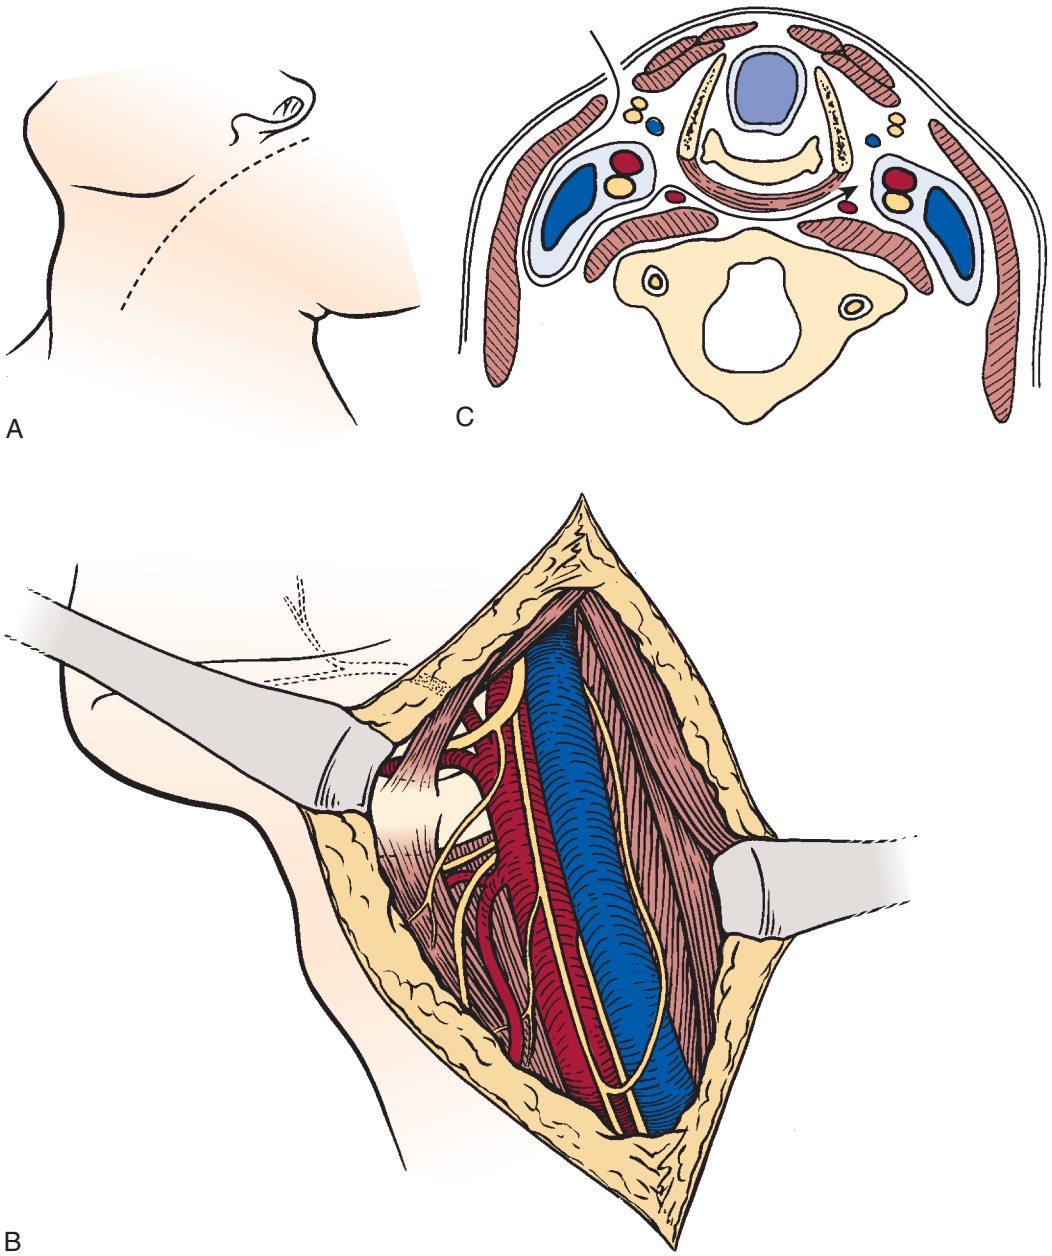

FIG. 18.9 Anterolateral retropharyngeal approach. (A) A skin incision is made from the mastoid along the anterior aspect of the sternocleidomastoid. (B) This approach involves dissection anterior to the sternocleidomastoid but posterior to the carotid sheath. (C) Neurovascular structures that are encountered in this approach include the carotid contents and branches, superior laryngeal nerves, hypoglossal nerve, and ansa cervicalis.

A longitudinal skin incision is made from the mastoid extending distally and anteriorly along the anterior aspect of the sternocleidomastoid muscle. The external jugular vein is identified and ligated, and the greater auricular nerve running parallel to the external jugular vein is spared if possible. The sternocleidomastoid now is prominent; if only a limited exposure (C1–C2) is required, consideration can be given to preserving the sternocleidomastoid. In most cases, the sternocleidomastoid and splenius capitis muscles are detached from the mastoid, leaving a fascial edge for later repair. The spinal accessory nerve enters the sternocleidomastoid approximately 3 cm distal to the mastoid tip, which should be identified and protected.[47]

Next, one can proceed laterally and posterior to the carotid sheath and dissect it free from the sternocleidomastoid. The carotid contents are retracted along with the hypoglossal nerve anteriorly and the sternocleidomastoid muscle and accessory nerve posteriorly. The plane between the alar and prevertebral fascia is developed with blunt dissection to expose the transverse processes and anterior aspect of C1–C3. The most pronounced bony prominence laterally is the transverse process of C1. Although the basiocciput, clivus, and sphenoid may be palpated through this approach, they are poorly visualized.

When the appropriate level is identified, a midline longitudinal incision is made in the middle of the vertebral body, and

the ligament and overlying muscles are dissected subperiosteally and laterally. Alternatively, if more lateral exposure is needed, the longus colli and capitis muscles can be separated from their bony insertion on the transverse process and retracted anteriorly. This provides direct exposure to the nerve roots, transverse processes, and vertebral artery, but disturbs the sympathetic rami communicantes and may cause Horner syndrome.

Complications

Complications common to the anterolateral and anteromedial retropharyngeal approaches include airway obstruction, hemorrhage, and nerve injury. Airway obstruction and difficulty swallowing secondary to hematoma or edema of the pharynx and larynx can be an immediate life-threatening complication. Typically, nasotracheal intubation is adequate; however, a tracheostomy can be considered either preoperatively or postoperatively for airway management if this complication is expected or encountered. Hemorrhage from the carotid artery, jugular vein, or their branches can occur and can be difficult to control.

Laryngeal and pharyngeal dysfunction can result from retraction of the laryngeal nerves. Patients should be advised preoperatively to expect difficulty with phonation and swallowing, especially in the early postoperative course. Problems can persist if the external branch of the superior laryngeal nerve is sacrificed or transected. In three of five cases reported by deAndrade and McNab,[37] persistent postoperative hoarseness, laryngeal fatigue, and inability to produce high tones persisted. Nerve injury to the spinal accessory nerve can occur, particularly with the anterolateral retropharyngeal approach. Care should be taken to identify and protect this nerve intraoperatively as iatrogenic damage can result in weakness of the sternocleidomastoid and trapezius muscles postoperatively.

Anterior Exposure of Lower Cervical Spine

Similar to approaches to the upper cervical spine, anterior exposures to the lower cervical spine can be divided into anterolateral and anteromedial approaches based on their relationship to the carotid sheath. First described by Southwick and Robinson,[46] the anteromedial approach employs the interval between the sternocleidomastoid laterally and the strap muscles and tracheoesophageal complex medially and is used in most cases. In special circumstances, the anterolateral approach described by Henry[48] and Hogson[49] may be used. Hogson[49] described an approach to the lower cervical spine in which dissection was done posterior to the carotid sheath to expose the anterior and lateral aspects. Verbiest[50] described a modification of the original approach for the exposure of the vertebral artery. Dissection anterior to the carotid sheath, as in the anteromedial Smith-Robinson technique, provides more lateral exposure to the cervical spine and may be better in cases in which the lesion is localized more laterally or if the vertebral artery must be exposed. The spinal nerve can also be identified posterior to the vertebral artery (Fig. 18.10).

To minimize injury to the recurrent laryngeal nerve, the cervical spine is often approached from the left, particularly

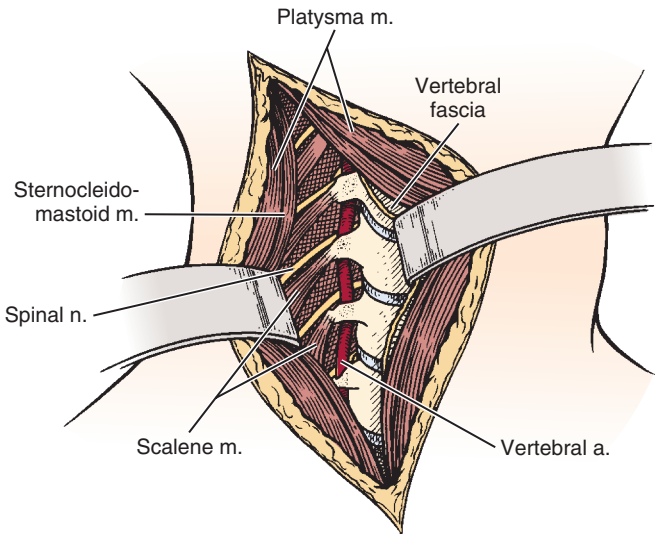

FIG. 18.10 Verbiest's approach. The sternocleidomastoid and carotid sheath are identified and retracted laterally, and visceral structures are retracted medially. The anterior tubercle of the transverse process is identified by palpation. Muscular insertions of the longus colli, longus capitis, and anterior scalene are dissected sharply to the bone, and the anterior tubercle is cleared of soft tissues. The costotransverse lamellae can be resected to provide exposure to the vertebral artery and spinal nerve lying posteriorly.

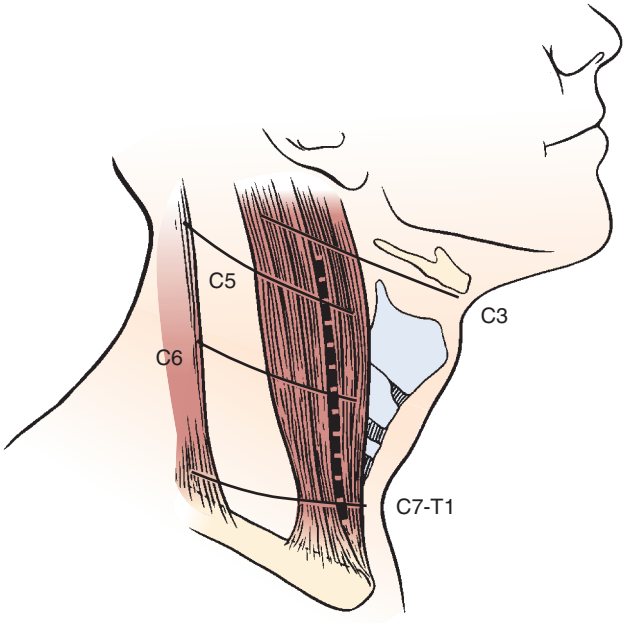

FIG. 18.11 Surface anatomy can help identify the approximate level of vertebral bodies in the cervical spine. The hyoid bone overlies C3, thyroid cartilage overlies C5, the cricoid ring is at C6, and the supraclavicular level is in the C7–T1 region.

at the C6–T1 region. Although a right-handed surgeon may prefer the right-sided approach, the recurrent laryngeal nerve is at greater risk of injury because it may leave the carotid sheath at a higher level on the right side. The hyoid bone overlies the third vertebra, the thyroid cartilage overlies the C4–C5 intervertebral disc space, and the cricoid ring is at the C6 vertebra (Fig. 18.11).[6] In many cases, when the neck is in

a significantly extended position, these landmarks may be displaced inferiorly in relationship to the vertebral bodies; moving the incision slightly higher can help accommodate for the shift. A horizontal incision is used in most cases, but a vertical incision anterior to the sternocleidomastoid may be necessary in cases in which multiple levels need to be exposed.

Anteromedial Approach

A transverse incision in line with the skin crease is made from the midline beyond the anterior aspect of the sternocleidomastoid muscle. The skin and subcutaneous tissue are undermined slightly, and division of the platysma muscle is completed. The platysma muscle may be divided either horizontally or vertically. Retraction of the divided muscle exposes the sternocleidomastoid muscle laterally and strap muscles medially. The anterior and external jugular veins may be encountered and can be ligated to improve exposure. The deep cervical fascia is divided between the sternocleidomastoid muscle and strap muscles, and blunt finger dissection is done through the pretracheal fascia while palpating and retracting the carotid sheath laterally.

A self-retaining retractor is positioned to expose the prevertebral fascia and longus colli muscles. One must be careful not to enter the carotid sheath laterally to avoid injury to the carotid artery, internal jugular vein, or vagus nerve. Great caution should also be exercised medially because the strap muscles surround the thyroid gland, trachea, and esophagus. The surgical dissection should not enter the plane between the trachea and esophagus because the recurrent laryngeal nerve is at risk. A sharp self-retaining retractor should be avoided to prevent perforation of the esophagus medially. It is also important to check for the temporal arterial pulse when the retractor is spread because prolonged occlusion of the carotid artery may cause brain ischemia and stroke. The superior thyroid artery is encountered above C4, and the inferior thyroid artery is seen below C6. These vessels should be identified and ligated as necessary. One should also be aware of the thoracic duct below C7 during the left-sided approach. Further dissection is performed by palpating the prominent disc margins ("hills") and concave anterior vertebral bodies ("valleys").

A hemostat is clamped to the perivertebral fascia to localize the level, and a lateral radiograph is taken. When the correct level is confirmed, the exposure is completed by dividing the pretracheal fascia and anterior longitudinal ligament in the midline to minimize bleeding and prevent injury to the sympathetic chain and subperiosteal mobilization of the longus colli laterally. Too vigorous lateral dissection may damage the vertebral artery or nerve roots, especially at the level of the intervertebral disc space.[20] At the level of the vertebral body, the anterior aspect of the foramen transversarium offers some protection to the vertebral artery.

Anterolateral Approach

By performing the dissection posterior to the carotid sheath, the anterolateral approach avoids the thyroid vessel, vagus nerve, and superior laryngeal nerve, and provides access to the anterior and lateral aspect of the cervical spine. Superior extension of this approach allows access to the upper cervical spine as described by Whitesides and Kelly[47] (see "Anterolateral Retropharyngeal Technique"). A transverse or oblique skin incision is made from the right side. The subcutaneous tissue and the platysma muscle are divided, and the branches of the external jugular vein are ligated, but the cutaneous nerves should be protected if possible. The posterior border of the sternocleidomastoid muscle is identified; blunt dissection should follow the fat pad through the posterior triangle of the cervical spine. The dissection should stay anterior to the anterior scalene muscle and anterior to the anterior tubercle of the transverse process to avoid injuries to the vertebral artery or nerve root. If retraction of the sternocleidomastoid muscle is difficult, the posterior third and the omohyoid muscle can be divided to enhance exposure. The cervical sympathetic plexus on the lateral aspect of the prevertebral musculature should be identified and protected. The prevertebral fascia and longus colli muscle are incised in the midline for subperiosteal exposure of the cervical spine. After palpation of the anterior tubercle of the transverse process, the anterior tubercle can be removed to gain access to the vertebral artery and venous plexus.

Complications

The most devastating complication is neurologic deterioration. Most spinal cord or nerve root injuries are associated with technical mishaps. In myelopathic patients, attention should be paid to proper positioning of the neck, fiberoptic nasotracheal awake intubation, and intraoperative monitoring of the spinal cord function. Utmost care should be taken when removing osteophytes and disc material in the lateral corner near the uncovertebral joint to avoid nerve root injury. If removal of the posterior longitudinal ligament or osteophytes is necessary because of perforating disc fragments or large osteophytes, an operating microscope should be used. If neurologic complications are discovered postoperatively, one should administer dexamethasone and obtain a lateral radiograph to determine the position of the bone graft. Computed tomography (CT) or magnetic resonance imaging (MRI) may be valuable in determining hematoma or cord contusion. If hematoma or bone graft is suspected to be the cause of postoperative myelopathy, expeditious re-exploration is required.

Airway obstruction after extubation may occur in the postoperative period. One must be certain that the patient can exchange air before extubation. In cases in which multiple vertebrectomy has been performed with retraction of soft tissues for a prolonged period, intubation should continue for a few days until retropharyngeal edema subsides. Corticosteroids may be used to decrease edema in these cases. Postoperatively, a patient who underwent a prolonged operation for decompression of the spinal cord should be intubated for 2 to 3 days until retropharyngeal edema subsides. Corticosteroids may decrease severe edema in the postoperative period. Airway obstruction and difficulty with swallowing because of retropharyngeal edema may require reintubation or tracheostomy.

Serious bleeding complications after anterior cervical surgery are rare, but hematoma-related wound complications are common, with an incidence of 5.6% in one series.[51] Arterial bleeding from the superior or inferior thyroid artery can be prevented by careful identification and ligation during surgery. Care should be taken not to dissect too far laterally because the vertebral artery is in danger along with the nerve roots. Tears on the vertebral artery should be repaired by direct exposure of the vessel in the foramen rather than merely packing the bleeding site. Injuries to the carotid artery or internal jugular vein are exceedingly rare. A hematoma rarely may be responsible for airway obstruction or spinal cord compression. The patient should have the head elevated in the immediate postoperative period because the source of bleeding is frequently venous. Meticulous hemostasis and placement of a drain should be routine to prevent these complications.

Esophageal perforation is a rare but serious complication of anterior cervical spine fusion, occurring in about 1 of 500 procedures. Sharp retractors must be avoided, and gentle handling of the medial soft structures is mandatory. In revision cases, the use of a nasogastric tube may help identify the esophagus intraoperatively. If perforation is suspected during surgery, methylene blue can be injected for better visualization. The perforation is frequently not recognized until the patient develops an abscess, tracheoesophageal fistula, or mediastinitis in the postoperative period.[52] The usual treatment consists of intravenous antibiotics, nasogastric feeding, drainage, débridement, and repair. Early consultation with head and neck surgeons is recommended.

Minor hoarseness or sore throat after anterior cervical fusion may be due to edema or endotracheal intubation, and occurs in nearly half of the patients. Recurrent laryngeal nerve palsy may be the cause of persistent hoarseness in a few patients, however. As many as 11% of patients may experience some degree of recurrent laryngeal nerve palsy following anterior cervical spine surgery,[53] with permanent hoarseness occurring in 2% to 4% of patients.[54] The superior laryngeal nerve is a branch of the inferior ganglion of the vagus nerve, and travels along with the superior thyroid artery to innervate the cricothyroid muscle. Damage to this nerve may result in hoarseness, but often produces symptoms such as easy fatiguing of the voice. The inferior laryngeal nerve is a recurrent branch of the vagus nerve that innervates all laryngeal muscles except the cricothyroid.

On the left side, the recurrent laryngeal nerve loops under the arch of the aorta and is protected in the left tracheoesophageal groove. On the right side, the recurrent nerve travels around the subclavian artery, passing dorsomedial to the side of the trachea and esophagus. It is vulnerable as it passes from the subclavian artery to the right tracheoesophageal groove. The recurrent laryngeal nerve should be located when working from C6 downward. The best guideline to its location is the inferior thyroid artery. The nerve usually enters the tracheoesophageal groove where the inferior thyroid artery enters the lower pole of the thyroid. It is also more common for the right inferior laryngeal nerve to be nonrecurrent where it travels directly from the vagus nerve and carotid sheath to the larynx. The incidence of nonrecurrent laryngeal nerve on the right side can be as high as 2.7%.[55]

If hoarseness persists for more than 6 weeks after anterior cervical surgery, laryngoscopy should be done to evaluate the vocal cord and laryngeal muscles. Treatment of the inferior laryngeal nerve should include waiting at least 6 months for spontaneous recovery of function to occur. Further treatment or surgery by the otolaryngologist may be necessary in persistent cases.

Injury to the sympathetic chain may result in Horner syndrome. The cervical sympathetic chain lies on the anterior surface of the longus colli muscles posterior to the carotid sheath. Subperiosteal dissection is important to prevent damage to these nerves. Horner syndrome is usually temporary but may be permanent in some cases. The incidence of permanent Horner syndrome is less than 1%. Ophthalmologic consultation may be needed for treatment of ptosis.

Anterior Approach to Cervicothoracic Junction

Anterior approaches to the cervicothoracic junction are challenging because of the proximity of the great vessels and overlying sternum and clavicle (Fig. 18.12). Three main approaches have been described to address access in this region: the modified anterior approach, the sternal-splitting approach, and the transthoracic approach.[56–58] Each approach has its own advantages and disadvantages, thus should be chosen accordingly. Theoretically, the modified anterior approach can provide visualization and access to the anterior spinal structures from C4 to T4, but requires resection of the medial clavicle and sternoclavicular joint. Similarly, the sternal-splitting approach, when combined with the anteromedial approach to the neck, offers access from C4 to T4 through retraction of the great vessels. Although the transthoracic approach provides adequate exposure to the upper thoracic spine, access to the cervical spine is limited to C7 at best. Given inherent accessibility challenges, multiple algorithms dependent on imaging and demographic variables have been developed to assess accessibility.[59,60]

Modified Anterior Approach

The patient is positioned supine on the operating table with a bump between the scapula. Typically, an angled incision is used for this approach. The transverse limb is made 2 cm proximal to and parallel to the left clavicle extending from the midline to the lateral border of the sternocleidomastoid. The transverse limb is generally left sided, as the left recurrent laryngeal nerve has a less variable path.[61] The vertical limb runs from the medial aspect of the transverse incision and extends just distally past the manubriosternal junction. The platysma is divided in line with the skin incision and undermined proximally and distally to mobilize the muscle. In some instances, the superficial veins and external jugular vein are mobilized. However, they may need to be cauterized as necessary for exposure.

The strap muscles and sternocleidomastoid are dissected and divided subperiosteally off the medial clavicle and

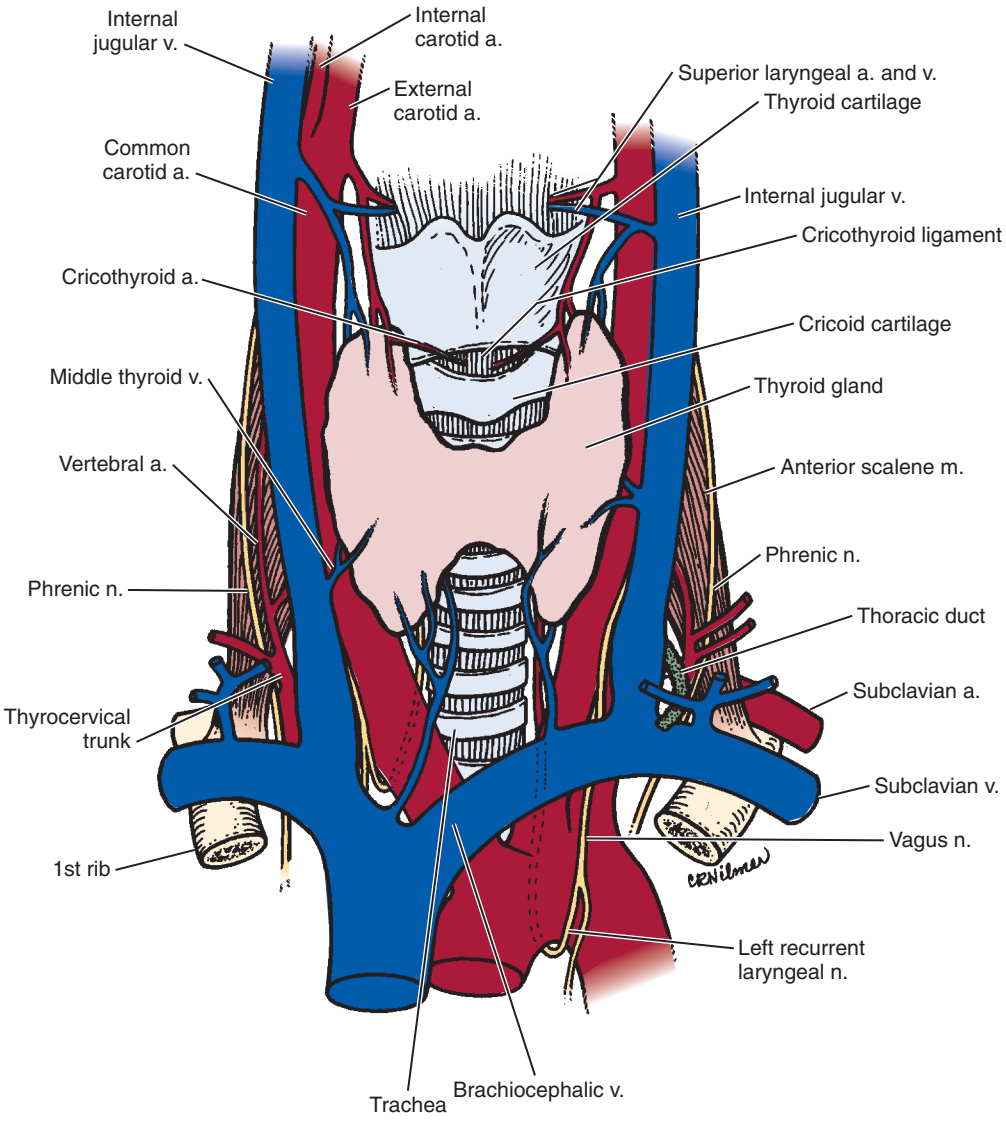

FIG. 18.12 Anterior access to the cervicothoracic junction is complicated by proximity of the great vessels and associated neural structures.

manubrium, and retracted proximally. With care taken to avoid the subclavian vein, the clavicle is osteotomized at the junction of the middle and medial third and disarticulated from the manubrium with division of the first costal cartilage. In some cases, the inferior thyroid vein may lie medially in the surgical field and require ligation for exposure.

Next, the interval is developed between the carotid sheath laterally and the strap muscles, esophagus, and trachea medially. The recurrent laryngeal nerve muscle must be identified from the right-sided approach, whereas the thoracic duct must be protected and spared with the left-sided approach. At this level, the recurrent laryngeal nerve already lies safely within the tracheoesophageal groove with a left-sided approach.

With the use of hand-held retractors, the cervicothoracic junction can now be accessed by carefully mobilizing the esophagus, trachea, and right brachiocephalic artery and vein toward the patient's right, while the left carotid sheath and brachiocephalic and subclavian veins are retracted to the left. The prevertebral fascia overlying the anterior aspect of the vertebrae from C4 to T4 can now be visualized.

Sternal-Splitting Approach

Combined with the anteromedial approach to the cervical spine, the sternal-splitting approach provides access to the cervicothoracic junction from C4 to T4, particularly in obese or muscular patients. A vertical skin incision is made anterior to the left sternocleidomastoid muscle and extended along the midline from the suprasternal notch proximally to the xiphoid process distally. Proximally, after division of the platysma muscle and superficial cervical fascia, blunt dissection is performed between the laterally situated carotid sheath and medial visceral structures. Distally, the subcutaneous soft tissue over the sternum is divided in line with the skin incision, and the retrosternal space is developed with blunt

finger dissection. This helps reflect the parietal pleura from the posterior surface of the sternum and costal cartilage. The sternum is cut longitudinally with an oscillating saw. The inferior thyroid vein located just proximal to the suprasternal notch must be avoided. A self-retainer is inserted to split the sternum.

Blunt dissection is performed from the cranial toward the caudal portion until the left brachiocephalic vein is exposed. As in the modified anterior approach to the cervicothoracic junction, the esophagus, trachea, left carotid sheath, left subclavian artery, and brachiocephalic vein are retracted to the patient's left, whereas the esophagus, trachea, and right brachiocephalic artery and vein are mobilized to the right. The prevertebral fascia can now be divided in the midline to provide access to the C4–T4 vertebral bodies.

Transthoracic Approach

With the patient in the left lateral decubitus position, the right chest is prepared and draped. The bony prominences are padded accordingly, and a left roll is placed in the axilla to prevent neurovascular compromise to the left upper extremity. A right-sided approach is preferred because of the location of the great vessels and heart in the left-sided approach. A standard thoracotomy centered on the third rib provides access to the upper thoracic vertebra, but exposure to the low cervical region is restricted. A first or second rib level entry does not improve access because these ribs are much shorter, and the scapula interferes posteriorly.

The incision is made beginning at the anterior axillary line and extending posteriorly to the lateral border of the paraspinal muscles. The scapula is retracted laterally by dividing the trapezius and latissimus dorsi muscles. The subscapular space is developed with blunt dissection, and the third rib is identified by counting down from the thoracic inlet.

While protecting the intercostal neurovascular bundle, the appropriate rib is subperiosteally dissected out and resected anteriorly and posteriorly as far as possible. A rib spreader is inserted, and the lung is retracted anteriorly. The parietal pleura is incised overlying the vertebral artery, making sure to identify the segmental vessels.

Complications

Postoperative weakness secondary to weakness of the shoulder girdle musculature from the joint resection can occur. The thoracic duct should be identified if approached from the left. If damaged, the thoracic duct should be doubly ligated proximally and distally to prevent chylothorax. Great caution should be taken to avoid injuries to the sympathetic nerves, the cupola of the pleura at the level of T1, the great vessels, and the thoracic duct, which passes into the left venous angle between the subclavian artery and the common carotid artery. Potential complications of this approach include restriction of scapular movement and paralysis of intercostal muscles owing to the muscle-splitting aspects of this dissection. We recommend use of this approach in older patients and perhaps in patients with malignant conditions.

Posterior Approaches

Posterior exposures to the cervical spine are among the safest and most used exposures for management of cervical spine disorders, allowing direct access to the posterior elements from the occiput to the thoracic spine.[6,62] The particular anatomy of the upper cervical spine and the transitional anatomy of the cervicothoracic junction should also be understood when approaching these regions posteriorly.

Posterior Approach to Upper Cervical Spine

The posterior approach to the upper cervical spine grants exquisite access to the posterior elements of the occiput, atlas, and axis, allowing for easy atlantoaxial and occipitocervical decompression and fusion. The exposure begins with a midline incision extending from the inion to the C4 spinous process, an incision length that can be tailored depending on the treated pathology. The incision should fall along an internervous plane in the midline that separates the muscles from the segmental innervation supplied by the right and left posterior rami of the cervical nerves. Staying in the midline, within the avascular plane of the ligamentum nuchae minimizes bleeding and the risk of injury to surrounding muscle tissue and neurovascular structures, while providing a stout tissue layer for tissue closure at the end of the case. This principle is especially important in the cervical spine as the posterior cervical musculature is particularly vascular.

If the location of pathology is at the occipitocervical junction, that is, in the case of basilar impression, fracture of the odontoid with C1 fracture, or tumor, bone landmarks can be used to determine the appropriate level. The external occipital protuberance and the spinous process of C2 can typically be easily palpated, with the incision made from the inion caudad approximately 8 cm. As discussed earlier, the dissection is continued through the ligamentum nuchae, and the paraspinal muscles are stripped from C3 to the occiput. The surgeon should be cautious when dissecting at the inferior edge of the foramen magnum because uncontrollable bleeding from a group of veins present in this location may be encountered. Sharp subperiosteal dissection of the external occipital protuberance and lamina is performed, and care is taken to protect the vertebral arteries at the lateral border of the atlas. With a fine curet or an elevator, the posterior atlanto-occipital ligament can be separated from the posterior lip of the foramen magnum if necessary.

The greater occipital nerve (C2) and the third occipital nerve cross the field and course laterally in the paracervical muscles. Subperiosteal dissection and avoidance of vigorous *lateral* dissection should prevent injury to these nerves. If occipital fixation is required, the inion is thickest at its prominence near the ridge, and the passage of wires is possible without violating both tables of the occiput. If screw fixation is being used, bicortical purchase is recommended for the occiput, and screw lengths of typically 10 to 12 mm can be accepted in this region.[63]

If access to the posterior elements of C1–C2 is necessary, the incision can be extended inferiorly. Palpation of the large

C2 spinous process and the posterior C1 ring confirms the correct level. The posterior arch of the atlas is deeper anteriorly than the occiput and C2 spinous process, and the facet joint of C1–C2 lies about 2.5 cm anterior to the C2–C3 joint. A large broad elevator is used to dissect the posterior paracervical muscles from the arches of C1 and C2, and caution should be taken to avoid plunging instruments into the spinal canal. A small curet can be helpful to remove the muscular attachments on the bifid spinous process of C2 while stabilizing the arch of C2. Capsular ligaments of the facets should be preserved to maintain stability.

The passage of sublaminar wires at the C1–C2 level is common because the spinal canal at this level is capacious, but passage at lower cervical levels is associated with increased risk of neurologic injury. The removal of the atlantoaxial ligament or atlanto-occipital membrane is not required except for laminectomy cases. Careful separation of the membrane or ligament from the bone is all that is usually needed to pass sublaminar wires. This separation can be performed with a small-angled curet or a small Freer elevator. Slight head flexion can also help by opening the space between the ring of C1 and the occiput. The mean thickness of the posterior ring is 8 mm, and the cortical bone is thin.[64] Great care must be taken not to fracture the posterior ring of C1 while dissecting the ligamentum flavum.

An additional technique to expose the lateral aspect of C1 or C2 is to elevate the periosteum with a small Freer elevator. This allows the vertebral artery to be protected at the lateral aspect of the C1 arch. Lateral dissection should not exceed greater than 1.5 cm from the midline in an adult and 1 cm in a child due to risk of injury to the vertebral artery.[65,66] The vertebral artery courses over the arch of the atlas and pierces the lateral angle of the posterior atlanto-occipital membrane, although preoperative imaging should be obtained to evaluate the course of the vertebral artery and rule out anomalous vascular anatomy.

Brief consideration is given here to the regional anatomy for the C1–C2 transarticular screw fixation (Magerl) technique,[67–69] C1 lateral mass and C2 pedicle screw (Harms) technique,[69,70] and C2 translaminar screw.[69,71] A thin-cut CT scan with sagittal reconstructions and/or MRI imaging are necessary to fully track vertebral artery course and structure. This imaging is especially important to obtain in rheumatoid patients in whom an anomalous or enlarged foramen transversarium is common, which may place the vertebral arteries at increased risk with this technique. Attention should be paid to the presence of a ponticulus posticus, an anomalous ossification overlying the vertebral artery as it runs in the superior sulcus of C1, which can occur in 15% of the population. Regardless of the technique used, the intraoperative use of anteroposterior and lateral fluoroscopy can inform screw inclination in the coronal and parasagittal plane.

Because of the amount of cephalad angulation required to place the C1–C2 transarticular screw, subperiosteal exposure should extend down to C4.[65] The main landmark is the medial part of the isthmus of the axis, which can be visualized directly by subperiosteal dissection of the C2 lamina proceeding along the bony contour around the spinal canal until the maximum width in the coronal plane is reached. A Kirschner wire (K-wire) can be used to retract the soft tissues containing the greater occipital nerve and accompanying the venous plexus. The point of entry can be approximated as 3 mm cranial to the C2–C3 facet joint and 3 mm medial to the lateral border of the C2 inferior facet. The drilling for the screw is strictly sagittal and extends through the pars interarticularis, before perforating the atlantoaxial joint approximately in the posteromedial part entering the lateral mass of the atlas.[72] Lateral drill excursion should be avoided to prevent additional risk of injury to the vertebral arteries.

In the case of placement of a C1 lateral mass screw, the C1–C2 joint is the key anatomic landmark to be identified.[70] This identification can be facilitated by caudal retraction of the C2 nerve, which exposes the posterior aspect of the lateral mass of C1.[69] Subperiosteal dissection must be carried out on the inferior edge of the posterior arch of C1. The starting point of the C1 lateral mass screw lies directly in the midportion in the lateral mass. Often, a small emissary vein is located at this point. The C2 pedicle screw is identified by delineating the medial border of the isthmus and pars of the axis, as in the C1–C2 transarticular screw. However, the trajectory of the C2 pedicle screw is more medial and follows the path of the pedicle, as would be expected.[69,70]

Technical challenges associated with the C1–C2 transarticular screw and C2 pedicle screw placement led to the development of the C2 translaminar screw. Use of this screw is possible because of the predictably large size of the C2 lamina combined with the fact that the use of this screw eliminates the possibility for vertebral artery injury.[69,71] The starting point is identified as the junction of the C2 spinous process and the lamina, and the trajectory of the screw parallels the down slope of the dorsal aspect of the contralateral lamina. Care should be taken not to breach the ventral aspect of the lamina, resulting in placement of the screw within the spinal canal and to ensure that the C2–C3 facet joint is not violated by placement of a screw that is too long.[71]

Posterior Approach to Lower Cervical Spine

A reverse Trendelenburg position minimizes venous bleeding and reduces CSF pressure (Fig. 18.13). The posterior approach uses a longitudinal midline incision that extends above and below the segments required for the procedure. This extension of the skin and subcutaneous tissues is necessary because the skin of the posterior neck is less mobile and thicker for retraction. The skin is incised sharply, and electrocautery is used to incise the ligamentum nuchae in the midline. With a wide, flat periosteal elevator such as a Cobb, the dissection is carried subperiosteally down the spinous processes. Inadvertent penetration of instruments into the spinal canal can be minimized by examining preoperative films for evidence of spina bifida and other bony defects and by realizing that, in the cervical spine, the laminae do not override each other as much as in the thoracic spine, resulting in wider interlaminar spaces. Care should be taken to stay subperiosteal because the bifid nature of the spinous processes may result in a bulbous expanse, and the dissection may err into the paraspinal musculature. A superficial plexus of

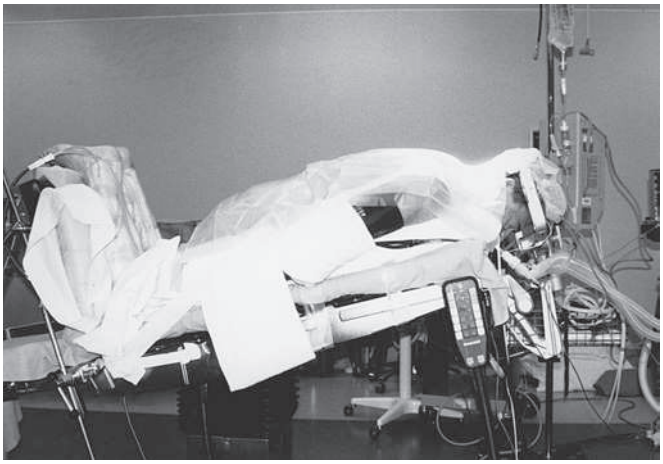

FIG. 18.13 Standard prone positioning for posterior cervical procedures. The reverse Trendelenburg position minimizes venous bleeding and reduces cerebrospinal fluid pressure.

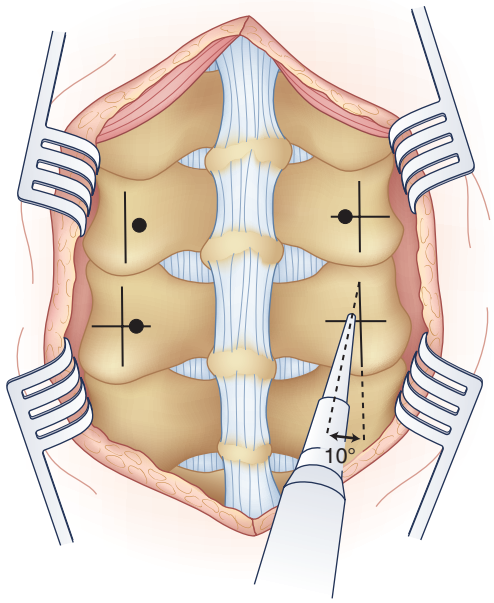

FIG. 18.14 The Roy-Camille technique for lateral mass screws. The entry point is at or near the anatomic center of the lateral mass and directed 10 degrees laterally.

veins may be encountered, which should be cauterized as needed. In general, subperiosteal dissection should be performed in a caudal-to-cephalad direction to minimize bleeding.

Subperiosteal dissection of muscles is performed to expose the spinous processes, lamina, lateral mass, and facet joints. Dissection should extend laterally to the medial third of the facet joint, with preservation of the capsule unless a fusion is planned. Extreme caution is needed during the exposure of the lamina and the interlaminar space to prevent dural tear and CSF leakage. Care should be taken at the lateral edge of the joint because the nerve root and vertebral artery lie anterior to the spinolamellar membrane of the adjoining transverse processes. Vigorous decortication or stripping may damage the thin bone and subsequently the nerve root and vertebral artery. The segmental artery at the lateral edge of the facet joints may be cauterized as it exits between the transverse processes. Various retractors may be used to facilitate exposure. For fusion cases, one should expose only the levels to be fused because creeping fusion extension is common. Supplementation of the fusion with posterior lateral mass plating may obviate the need for a halo vest postoperatively.

First popularized by Roy-Camille and colleagues,[73] placement of posterior cervical screws requires a thorough understanding of the lateral mass anatomy to minimize injury to associated neurovascular structures. Different entry points and screw orientations have been recommended. In the original description by Roy-Camille and colleagues,[73] the entry point was the center of the lateral mass, with the screw angled 10 degrees laterally (Fig. 18.14), whereas Magerl recommended the drilling angle to be 25 degrees laterally and 45 degrees superiorly. An and colleagues[5] found that, by orienting the screw 15 degrees cephalad and 30 degrees laterally with an entry point 1 mm medial to the anatomic center of the lateral mass, the facet joint and nerve root are avoided.

Posterior Approach to Cervicothoracic Junction

Lesions of the cervicothoracic junction are generally anterior, for which extensive anterior approaches with or without posterior fixation are usually required. Lesions that may require posterior stabilization include lesions resulting from tumors, trauma, postlaminectomy instability, or infection. If the posterior elements are intact, the simple triple-wiring procedure can be done for a short fusion, or rods may be used for a longer fusion, using a standard posterior approach.

Pedicle screw fixation is an alternative technique if the posterior elements are deficient. The transpedicular technique at the cervicothoracic junction is an exacting procedure with very little margin for error. Through cadaveric studies, the pedicle landmarks and anatomic characteristics of the cervicothoracic region were found. A standard posterior approach is used with the dissection performed to expose the lateral mass and to the tips of the transverse processes of the upper thoracic vertebrae. The facet joint to be fused is cleaned of its capsule, and the articular margins are identified. The entry point of the pedicle lies at the intersection of a horizontal line at the midportion of the transverse processes and a vertical line at the lamina–transverse process junction. This pedicle entrance point is 1 mm inferior to the facet joint and the middle point from the medial to the lateral margins of the facet joint. The outer cortex is decorticated at this point with a small bur, and a small Penfield elevator or straight curet is used to probe bluntly and enter the pedicle. A 2.5-mm drill may be used to enter the pedicle when it is identified. Medial angulation is required for entry of the pedicle into the vertebral body. Medial angulation has been observed to vary between individuals, thus it must be measured preoperatively in preparation for surgery. An et al. most recently reported that medial angulation averages 35.85 degrees at C7, 31.65 degrees at T1, and 23.35 degrees at T2.[74] Compared with the pedicles of the lumbar spine, the superoinferior diameter of the thoracic pedicles at the cervicothoracic junction is greater than its

mediolateral diameter, which leaves little margin for error in the mediolateral plane.[74]

Complications

Complications associated with posterior approaches to the upper and lower cervical spine are uncommon but can be catastrophic. Bleeding can be minimized by staying subperiosteal and within the midline to prevent entering into the paraspinous musculature. The arch of the atlas should be dissected laterally only approximately 1.5 cm because the vertebral artery is at risk. One should minimize dissecting at the inferior edge of the foramen magnum to prevent uncontrollable venous bleeding.

Neurologic injury is a devastating complication of spine surgery. Care is required during passage of sublaminar wires or application of the screws to prevent injury to the brain or spinal cord. Dissection on the ring of the atlas must be done in a gentle manner because the direct pressure may result in fracture or slippage of an instrument into the spinal canal. A thorough understanding of the size, orientation, and relationship of the pedicles and lateral masses to surrounding neurovascular structures is imperative before the use of spinal instrumentation is undertaken. Posterior fusion without decompressive laminectomy tends to compress the spinal canal.

PEARLS

1. The anterior tubercle of the transverse process of C6 is an important palpable surface landmark for anterior cervical approaches.
2. The key to understanding the anterior approach to the cervical spine lies in recognizing the various investing fascial layers of the neck.
3. Placement of the deep retractors anteriorly should be deep to the longus colli to reduce the risk of injury to the sympathetic chain.
4. Posteriorly, the first bony prominence palpated inferior to the occiput is the spinous process of C2.
5. Reformatted fine-cut CT scans of the cervical spine help to improve understanding of the bony anatomy.

PITFALLS

1. The variable course of the vertebral artery as it ascends through the cervical spine places it at risk for injury during the anterior and posterior cervical approach.
2. The incorrect approach may be chosen without careful preoperative imaging review.
3. Increased rates of injury to surrounding structures may be observed if a modified anterior approach to the cervical spine is not used.
4. Increased bleeding is likely with dissection away from the midline that is not subperiosteal.
5. Airway obstruction after extubation may occur in the postoperative period after anterior and posterior cervical procedures.

KEY POINTS

1. Understanding the surgical anatomy of the cervical spine requires knowledge of the bony, ligamentous, muscular, and neurovascular anatomy of the neck and the complex relationship these structures have to one another.
2. The surgical approach selected should take into account the site of the pathologic process, the health of the patient, and the skill and comfort level of the surgeon with each particular exposure.
3. Understanding the advantages and limitation of each surgical exposure improves patient outcome and reduces complications.
4. Anatomic and surgical considerations at the occipitocervical and cervicothoracic junction are particularly challenging and should be thoroughly understood before approaching pathologic processes in these regions.
5. Complications of the cervical spine are infrequent but potentially devastating; careful preoperative planning, precise surgical technique, and a high index of suspicion should be maintained to minimize and identify complications.

19 CHAPTER Anatomy of the Anterior Cervicothoracic Spine

Kenneth A. Hood
Shyam Shridharani

The cervicothoracic spine corresponds to the region just superior to the mediastinum and extends into the sternum and T4–T5 intervertebral disc space. In this region, knowledge of the vascular and neural anatomy is of utmost importance. The left brachiocephalic vein is found posterior to the upper sternum and lies directly posterior to the thymus gland. The right and left brachiocephalic veins merge behind the right first intercostal space to form the superior vena cava. The superior vena cava drains into the right atrium behind the third costal cartilage.

The recurrent laryngeal nerve is a branch of the vagus nerve that supplies the intrinsic muscles of the larynx with the exception of the cricothyroid muscles. Injury to this nerve can result in dysphonia and dysphagia. The left recurrent laryngeal nerve can be found emerging from the vagus nerve anterior to the arch of the aorta between T1 and T3. The phrenic nerve can also be found in this region, anterior to the arch of the aorta (Fig. 19.1). From there, its course is noted to predictably travel in the tracheoesophageal groove. The right recurrent laryngeal nerve, on the other hand, branches off the vagus nerve in the upper cervical region and loops around the right subclavian artery. It can also course anteriorly behind the thyroid before entering the tracheoesophageal groove.

Given the important function of the recurrent laryngeal nerve, there has been much debate as to whether a left- or right-sided approach is safer, minimizing risk to the nerve. In their classic work, Tew and Mayfield report the asymmetric course between the right and left recurrent laryngeal nerves.[1] According to their work, the left recurrent laryngeal nerve takes a longer, more predictable, protected course around the arch of the aorta. Because of this, they believed that a left-sided approach minimized the risk of injury to the recurrent laryngeal nerve. Other work has reported no statistical difference between nerve injury rates and side of approach.[2] Overall, for anterior surgery, the reported incidence of dysphonia ranges from 2% to 30%, and the incidence of dysphagia ranges from 28% to 57%.[3]

Another important neural structure in the anterior cervicothoracic spine is the phrenic nerve. The phrenic nerve innervates the diaphragm. It courses anterior to the pulmonary hilum before reaching the diaphragm.

Last, mention should be made of the thoracic duct, which is the largest lymphatic vessel in the body. It typically starts at the level of the twelfth thoracic vertebra and enters the thorax through the aortic opening of the diaphragm between the aorta and azygos vein. In the mediastinum, it is located on the left side behind the arch of the aorta and ascends between the left subclavian artery and the esophagus, and drains at the angle of junction of the left subclavian vein and left internal jugular vein.

Surgical Approaches to the Anterior Thoracic Spine

Low Anterior Cervical and High Transsternal Approach

The cervicothoracic junction is a biomechanical transition zone between the lordotic cervical spine and the kyphotic thoracic spine. This approach allows for exposure of the lower cervical spine and upper thoracic spine, from C7 to T4. A successful approach to this region requires navigation through numerous important neurovascular structures. Indications for this approach include infectious, traumatic, and neoplastic processes that require decompression and fusion or corpectomy.

The patient is positioned supine on a radiolucent table. A towel roll or bump is placed between the scapulae, allowing for gentle neck and shoulder extension. The arms are padded and tucked at the sides. The shoulders are gently taped downward and the neck is turned slightly away from the approach side, allowing for improved access and fluoroscopic visualization. The shoulders should not be overaggressively taped, as this can cause a traction injury to the brachial plexus. The table can be positioned in slight Trendelenberg to minimize venous engorgement and pooling.

As previously mentioned, there is controversy as to which side the approach should be performed. Classically, a left-sided approach is performed as the recurrent laryngeal nerve is thought to follow a more predictable course in the tracheoesophageal groove, minimizing risk of injury.

After standard sterile preparation and drape, a skin incision is made from the anterior border of the sternocleidomastoid to the sternal notch (Fig. 19.2A). For cases requiring full exposure, from C7 to T4, the vertical limb of the incision can

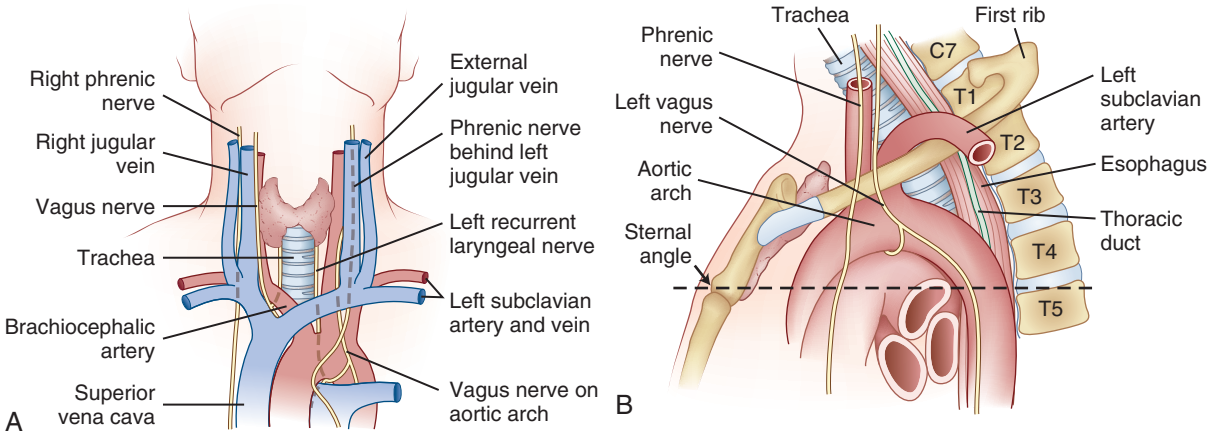

FIG. 19.1 (A) Anteroposterior view of cervicothoracic junction. (B) Lateral view of cervicothoracic junction.

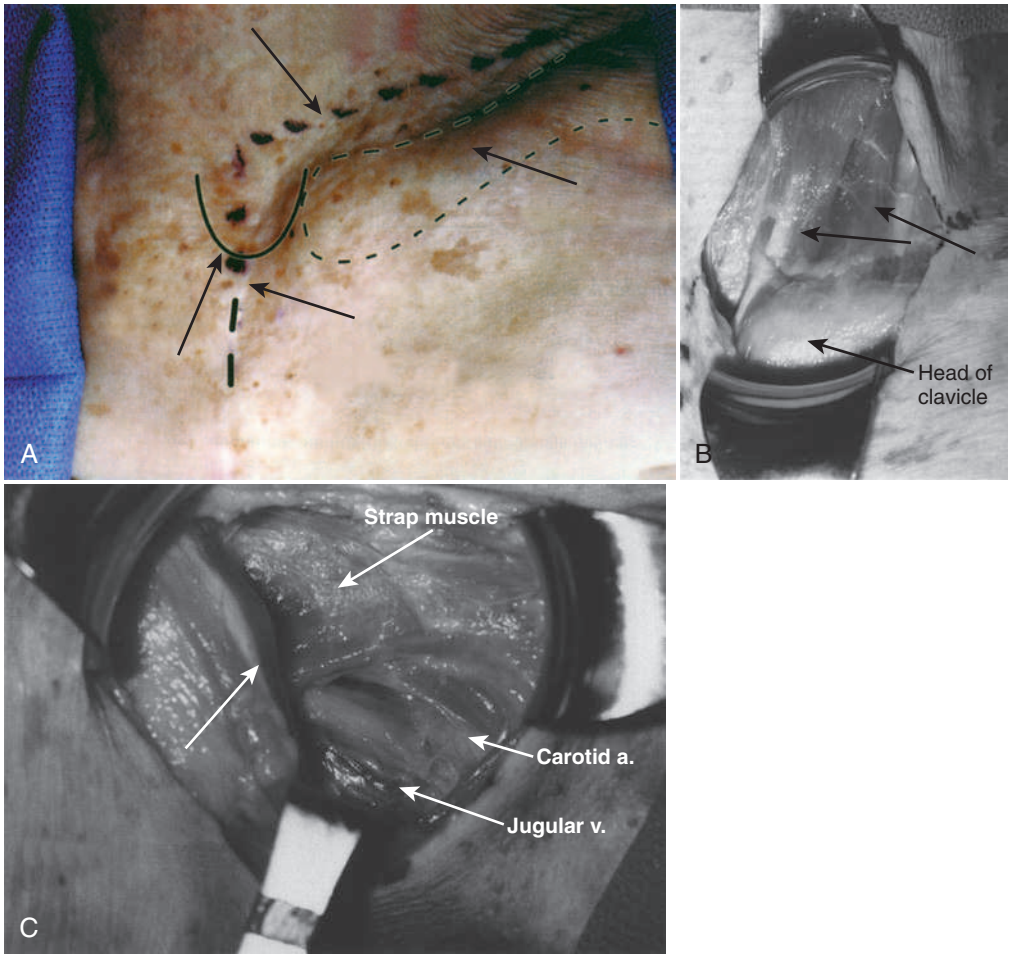

FIG. 19.2 (A) Inverted L-shaped incision for cervicothoracic junction. Midsternal extension of incision can be extended further vertically for more exposure distally. (B) Insertion of sternocleidomastoid muscle into clavicular head. (C) Sternocleidomastoid muscle retracted laterally revealing underlying strap muscle. Carotid sheath and jugular vein should be mobilized laterally as well.

be carried inferiorly over the middle of the manubrium to the level of the third costal cartilage. Subcutaneous dissection is performed down to the platysma. Once the platysma is well defined, it is carefully split in a longitudinal fashion. One should avoid injuring the underlying jugular veins, but they can be sacrificed if they hinder the approach.

Next, the sternocleidomastoid and strap muscles are identified at their insertion onto the clavicle (Figs. 19.2B–C). The clavicular and manubrial heads of the sternocleidomastoid are elevated proximal and lateral in a subperiosteal manner. The strap muscles are similarly elevated medially. Subperiosteal exposure should be undertaken until the ipsilateral half of the

manubrium and junction of the medial and middle third of the clavicle are exposed.

The clavicle is cut at the junction of the medial and middle third with an osteotome or oscillating saw. Care should be taken to ensure that the underlying neurovascular structures are protected during this process. Once free laterally, the clavicle is gently lifted up and disarticulated from the manubrium.

For greater distal exposure, a sternal splitting approach can be performed. This involves splitting the manubrium down the midline to the level of exposure required. Retrosternal adipose tissue and the thymus are retracted and protected. The sternum is then exposed subperiosteally. The manubrium is subsequently split with an oscillating or Gigli saw. The inferior thyroid vessels can be ligated if necessary and the left innominate vein is retracted caudally or ligated (if necessary). Care should be taken not to injure the thoracic duct, which is located left of the esophagus starting at T4 as it ascends to its junction with the left internal jugular vein and subclavian vein.

The remainder of the dissection is similar to the Smith-Robinson approach. The interval between the trachea and esophagus medially and the carotid sheath laterally is identified and developed. When placing retractors it should be ensured that they are safely placed to avoid injury to the recurrent laryngeal nerve, which lies in the tracheoesophageal groove. The right brachiocephalic artery can be taken to the right along with the trachea and esophagus. The left brachiocephalic and subclavian veins are retracted inferiorly and to the left. The longus colli muscles on either side of the spine are identified and the prevertebral fascia is spread with a Kittner, exposing the anterior thoracic spine.

Transpleural Transthoracic Third Rib Resection

An alternative approach to the low anterior cervical high transsternal approach is the transpleural transthoracic third rib resection. This approach allows excellent exposure of the anterolateral thoracic spine from T1 to T4. The indications for this approach are similar. The drawbacks to this approach include the need for mobilization of the scapula and violating of the chest wall musculature and pleural space.

For this approach, a double-lumen endotracheal tube should be placed by anesthesia to allow for isolated lung deflation on the approach side. The patient is positioned in the lateral decubitus position with the approach side up. The knees and elbows are gently flexed and the arms are abducted. An axillary roll is placed and all bony prominences are padded. The patient can be secured to the table via bolsters or a beanbag. The approach-side arm can be supported by stacked pillows/towels or an arm holder. The area of prep and drape is demarcated from the shoulder to above the iliac crest (cephalad-caudad) and from the midline of the spine posteriorly to the umbilicus anteriorly (posterior-anterior).

The incision is carried from the paraspinous area at approximately T1 distally along the medial border of the scapula to the seventh rib (Fig. 19.3). It is then carried laterally and anteriorly toward the costal cartilage of the third rib. The trapezius and latissimus dorsi are divided, and the scapula is retracted cephalad and medially (Fig. 19.4). The third rib is identified. It should be kept in mind that the second rib is typically the easiest rib to palpate, as it is elevated relative to the surrounding ribs. The first rib sits medial to the second rib.[4]

FIG. 19.3 Patient is positioned in lateral position on a Jackson spinal table with incision marked for a high transthoracic approach. (From Le HN, Kim DH. Anterolateral transthoracic approaches to the cervicothoracic junction [transaxillary approach, transpleural transthoracic third rib resection approach]. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine.* Philadelphia: Elsevier; 2006.)

The approach-side lung is now selectively deflated. The third rib is skeletonized in a subperiosteal manner (Fig. 19.5). Anteriorly, this can be performed with Bovie electrocautery and curettes. A Doyen is a great tool for performing posterior subperiosteal dissection around the rib while protecting the underlying neurovascular bundle (Fig. 19.6). The third rib is cut as far anteriorly and posteriorly as possible and can be used for bone graft (Fig. 19.7). The third rib bed—consisting of the periosteum, endothoracic fascia, and parietal pleura—is transected, allowing entrance into the thoracic cavity (Fig. 19.8). A chest spreader can be placed along with a second retractor at a right angle to allow for maximum visualization. The lung is retracted and protected with a malleable retractor and moist lap sponge (Fig. 19.9).

The aorta, spine, parietal pleura, veins, and sympathetic plexus are identified. Next, the parietal pleura is gently incised in a longitudinal fashion over the indicated disc space. This area is relatively avascular as compared to directly over the vertebral body. The vertebral body is then exposed and the intercostal arteries and veins are ligated and cut. Exposure can be extended as necessary (Fig. 19.10).

Closure for this approach is as follows. The parietal pleura is repaired, if feasible. Lung reexpansion is then performed. The ribs are reapproximated with heavy nonabsorbable suture or wire in figure-of-eight fashion utilizing a rib reapproximator. Care should be taken not to injure the neurovascular bundle of the caudad rib being reapproximated when using the rib reapproximator. The lung should also be protected during this process. Last, a chest tube is placed through a separate incision at the level of the ninth intercostal space and set to water seal.

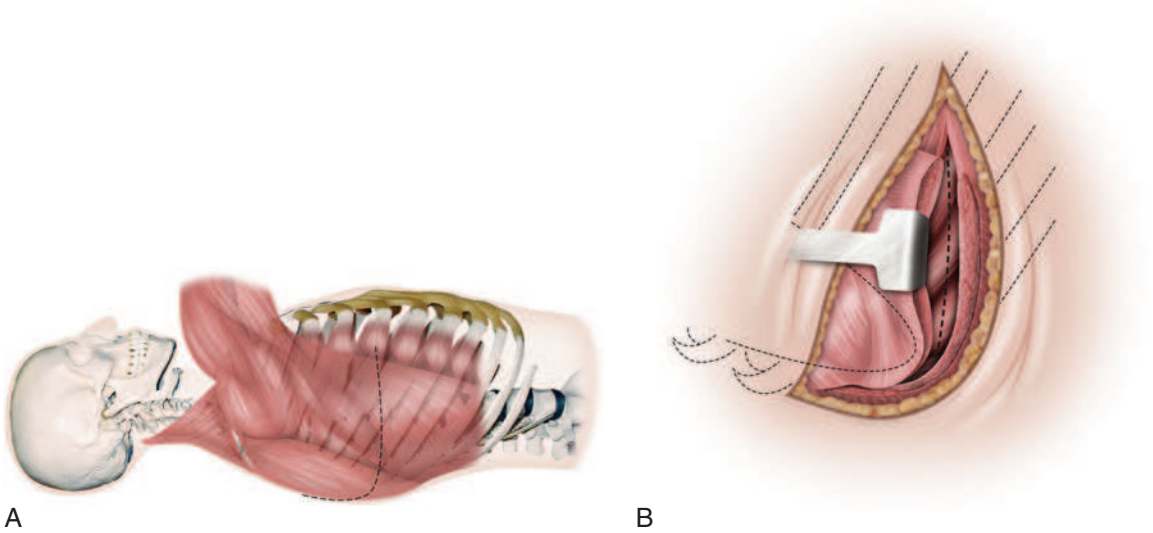

FIG. 19.4 Muscular exposure. (A) Note the relationship of the periscapular muscular anatomy. (B) Retracting or detaching the latissimus muscle will reveal the underlying upper thoracic ribs and the attachments of the serratus anterior muscles. (From Le HN, Kim DH. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

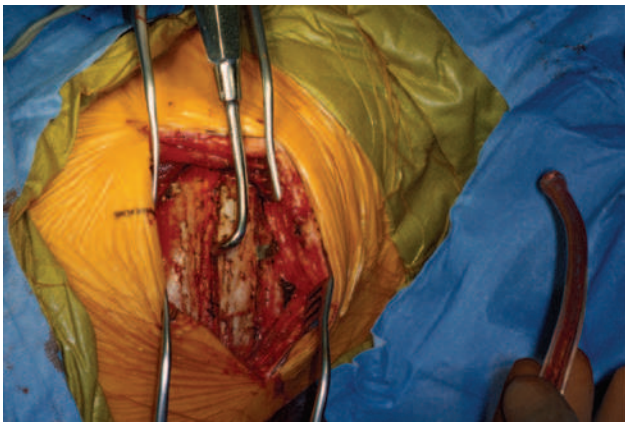

FIG. 19.6 A posterior subperiosteal dissection of the third rib is performed using a doyen. (From Le HN, Kim DH. Anterolateral transthoracic approaches to the cervicothoracic junction [transaxillary approach, transpleural transthoracic third rib resection approach]. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

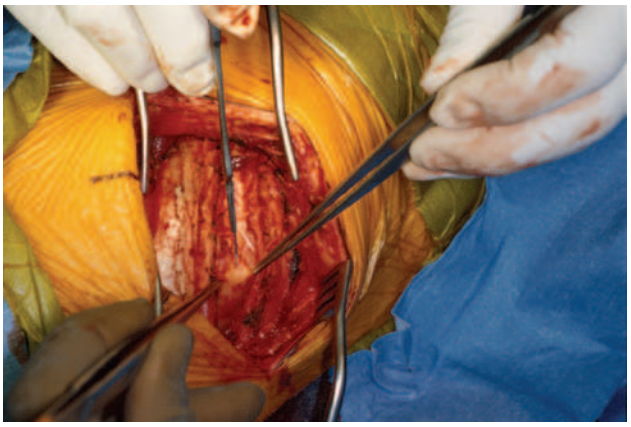

FIG. 19.8 Third rib bed consisting of periosteum, endothoracic fascia, and parietal pleura is identified and transected to enter the thoracic cavity. (From Le HN, Kim DH. Anterolateral transthoracic approaches to the cervicothoracic junction [transaxillary approach, transpleural transthoracic third rib resection approach]. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

FIG. 19.9 Operative exposure. A chest spreader can then be inserted and opened after rib resection. (From Le HN, Kim DH. Anterolateral transthoracic approaches to the cervicothoracic junction [transaxillary approach, transpleural transthoracic third rib resection approach]. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

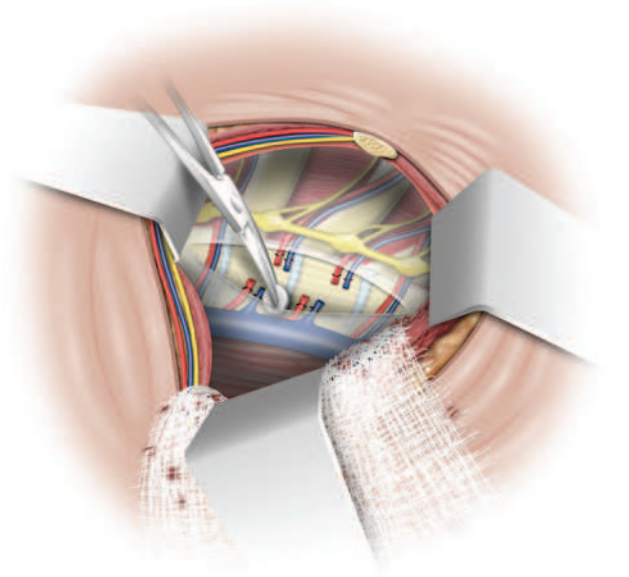

FIG. 19.10 Appropriate intercostal arteries and veins are dissected, ligated, and cut. (From Le HN, Kim DH. Anterolateral transthoracic approaches to the cervicothoracic junction [transaxillary approach, transpleural transthoracic third rib resection approach]. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

Thoracotomy (Anterior) Approach to the Thoracic Spine

The transthoracic approach offers extensile exposure of the anterior vertebral bodies from T6 to T12.[4] The benefits of this approach include excellent access to the anterior column and less risk of direct injury to the neural elements. Indications for this approach include treatment of vertebral osteomyelitis, resection of the vertebral body for tumors and trauma, deformity correction, and decompression of the anterior thoracic spine. Despite this, the transthoracic approach is rarely used secondary to the advent of posterior-based approaches that allow the surgeon to use the same procedures with less morbidity and risk.

The patient is intubated by anesthesia using a double-lumen endotracheal tube with lung isolation.[5] This will allow for selective lung deflation based on the approach side. The patient is then placed in the lateral decubitus position with the head in neutral position and an axillary roll or pad placed underneath the downside axilla to protect the brachial plexus. The arms are slightly abducted and the elbows slightly flexed. The downside leg is slightly flexed at the hip and the knee; the upside leg is slightly extended and adducted to allow for soft tissue tension, which aids in opening the intercostal space. All bony prominences must be well padded. The patient is secured in the lateral decubitus position via a beanbag or padded bolsters (Fig. 19.11A).

Although the approach can be made from the left or right side, the right side is preferred if the approach is to be made above T10, as it avoids manipulation of the aorta. If the approach is for access from T10 and caudad, a left-sided approach is preferred since the liver elevates the diaphragm on the right side in this region.

Localization of the operative level is then performed with the aid of fluoroscopy and palpation. The rib to be resected should correspond to two levels above the operative vertebral body level given the oblique nature of the rib. Once this is confirmed, the rib is marked from the posterior angle of the rib to the anterior margin.

The skin and subcutaneous tissues are incised with a No. 10 blade scalpel (Fig. 19.11B). Further dissection is carried out with Bovie electrocautery. The latissimus dorsi is identified and incised in line with the skin in an incision over the course of the rib. After completing dissection through the latissimus dorsi, the posterior margin of the serratus anterior is encountered and incised in a similar fashion. At this point, the rib should be visible. Subperiosteal dissection is then performed, skeletonizing the superficial surface of the rib without violating the inferior margin since this is where the neurovascular bundle runs. The intercostal muscles are then bluntly released from the superior and inferior margins of the rib using an Alexander Farabeuf periosteotome. Tissue attachments to the undersurface of the rib are then carefully released in a subperiosteal fashion without violating the parietal pleura using a Doyen dissector. The rib is then cut with a rib cutter at the costotransverse junction posteriorly and the costal margin anteriorly. Sharp bony edges at the margins of resection are smoothed with a bone rasp. Bony bleeding is controlled with bone wax. The resected rib can be saved and used for bone graft.

Following rib resection, the appropriate lung corresponding to the operative side is selectively deflated. The pleural cavity is then entered with Metzenbaum scissors. Rib spreaders can be placed at right angles to aid in visualization. A malleable retractor padded with moist lap sponges can be used to further retract and protect the deflated lung. One of the major complications associated with this approach is microatelectasis. In order to help prevent this, the lung can be periodically reinflated by the anesthesiologist.

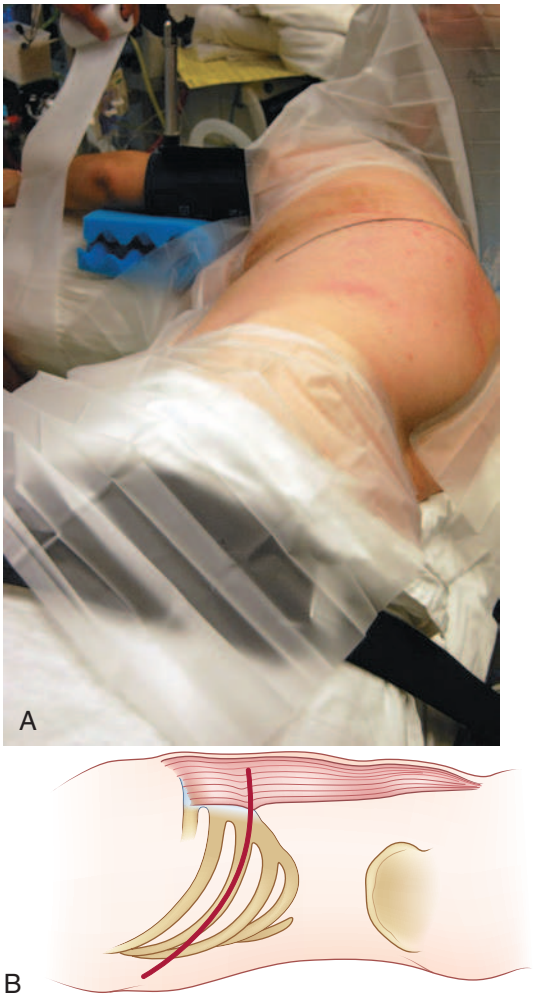

FIG. 19.11 (A) The patient is placed in the lateral decubitus position. The arms are abducted and elbows are slightly flexed in a position of comfort, using blankets or pillows to hold the position. (B) The thoracotomy incision is centered over the rib to be resected. The incision is drawn from the posterior angle of the corresponding rib and following its curvature anteriorly. Typically, the numbered rib that is resected is considered to be two levels above the expected working level.

The parietal pleura is incised longitudinally over the pertinent disc space with atraumatic pickups and Metzenbaum scissors. The parietal pleura is retracted laterally. Underlying segmental vessels that interfere with access are carefully dissected and ligated with several vascular clips or 2-0 silk ties. Ligation should be performed away from the aorta in order to minimize the risk of loosening of the clips or ties. Further cephalad or caudad exposure is gained by further longitudinal release of the parietal pleura and ligation of segmental vessels. It is important not to tie off more segmental vessels than necessary, as blood supply to the spinal cord from these vessels is variable and may result in inadvertent cord ischemia. In an animal model, it has been shown that ligation of bilateral segmental arteries at 4 or greater consecutive levels can produce ischemic cord dysfunction.[6]

Upon completion of the procedure, the parietal pleura is repaired and the lung is reinflated. A chest tube is then placed through the ninth intercostal space. The ribs are then reapproximated using a rib approximator and the interval is secured in place with heavy nonabsorbable suture. Routine subcutaneous and skin closure is then performed and a sterile dressing is placed.

Endoscopic Anterior Approach to the Thoracic Spine

The benefits of an endoscopic approach to the anterior thoracic spine include reduced postoperative pain levels, hastened recovery, and minimization of common complications associated with open thoracotomy approaches.[7,8] The indications for this approach are the same as those of an open thoracotomy approach: traumatic, degenerative, infectious, and neoplastic etiologies requiring access to the anterior vertebral body and disc space. Contraindications to the endoscopic approach include patients with cardiopulmonary insufficiency, acute posttraumatic respiratory failure, or coagulopathy. A relative contraindication is a patient with previous surgical interventions or infectious diseases of the lung, as the patient may have excessive adhesions.[9]

For this approach, equipment includes a 30-degree endoscope connected to a xenon light source and high-definition camera. Additionally, specially made instrumentation for soft tissue handling, disc space preparation, and bone resection are required. Consideration should be given to performing this procedure in conjunction with a thoracic surgeon. At a bare minimum, a thoracic surgeon should be on standby to assist should a complication arise or the need to convert to an open procedure occurs.

The patient is intubated with a double-lumen endotracheal tube to allow for selective lung deflation. The patient is positioned in the lateral decubitus position. All bony prominences are padded. An axillary roll is placed under the downside axilla. The patient is secured with a beanbag or bolsters. The patient should be secured well to the table since table rotation of up to 15 degrees can be helpful for visualization intraoperatively. The table should be flexed to open the intercostal spaces.

The level of interest is marked on the lateral thoracic wall utilizing a lateral fluoroscopic image (in reference to the patient's body). There are several described working portal configurations.[10] Traditionally, two to three working portals and two additional portals are used. The working portal is marked directly above the lesion in line with the posterior axillary line. The portal for the endoscope is marked cranial to the working portal approximately 2 intercostal spaces in line with the midaxillary line. The portal sites for suction and retraction are placed anterior to these portals[9] (Fig. 19.12).

The ipsilateral lung is deflated and a 1-inch oblique incision is made over the site of the superior endoscope portal. This portal hole is always created first, as it minimizes risk to the liver, diaphragm, and spleen. The approach is made using a minithoracotomy technique and the chest cavity is entered with a blunt clamp or thoracoscopic introducer. Entry should be made on the superior portion of the rib in order to avoid the neurovascular bundle on the undersurface of the rib.

A 10-mm, 30-degree rigid scope is inserted through a 10-mm trocar at this portal site. The remaining portals are

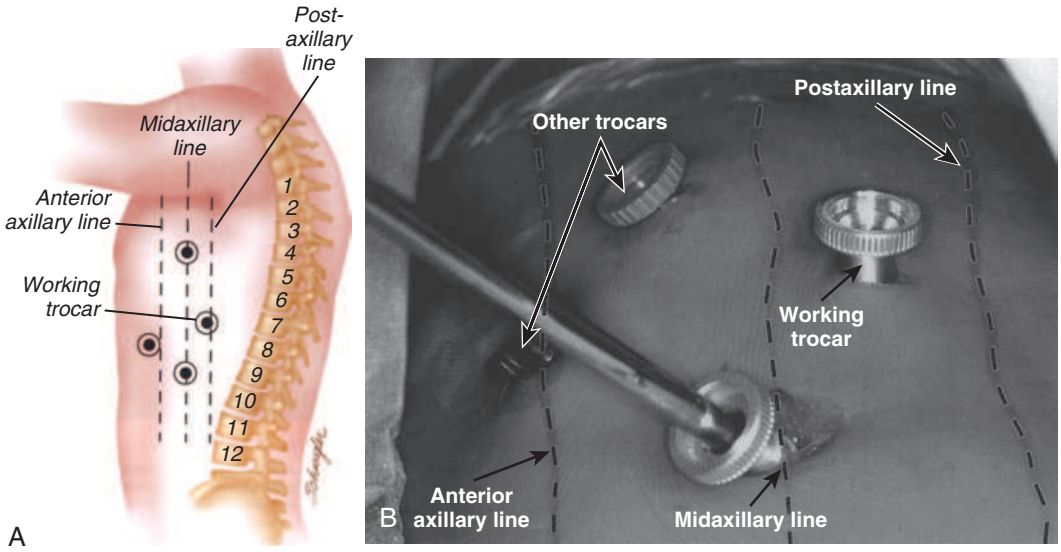

FIG. 19.12 (A) Diagram of trocar positions for T7–T8 pathology. (B) Actual trocar positions.

placed under direct thoracoscopic visualization. At this point, the patient can be rotated up to 15 degrees anteriorly and placed in the Trendelenberg position for work in the lower thoracic spine or reverse Trendelenberg for work in the upper thoracic spine. This allows the lung to fall away from the surgical field.

Diagnostic thoracoscopy is performed and the target level is identified. The ribs can be counted internally by a blunt palpation with a grasping instrument to confirm the appropriate surgical level. Once the appropriate level is identified, a 20-gauge needle or Kirschner wire (K-wire) is placed percutaneously into the disc space and confirmed with a fluoroscopic image.

With the appropriate surgical level confirmed, the parietal pleura over this level is cut over the rib head with cautery. The free edge of the pleura is then grasped and released cephalad and caudad with a hook dissector to expose the operative level(s). If access to the vertebral body is necessary, the segmental vessels need to be clipped and ligated.

If vertebral body work is necessary, the rib head is exposed and the costovertebral ligaments are released. The rib is then cut 2 to 3 cm from its attachment to the spine using a burr or Kerrison rongeur and the rib head is removed. Removal of the rib head allows for clear visualization of the disc, pedicle, and posterior vertebral margin. Resection of the superior vertebral body and pedicle allows for exposure of the exiting nerve root and spinal canal.

At the end of the procedure, hemostasis should be achieved. Tears involving the visceral pleura should be repaired. A chest tube is placed through the inferiormost portal, secured with 2-0 silk ties to the skin, and placed on a water seal. The lung is reinflated under direct visualization and a radiograph is obtained to ensure full lung reexpansion. The fascia and skin of each portal is closed in a layered fashion.

Postoperatively, serial chest radiographs are obtained until it is felt that they can be safely discontinued. The chest tube can be discontinued once output is less than 150 mL over a 24-hour period and no air leak is present.

Anterior Anatomy of the Thoracolumbar Junction

The thoracolumbar junction spans from T10 to L2. It is the transition zone between the rigid kyphotic thoracic spine and the mobile lumbar spine. Because of this transition, the thoracolumbar spine is predisposed to a high proportion of trauma.[11]

Across the thoracolumbar junction, the aorta lies to the left of the midline; the azygos vein, splanchnic nerves, and thoracic duct lie to the right of midline. In the thoracolumbar spine, the segmental arteries run horizontally from the aorta toward their respective vertebral body.

The diaphragm is the dome-shaped structure of muscle and fibrous tissues that separates the thoracic cavity from the abdomen. The diaphragm is made up of two main parts: the clover-shaped central tendon and a peripheral muscular portion that attaches to the chest wall. The sternal portion of the diaphragm is made up of two small muscular segments that attach to the posterior aspect of the xiphoid process. The costal portion of the diaphragm is made up of several wide muscle segments whose origins are found on the internal surface of the inferior six ribs and costal cartilages. The lumbar portion of the diaphragm attaches to the spine at L1 through the left and right crura, which blend with the anterior longitudinal ligament. Additional spine attachments come from the medial and lateral arcuate ligaments. The medial arcuate ligaments arise from the crura and bridge the psoas muscle, inserting onto the transverse processes of L1. The lateral arcuate ligament arises from the L1 transverse process, bridges the quadratus lumborum, and attaches to the twelfth rib.

Anterior Approach to the Thoracolumbar Spine

The indications for anterior approach to the thoracolumbar spine include traumatic, infectious, and malignant etiologies between T10 and L2. Additionally, this approach can be employed for deformity correction as well as to treat pseudoarthrosis.

Similar to thoracotomy approaches, a double-lumen endotracheal tube should be used to allow for selective lung

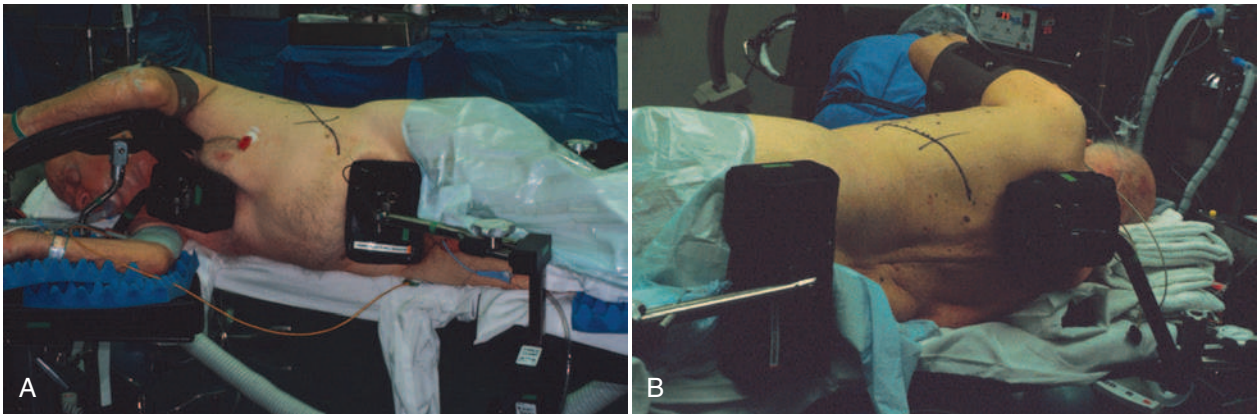

FIG. 19.13 Left-sided lateral approach positioning. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

deflation. A nasogastric tube should also be in place. The patient is positioned in the lateral decubitus position with the approach side up. A left-side approach offers the advantage of avoiding the need to mobilize the thin-walled vena cava as well as risking a view obscured by the liver. If the vena cava is injured, it can bleed profusely and can be very difficult to repair. Sometimes, however, a right-sided approach is necessary as dictated by the surgical pathology, such as in the case of treating the apex of a scoliotic curve.[12]

After placing the patient in the lateral decubitus position with the operative approach side up, the patient can be secured with a beanbag or bolsters. All bony prominences about the lower extremities should be padded. An axillary roll is placed. The down leg is straightened; the top leg is flexed and slightly externally rotated to help relax the psoas muscle. Pillows can be placed between the legs to aid in positioning. The arms are abducted and slightly flexed at the elbow. The upside arm can be supported by an arm holder, pillows, or blankets. The patient is further secured to the table by placing tape over the hip and shoulder or upper chest. Care should be taken to avoid placing the tape directly over the breast and nipple. Fluoroscopy is then used to mark the operative levels and incision. Typically, the ninth, tenth, eleventh, or twelfth rib is selected, depending on the exposure required. The skin incision is marked from the posterior angle of the corresponding rib anteriorly along its course and ending distally at a level just lateral to the pubic symphysis. The length of the incision can be altered depending on the exposure necessary (Fig. 19.13).

Standard sterile prep and drape is performed. A No. 10 blade scalpel is used to make the skin incision over the aforementioned distribution. Subcutaneous dissection is performed with Bovie electrocautery. The latissimus dorsi and external oblique are split with cautery in a layered fashion. The rib is superficially exposed posteriorly from the costotransverse junction anteriorly to the costal margin. Next, the rib is dissected in a subperiosteal manner. When working on the undersurface of the rib, a Doyen can be helpful. Care should be taken to avoid injuring the underlying neurovascular bundle and parietal pleura.

FIG. 19.14 A rib cutter is used to cut the tenth rib to expose the pleura underneath. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

The rib is cut anteriorly at the costal margin and posteriorly at the costotransverse junction. The resected rib can be saved and used for bone graft (Fig. 19.14). Bleeding from the cut edges is controlled with bone wax.

After rib resection, the lung is selectively deflated on the approach side. The pleura is identified and protected by splitting the undersurface of the costal cartilage anteriorly (Fig. 19.15). The retroperitoneal space is entered through the split costal cartilage (Fig. 19.16). If the twelfth rib is being resected, the diaphragm attaches superiorly and the transverse abdominis attaches inferiorly. The diaphragm can be retracted superiorly and the transverse abdominis inferiorly, allowing entrance into the retroperitoneum. The peritoneum is bluntly swept off the diaphragm and abdominal muscles (Fig. 19.17). If necessary for exposure, the external oblique, internal oblique, and transverse abdominis muscles are incised.

With the rib resected and the peritoneum safely swept away, a rib retractor is placed. A malleable retractor covered with a moist lap sponge is then placed to further protect the

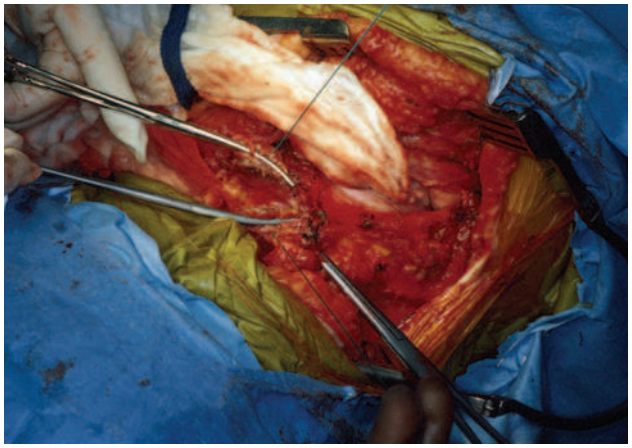

FIG. 19.15 The costal cartilage is split and serves as a landmark for closure. Careful dissection underneath the split cartilage will expose the peritoneal fat, which will lead to the retroperitoneal space. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

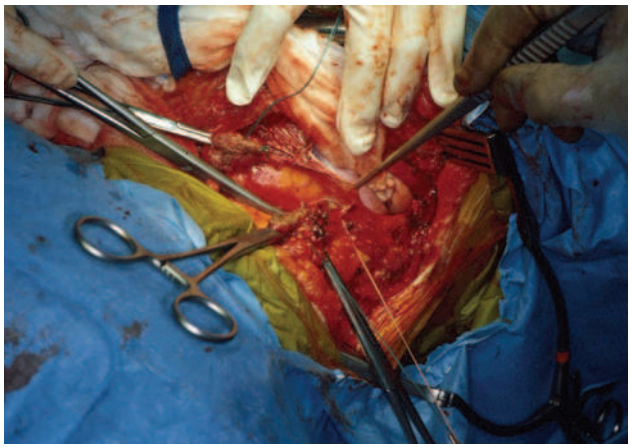

FIG. 19.16 The split costal cartilage is tagged temporarily. The retroperitoneal fat is identified. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

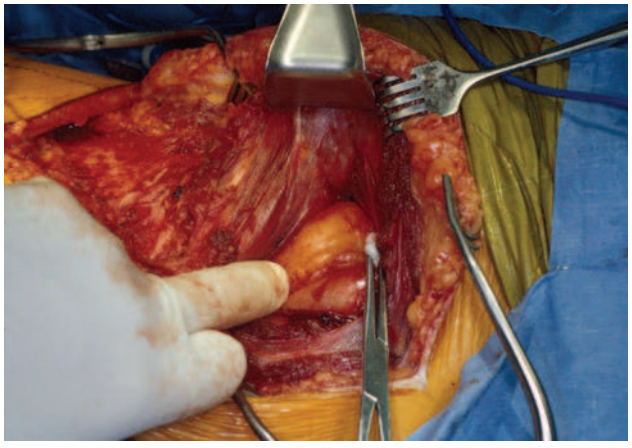

FIG. 19.17 The retroperitoneal space is entered by pushing the peritoneal fat along with the peritoneal content toward the midline. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

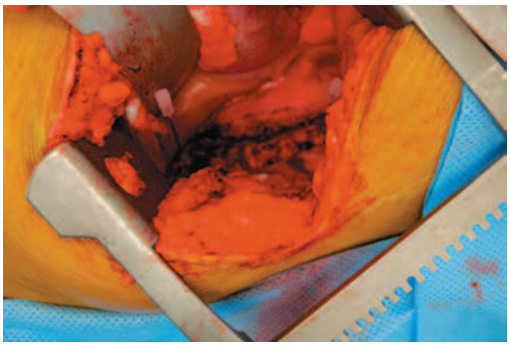

FIG. 19.18 A rib spreader can be used to provide retraction for entry into chest cavity. The lung is further protected with a malleable retractor shielded with a sponge.

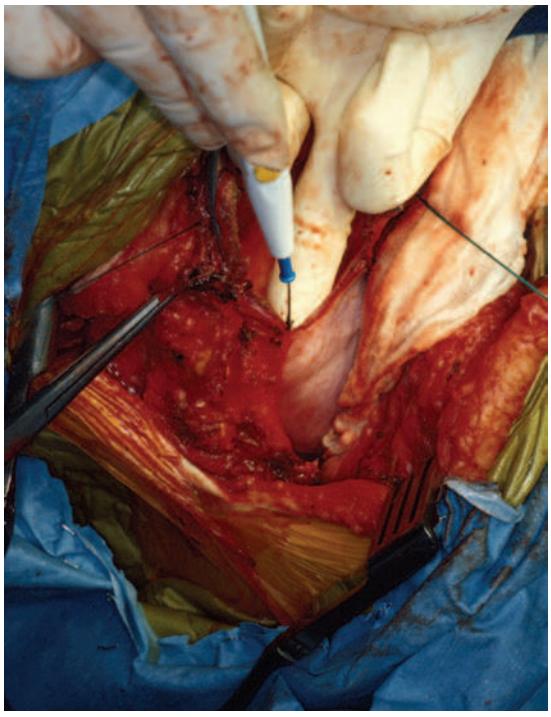

FIG. 19.19 The diaphragm is carefully cut peripherally. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

lung. A second retractor placed perpendicular to the first retractor can be placed for improved visualization, if necessary (Fig. 19.18).

The thoracoabdominal cavity is entered and the peritoneum is carefully swept off the psoas and undersurface of the diaphragm. The diaphragm, which should be clearly delineated at this point, is incised circumferentially to release it (Fig. 19.19). A cuff of muscle 1 cm in size should be left and tagged for reapproximation at the end of the case (Fig. 19.20). The crus can be taken down from its attachment at L1 if access to T12 and L1 vertebral bodies is necessary.

For access to the thoracic spine, the parietal pleura is incised, exposing the vertebral body. The intercostal vessels are tied and ligated in order to mobilize the major blood vessels to allow access to the vertebral body of interest. They

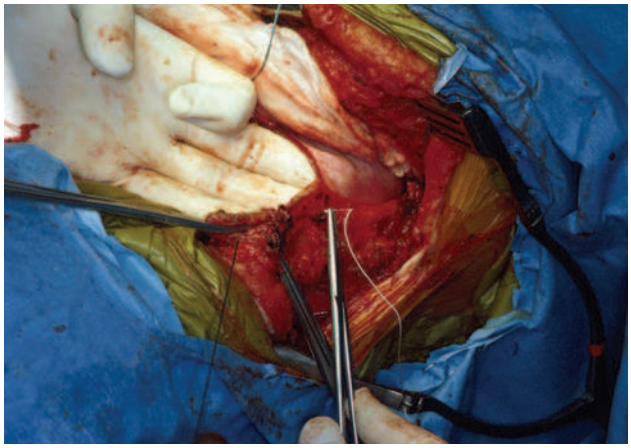

FIG. 19.20 Temporary tagged sutures are used while cutting the diaphragm, which will serve as a landmark for closure. (From Thongtrangan I, Le HN, Park J, Kim DH. Thoracolumbar and lumbar spines. In: Kim DH, ed. *Surgical Anatomy and Techniques to the Spine*. Philadelphia: Elsevier; 2006.)

should be tied and ligated greater than 1 cm from their respective foramen. Care should be taken not to injure the sympathetic plexus, which is in close proximity to the intercostal vessels. If mobilization of the psoas muscle is required in the lumbar spine for exposure, it should be done subperiosteally to avoid injuring the lumbar plexus.

A layered closure for this approach should be performed. The previously tagged diaphragm attachments are repaired with nonabsorbable heavy suture. The parietal pleura is repaired, if possible. The abdominal muscles are repaired in a layered fashion. Lung reexpansion is performed. A chest tube can be placed, if necessary. Care should be taken to ensure that the junction of the diaphragm and abdominal musculature is securely reapproximated to prevent hernia formation.

Posterior Anatomy of the Thoracic Spine

The posterior thoracic spine is covered by a superficial, intermediate, and deep muscle layer (Fig. 19.21). The superficial layer consists of the trapezius and latissimus dorsi muscles. Deep to these muscles, but still considered part of the superficial layer, are the rhomboid major and minor muscles. All of the superficial muscles are innervated by peripheral nerves. The intermediate layer is comprised of the serratus posterior inferior and superior muscles. These muscles are innervated by the anterior rami of the thoracic nerves. Deepest of all, the erector spinae muscles are found (semispinalis, multifidus, and rotatores muscles; see Fig. 19.21). The erector spinae muscles are innervated by the posterior rami of the thoracic nerves. The fascia invests the erector spinae muscles dorsally and ventrally. The dorsal layer constitutes the thoracodorsal fascia. Laterally, the thoracodorsal fascia blends with the aponeurosis of the transverse abdominis muscle; caudally it attaches to the iliac crest and lateral crest of the sacrum.[10] Posterior thoracic spine approaches typically exploit planes that avoid direct injury to the nerves that innervate the posterior musculature.

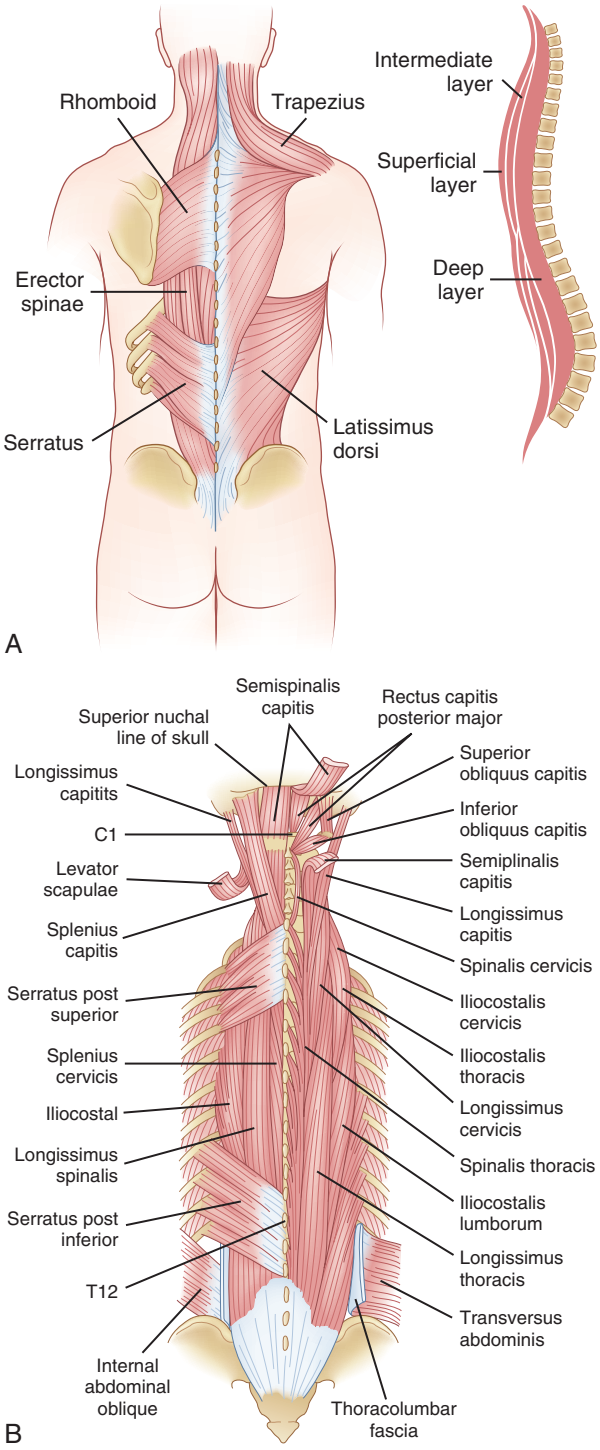

FIG. 19.21 (A) Muscles of the thoracic spine. (B) Intermediate and deep muscles of the thoracic spine. (B, From An HS. *Principles and Techniques of Thoracic Surgery*. Baltimore: Williams & Wilkins; 1998.)

The ligamentous structures of the thoracic spine from dorsal (superficial) to ventral (deep) are the supraspinous ligament, interspinous ligament, ligamentum flavum, posterior longitudinal ligament, and anterior longitudinal ligament (Fig. 19.22). The supraspinous ligament attaches the tips of the spinous processes. The interspinous ligament attaches the spinous process to the adjacent spinous processes with obliquely oriented fibers. The ligamentum flavum runs from

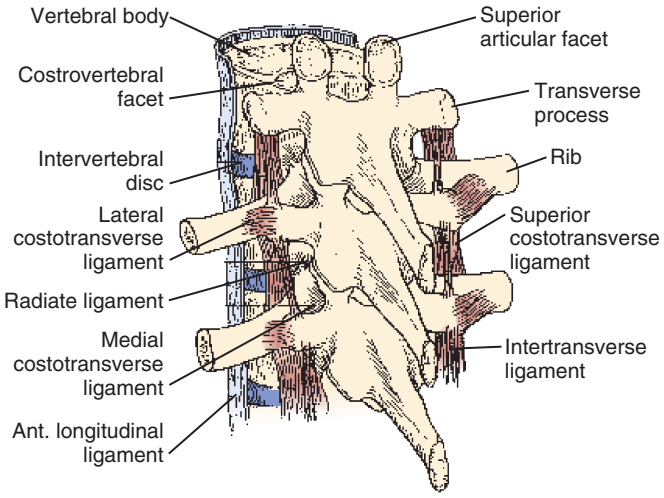

FIG. 19.22 Ligaments of the thoracic spine. (From An HS. *Principles and Techniques of Thoracic Surgery*. Baltimore: Williams & Wilkins; 1998.)

the undersurface of the trailing margin of the cephalad vertebra and inserts on the top portion of the caudad lamina. Of all the ligamentous structures supporting the thoracic spine, the ligamentum flavum is the strongest and most robust. It provides extension support to the adjacent vertebrae. The posterior longitudinal ligament runs along the dorsal aspect of the vertebrae and intervertebral discs and the anterior longitudinal ligament runs ventrally.

The thoracic vertebrae are made up of the vertebral body, pedicles, superior and inferior articular facet, transverse costal facet, pars interarticularis, lamina, and spinous process. There are 12 thoracic vertebral bodies. Vertebral body size sequentially decreases from T1 to T3, then sequentially increases to T12.[13] The spinous processes in the thoracic spine project posteroinferiorly with the tip of the spinous process overlying the preceding vertebral body.

The thoracic ribs articulate with the thoracic vertebral bodies via the transverse costal facet starting at T1. The first rib articulates only with T1. Ribs 1 through 7 have direct attachments to the sternum, thus are referred to as true ribs. Ribs 8 through 10 connect via costal cartilage to the rib above and are called false ribs. Ribs 11 and 12 are floating ribs, and have no attachment point other than to their corresponding vertebral body.[13] The rib heads of ribs 1 through 10 overlie the adjoining intervertebral disc space via two types of articulations: the costovertebral articulation and the costotransverse articulation. The costovertebral articulation is between the rib head and the vertebral body. This articulation is stabilized by the articular capsule, radiate ligament, and intraarticular ligaments. The costotransverse articulation is between the neck and tubercle of the rib and the transverse process.

The facet joints of the thoracic spine have a unique orientation. They are oriented in a more coronal plane and undergo transition from T1 to T12. At T1, the superior facet faces up and back, whereas the inferior facet faces down and forward. Progressing caudad, the superior facet transitions to facing up, back, and slightly lateral. The inferior facet faces down, forward, and more medial. This orientation allows for some rotation. The superior facet contains articular cartilage on its dorsal surface; the inferior facet has articular cartilage on its ventral surface. The pars interarticularis is the portion of bone that connects the superior and inferior articular processes.

Since the advent of pedicle screw fixation and its current widespread use for posterior instrumentation, understanding the anatomy of the thoracic pedicle has become paramount. The pedicle of each vertebral body is located at the base of each facet (Fig. 19.23). There have been numerous studies looking at the morphology of the thoracic pedicles.[14–19] Projecting from their respective vertebrae, thoracic pedicles angle posteriorly and laterally. Moving from cephalad (T1) to caudad (T12), the pedicle aims successively less medially (see Fig. 19.23). The superoinferior pedicle diameter is larger than the mediolateral diameter.[3] The smallest pedicle diameter (medial to lateral) is typically found at T4. In terms of strength, the medial pedicle wall is two to three times stronger than the lateral wall.[14]

The transverse process is found at the junction of the pars interarticularis and facet. The associated nerve root is anterior and superior to the transverse process. The associated dorsal rami are found anteroinferiorly.[1] Protecting the underlying nerve root is an intertransverse aponeurosis.

Posterior Approaches to the Thoracic Spine

The posterior-based approaches to the thoracic spine are the workhorse approaches for a majority of pathologies, including degenerative, traumatic, infectious, and neoplastic conditions. Slight variations in approach allow the surgeon access to midline, lateral, dorsal, and ventral aspects of the spinal column while avoiding associated morbidity with thoracotomy approaches.

Posterior Approach for Decompressive Laminectomy and Fusion

After successful induction of anesthesia, the patient is placed in the prone position. Either a Jackson frame or regular operating room bed with chest rolls is ideal. This allows the abdomen to rest free of pressure, decreasing venous engorgement of the epidural venous plexus, which helps minimize blood loss. Localization is then performed with the aid of fluoroscopy and palpable landmarks. The superior border of the scapula corresponds to T3, the inferior angle of the scapula corresponds to T7, and the most prominent spinous process corresponds to C7. Fluoroscopic visualization of the upper thoracic region can prove difficult secondary to overlap from the shoulders. A combination of anteroposterior (AP) and lateral fluoroscopy should be used to ensure that the appropriate surgical level(s) is marked. The skin is then marked in the midline, directly over the spinous process from the cephalad to caudad surgical level.

A No. 10 blade scalpel is used to incise the skin in this distribution. Subcutaneous dissection is performed with Bovie electrocautery. Subperiosteal dissection is then undertaken by separating the muscular attachments from the spinous process and lamina. Subperiosteal dissection helps minimize blood

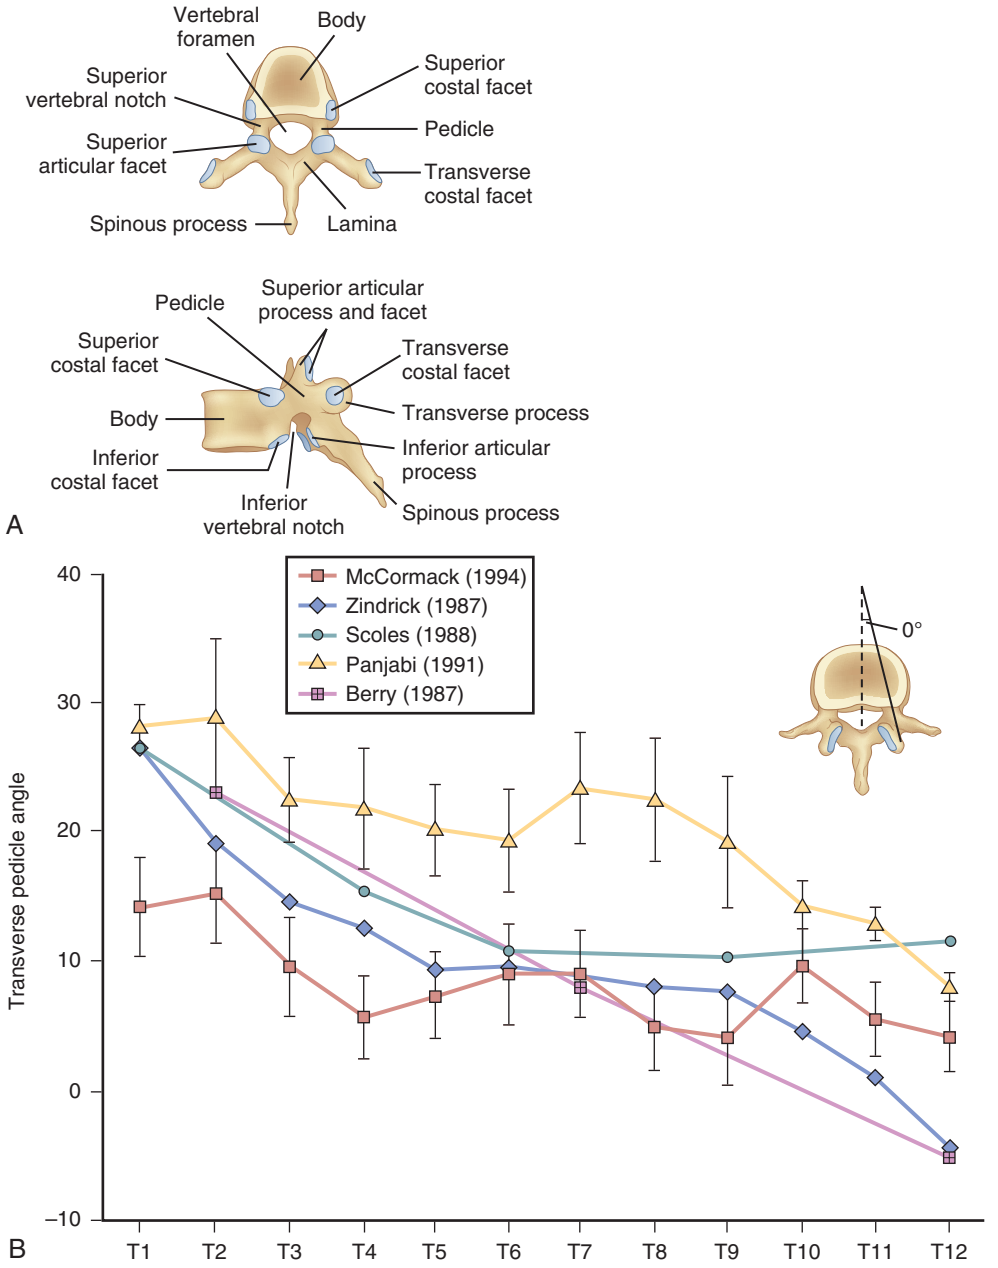

FIG. 19.23 (A) Osseous structure of the thoracic spine and thoracic vertebra. (B) Transverse pedicle angles found in five different studies. (A, From Netter FH. *Atlas of Human Anatomy*. 2nd ed. Philadelphia: Elsevier; 1998. B, From McCormack BM, Benzel EC, Adams MS, et al. Anatomy of the thoracic pedicle. *Neurosurgery.* 1995;37: 303-308.)

loss. Superficially, in the upper thoracic spine, the rhomboid and trapezius muscle attachments are encountered. In the lower thoracic spine, the latissimus dorsi attachments are encountered. Deep to these superficial attachments are the erector spinae and transversospinal muscle attachments. The muscles are retracted laterally and self-retaining retractors are placed.

When performing laminectomy alone, the lateral margins of the lamina and pars interarticularis are exposed while being sure to avoid violating the facet joint capsule. Violating the facet joint capsule when performing wide laminectomy can lead to iatrogenic instability.[20] Care should be taken when exposing the lateral margins of the pars interarticularis and facet joints, as unnecessary bleeding can result.

The next step is performing the laminectomy. There are several ways to accomplish laminectomy in the thoracic spine. A gentle, relatively atraumatic technique that minimizes pressure on the thoracic cord is to use a high-speed burr to create a trough on both sides of the lamina at the junction of the lamina and corresponding facet joint. To complete the troughs, No. 1 and No. 2 Kerrison rongeurs are used. Care should be taken to avoid violating the underlying dura during this process. Once the troughs are complete, the lamina is gently lifted and underlying ligamentum flavum and adhesions are

gently released from the undersurface of the caudad margin of the lamina. Using a combination of curettes, No. 1 and No. 2 Kerrison rongeurs, the laminectomy is completed. Further decompression, including partial medial facetectomy and foraminotomy, is performed depending on the degree of decompression necessary.

After ensuring hemostasis has been achieved, the wound is closed in standard fashion.

Transpedicular Approach

The posterior transpedicular approach was first described by Patterson and Arbit in 1978 for approaching thoracic disc herniations.[21] As the approach has gained popularity, its indications have expanded to include tumor, infectious, and traumatic etiologies. The approach can be performed unilaterally or bilaterally depending on the need for isolated access to the posterolateral aspect of the vertebral body and disc space on one side versus the need for bilateral access, as in the case of tumors affecting both nerve roots or for complete discectomy.

A unilateral transpedicular approach is less destabilizing than a bilateral transpedicular approach. However, the bilateral transpedicular approach can allow one to perform near-circumferential decompression, such as in the case of extensive tumor involvement or if there is a need for complete discectomy. In fact, this approach can be used to perform circumferential decompression and vertebrectomy.[22,23] If bilateral transpedicular approaches are being performed, serious consideration should be given to stabilization to prevent iatrogenic instability and deformity.

After intubation, the patient is placed in the prone position on a Jackson table or radiolucent table with chest rolls. Image intensification is then used to mark the surgical levels. Standard sterile prep and drape is performed.

A midline incision is then made over the surgical level(s) being addressed. Subperiosteal dissection is performed laterally until the lamina and facet joint of the level to be treated is exposed. This is undertaken bilaterally if bilateral transpedicular approaches are being used.

The pedicle overlying the disc herniation or level to be treated is identified. For a thoracic disc herniation, the caudal pedicle is adjacent to the intervertebral disc (i.e., the T9–T10 disc is adjacent to the T10 pedicle). To help further identify the pedicle, spinal cord and affected nerve root laminectomy can be performed prior to pedicle removal. Once the pedicle is identified, it is entered with a high-speed burr and the central, cancellous portion is removed to the depth of the pedicle vertebral body junction. Intraoperative fluoroscopy can be useful for this portion of the procedure to help safely guide the surgeon down the pedicle as well as aid in depth of resection. After removal of the cancellous portion of the pedicle has been achieved, the remaining cortical wall is taken down with either a pituitary rongeur or down-biting curettes. In the classical approach, only the medial and superior borders of the pedicle are resected, but the entire pedicle can be taken down if necessary. Decompression is then performed in a lateral to medial trajectory, with care taken to avoid injuring the spinal cord and nerve root (Fig. 19.24).

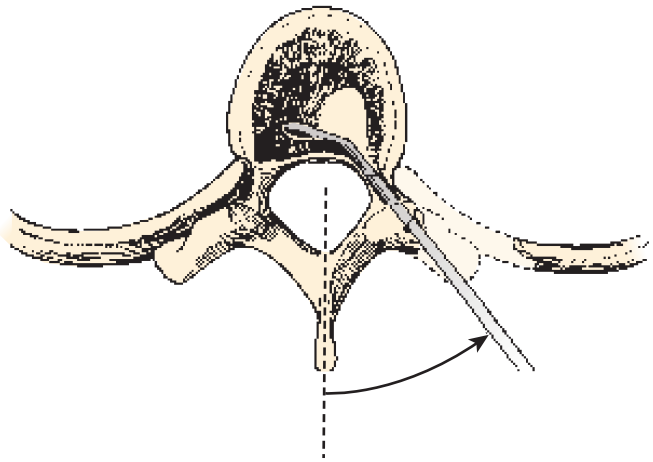

FIG. 19.24 The transpedicular approach.

Costotransversectomy

First described in 1894 by Menard, the costotransversectomy approach was originally created for the treatment of spinal abscess.[24] Since its first description, many variations and alternate indications have been established. The approach allows near-circumferential access to the anterior thoracic spine while avoiding the potential morbidity associated with an anterior approach. Additionally, this approach allows for single-stage surgery, with the ability to decompress and stabilize simultaneously. Current indications include thoracic disc herniations, fractures, tumor, infection, and deformity.[25]

Traditionally, the patient is placed in the prone position on a Jackson table or radiolucent table with chest rolls. Alternatively, the patient can be placed in a semiprone or modified lateral decubitus position. The table should allow circumferential fluoroscopic visualization of the surgical level. Having the ability to airplane the table can help aid in visualization.

Fluoroscopy is used to help mark the skin incision at the appropriate surgical level(s). Sterile prep and drape is performed. Attention should be given to ensuring that wide draping is achieved, as this approach involves partial rib exposure.

There are several incision variations that can be used. Ultimately, the decision regarding which incision to use depends on the indication for the procedure and whether or not laminectomy and/or instrumentation is required. Traditionally, a curvilinear incision approximately 8 cm lateral to the spinous process of the surgical level that is 10 to 13 cm in length has been described (Fig. 19.25). [4] Since most procedures involve scenarios requiring simultaneous laminectomy and/or stabilization, the following technique is described from a midline posterior approach.

Using the previously described standard posterior approach to the thoracic spine, subperiosteal dissection is performed exposing the lamina and transverse process. Further lateral dissection is carried posteriorly and laterally along the corresponding rib approximately 6 to 8 cm depending on the extent of exposure required. The transverse process and rib

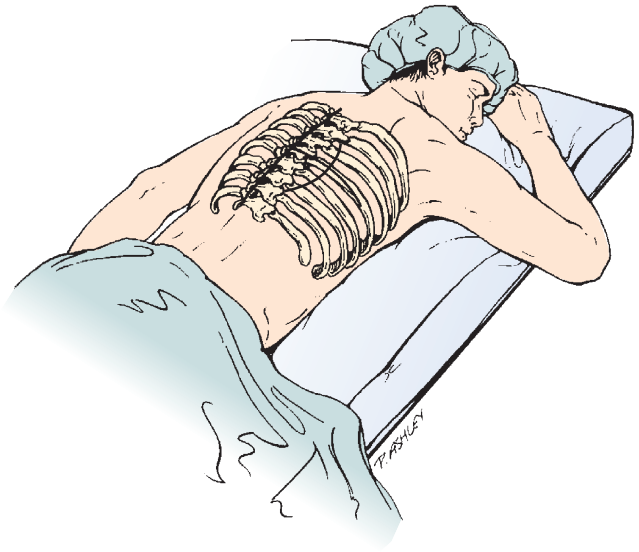

FIG. 19.25 A median or paramedian incision may be made straight or curved centered over the desired vertebral level. Traditionally, a curvilinear incision about 8 cm lateral to the intended spinous process and 10 cm to 13 cm long has been used.

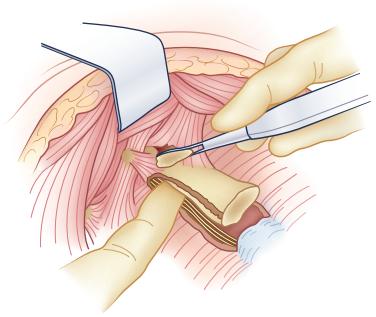

FIG. 19.26 The rib and its arthrodial junction can now be disarticulated. A subperiosteal dissection is done along the pedicle and upper and lower vertebral body to separate the pleura from the vertebral wall.

are then dissected circumferentially using a periosteal elevator, rib dissector, or curettes. Great care should be taken to avoid violating the underlying pleura and the neurovascular bundle, which travels on the underside of the rib. Once entirely skeletonized, the rib is cut laterally with a rib cutter or large Kerrison rongeur. The rib is then gently lifted up and away from the underlying pleura and neurovascular bundle, and disarticulated from the costovertebral joint attachment with Bovie electrocautery or curettes, removing the rib en bloc (Fig. 19.26). If a fusion is being performed, the rib can be used for bone graft. The corresponding transverse process can also be resected for further visualization of the pedicle and lateral vertebral body. Bone bleeding is controlled with bone wax.

Next, the lateral pedicle wall is identified and careful subperiosteal dissection is performed along the lateral aspect of the vertebral body with a Cobb elevator while protecting the underlying pleura. Dissection is carried ventral until the

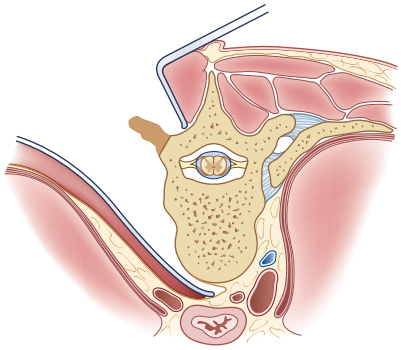

FIG. 19.27 A subperiosteal dissection is done along the pedicle and upper and lower vertebral body to separate the pleura from the vertebral wall.

anterior margin of the vertebral body is reached. A malleable retractor is then placed to create a working window and protect the underlying pleura and vascular structures (Fig. 19.27).

Lateral Extracavitary Approach

The lateral extracavitary approach was developed by Larson and colleagues at the University of Wisconsin in 1976, after expanding on the work of Menard and Capener.[26] This approach is an expansion of the costotransversectomy approach, allowing for greater exposure and visualization of the ventral thecal sac. The indications for this approach include tumors, infection, trauma, and treatment of thoracic disc disease.[27] This approach can be utilized throughout the entire thoracic spine. Similar to the costotransversectomy, it is a versatile approach that avoids the need for formal thoracotomy.

The patient is placed in the prone position on a Jackson table or radiolucent surgical bed with chest rolls. The patient should be secured to the table to allow for bed rotation of 20 to 30 degrees if necessary.

Once positioned, localization for the skin incision is performed with the aid of the fluoroscope. The patient should be draped widely to allow for formal thoracotomy, if necessary.

After prep and drape, a midline incision centered over the spinous process of the level of interest is made. The superficial and deep fascia to trapezius and latissimus dorsi are incised. Depending on surgeon preference, the incision can be carried laterally in hockey stick fashion 8 cm if a wider exposure is needed. In the lower thoracic spine, the fibers of the trapezius are close to the transverse process of the rib. A plane is now established to expose the lateral margin of the paraspinal muscles. Working lateral to medial, the paraspinal muscles are elevated subperiosteally and retracted. Similar to the costotransversectomy approach, the rib of interest is skeletonized utilizing the subperiosteal technique while being careful not to damage the underlying parietal pleura. The transverse process of the rib and the lamina on the operative side are similarly exposed. The transverse process is removed. If more exposure is required, the cephalad rib can be similarly exposed, allowing for even greater visualization.

The rib is cut laterally with a rib cutter or large Kerrison rongeurs. As opposed to the limited rib resection with

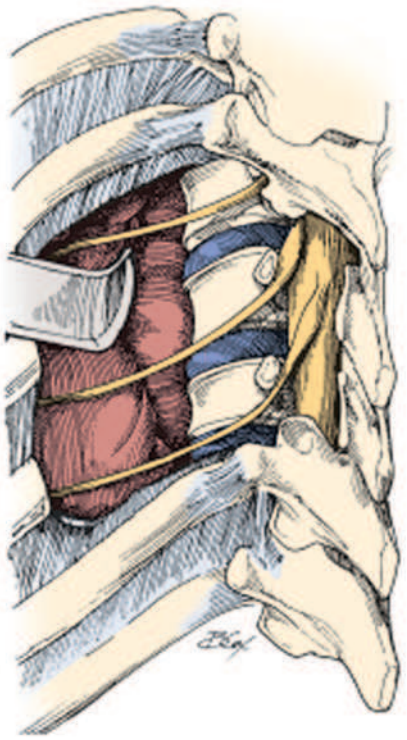

FIG. 19.28 When posterolateral structures of the transverse process and pedicle have been removed, exposure should be adequate for discectomy.

costotransversectomy, approximately 12 cm of rib can be resected with the lateral extracavitary approach. Once cut laterally, it is gently lifted off the underlying parietal pleura and detached medially from its vertebral body and costal attachments.

The neurovascular bundle is visualized and traced back to the neural foramen, allowing for identification of the corresponding pedicle. The pedicle is now very carefully taken down with a high-speed burr or rongeur while not violating the underlying dura.

Upon complete pedicle and transverse process resection, good visualization of the disc space should be achievable (Fig. 19.28). Depending on the indication for the approach, discectomy is then performed followed by corpectomy.

Corpectomy can be performed from pedicle to pedicle with a combination of curettes, high-speed burr, and pituitary rongeur. Great caution should be exercised during corpectomy to avoid injuring the ventral dura and spinal cord. To improve visualization, the bed can be rotated 20 to 30 degrees away from the operating surgeon. Additionally, a thin shell of posterior vertebral body cortex can be left behind until central and ventral corpectomy has been completed. This remaining shell of bone can then be carefully removed, pushing it away from the ventral dura.

After completion of the corpectomy, the corpectomy cage and/or graft is placed and positioning confirmed with fluoroscopy. If posterior pedicle screw and rod stabilization is to be performed, a separate, standard, midline fascial incision and approach is performed medial to the paraspinal muscles, elevating them in a subperiosteal manner.

Upon completion of corpectomy and stabilization, the pleura is examined for any breaches. If a breach is identified, it is repaired. If the breach is considered significant, chest tube placement may be necessary.[28]

Minimally Invasive Approaches to the Thoracic and Thoracolumbar Spine

Recent advances in techniques have led to the development of minimally invasive approaches to the thoracic and thoracolumbar spine that exploit the same tissue planes as traditional open procedures but achieve access through smaller incisions and less tissue disruption. Potential benefits of minimally invasive approaches include less postoperative pain, quicker recovery, and avoiding complications and morbidities associated with larger open procedures. Early results are promising, with complication rates ranging from 4.8% to 13.5%.[28,29] That being said, they can be technically demanding and, if complications do arise, they can be difficult to manage through the small access site.

Minimally invasive lateral approaches to the thoracic spine have been described.[29,30] Similar techniques have been applied to traumatic fractures requiring corpectomy.[31] The patient is positioned in the true lateral decubitus position similar to thoracotomy approaches. A transthoracic or retropleural approach can be utilized. For the transthoracic approach, a 3- to 4-cm oblique incision paralleling and between the ribs of interest is made. The intercostal muscles and parietal pleura are incised in line with the skin incision, allowing entry into the thoracic cavity. Depending on the exposure required, a portion of the rib can be resected. Care should be taken to avoid injuring the neurovascular bundle that lies on the undersurface of the rib.

If a retropleural approach is utilized, a 6-cm oblique incision following the course of the rib is made in the midaxillary line. Approximately 5 cm of rib is then carefully subperiosteally dissected and resected, with care taken not to violate the parietal pleura or neurovascular bundle. The plane between the endothoracic fascia and parietal pleura is developed and the pleura mobilized anteriorly until the lateral side of the vertebral body, pedicle, and disc space are exposed. If a left-sided approach is performed, the aorta and hemizygos vein are retracted anteriorly with the pleura. An expandable retractor system is then placed, protecting the surrounding structures and allowing focal access to the surgical pathology. Standard surgical techniques are employed. For corpectomies, an expandable cage can be utilized.

KEY POINTS

Low Anterior Cervical and High Transsternal Approach

1. The plane between the midline esophagus and airway and the carotid sheath laterally is utilized with this approach.
2. A left-sided approach should be considered given the predictable course of the recurrent laryngeal nerve on this side.
3. Turning the head away from the approach side and gently taping the shoulders downward will improve access and fluoroscopic visualization.

Transpleural Transthoracic Third Rib Approach

1. A double-lumen endotracheal tube should be used to allow for selective lung deflation.
2. The first rib sits medial and recessed to the second rib. The second rib is typically the highest palpable rib.
3. The parietal pleura should be entered over the relatively avascular disc space as opposed to directly over the vertebral body in order to avoid inadvertent injury to the intercostal vessels.
4. A chest tube should be placed at the end of the case.

Thoracotomy (Anterior) Approach to the Thoracic Spine

1. A right-sided approach should be considered above T10 to avoid having to manipulate the aorta. Below T10, a left-sided approach should be considered to avoid working around the liver.
2. Ligation of the segmental vessels should be performed away from the aorta to minimize the risk of the ties or clips loosening.
3. The parietal pleura should be entered over the relatively avascular disc space as opposed to directly over the vertebral body in order to avoid inadvertent injury to the intercostal vessels.
4. A double-lumen endotracheal tube should be used to allow for selective lung deflation.

Endoscopic Anterior Approach to the Thoracic Spine

1. A double-lumen endotracheal tube should be used to allow for selective lung deflation.
2. The initial trocar is placed using blunt dissection on the superior margin of the intervening rib, avoiding damage to the neurovascular bundle on the undersurface of the rib. Subsequent trocars are placed under direct thoracoscopic visualization.
3. A chest tube should be placed through the inferiormost trocar site.
4. A chest radiograph should be obtained at the end of the case prior to complete closure to ensure full reexpansion of the lung.

Anterior Approach to the Thoracolumbar Spine

1. A double-lumen endotracheal tube should be used to allow for selective lung deflation.
2. The peritoneum is bluntly released from the diaphragm and abdominal musculature.
3. Care should be taken to avoid injuring the sympathetic chain in the thoracic cavity and the lumbar plexus in the abdominal cavity.
4. Special attention should be given to closure at the junction of the diaphragm and abdominal musculature to avoid hernia formation.

Posterior Approach for Decompressive Laminectomy and Fusion

1. Subperiosteal dissection is employed to minimize bleeding.
2. A high speed burr is used to create bilateral troughs at the junction of the lamina and facet joints for the laminectomy. The troughs are completed with small Kerrison rongeurs, and the lamina is carefully and gently removed in its entirety. This minimizes pressure on the spinal cord.

Transpedicular Approach

1. This approach may not be ideal for decompression of central pathology.
2. Care should be taken not to retract the spinal cord. If necessary, additional bone should be resected for visualization.
3. Turning the bed away from the operating surgeon can aid with ventral visualization.
4. Pedicle entry and takedown should be performed under fluoroscopic guidance to aid in proper trajectory and depth.

Costotransversectomy

1. The neurovascular bundle on the undersurface of the rib is protected during rib resection.
2. This approach utilizes a more lateral trajectory as compared to the transpedicular approach.
3. Additional visualization can be achieved by taking down an adjacent rib.

Lateral Extracavitary Approach

1. This approach is similar to a costotransversectomy approach. However, a large portion of the rib is resected, providing additional exposure.
2. The ventral dura can be protected during corpectomy by leaving a thin shell of dorsal vertebral body behind until central and anterior portions of the corpectomy are complete. This remnant shell can then be gently pushed away from the dura into the corpectomy cavity and removed safely.
3. Improved central and contralateral visualization can be achieved by rotating the bed away from the operating surgeon 20 to 30 degrees.
4. Any violation of the parietal pleura should be repaired, if possible. Consideration should be given to placing a chest tube.

Minimally Invasive Approaches

1. A transthoracic or retropleural approach can be performed through a minimally invasive approach.
2. Early results of minimally invasive lateral approaches to the thoracic and thoracolumbar spine are promising.
3. One should be prepared to convert to a traditional open technique should a complication arise or minimally invasive access is not achievable.

Nitin N. Bhatia

Selection of Approach to the Lumbar Spine

Once the decision has been made to operate, the surgeon must choose the best procedure and approach. When considering the options in the lumbar spine, many factors must be taken into account. First is the location of the pathology. Disease or deformity that primarily involves the vertebral bodies may be most easily approached through the abdomen or flank. The posterior elements are most easily approached through a posterior, midline incision. Second, the morbidity of each approach must fit the risk tolerance of each individual patient. For example, it may be preferable to avoid an anterior approach in a young male who has pathology at L5–S1 to avoid the risk of retrograde ejaculation.[1–3] With the advent of minimally invasive techniques, decreasing overall morbidity from tissue dissection must be weighed against more complete visualization that the more traditional open approaches provide. Chapter 21 discusses lateral and posterior approaches to the lumbar spine and their pros and cons.

Minimally Invasive Lateral Approach to the Spine

The concept of minimally invasive spine surgery is attractive to both patients and surgeons alike. Decreased postoperative pain, shorter hospital stay, and quicker return to activities support the use of minimally invasive techniques whenever possible.[4–8] One such technique is lateral access to the spine.[9] This can be used for multilevel interbody fusions to correct kyphoscoliosis, for interbody support when treating adjacent segment degeneration or multilevel fusions, or to drain a psoas abscess (Fig. 20.1). With this approach, access to the spine from T7 down to L4–L5 is possible. However, L4–L5 is often difficult to reach due to a high-riding iliac crest, and a lateral interbody fusion at this level is controversial at this time. The means to accessing L5–S1 laterally has not been developed.

Technique

Once the patient has been intubated and prophylactic antibiotics given, the patient is placed in the lateral decubitus position. When correcting a kyphoscoliosis, it is often easier to perform the lateral approach on the side of the concavity. When planning to perform a lateral interbody fusion, we advise studying the preoperative anteroposterior (AP) and lateral radiographs and the axial magnetic resonance images (MRIs) to determine if this procedure is feasible. The AP and lateral radiographs will show if the iliac crests are too high (see Figs. 20.1A–B). The axial MRI should also be evaluated to see where the nerves are preoperatively (Fig. 20.2). If the nerve is in the middle of the disc space, the surgeon may attempt to approach from the other side or plan for a different procedure.

The table should be flexed slightly to increase the distance between the iliac crest and the rib cage, and the patient secured with tape over the greater trochanter and chest wall (Fig. 20.3). Care should be taken not to flex the table too much, as that may put increased strain on the psoas and lumbar plexus. The leg on top should also be flexed, abducted with pillows, and externally rotated to relax the psoas. A cross-table AP should be taken and the table should be rotated to place the patient in a true AP position (Fig. 20.4A). A corresponding lateral fluoroscopic image should also be taken to verify that access to the disc space is possible (Fig. 20.4B). Minor adjustments should be made to the table to obtain a true lateral.

Once the patient has been prepped and draped, start with the lateral image. A radiopaque marker is placed over the center of the affected disc space (Fig. 20.5). Once this point has been identified, a mark is made. Through this mark, a small incision will be made for insertion of the dilators and an expandable retractor, which will provide access to the lateral spine. A second mark is made posterior to this first mark at the border between the erector spinae muscles and the abdominal obliques (Fig. 20.6). At this second mark, a transverse incision about 2 cm long is made to accommodate the surgeon's index finger. Finger dissection is used down to the lumbodorsal fascia. A clamp, or scissors, can be used to spread the fascia and muscle fibers and provide entry into the retroperitoneal space. Once an opening is created, the index finger is used to sweep the peritoneum anteriorly and to palpate the psoas muscle (Fig. 20.7AB). Sweep the index finger inferiorly to feel the inner table of the iliac crest (if in the lower lumbar spine) to verify that you are in the abdominal cavity.

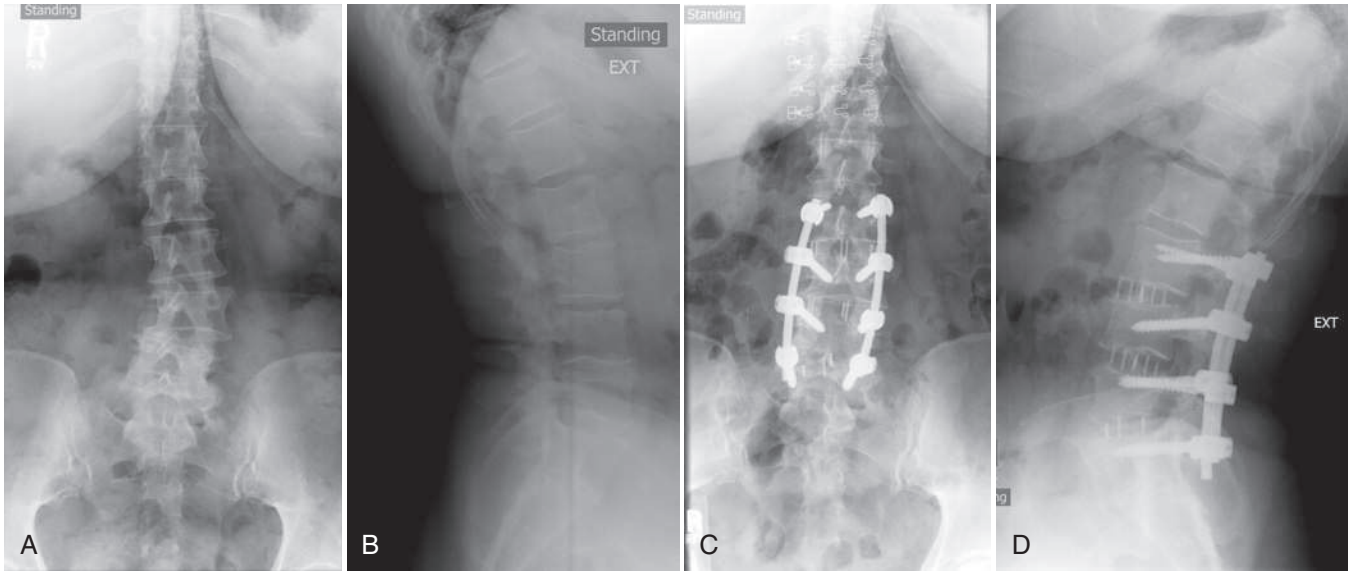

FIG. 20.1 (A–B) Anteroposterior and lateral radiographs of a 71-year-old woman with degenerative scoliosis. (C–D) Anteroposterior and lateral radiographs after L3–L4 and L4–L5 lateral interbody fusions and minimally invasive transforaminal lumbar interbody fusion at L5–S1.

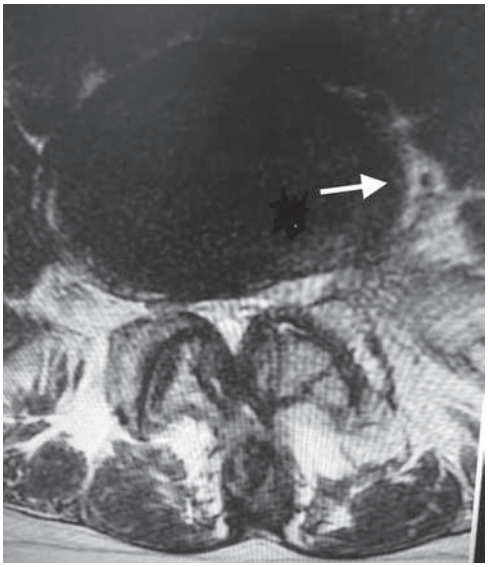

FIG. 20.2 Axial magnetic resonance image showing nerve roots in the axial plane. *Arrow* is pointing to the ventral nerve root. In this case, the surgeon may wish to approach from the right side to avoid the nerve root here.

FIG. 20.3 Patient placed in right lateral decubitus position with table flexed to increase the distance between his ribs and iliac crest.

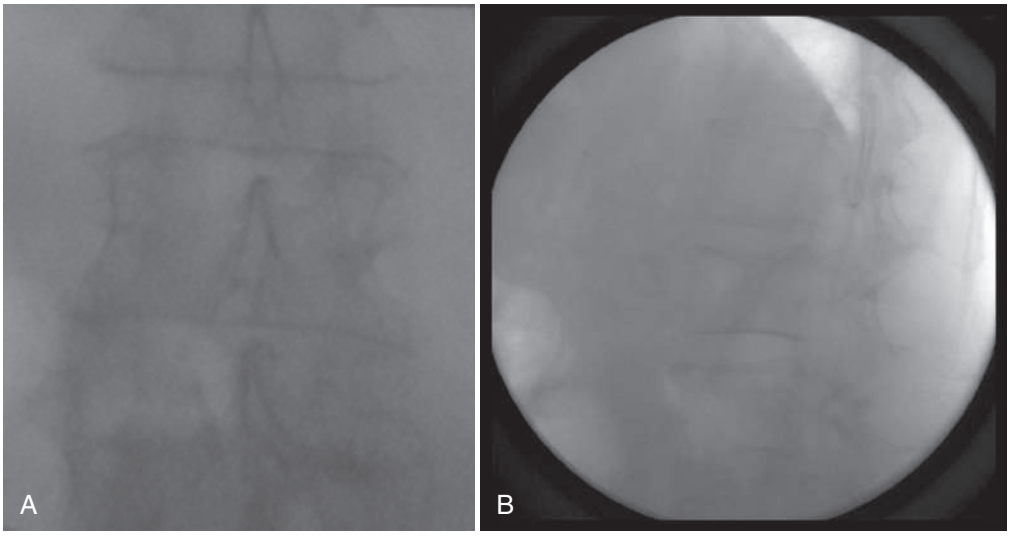

FIG. 20.4 (A) Cross-table anteroposterior (AP) position showing a true AP view. The endplates are parallel and the spinous process is midline. (B) Corresponding lateral fluoroscopic image showing parallel endplates and superimposed pedicles.

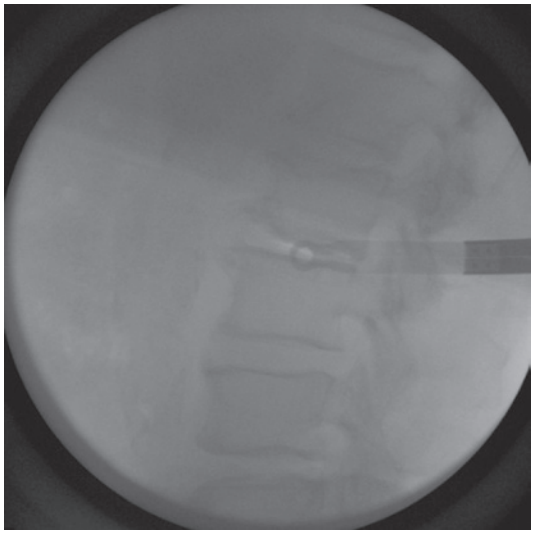

FIG. 20.5 Fluoroscopic image showing center positioning over the disc space. A mark is made on the skin here.

FIG. 20.6 Two-incision technique shown with lateral and posterolateral marks. The posterolateral incision is made about the length of the surgeon's index finger away from the lateral incision. From this mark, the surgeon should also measure the distance to the spine to make sure to be able to reach the psoas from this incision.

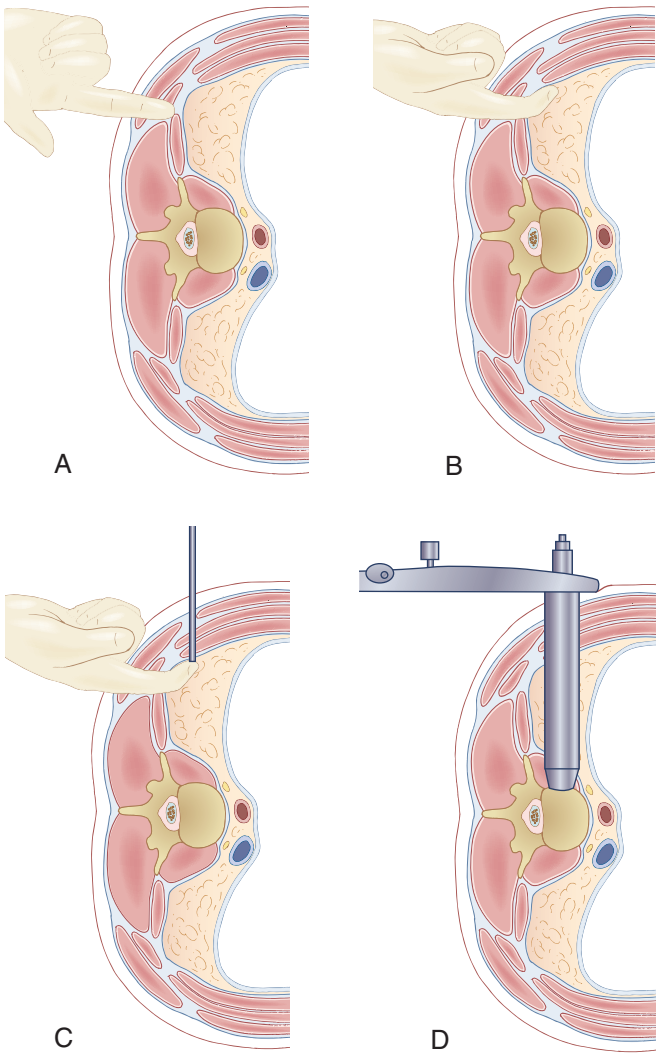

FIG. 20.7 (A–B) The surgeon uses digital palpation to sweep the abdominal contents anteriorly and create a cavity in the retroperitoneal space. (C) The index finger guides the initial dilator down to the psoas. (D) Once the initial dilator is secured in place with a K-wire, larger dilators are used to spread the psoas under neuromonitoring, and a retractor is placed over the dilators.

Once the psoas is identified, the index finger is swept up to the previously made direct lateral mark. A 2-cm incision is made and the external and internal oblique muscles and the transverses abdominis muscles are split; dilators are placed through this opening. The index finger, which is already in the retroperitoneal space, guides the initial dilator onto the psoas (Fig. 20.7C). The fibers of the psoas are then split with the dilator, using neuromonitoring as a safety measure, if desired. A lateral radiograph should be taken to verify the central position of the dilator at the desired disc space. Once the position of the initial dilator is secured by placing a Kirschner wire (K-wire) through the dilator and into the disc space, larger dilators are used to spread the psoas under neuromonitoring. Then, an expandable retractor is placed over the dilators (Fig. 20.7D). Once the retractor is secured to the table, the dilators are removed to provide lateral access to the disc (Figs. 20.8). A neuromonitoring probe can be used to check for any nerves that may be crossing the working window of the retractor. If a nerve is detected, the K-wire should be repositioned away from the nerve and the psoas redilated. If this fails, conversion to another means of interbody fusion should be considered, as repeated positioning of the retractor, or pressure on the nerve, could result in postoperative paresthesias or palsies.

AP and lateral radiographs should be taken at this point to verify that the retractor is docked on the disc space and that the retractor is positioned over the center of the disc. Once appropriate positioning has been confirmed, the retractor should be secured in place. A lateral discectomy is then performed in standard fashion with shavers, curettes, and rasps. Care must be taken not to violate the endplates because much of the correction from a lateral interbody fusion is based

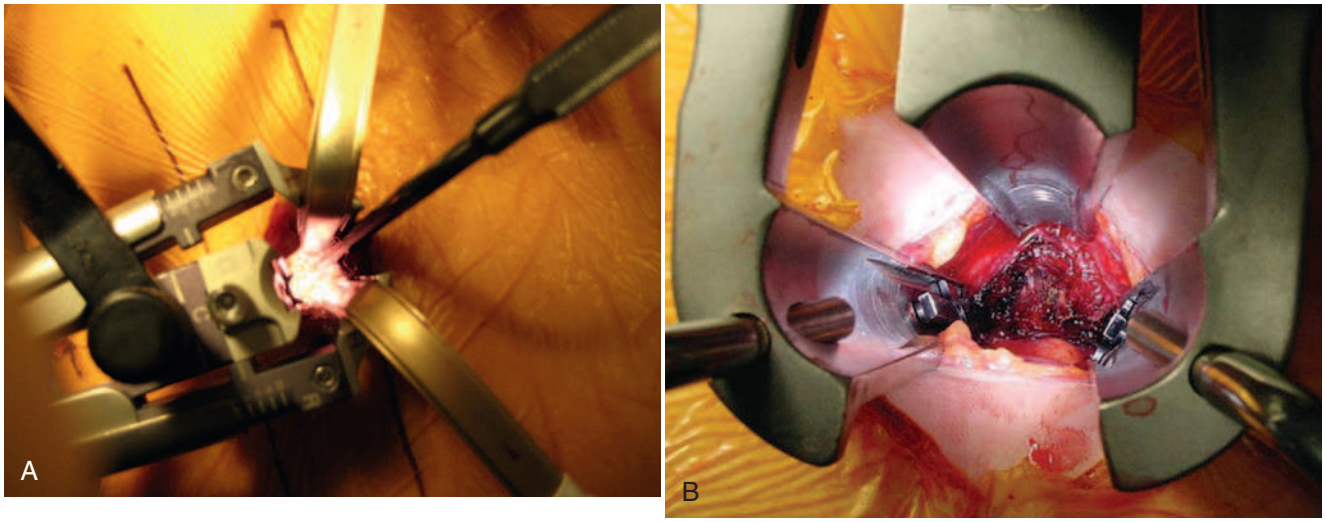

FIG. 20.8 (A) Once the retractor is deployed, soft tissue over the disc space must be cleared away. Use a probe to detect any nerves that may cross the field. (B) The disc can be visualized after the psoas muscle has been cleared from the field of view.

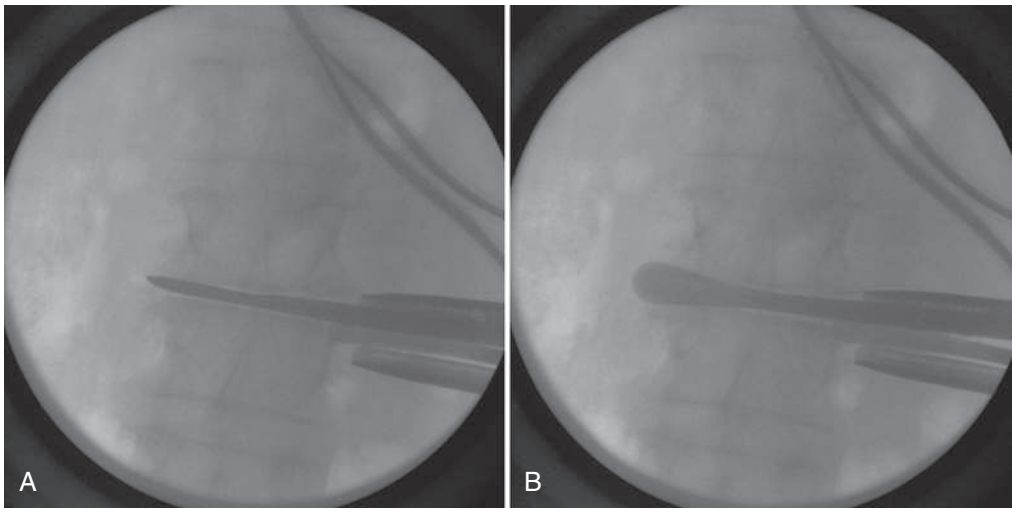

FIG. 20.9 (A) A Cobb elevator is used to release the contralateral anulus. This aids in the coronal correction of the deformity. (B) Rotating the Cobb elevator 90 degrees will further release the contralateral anulus.

on distraction and a compromised endplate will allow the endplate to subside. A Cobb elevator should be used to release the contralateral anulus (Fig. 20.9). Releasing the contralateral anulus loosens the spine in the coronal plane and aids in the correction of coronal plane deformities. Sizers and trials are then used to determine the optimal implant size (Fig. 20.10). The implant is then filled with the surgeon's graft or fusion enhancer of choice and impacted across (Fig. 20.11). The wound is then closed in layers. No drains are typically necessary.

Complications

Since minimally invasive lateral access to the spine is a relatively new procedure, publications regarding the efficacy and complication rates are sparse. Numbness in the lateral thigh and psoas weakness have been noted by some physicians; however, the rate still remains unknown.[10–12] To minimize this risk, open the retractor just enough to perform the lateral discectomy. Exuberant deployment of the retractor may place undue pressure on the nerve roots and/or the psoas itself. Limiting the amount of time that the retractor is open is also advised to decrease the length of time that the nerves are under pressure. In addition, neuromonitoring is advised to decrease the possibility of nerve injury.

Injury to the bowel and vessels have also been reported.[13] It is recommended that this procedure be done at a facility where a general or vascular surgeon is available. One method to decrease the rate of bowel or vascular injury is to place the initial dilator under direct visualization. After the lateral incision has been made, the retractor can be passed down to the psoas. Then, the initial dilator is placed through the psoas under direct visualization.

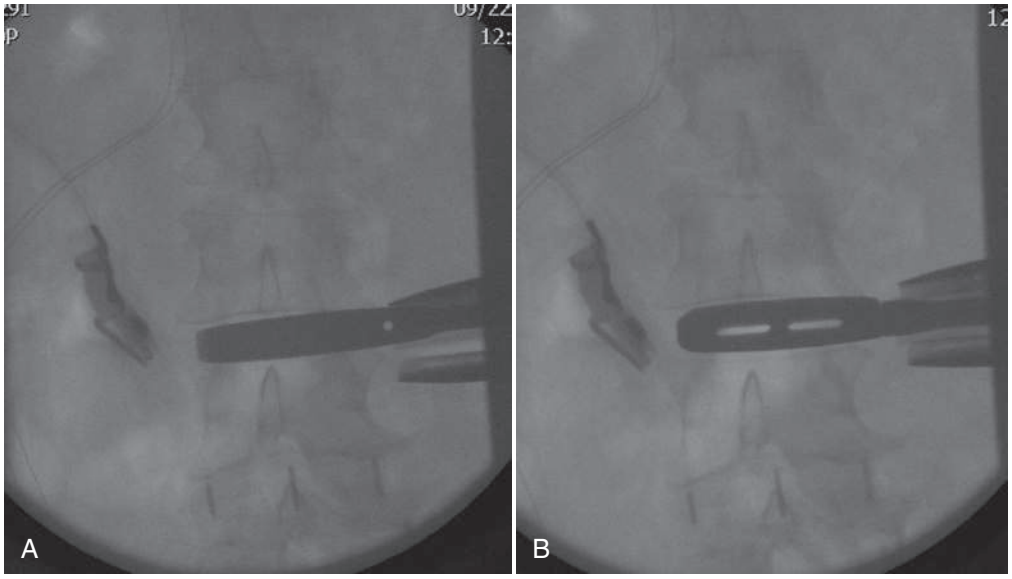

FIG. 20.10 Trialing of the disc space with a (A) paddle trial and (B) implant trial.

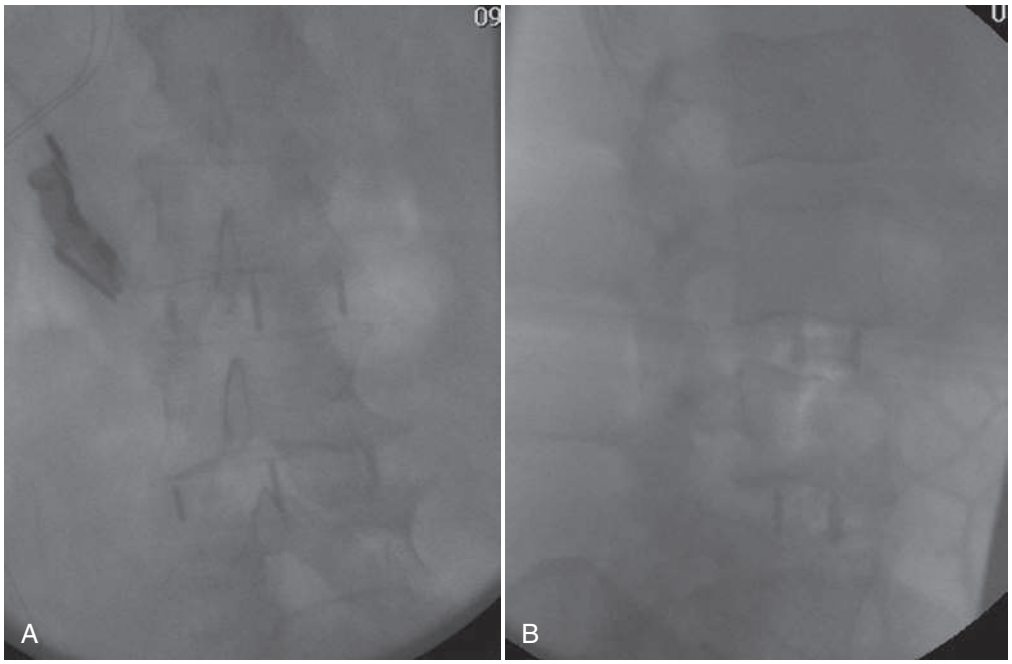

FIG. 20.11 Final (A) anteroposterior and (B) lateral radiographs after two-level lateral interbody fusion.

Posterior Approach to the Lumbar Spine

The posterior approach through a midline, longitudinal incision is the most common approach to the lumbar spine. It provides direct access to the spinous processes, laminae, facets, and even the pedicles, as well as lateral aspects of the vertebral bodies at all levels of the lumbar spine. The pedicle starting holes and transverse processes can be reached by dissecting and retracting the paraspinal muscles laterally. Through this approach, it is possible to perform most of the spine procedures currently practiced today, including microdiscectomies, laminectomies, and most fusion procedures. The posterior aspect of the vertebral body and disc space over the lower lumbar levels can be reached following laminectomy by retracting the dura; however, the exposure is limited.

It is important to bear in mind that anatomic variations exist among individuals, which must be taken into account when planning surgery. The intercrestal line typically crosses at L4–L5; however, this is not a rigid anatomic finding. A lateral radiograph will show where the intercrestal line is. Also, lumbarization or sacralization of the last vertebral segment can confuse the surgeon when localizing the level of pathology. Additionally, a spina bifida occulta or an unusually wide interlaminar space may exist. To avoid inadvertent injury to the dura or nerve roots with a Bovie or periosteal elevator during the exposure, the surgeon should study radiographs prior to surgery to look for these abnormalities.

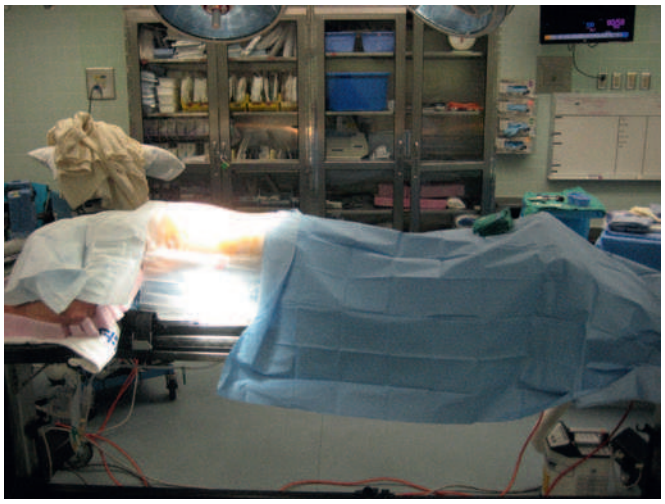

FIG. 20.12 Patient in standard prone position. Note how the area beneath the patient is cleared of wires to accommodate imaging.

Technique

Position the patient prone to allow the abdomen to hang free of pressure (Fig. 20.12). This will reduce venous plexus filling around the cauda equina by permitting the venous plexus to drain directly into the inferior vena cava. Also, the anesthesiologist should check the patient's eyes and the surgeon and nurses should assess the bony prominences to ensure that they are well padded. If a microdiscectomy or decompression is to be performed, flexing the lumbar spine on a Wilson frame or similar table is recommended to open up the interspinous spaces. If a fusion is also to be performed, placing the patient on a Jackson table is recommended to maintain the lumbar lordosis. A solution containing epinephrine in a 1:500,000 concentration may be injected into the subcuticular tissues and muscles to decrease blood loss.

A midline incision is made between the spinous processes of the levels to be exposed, and the erector spinae and multifidus muscles are dissected from the bony elements (spinous processes, interspinous ligaments, laminae, facet joints, and transverse processes) as needed for the levels that must be visualized, using electrocautery or sharp dissection (Fig. 20.13). The paraspinal muscles should be elevated subperiosteally to minimize blood loss. Care should be taken not to injure the facet joint capsules and interspinous ligaments in areas where motion will be expected following the operation. If the transverse processes must be reached, continue dissecting down the lateral side of the facet joints and onto the transverse process itself. Close to the facet joints and the pars interarticularis are the vessels supplying the paraspinal muscles segmentally.

If these vessels are cut, they can bleed vigorously. Cauterization is necessary to stop these bleeders. The posterior primary rami of the lumbar nerves run with these vessels.

In order to perform a decompression or a discectomy, it may be necessary to remove the ligamentum flavum. The superficial ligamentum flavum blends laterally into the facet joint capsule. Use a forward-angled or small straight curette to detach the superficial and deep layers of the ligamentum

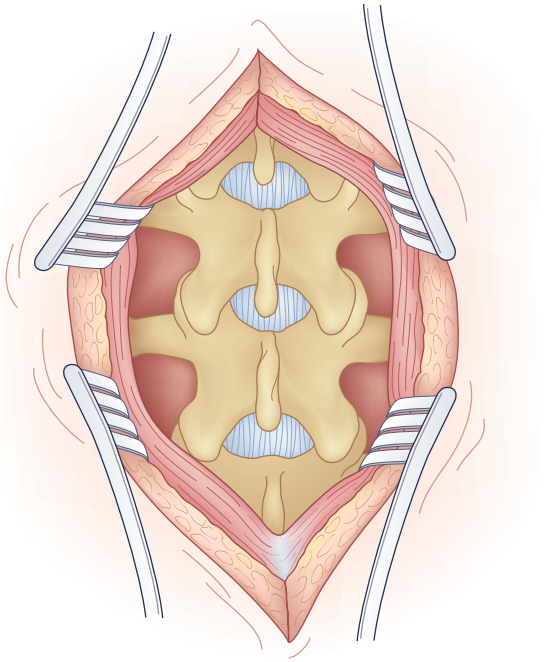

FIG. 20.13 Exposure of the lumbar spine.

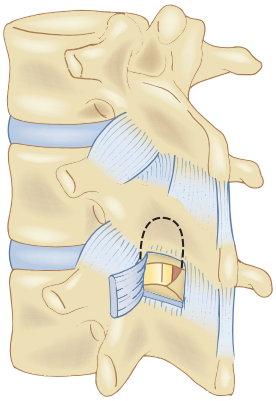

FIG. 20.14 Removal of the ligamentum flavum. (From Benzel E. *Spine Surgery: Techniques, Complication Avoidance, and Management*. Philadelphia: Churchill Livingstone; 2004.)

flavum from the caudal edge of the cephalad lamina. Sweep the curette medial to lateral and advance the curette with each successive sweep to detach the ligamentum flavum from the lamina. The ligamentum flavum typically inserts over the caudal 50% of the undersurface of the lamina. Place a small, angled elevator under the ligamentum flavum to lift it off the dura and protect the latter. A Kerrison rongeur, pituitary rongeur, or knife can be used to remove the ligamentum flavum. The epidural fat, the dura, the nerve root, and the epidural veins can be seen once the ligamentum flavum has been removed (Fig. 20.14).

If a discectomy or exploration of the disc space is required, it can typically be performed through this opening. Removal of a portion of the lamina (laminotomy) may need to be done to adequately access the disc space. A Penfield 4 can then be used to help mobilize the traversing nerve root and a nerve root retractor can be used to gently retract the nerve roots

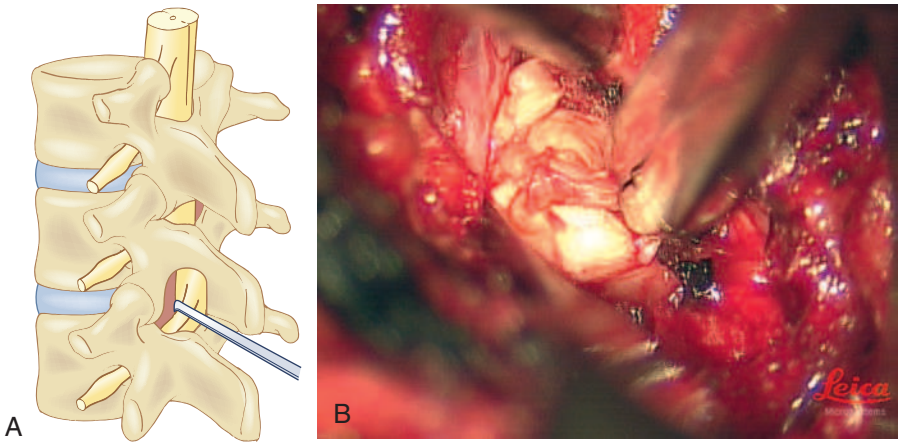

FIG. 20.15 (A) Exposure of the lumbar disc by retracting the thecal sac medially. (B) View of microdiscectomy under a microscope. The thecal sac is retracted medially by a nerve root retractor. ((A, From Benzel E. *Spine Surgery: Techniques, Complication Avoidance, and Management.* Philadelphia: Churchill Livingstone; 2004.)

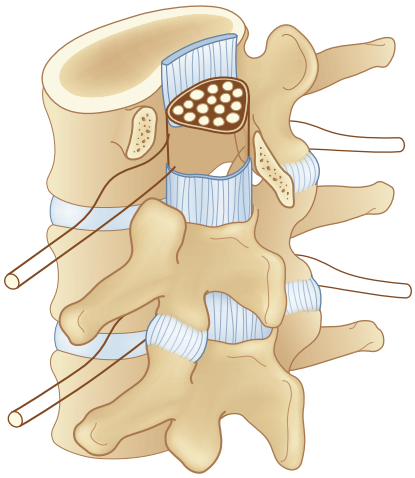

FIG. 20.16 Structures relative to the pedicle.

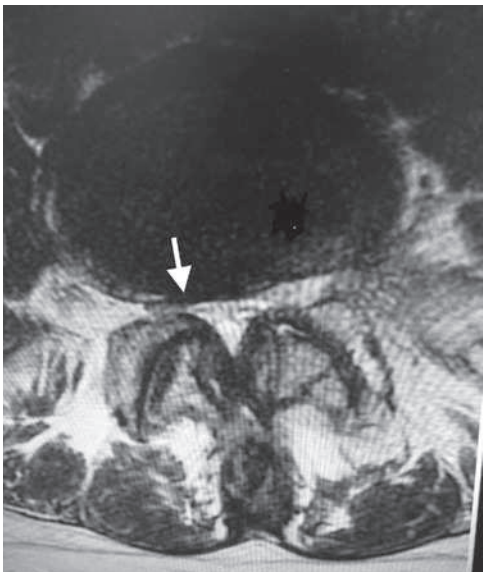

FIG. 20.17 Axial magnetic resonance image of the lumbar spine. The *arrow* is pointing to the lateral recess.

medially (Fig. 20.15). Care must be used not to retract too vigorously to avoid too much tension on the exiting nerve root. Bleeding from the epidural veins commonly occurs. Hemostasis can be obtained with bipolar cautery and/or the use of cottonoids, Surgicel, and thrombin-soaked Gelfoam. Cottonoids can be placed in the cephalad and caudal extremes of the exposure to collapse the vessels and provide a working window. The key to intracanal anatomy is the pedicle (Fig. 20.16). The disc space is just cephalad to the pedicle, and the intervertebral foramen above the pedicle accommodates the exiting nerve root. The traversing nerve root lies just medial to the pedicle and exits the intervertebral foramen caudally. The disc space can be found by retracting the traversing nerve root medially and exploring the space above the pedicle. Feel for the disc space with a Penfield 4. It should be a raised, white, soft structure.

If a total laminectomy is needed to decompress or expose the dura and nerve roots, remove the fascia entirely from the tip of the spinous process bilaterally. Dissect the muscles off of the spinous processes and lamina subperiosteally and take care to protect the facet joints. The pars interarticularis must be exposed fully to avoid transecting it during the decompression. A rongeur can be used to remove the spinous processes. The laminectomy may be performed many ways. A high-speed burr may be used to thin the lamina down to a thin cortical shell over the dura and then removed with a Kerrison rongeur. Alternatively, the tip of a rongeur may be inserted under the caudal edge of the cephalad lamina to remove the lamina. Use the rongeur to cut from the underside in an upward direction. This will lessen the chance of catching dura. A Kerrison rongeur can be used to complete the laminectomy near the pars and the cephalad edge. To adequately decompress the nerve roots, the lateral recesses and intervertebral foramen must also be explored (Fig. 20.17). A Woodson elevator or dural guide may be used to gently compress the dura and expose the lateral recesses. This will expose the ligamentum flavum in the lateral recess and intervertebral foramen. This ligamentum flavum should be removed to perform an adequate decompression. The medial aspect of the caudal pedicle marks the medial

border of the intervertebral foramen. Often, osteophytes from the facet joints compress the exiting nerve root. Care must be taken when removing these osteophytes to avoid injury to the exiting nerve root and to avoid iatrogenic instability caused by too much removal of the facet joint. Typically, removal of less than 50% of the facet joint will preserve its stability. This may necessitate the use of a 1- or 2-mm Kerrison rongeur. The use of curved Kerrison rongeurs can be helpful here. Bearing in mind that the facet joints are oriented sagittal in the lumbar spine, cutting the undersurface of the facet joint provides a greater means of decompressing the nerve roots while preserving the overall stability of the joint.

With the advent of pedicle screw fixation for the lumbar vertebrae, there are now several additional anatomic relationships that are of importance at the level of the posterior bony elements. The location of the pedicles is identified by anatomic landmarks and by radiography or image-intensification fluoroscopy in the operating room.

In the lumbar region, the center of the pedicles is usually at the inferolateral edge of the facet joint, on an imaginary transverse line bisecting the transverse processes (Fig. 20.18). However, if there is severe facet arthrosis, the lateral edge of the facet joint may be lateral to the true pedicle entry site. In these cases, also refer to the pars interarticularis. The lateral border of the pars typically corresponds to the medial border of the pedicle. In the lumbar region, from this point, one may use a pedicle finder, with a 20-degree medial inclination at L5, 10 degrees at L4, 5 degrees at L3 and L2, and no inclination at L1 (Fig. 20.19). One may follow the progress of the pedicle finder by feeling inside the pedicle with a pedicle feeler and by checking with the image intensifier or by radiographs. In the lateral view, the probe/marker should be parallel to the disc space.

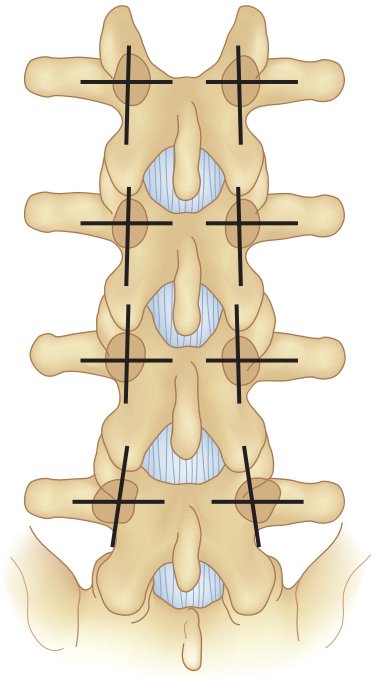

FIG. 20.18 Pedicle entry points.

Posterolateral Approach to the Lumbar Vertebral Bodies

The posterolateral approach provides direct access to the transverse processes and the mammillary processes of the facets through a longitudinal paraspinal incision, retracting the erector spinae muscles medially. This area provides an excellent bed for posterolateral lumbosacral fusion even in the face of preexisting pseudarthrosis, laminar defects, or spondylolisthesis. This approach is the basis for minimally invasive transforaminal lumbar interbody fusions.

Technique

General endotracheal anesthesia is recommended for this procedure. The patient is placed on the operating table in the prone position with chest rolls on either side of the thorax to protect ventilation or on a radiolucent table with chest and hip pads.

A longitudinal paramedian incision is made at the lateral border of the erector spinae muscles (approximately 2 fingerbreadths from the midline) centered over the level of interest. The incision is extended to the lumbar fascia, and the erector spinae muscles are identified. The interval between the erector spinae muscles and the multifidus is found after opening the fascia, and dissection proceeds between these muscles down to the facet joints and the transverse processes of the vertebrae (Fig. 20.20). The paraspinal muscles are retracted medially, the transverse process at the desired level is tagged with a radiopaque marker, and radiographs are made to confirm the vertebral level. For a minimally invasive transforaminal interbody fusion, this exposure is adequate to perform a decompression and fusion.

If access to the vertebral body is desired, the dissection can be carried further anteriorly. The transverse process is divided with an osteotome and is retracted laterally with its musculotendinous attachments. The vertebral pedicle is palpated, and the lumbar nerves are identified and protected as they leave their foramina above and below the pedicle (Fig. 20.21). The psoas muscle is carefully separated from the vertebra using a

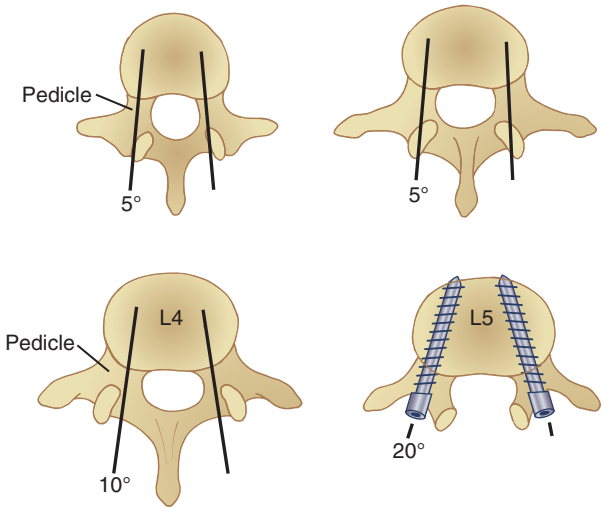

FIG. 20.19 Transaxial position of the pedicle screws.

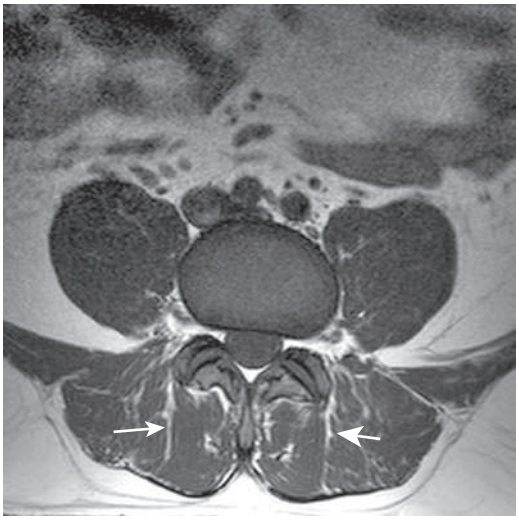

FIG. 20.20 Cross-section of the lumbar spine and paraspinal structures at the level of the third lumbar vertebra. The arrows point to the interval between the erector spinae muscles and the multifidus.

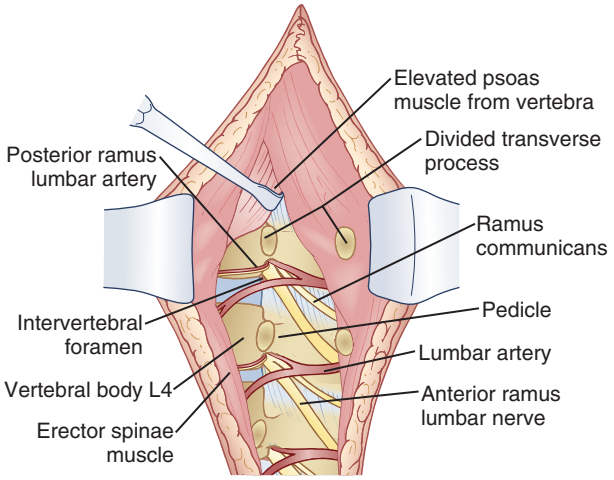

FIG. 20.21 Lumbar vertebrae as viewed from the posterolateral approach. The dissection proceeds directly anterior to the stump of the transverse process, along the pedicle of the vertebral body in front. Note the lumbar segmental vessels draped over the waist or midportion of the vertebral bodies. By dissecting directly anterior to the pedicles, one can avoid these vessels as well as the lumbar nerves leaving the neural foramina below the pedicles.

periosteal elevator. The lumbar vessels lie on the waist or midportion of the vertebral body posterior to the psoas muscle and should be separated from the body during this portion of the dissection. They may be clamped and cauterized, if necessary. An opening may be made in the lateral aspect of the vertebral body anterior to the pedicle, using a curette or drill (Fig. 20.22). The lesion may be identified grossly at this time, but should be verified radiographically with a curette placed within the lesion. Through this approach, specimens may be obtained from the lateral, central, or anterior aspect of the vertebral body or pedicle. The lesion may be curetted, and small chips of cancellous bone graft may be installed to stimulate osteogenesis within a sterile defect. The wound is

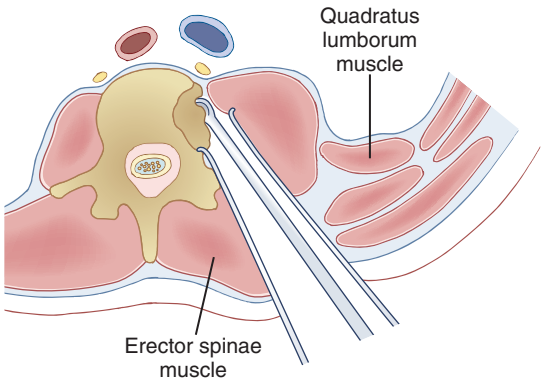

FIG. 20.22 Posterolateral approach to the lumbar vertebrae, lateral to the erector spinae muscle mass and behind the psoas. The transverse process is divided and retracted laterally with its musculotendinous insertions to gain access to the lateral aspect of the vertebral body.

copiously irrigated with saline and inspected for hemorrhage. The margins are allowed to fall together, and the lumbar fascia is closed with interrupted sutures. The skin is repaired, and the patient is nursed with some form of external spinal support, depending on the postoperative stability of the spine.

PEARLS

1. For lateral interbody fusions, it is often easier to adjust the table to get the perfect AP and lateral, and just have the C-arm rotate between 0 degrees and 90 degrees.
2. For lateral interbody fusions, take frequent images to ensure good position. Since you are using a smaller incision and thus see less, you must rely on imaging more to make sure that you are in the right position.
3. For lateral interbody fusions, study the MRI preoperatively to get an idea of where the nerves are. If the neuromonitor shows that the nerve is in the field, be prepared to convert to another form of interbody fusion.
4. To adequately decompress the nerve roots, the lateral recesses and intervertebral foramen must also be explored.

PITFALLS

1. For lateral interbody fusions, aggressive deployment of the retractor or repeated passes with the initial dilator may injure the nerve.
2. For lumbar decompressions, be careful about removing too much of the pars or facet joints to avoid iatrogenic instability.
3. When placing pedicle screws, if there is severe facet arthrosis, the lateral edge of the facet joint may be lateral to the true pedicle entry site.

KEY POINTS

1. Lateral interbody fusion is a good technique for correction of degenerative scoliosis, multilevel fusions, or adjacent segment degeneration. This can be done in a minimally invasive fashion that will improve recovery while maximizing results.
2. Since the lateral approach to the spine requires traversing the psoas, neuromonitoring is required to decrease the risk of nerve injury. Also, since the incision is smaller and less tissue dissection is done, there is a greater reliance on imaging.
3. The posterior approach to the lumbar spine is commonly used for microdiscectomies and lumbar decompressions.

4. The key to intracanal anatomy is the pedicle. The disc space is just cephalad to the pedicle, and the intervertebral foramen above the pedicle accommodates the exiting nerve root. The traversing nerve root lies just medial to the pedicle and exits the intervertebral foramen caudally.
5. The posterolateral approach provides direct access to the transverse processes and the mammillary processes of the facets through a longitudinal paraspinal incision, retracting the erector spinae muscles medially. This is a muscle-splitting approach and is the basis for minimally invasive transforaminal lumbar interbody fusions.

Steven R. Garfin

History

A variety of approaches to the interbody space exist to surgically manage pathologies of the lumbar spine.[1] The advantage of interbody fusions over posterolateral fusions are superiority in fusion rates as well as segmental coronal and sagittal correction.[2–4] Open anterolateral thoracolumbar approaches have been associated with vascular/bowel injury, abdominal hernia, ileus, and retrograde ejaculation.[5] However, the minimally invasive lateral retroperitoneal transpsoas approach has minimized these approach-related complications.[6,7] Open posterior approaches are associated with significant infection rates, blood loss, operative time, length of hospital stay, prolonged recovery, and delayed return to work due to procedural morbidity.[8]

Following instrumentation advances in visualization, lighting technology, and specialized surgical instruments fit for smaller incisions, minimally invasive surgery (MIS) became progressively more popular. After Obenchain et al. described a laparoscopic approach to anterior lumbar interbody fusion (ALIF) in 1991, MIS techniques to the spine began to rapidly evolve.[6,9] Pimenta has been given credit for being the creator of the minimally invasive lateral retroperitoneal transpsoas approach for lateral lumbar interbody fusions (LLIFs) in 2001.[6] However, Harmon described the approach in 1963.[10,11] MIS approaches such as LLIFs were developed for several reasons, including the ability to meet increasing patient demands and expectations for shorter hospital stays, earlier return to work, improved cosmesis, and decreased postoperative pain.[12–14] Last, LLIFs can be used for any condition that requires access to the interbody space from the mid to upper thoracic spine (e.g., T6, occasionally T5) through L4–L5. The lateral approach is possibly best suited for levels L2 to L4 due to anatomic considerations (the 12th rib and iliac crest).

Indications

Absolute indication for interbody fusion (ALIF, posterior lumbar interbody fusion [PLIF], transforaminal lumbar interbody fusion [TLIF], LLIF) is the treatment of pseudarthrosis.[12,15–17] Relative indications are foraminal height loss, coronal tilt/lateral-listhesis, flatback, and long adult thoracolumbar fusions.[12,15–17] Interbody fusions provide superior fusion rates over posterolateral fusions due to the mechanical and biologic advantage of the interbody space.[18–24] The interbody space is under compression and load sharing while having a large surface area.[18–24] However, the posterolateral space is under tension, has muscle creep, and has limited surface area.[18–24] Therefore, interbody fusion is indicated for pseudarthrosis following posterolateral fusion. Furthermore, multilevel posterolateral lumbar fusions have significantly high pseudarthrosis rates compared to interbody fusions.[25,26] Therefore, multilevel fusions have a relative indication for interbody fusion.

Advantages

LLIF and ALIF have superior fusion rates over TLIF due to mechanical and biologic factors: a more thorough discectomy and large surface area of graft extending to the apophyseal ring bilaterally.[18–24] In regard to foraminal height restoration and indirect decompression, ALIF, TLIF, and LLIF provide significant height restoration compared to posterolateral fusion, with LLIF and ALIF providing superior height restoration.[27–35] In regard to coronal tilt and lateral-listhesis, LLIF and TLIF are superior to ALIF and posterolateral fusions.[36–41] In regard to lumbar lordosis, ALIF and LLIF are superior to TLIF.[36,42,43] In regard to morbidity, ALIF and LLIF provide shorter operative time, decreased blood loss, shorter length of stay, and shorter time to return to work compared to open TLIF.[12,44,45] Furthermore, LLIFs minimize ileus-related issues compared to ALIF.[41,46-48] Last, LLIF allows for the option of an anterior column reconstruction or release (ACR), which can achieve similar lordosis correction as pedicle subtraction osteotomy.[49,50] One caveat is that ACRs require a mobile disc and are not applicable for fixed sagittal imbalance.

Contraindications

L5–S1 interspace is a relative contraindication to LLIF since the iliac wing precludes access to the disc space. L4–L5 may

also occasionally be obstructed by the iliac crest and a lumbarized sacrum has been described as a relative contraindication to this approach.[51] The more caudal levels carry a higher risk of injury to iliac vasculature and lumbar plexus because the lumbar plexus begins to course more anteriorly and the iliac vasculature more laterally.[41] In most cases, access to L5–S1 is limited by a high lateral ilium, anterior course of the neural elements over the lateral disc at that level, and/or the vasculature. Uncommonly, L5–S1 may be approached when the intercrestal line transects the mid to lower L5 body or the L5–S1 disc. Rostrally, the 12th rib may obstruct access from T12 to L2, which may require rib excision or manipulation.

Other contraindications to LLIF include bilateral retroperitoneal scarring from prior approaches (e.g., nephrectomy, retroperitoneal abscess and subsequent scarring), high-grade spondylolisthesis, and pregnancy.[47,52,53] In high-grade spondylolisthesis, the more anterior exiting nerve root is horizontalized and creates difficulty in the placement of even the smallest interbody graft.

LLIF may also be potentially contraindicated if direct decompression is required, such as with congenital stenosis, large posterior osteophytes, severe facet hypertrophy with lateral recess stenosis, sequestered disc, and radiculopathy that persists in flexion.[27]

Special consideration should be taken with stand-alone LLIF without posterior instrumentation since lateral fixation alone may not provide sufficient stabilization.[54] Stand-alone LLIF may be contraindicated at levels under high biomechanical stress such as isthmic spondylolisthesis, osteoporosis, or adjacent fusion.[54] Levels at the apex of deformity or associated pars fracture may require posterior instrumentation.[54]

Technique

LLIF is a lateral approach to the intervertebral disc space and/or vertebral body through a less invasive (or minimally invasive), retroperitoneal-transpsoas approach. The patient is positioned in the lateral decubitus position, typically left side up, with axillary roll in place and moderate-sized "sticky" rolls for anterior and posterior stabilization (Fig. 21.1). Patients are taped carefully; at times, the table may be bent to level the iliac crest away from the disc space. Orthogonal, anteroposterior, and then lateral fluoroscopic images are taken (Fig. 21.2). The vertebral bodies and disc spaces are marked superficially on the skin under fluoroscopy to determine the appropriate direct lateral incision. A second, posterolateral, 1.5- to 2.0-cm incision is made just above the pelvis within one fingerbreadth length from the direct lateral incision (Fig. 21.3). The trajectory of this posterolateral incision is lateral to the paraspinal muscles and medial to the oblique muscles in an avascular plane to enter the retroperitoneal space (see Fig. 21.3). The posterolateral incision allows the surgeon to enter the retroperitoneal space safely from a posterior approach by starting behind the transverse process and marching anteriorly to the psoas (see Fig. 21.3). The purpose of this incision is to avoid entering into the peritoneum when going from the direct lateral approach, thus preventing an inadvertent bowel injury. Once your finger is on the psoas, bring the index finger to the deep surface of the oblique muscles to determine the safe trajectory of the direct lateral approach (Fig. 21.4). With the lateral skin incision marking, center it over where you palpate your finger in the retroperitoneal space. Develop the lateral approach dissection to the external oblique muscle. Again, check the trajectory through the oblique muscles by bringing your finger in the retroperitoneal space to the psoas;

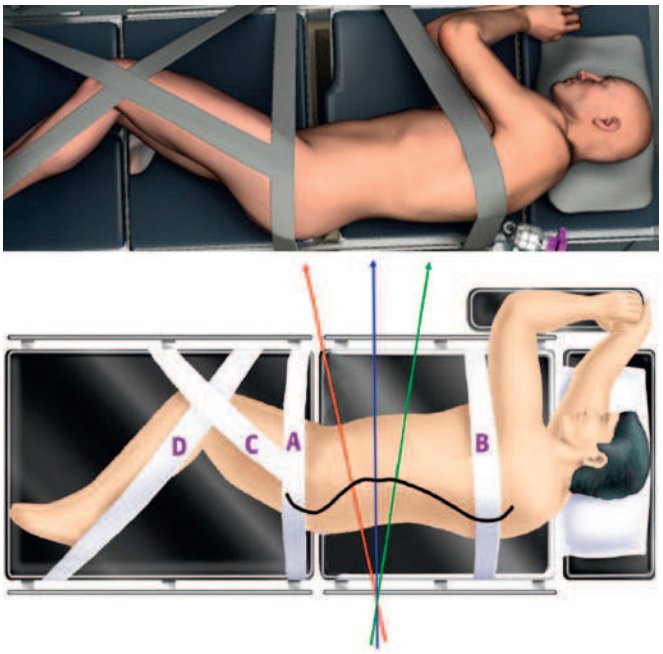

FIG. 21.1 Lateral decubitus positioning for lateral lumbar interbody fusion to minimize upper and lower extremity neurapraxia and proper taping technique of the iliac crest *(A)*, chest *(B)*, greater trochanter *(C)*, and leg *(D)* to secure the patient to the operating room bed.

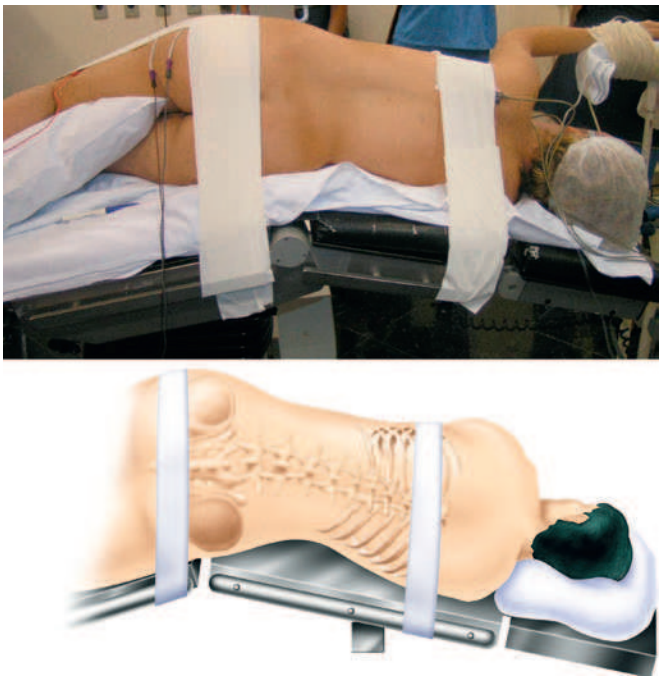

FIG. 21.2 Breaking of the operating room bed to position the iliac crest away for L4–L5 access and even L5–S1 with angled instruments.

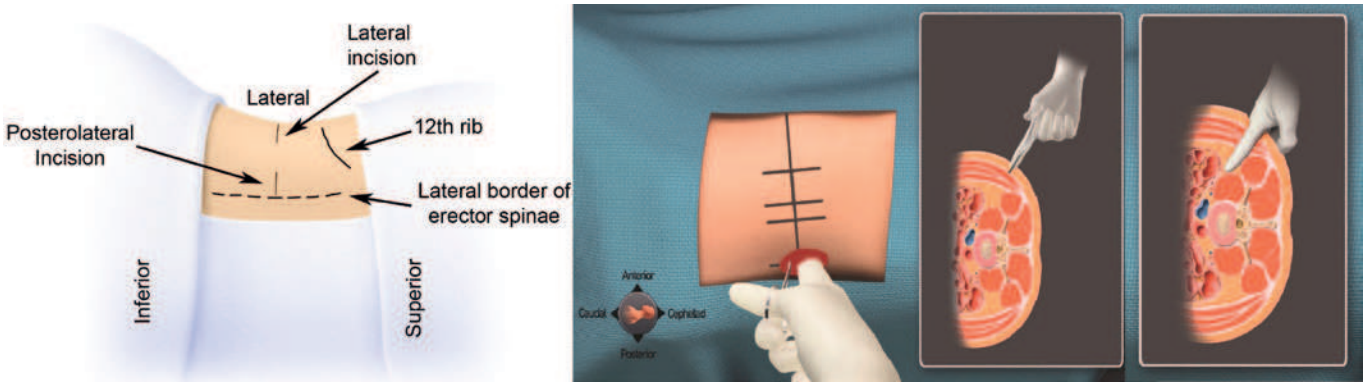

FIG. 21.3 The posterolateral incision allows for a safe trajectory with the direct lateral approach through the retroperitoneal space to prevent bowel injury.

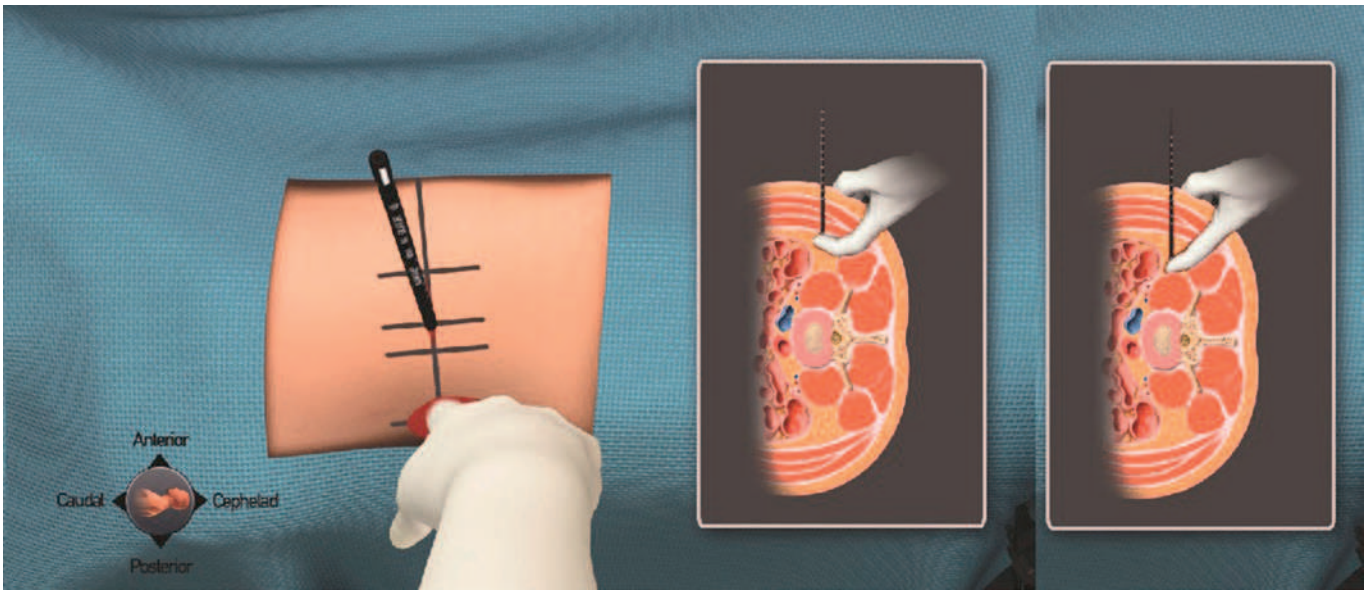

FIG. 21.4 From the posterolateral incision, palpate the psoas and bring the index finger to the undersurface of the abdominal wall to guide the trajectory of the initial dilator safely away from the bowel.

then, go directly vertical from there to the undersurface of the oblique muscle (see Fig. 21.4). Allow your finger to sweep the retroperitoneal fat anteriorly for a safer corridor. Blunt dissection through the oblique muscles and transverse abdominal fascia is made with two Kocher clamps at the same time. The Kocher clamps spread in opposite directions of each other to develop the plane through the muscles in line with their fibers to avoid segmental innervation disruption of the muscles and subsequent pseudohernia. Through this passage hole, place the first dilator (see Fig. 21.4). Let the finger from the posterolateral incision localize the midpoint of the psoas and feel the peak of the disc space (Fig. 21.5). Dock the dilator on this spot and obtain a lateral radiograph to determine that you are at the correct level and centered on the posterior 40% of the disc space (Fig. 21.6). Now, stimulate the dilator and rotate it in all directions to determine proximity of the lumbar plexus (Fig. 21.7). Pass a guidewire through the dilator to anchor the dilator to the disc space (Fig. 21.8). Place larger dilators sequentially. With each dilator, stimulate in all directions to determine the proximity of the lumbar plexus (Fig. 21.9).[6] Slide the retractor

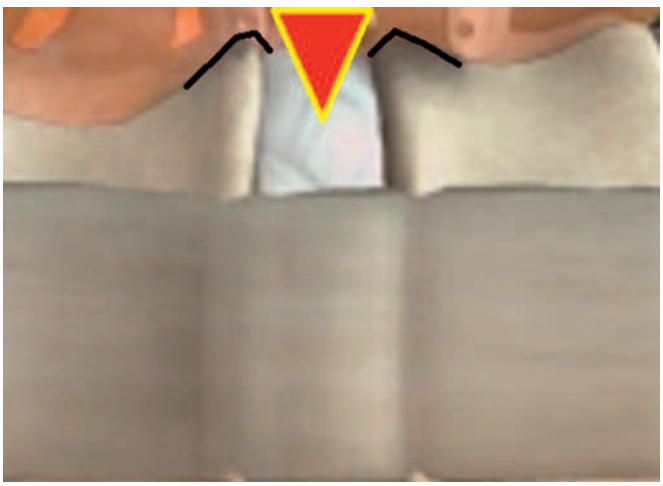

FIG. 21.5 On palpation, the disc space is the peak compared to the valley of the vertebral body.

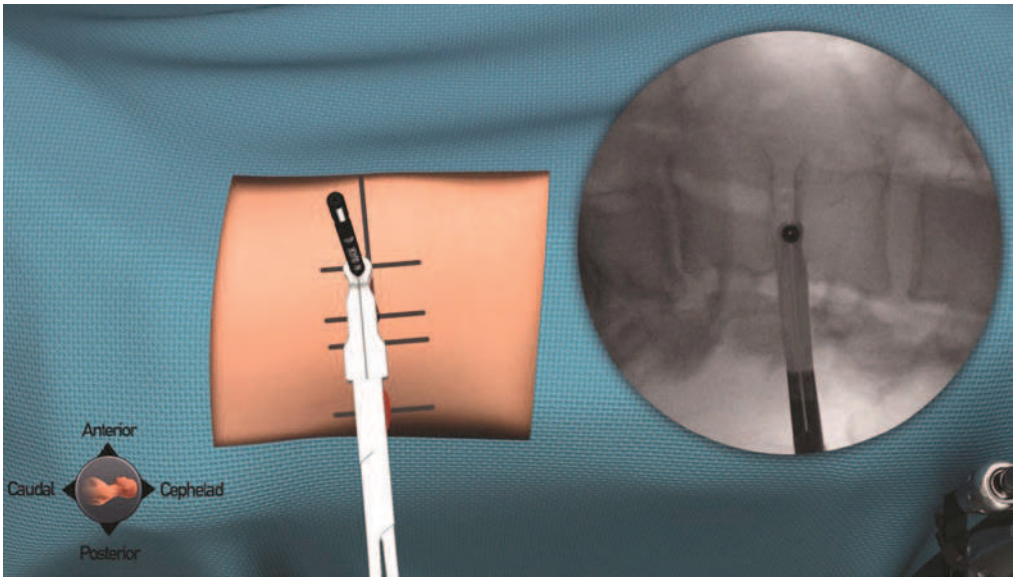

FIG. 21.6 Dock the dilator on the posterior 40% of the disc space in the lateral plane to get access to the anterior 60% of the disc space.

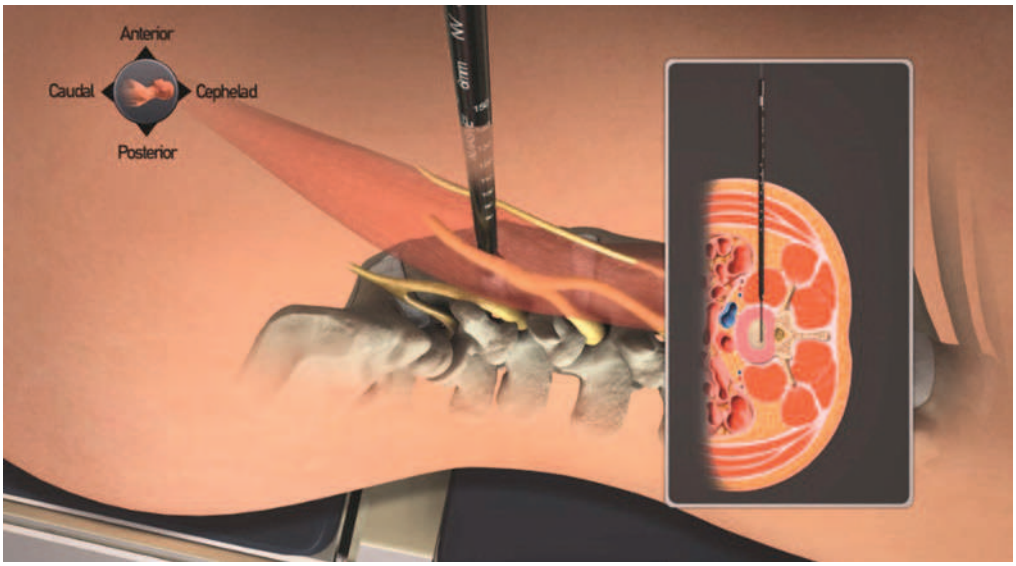
FIG. 21.7 Rotate the dilator 360 degrees while stimulating to ensure that the lumbar plexus is a safe distance from the dilator in all directions.

over the final dilator and obtain an anteroposterior radiograph to determine whether the retractor is centered over the disc with regard to cranial-caudal orientation (Fig. 21.10). Open the anteroposterior retractor blades, which will translate the anterior blade anteriorly toward the anterior longitudinal ligament to give access to the anterior 60% of the disc space (Fig. 21.11). Pivot the up-down retractor blades, which will slide the top and bottom blades cranially and caudally over the disc space and lateral osteophytes, respectively, for complete access to the disc (Fig. 21.12). Turn on the light source. Obtain an anteroposterior radiograph to establish that the up-down blades have passed the osteophytic lateral edges of the vertebral body, above and below the disc space, therefore avoiding inadvertent endplate fractures (see Fig. 21.10). At this point, it is optional to pass the shim into the disc to anchor the retractor firmly into the disc space (Fig. 21.13). Remove the guidewire. It is recommended at this point to take the nerve probe to find the lumbar plexus and determine if the anterior and posterior blades are a safe distance from it. Perform the annulotomy. Through the annulotomy, place the Cobb retractor directed toward the inferior endplate to release the anulus from it (Fig. 21.14). Perform this under lateral fluoroscopy to avoid injury to the endplate. Take the Cobb retractor to the contralateral side and rotate it 90 degrees to distract the contralateral anulus (see Fig. 21.14). Perform the same task with the Cobb retractor angled toward the superior endplate. The disc material is then removed via a combination of blunt dilators, shavers, ring curette, and pituitary (Fig. 21.15). Place a trial cage and obtain anteroposterior and lateral images to determine the correct size for lordosis, coronal tilt, and lateral-listhesis correction,



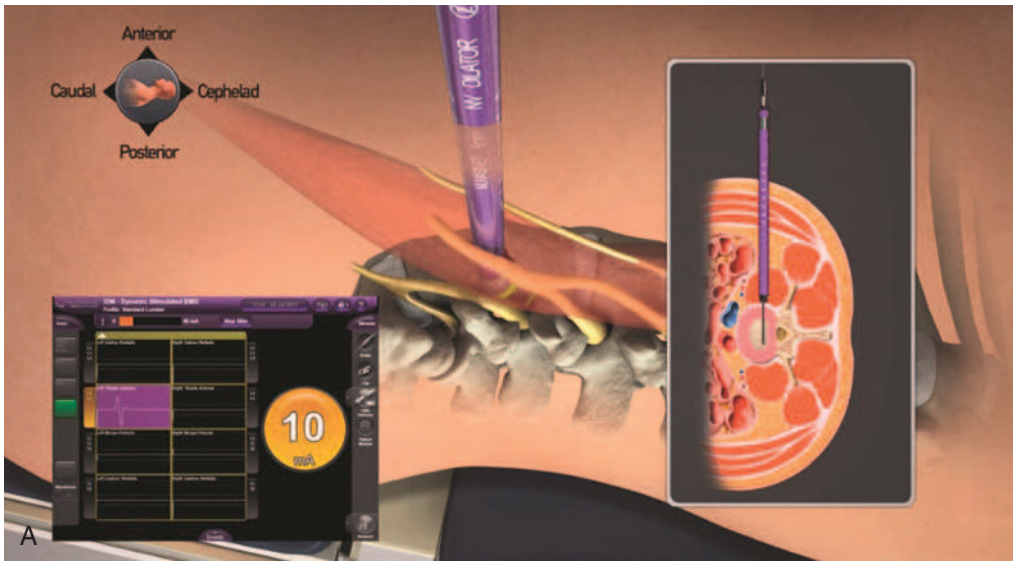


FIG. 21.8 Anchor the dilator to the disc space with a guide wire when the position has been determined as safe and adequate for the discectomy.

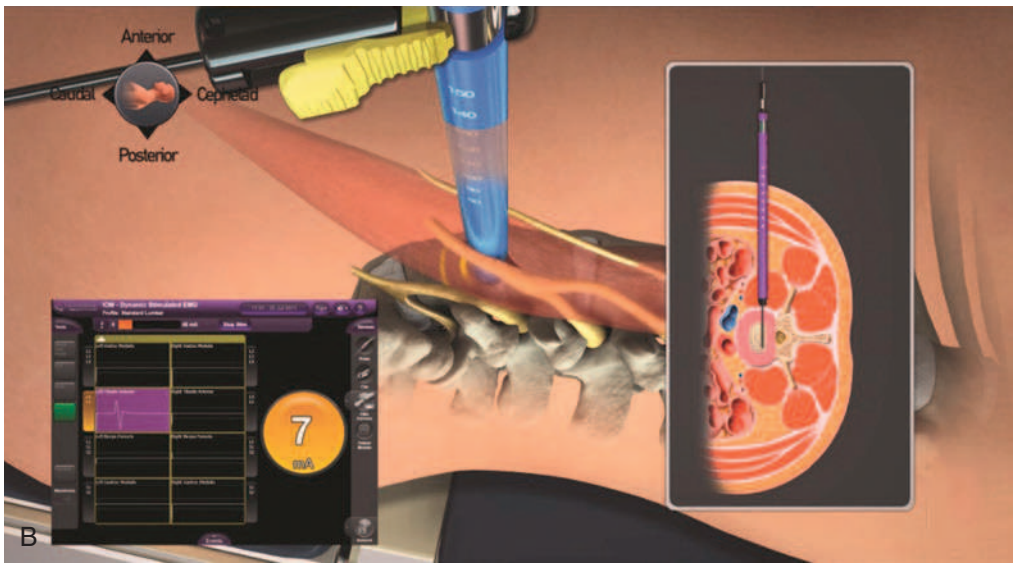

FIG. 21.9 Sequentially dilate to larger sizes while stimulating each time to confirm safety of the corridor to the disc space.

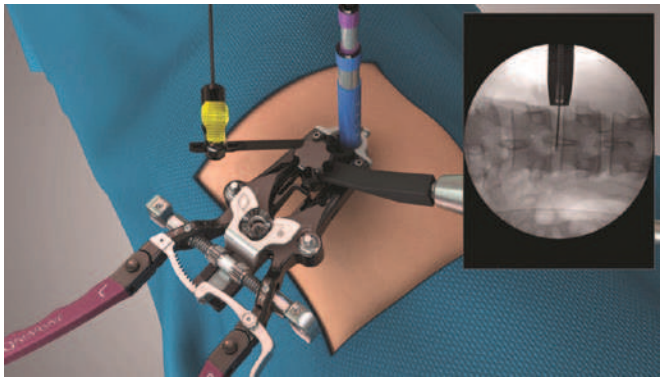

FIG. 21.10 After sliding the retractor over the final dilator, obtain a radiograph to confirm that the cranial and caudal blades are centered over the disc space to prevent inadvertent entry and/or fracture of the endplates.

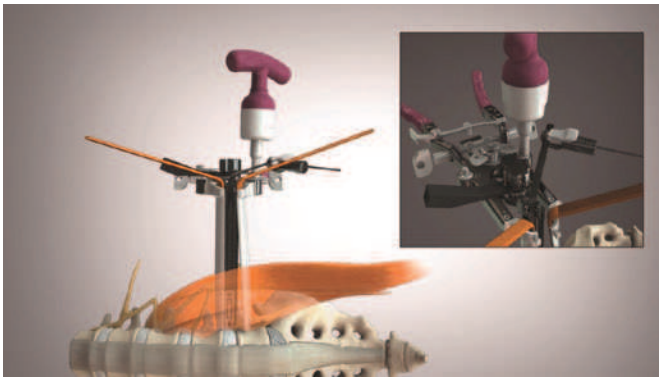

FIG. 21.12 The cranial and caudal retractor blades can be pivoted to get over the lateral osteophytes overlying the disc space.

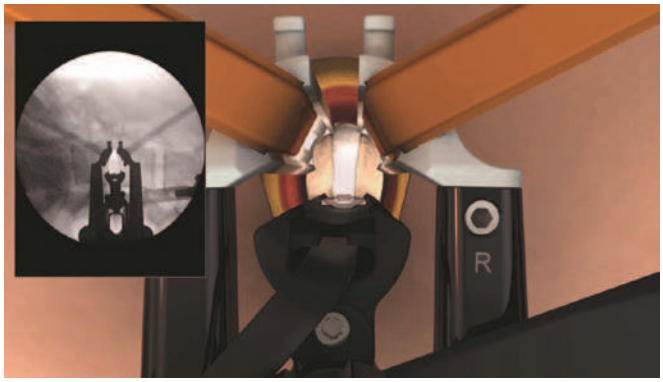

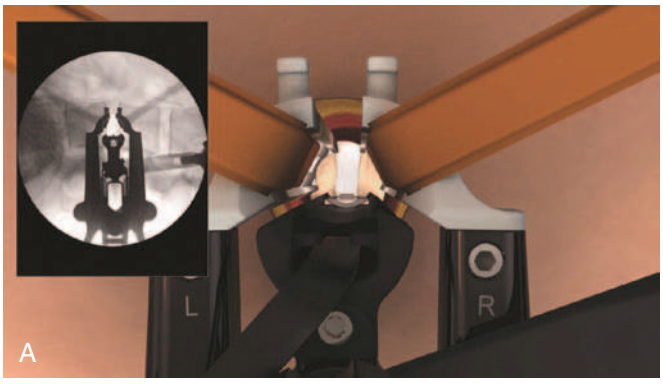

FIG. 21.11 Open the retractor anteriorly to give access to the disc space.

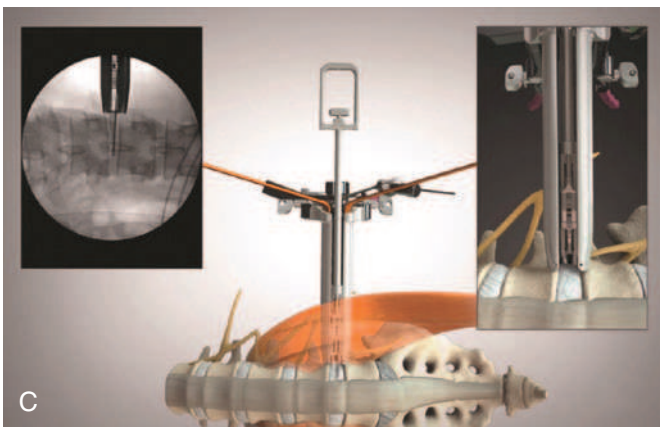

FIG. 21.13 Placement of the shim anchors the retractor to the disc space. (A) Shim in the lateral view. (B) Shim blade inserter. (C) Removal of wire in the disc space after anchoring of the shim into the disc to further stabilize the retractor to the disc space.

as well as foraminal height restoration (Fig. 21.16). Place the final graft, packed with the surgeon's preferred biologic for bone growth, with the assistance of shims to prevent endplate strain and/or fracture (Fig. 21.17).

Anatomic Considerations

Lumbar Plexus

A thorough understanding of the regional anatomy is essential to avoid complications with the lateral approach. The close proximity of the lumbar plexus poses a risk for permanent and disabling nerve injury, manifested by weakness or radiculopathy. Meticulous examination of the preoperative magnetic resonance imaging (MRI) for relation of the lumbar plexus to the disc space, use of real-time neuromonitoring and biplanar fluoroscopy, and careful dissection of the iliopsoas can aid in a safe approach.

Multiple studies have attempted to map out the relationship of the lumbar plexus within the psoas and identify safe corridors or "safe zones" for accessing each disc space to avoid injury to the plexus and the genitofemoral nerve.[55] An early cadaveric study by Moro et al. examined the lumbar plexus through axial cuts of the lumbar spine and determined the safe zone for the lateral retroperitoneal approach, excluding the genitofemoral nerve, for L4–L5 and above.[55] A cadaveric study

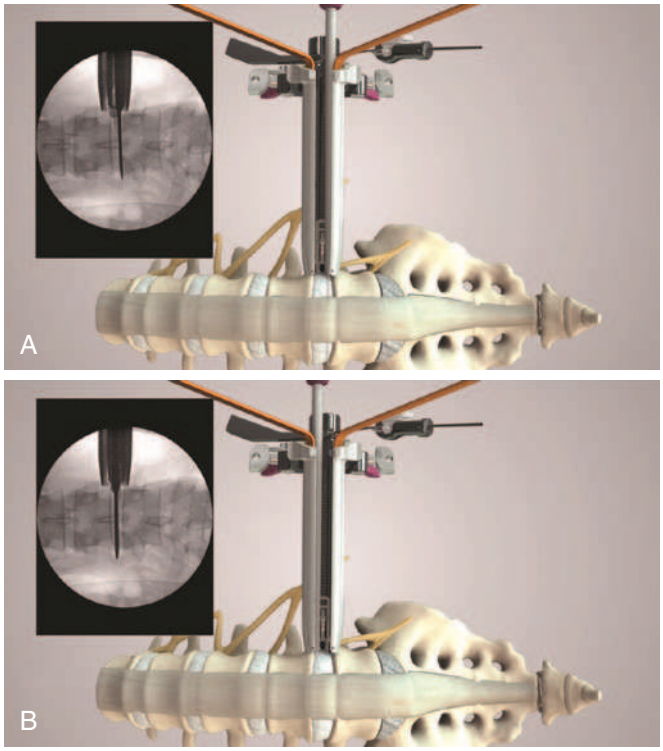

FIG. 21.14 Release the anulus from the endplate with a Cobb retractor and advance through the contralateral anulus in a controlled fashion to release it while avoiding a contralateral plexus injury.

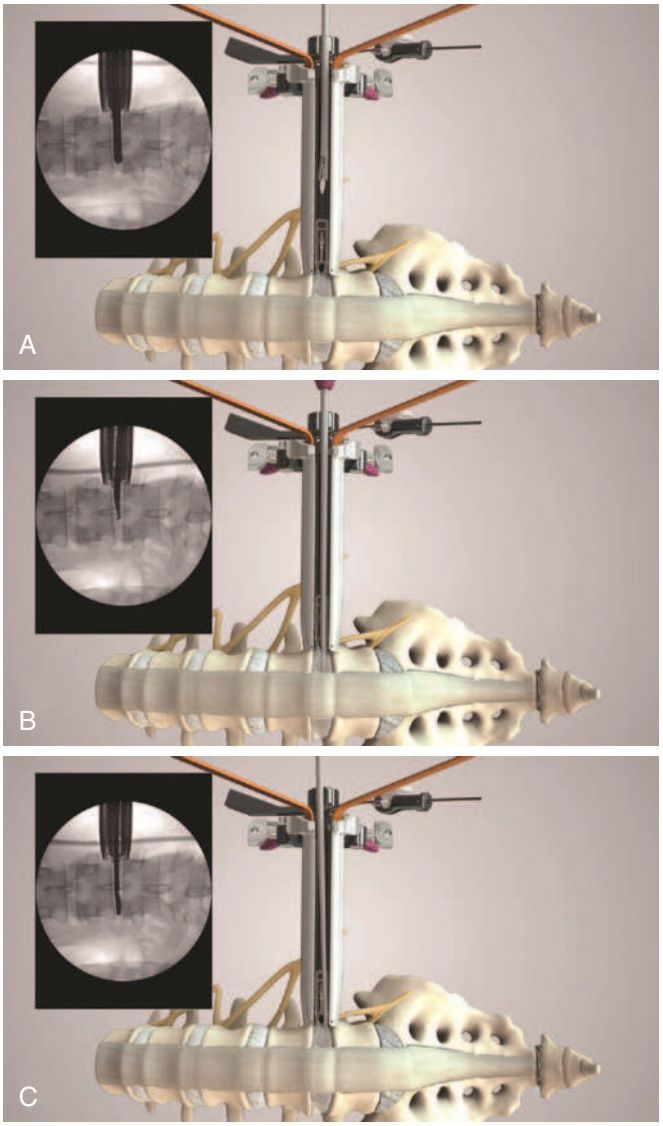

FIG. 21.15 Complete a thorough discectomy and endplate preparation to enhance the biologic environment for a fusion.

by Benglis et al. demonstrated that the lumbar plexus lies on the dorsal surface of the psoas at a cleft between transverse process and vertebral body and there is a general trend toward progressive dorsal to ventral migration as the psoas descends from L1 to L5, with the L4–L5 disc space being most vulnerable to nerve injury.[56] Park et al. showed the transpsoas exiting nerve roots to be a relatively safe distance from the center of the intervertebral disc space with the exception of a few anatomic variants.[57]

In a 2010 cadaveric study, Uribe et al.[55] further examined the relationship of the lumbar plexus to the disc space, in which the authors separated the vertebral body into four zones on the sagittal plane, each representing a quarter of the distance across the body (Fig. 21.18).[58] In their anatomic study, the safe zone for levels L1–L2, L2–L3, and L3–L4 were at the middle posterior quarter of the vertebral body (zone III) and for L4–L5 at the midpoint of the vertebral body (junction of zones II and III).[55,58] The genitofemoral nerve was found to be at risk at zone II when it moves ventrally at L2–L3 and then ventrally at zone I as it migrates caudally.[55]

Although safe zones are useful guidelines, heterogeneity exists in the relationship between the lumbar plexus and the psoas. Meticulous preoperative planning, judicious dissection without excessive pressure or manipulation of the psoas, direct visualization of the surgical field, and the use of electrophysiologic monitoring are essential for success.

Immediately after incision, caution should be taken when splitting the lateral abdominal musculature to avoid injury to the L1 branches of the iliohypogastric and ilioinguinal nerves (encountered between the internal and external obliques) as

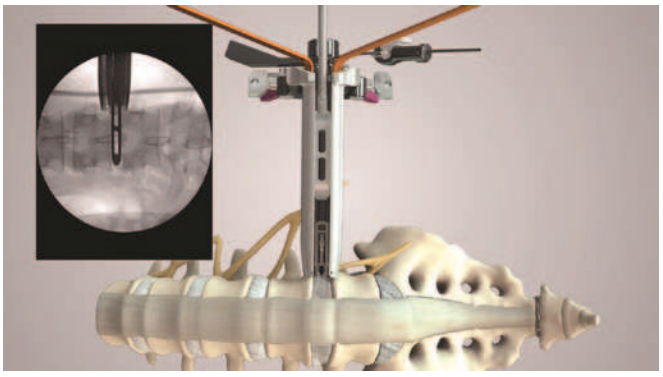

FIG. 21.16 Trial for the proper graft height and lordotic angle to optimize lordosis and/or coronal correction while providing enough foraminal height for an indirect decompression.

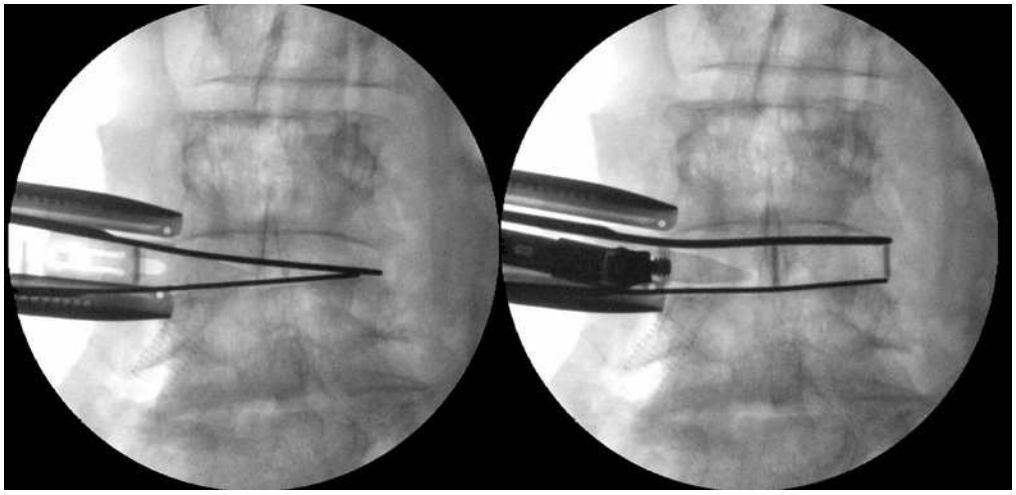

FIG. 21.17 Impact the final graft over shims to provide smooth translation of the graft to the contralateral side while preventing strain and/or fracture of the endplates.

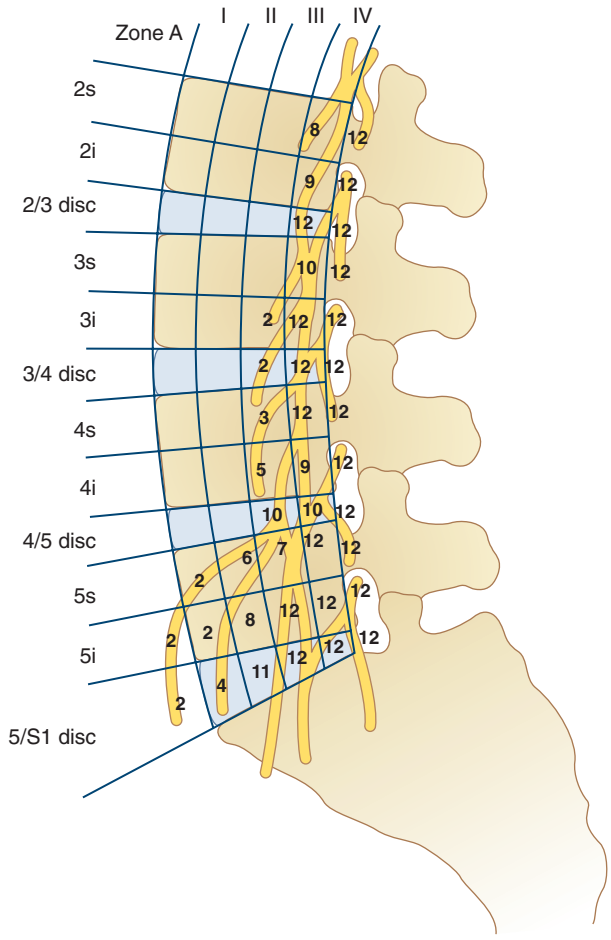

FIG. 21.18 Safe zone and the four quadrants of the disc space. (From Arnold PM, Anderson KK, McGuire RA Jr. The lateral transpsoas approach to the lumbar and thoracic spine: a review. *Surg Neurol Int.* 2012;3:S198–S215.)

well as for "pseudohernia" prevention related to denervation of the oblique muscles and resultant paresis of the abdominal wall as described by Dakwar et al.[59] After development of the retroperitoneal plane by finger dissection, careful dissection of the iliopsoas must be performed to avoid injury to the muscle and its intrinsic motor branches with dilators or retractor positioning/tension. Additionally, the amount and duration of retraction used and operative time per level should be taken into consideration in order to decrease the likelihood of traction injury to nerves.[60]

Advanced imaging should be evaluated for neurovascular anatomy and its course with respect to the psoas and operative level. Use of axial MRI (Fig. 21.19) to evaluate the size of the psoas, rotation of the vertebral bodies, neurovascular anatomy, and how the lumbosacral plexus migrates within the psoas from proximal to distal is especially helpful in surgical planning.[12,61] A large psoas may present challenges to safe transpsoas entry, as can the location of the 11th or 12th rib during access to the upper lumbar spine, alerting the surgeon to the need for rib resection or use of an intercostal approach.

Our preference is to minimize "breaking" of the table to a degree that is necessary to access the operative level(s). The tension of the psoas is assessed by palpation in every procedure to minimize excessive traction of the lumbar plexus. If breaking the table is required for lateral disc space access, we have found that "unbreaking" the table after only the inner dilator and wire are in can substantially decrease psoas tension while maintaining safe access with little anatomic distortion.

Real-time, directionally stimulated neuromonitoring is employed intraoperatively to determine the proximity of the exiting and traversing neural elements. The genitofemoral nerve, most commonly seen at the L3–L4 lumbar level within the more superficial dissection plane, should be directly visualized and requires special attention because it is primarily a sensory nerve and not detected by triggered or free-run electromyography.[60]

Vascular Anatomy

The retroperitoneal space houses the great vessels, including the aorta, inferior vena cava, and common iliacs. Vascular anatomy should be well visualized and carefully evaluated on preoperative MRI. Regev et al. found that the highest risk of injury to the retroperitoneal vessels was at L4–L5 due to the

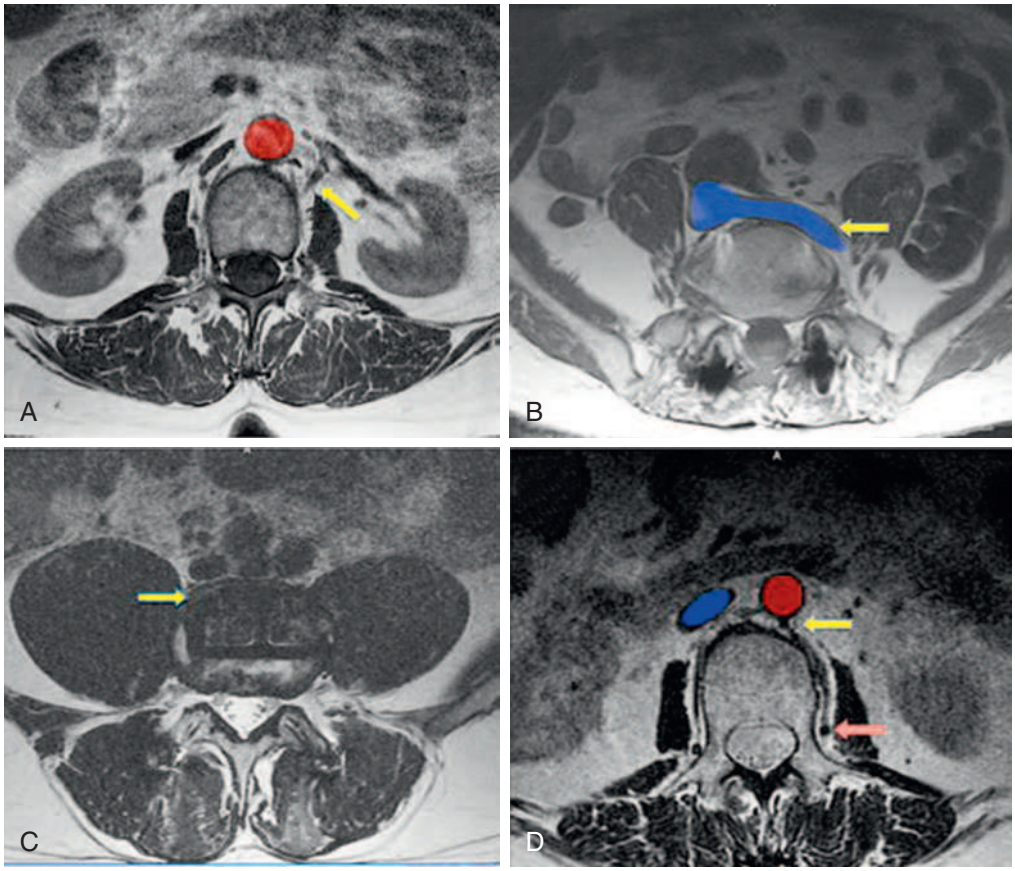

FIG. 21.19 (A) Axial T1 magnetic resonance image (MRI) of the lumbar spine showing anastomosis between the renal and segmental vessels in close proximity to the L1–L2 disc space (*arrow*). *Red area*, abdominal aorta. (B) Axial T1-weighted MRI of the lumbar spine at the L5 level showing the left common iliac vein. *Blue area*, inferior vena cava. *Yellow arrow*, left common iliac vein. (C) Axial T2-weighted MRI of the lumbar spine at the L3–L4 level. *Yellow arrow*, lateral lumbar interbody fusion cage. Note the close proximity of the cage and the great vessels. (D) Axial T2-weighted MRI of the lumbar spine. *Red area*, abdominal aorta. *Blue area*, inferior vena cava. *Yellow arrow*, lumbar arteries branching off the aorta. *Red arrow*, proximal vessel of lumbar arteries anastomosis. (From Alkadhim M, Zoccali C, Abbasifard S, et al. The surgical vascular anatomy of the minimally invasive lateral lumbar interbody approach: a cadaveric and radiographic analysis. *Eur Spine J.* 2015;24[Suppl 7]:906–911.)

more posterior location of the retroperitoneal vessels.[62] Furthermore, the risk of vasculature injury is further increased with rotatory deformities.[62] Rare contralateral injuries to vasculature can also occur; therefore, particular care should be taken with the use of instruments when dissecting across the disc space and when inserting the interbody graft.[63,64]

High Iliac Crest/Lumbosacral Junction

During preoperative evaluation, standing anteroposterior lumbar radiographs should be scrutinized for access to the operative level, with particular attention to the height of the lateral iliac crest and angle required for accessing L4–L5. Positioning the patient in a true lateral decubitus position with lateral bending (see Fig. 21.1) of the torso can increase the distance between the iliac crest and ribs. However, this must be weighed against the increased tension and traction placed on the psoas and lumbar plexus.[60,65] In most cases, access to L5–S1 is limited by a high lateral ilium, anterior course of the neural elements pulled directly across the lateral disc, and/or the vasculature, precluding safe access. Uncommonly, L5–S1 may be approached when the intercrestal line transects the mid to lower L5 body or the L5–S1 disc space. Angled instruments are also an option to improve access.

Scoliosis

Special consideration must be made in scoliosis patients. Identify abnormal displacement of vascular structures with severe rotational deformity and approaching from the convex side because the approach angle is more rostral. Preoperative planning with identifying the lumbar plexus, iliac vein and artery, aorta, and inferior vena cava on MRI is important to determine which side is safer to approach (see Fig. 21.19).[56,66,67]

Thoracolumbar Junction

Rostrally, the 12th rib may obstruct access from T12 to L2, which may require excision or manipulation. Partial rib resection can be commonly performed in thoracolumbar approaches

with little morbidity. Another technique to improve access is to place a bump or roll under the contralateral flank to help increase the distance between the 12th rib and iliac crest (see Fig. 21.2).[6]

A retrodiaphragm approach can be done by partial rib resection and using the rib posteriorly as a guide to the disc space and as a plane to retract the diaphragm anteriorly. Care should be taken not to injure the diaphragm. Sometimes a transdiaphragm approach is required for the thoracolumbar junction since the diaphragm cannot be mobilized sufficiently to gain access to the disc. With significant diaphragm dissection, the diaphragm should be repaired prior to closure.

Thoracic Spine

Partial rib resection can be commonly performed in anterolateral thoracic approaches with little morbidity. Several other techniques to minimize rib resection or preserve this anatomy have been utilized, including performing LLIF in between ribs. If that technique is performed, expansion of the lateral access retractor should be minimized to prevent prolonged compression of the neural elements on the rib underside for risk of postoperative radicular/rib pain.

Complications

Although the minimally invasive nature of LLIF avoids many serious approach-related risks of the anterior and posterior techniques, there exists a significant risk of neurologic injury. The most common and well-documented complication is lumbar plexus nerve root injury from either direct compression, laceration, or traction while traversing the psoas or through prolonged retraction.[12,13,47,59,65,68,69] In the largest series of LLIF cases, Rodgers et al. reported a 0.66% incidence of transient hip flexor weakness that occurred only when approaching the L4–L5 level and a 6.2% overall complication rate.[12] These authors contend that approach-related complication rates of LLIF are lower than the traditional open approaches, including posterolateral lumbar fusion, PLIF, TLIF, and ALIF. However, it should be noted that these rates are significantly lower than other smaller series reported in the literature. Moller et al. found in their series of 53 patients that 36% of patients experienced subjective hip flexor weakness, 23% experienced thigh numbness, and 25% experienced thigh pain.[13] Hip flexion weakness resolved in 84% at 6 months, with most patients returning to baseline at 8 weeks; 69% and 75% of patients with thigh numbness and pain, respectively, returned to baseline at 6 months and with many reporting improvement at 8 weeks. Cummock et al. observed thigh pain and numbness in 39% and 42.4% of 59 patients, respectively, and nearly half resolved at 3 months and 90% resolved at 1 year.[70] Pumberger et al. reviewed 235 patients who underwent LLIF and found sensory deficits in 1.6% of patients, psoas motor deficit in 1.6%, and lumbar plexus deficit in 2.9% at 12 months follow-up.[71]

Transient hip flexor weakness and pain that occurs in the absence of sensory deficits is thought to be due to splitting of the psoas muscle fibers rather than a neurapraxia. Weakness is typically transient and resolves within 3 months.[46] Longer duration of retraction has been suggested to predict postoperative weakness.[46] If a nerve injury is suspected, electrodiagnostic studies have been recommended at 6 weeks and 3 months postoperatively. If no clinical recovery is observed, some surgeons perform a limited electromyographic test monthly over the subsequent 3 months to evaluate for reinnervation.[65]

Although rare, permanent or disabling nerve injury may occur. Knight et al. reported two cases of L4 nerve injury in their study of 58 patients.[69] The incidence appears to be higher in scoliosis patients, with Tormenti et al. reporting five of eight patients treated with LLIF for adult degenerative scoliosis suffering persistent sensory and motor radiculopathy.[37]

The incidence of lumbar plexus nerve root injuries varies widely, in part due to inconsistency in the literature regarding diagnosis and evaluation. Ahmadian et al. therefore developed a diagnostic standardization of and classification for postoperative nerve injuries seen with LLIFs that correspond to sensory dermatomal zones.[65]

The retroperitoneal nature of the approach also exposes thoracoabdominal structures to potential injury that can be significant. Reported complications include bowel perforation,[37,72] incisional hernias,[12,59] pleural effusions,[37] kidney lacerations,[47] retrocapsular hematoma,[73] abdominal wall paresis,[59,74] and pseudohernia.[59,74] Each case of bowel perforation required emergent exploratory laparotomy with resection of bowel. When operating in the thoracolumbar spine, the pleural space can be violated, leading to pleural effusion and requiring careful intraoperative evaluation to evaluate whether a chest tube is needed.

The most common implant-related complication is symptomatic graft subsidence, which can lead to pseudarthrosis, back and/or leg pain, adjacent vertebral body fractures, or neurologic complications. Rodgers et al. reported 3 cases of subsidence in 600 patients that required reoperation due to adjacent vertebra fracture, graft fracture, and screw penetration of the endplate.[12] Other authors have reported early subsidence with stand-alone LLIFs due to excessive motion that resolved after posterior instrumentation was performed.[27] Karikari et al. reported a 16.7% incidence of subsidence in a series of patients older than 70 years of age who underwent LLIF for degenerative conditions.[17] Excessive motion and osteoporotic bone are the common etiologies for graft subsidence, but "overstuffing" the interbody space and endplate perforation can be precursors to subsidence. Consideration for supplemental posterior instrumentation should be made that includes patient's bone mineral density. The risk of subsidence is theoretically lower with the use of wider LLIF cages with larger surface contact area and greater distribution of force throughout the apophyseal ring.[27]

Outcomes

The minimally invasive lateral approach for interbody fusion has shown promise in minimizing approach-related morbidity by minimizing surgical dissection and soft tissue

trauma with shorter operating room time, shorter hospital stay, and decreased blood loss while maintaining equivalent or improved clinical and radiographic outcomes compared to traditional open anterior or posterior approaches.[12–14]

In 2013, Ahmadian et al. reported in a series of 31 patients who underwent LLIF for grade I or grade II spondylolisthesis that there was significant reduction in anterolisthesis, with 27 of 31 achieving complete reduction of the spondylolisthesis.[65] At 6 months, all patients had clinical and radiographic evidence of fusion on computed tomography (CT) and plain radiographs as well as significant improvements in Oswestry Disability Index (ODI), visual analog scale (VAS), and Short Form-36 scores.

The lateral approach has been shown to be a feasible operative treatment for adjacent-segment degeneration. In a prospective series of 100 patients who underwent LLIF for adjacent-segment degeneration, Rodgers et al. reported significant improvement in VAS pain scores (from 8.6 to 2.8), low complication rate (9%), and evidence of radiographic and clinical fusion at 6 months.[47] The benefit of utilizing an alternative lateral approach avoids the technically challenging task and increased risk of complications with reoperation through the prior anterior or posterior scar.[46]

With obese patients, the lateral approach has been suggested to be a favorable alternative. In a comparative series of 313 obese and nonobese patients who underwent LLIF for degenerative conditions, Rodgers et al. found no greater incidence of complication.[75] This finding is not seen with traditional open anterior or posterior fusion approaches in which body habitus presents a technical challenge and has been shown to increase rates of infection and other complications.[76]

The use of LLIF for deformity correction in adult degenerative scoliosis (ADS) has been shown to result in lower complication rates, shorter operative times, and less blood loss with equal or better clinical and radiographic outcomes when compared to traditional open anterior or posterior approaches.[12,27,40,47,73,77,78] This is particularly relevant to the elderly patient population that suffers from ADS given that they frequently have coexisting osteoporosis and multiple comorbidities that put them at higher risk for pseudarthrosis, hardware failure, and other complications with multilevel deformity correction.[79,80] Complication rates of up to 66% have been reported.[81] Charosky et al. reported a 39% complication rate with 20% requiring reoperation in 306 patients undergoing primary ADS treatment by traditional anterior, posterior, or combined approaches.[82] Daubs et al. reported a 37% complication rate, with 20% major complications in patients over 60 years.[83] In a large prospective series of 107 patients who underwent LLIF for ADS, Phillips et al. demonstrated significant improvements in clinical and radiographic outcomes at 24 months with a lower incidence of complications (24%, with half being minor complications).[47] The lower rate is likely attributed to the lateral approach avoiding mobilization of abdominal viscera and great vessels or dissection of the posterior musculature.[47] Perioperative morbidity is also decreased by the minimally invasive nature of the lateral approach, which minimizes surgical morbidity and allows for early ambulation and shorter hospital stay.[12–14] Although minor complications of hip flexor weakness and thigh pain have been reported, most are transient and resolved by 6 months.[13]

Coronal deformity correction achieved with LLIF for ADS has been reported to be similar to that achieved by traditional approaches. Wang and Mummaneni reported a mean coronal correction of 20 degrees (63%) in 23 patients with a solid fusion at all interbody levels.[39] Anand et al.[73] reported a 15-degree correction (68%) in 28 patients, all of whom fused and maintained their correction at 12 months. Acosta et al.[13] reported an 11.7-degree correction (55%) in eight patients. Tormenti et al.[37] reported a 70% curve correction in eight patients. Phillips et al.[46] reported a 7.4-degree (35%) correction in 107 patients, with greater correction seen with posterior instrumentation. In comparison, in a systematic review of 49 publications on ADS deformity correction, mean postoperative coronal correction was 40.7%.[84] Anand et al. also reported significant improvements in VAS and ODI scores with no major complications.[73] Uribe et al. demonstrated that deformity corrections in a series of 39 ADS patients were all maintained with ongoing improvement in VAS pain scores up to 3 years postoperatively.[49] Dakwar et al. reported that all 25 adult deformities in their series maintained correction at 2 years, achieved fusion on CT and plain radiographs, and experienced significant improvement in VAS and ODI scores with only minor complications.[85] Ozgur et al. reported excellent clinical and radiographic results equal to or superior to traditional approaches with no major complications in their 62 patients.[16] Wang and Mummaneni also encountered no intraoperative complications.[39] Pimenta et al. and Benglis et al. independently found significant deformity correction with significant mid- to long-term clinical outcomes in their individual series of ADS patients who underwent LLIF.[86,87]

The anterior column fusion rates achieved with LLIF are equivalent or greater than traditional approaches such as ALIF, for which 92% to 97% have evidence of fusion on CT at 12 months.[88] A 96% fusion rate by CT and over 90% patient response of "satisfied or very satisfied" was reported by Rodgers et al. at 12-month follow-up in a series of 66 patients who underwent LLIF of 88 levels.[89] Similarly, Ozgur et al. reported radiographic evidence of fusion after LLIF for degenerative disease in 91% of 62 patients with 113 levels, and significant improvement in VAS and ODI scores at 24 months.[16] This high rate of fusion is consistent with a low incidence of revisions for pseudarthrosis. Phillips et al.[46] observed a 2% rate of revision for pseudarthrosis, which is superior to rates of 0% to 19%[90-94] reported for anterior and/or posterior approaches.

Indications for the MIS lateral approach have expanded to the thoracolumbar junction, including corpectomy and reconstruction. Addressing anterior column pathology in the thoracic spine is technically challenging and a thoracotomy can lead to poor pulmonary function postoperatively, with major complications reported in up to 12% of patients.[95] Khan et al. followed a series of 25 patients who underwent an MIS lateral approach for corpectomy and observed shorter operative times, decreased blood loss, decreased use of blood products, shorter postoperative time to extubation, and significant pain relief compared to a standard open corpectomy.[96] The benefit

is attributed to the minimally invasive nature of the approach and the absence of prolonged lung deflation. Karikari et al.[17] reported a series of 22 patients who underwent LLIF for thoracolumbar disease, including degeneration, tumor, adjacent-segment disease, disc herniation, and infection. They observed that 95.5% of patients achieved a substantial clinical benefit and demonstrated evidence of fusion at 6 months postoperatively. Although deformity correction was less pronounced than with the traditional open thoracolumbar approach, no major complications occurred. The MIS lateral approach to the thoracolumbar spine may be a well-suited safe alternative for elderly patients or those with significant comorbidities, and in multiple other settings including trauma, infection, tumor, and corpectomies for canal decompression for a variety of pathologies.

In regard to costs, Lucio et al. performed a cost analysis for two-level LLIF and two-level PLIF for degenerative lumbar disease; they showed a cost saving of $2825.37 (10.4%) per patient in the early perioperative period with LLIF.[97] The costs were calculated from the index procedure, transfusions, reoperations, and residual events, which were defined by hospital readmissions, emergency department visits, postoperative rehabilitation, and additional diagnostics. These authors also reported shorter hospital stay and decreased blood loss in the LLIF group.

Summary

LLIF has evolved over decades into a safe and common procedure. LLIFs provide superior fusion rates compared to other fusion options. LLIFs provide indirect decompression of foraminal, lateral recess, and central stenosis. With osteoporosis, LLIF allows load sharing over a large footprint on the apophyseal ring and decreases osteoporotic-related hardware complications. Preoperative MRI evaluation is imperative to identify the neurovascular anatomy to prevent vascular and lumbar plexus injuries. LLIFs provide significant coronal and sagittal correction in ADS compared to traditional open procedures. Anterior column reconstruction through the lateral approach provides equivalent sagittal plane correction as pedicle subtraction osteotomy with significantly less blood loss. LLIFs meet the demand for earlier postoperative recovery and return to work. Lateral interbody fusions limit infection rates compared to open posterior fusions with the obese population. Last, minimally invasive lateral interbody fusion is cost-effective and provides health care savings compared to other lumbar fusion options.

22 CHAPTER Anatomy, Nonoperative Results, Preoperative Injections, and Prescriptions

Jeffrey L. Chen
Timothy J. Furnish
Mark S. Wallace

The literature for spinal injections is rife with small studies of limited quality. There are multiple difficulties with the research on invasive pain therapies. First has been a lack of funding for large-scale, high-quality, randomized controlled trials (RCTs). This is partially due to the fact that there are no device or pharmaceutical companies with a vested interest in funding research on these therapies. Second, pain is, by definition, a subjective experience. As with studies of therapies for psychological disorders, there is a significant and growing placebo effect in pain studies, which confounds the ability of studies to show a significant response over placebo.[1] Alternatively, the natural course for many patients with new-onset spinal pain from disc herniation or other causes is to improve. Injection therapies that do show improvement over time may, in part, reflect the natural healing process and overrepresent the effects of these interventions. Third, there is substantial variability in the way that trials of some of these therapies have been conducted. Some of the earlier trials of interlaminar and caudal epidural steroid injections were done before fluoroscopy and epidural contrast were routinely used. Comparing these blind injections to the current standard of practice is problematic. For many interventional pain procedures, the bulk of the studies performed have been observational, retrospective, or otherwise of limited quality. Last, many studies that purport to be placebo controlled have compared an active treatment to something less than clearly a sham treatment. For example, some studies have compared epidural steroids to steroids given via another route. Other studies have compared epidural injections to local anesthetic injections. There is some evidence that simply injecting saline or other solutions into the epidural space has a therapeutic effect.[2] Thus, the selection of a reasonable sham for double-blind trials has been problematic and even RCTs with epidural saline as a control may underestimate the effects of such interventions.

Anatomic Considerations in Spinal Pain

In order for a spinal structure to transmit painful impulses into the central nervous system (CNS), the structure must be innervated with nociceptors. There are numerous structures within the spine that are capable of transmitting pain when diseased. Often, more than one structure can be diseased and transmit pain, making it challenging to identify the pain generator. Spinal injections can be useful, both diagnostically and therapeutically, in the treatment of spine pain. However, they should follow a careful history, physical examination, and diagnostics tests. An understanding of the anatomy and innervation of the spine is critical when utilizing spinal injections for diagnosis and treatment.

The innervation of the spine is complex, as both the sensory and sympathetic nervous systems contribute to pain pathways. The posterior aspect of vertebrae and discs as well as all structures posterior to the vertebrae (i.e., neural foramen, facets, and so on) are innervated segmentally from each spinal root. However, since the sensory innervation of the anterior and lateral portion of the vertebrae and discs travels via the sympathetic nervous system, only the thoracic spinal nerves and upper two lumbar spinal nerves transmit sensory fibers segmentally into the spinal cord. The anterior cervical spine and lower anterior lumbar spine transmit sensory fibers through the first 2 to 3 thoracic nerve roots and upper lumbar nerve roots, respectively.

Zygapophyseal Joint (Facet Joint)

The facet joints are true diarthrodial joints with a rich nerve supply transmitting both nociception and mechanoreception.[3] The synovial membrane of the facet joints is rich in free nerve endings associated with painful sensation.[4] In addition, morphologic studies on human[5–8] facet joints support the role of the facet joint in low back pain. A recent study in degenerative human facet joints and facet joint capsular tissue harvested at the time of surgery showed an upregulation in inflammatory cytokines and neuropeptides (nerve growth factor) that can sensitize and activate nociceptors.[9]

The pain patterns that result from facet joint pathology have been described by several investigators. Because these joints are deep structures, there is a higher ratio of C fiber to A-delta fiber innervation. This results in poorly localized pain with a wide referral pain pattern from the ipsilateral lumbar area to the ipsilateral posterior thigh. These referral patterns may result in secondary zones of reflex muscle spasm and resultant trigger points.

All facet joints are innervated segmentally by a medial branch of the posterior ramus of the nerve root. However, segmental innervation differs between the cervical, thoracic, and lumbar spines. The cervical facet joint receives innervation from one level above and below, with the medial branch located along the waist of the articular process above and below the joint articulation. For example, the C3–C4 facet joint is innervated by the C3 and C4 medial branches. The C2–C3 facet joint receives innervation from the third occipital nerve as it courses across the anterior lateral portion of this joint as well as innervation from the C3 medial branch. The thoracic facet joint medial branch travels superior to the tip of the transverse process and courses proximally over the pedicle to reach the joint capsule. Lumbar facets are supplied by a medial branch at the corresponding level and a branch from one level above. For example, the L4–L5 facet joint is innervated by the L3 and L4 medial branch. The L5–S1 facet joint is innervated by the L4 and L5 medial branches as well as a branch from the posterior rami of S1.

Sacroiliac Joint

As with the facet joint, there has been controversy on the sacroiliac (SI) joint as a cause of low back pain. Like the facet joints, the SI joint is richly innervated with both free nerve endings and mechanoreceptors. The innervation has been extensively described and supports this joint as a pain-sensitive structure.[10,11] Most of the innervation of the SI joint is supplied dorsally from L4–S4 nerve roots, which results in the bulk of the innervation occurring in the dorsal segment of the joint.[12]

Pain from the SI joint is usually referred to the buttocks, groin, posterior thigh, and occasionally, below the knee.[13–15] Because of the anatomic location of the SI joint, this structure is difficult to examine, and many of the provocative tests can result in false-positives and intertester differences.[16,17]

Intervertebral Disc

It is clear that the outer one-third of the intervertebral disc (ID) is well innervated; however, there is controversy regarding whether this is a pain-producing structure.[18–20] There is little, if any, controversy over the role that a herniated disc plays in producing radicular pain; however, controversy arises over isolated disc pathology without nerve compression as a cause of axial low back pain. Nerve endings capable of transmitting pain impulses are abundant in the outer one-third of the anulus fibrosus in both the cervical disc[21] and the lumbar disc.[22] In addition, nerves within the ID contain neuropeptides that are involved in pain transmission.[23] Injuries in the anulus fibrosus may result in pain while the external appearance of the disc remains normal and before nerve roots are affected.[24]

The referral pattern of pain originating solely from the disc is similar to that produced by facet joint pain.[25] The pain from diseased intervertebral discs may not arise directly from the disc, but rather from other structures that develop abnormal stresses as a result of the diseased disc.[26] Other structures surrounding the disc are known to have pain fibers (e.g., facet joints, anterior and posterior longitudinal ligaments).

Ligaments of the Spine

There are many ligamentous structures in the spine that are innervated with free nerve endings. However, there is variability in the density of this innervation. Of all of the ligamentous structures, the posterior longitudinal ligament appears to be the most heavily innervated with free nerve endings[27,28] and the ligamentum flavum the least innervated.[29] Degenerative changes within these ligaments may result in sensitization of free nerve endings, leading to chronic pain. In addition, the close proximity of the anterior and posterior longitudinal ligament to the discs makes the structures susceptible to exposure to the disc contents in the event of disc rupture. The disc contents may induce an inflammatory process in these ligaments, leading to pain.

Nerve Root

The nerve root is innervated by the sinuvertebral nerve, which branches from the segmental nerve and travels backward into the neural foramen. The arachnoidal covering of the nerve root is heavily innervated and a source of pain. Mechanical compression or irritation of these structures can lead to pain in the extremities that is associated with neurologic changes. The nerve root may be stimulated mechanically by disc herniation, osteophyte formation, foraminal narrowing due to degenerative disc disease, or tumor invasion. In addition, it has been postulated that both the disc contents and the facet joint contents may induce an arachnoiditis; however, Haughton et al.[30] showed this only to be true for the disc contents.

Cervical Spine Injections

Cervical epidural steroid injections have been performed from both an interlaminar and transforaminal approach. All epidural injections carry a small risk of complications. However, the cervical transforaminal approach, more than other spinal locations or approaches, has been associated with rare but significant complications, including spinal cord injury, stroke, and death.[31–33]

The majority of studies of cervical epidural injections have utilized the interlaminar approach. In two recent reviews of cervical epidural steroid injections, seven RCTs for the treatment of axial or radicular pain of cervical spinal origin were evaluated.[34,35] Only three of the seven studies were performed using fluoroscopy. Of the studies for cervical radicular pain, only one study made use of fluoroscopic guidance. All of the studies showed significant pain improvement but no differences between epidural steroid treatment and active-control groups, with the exception of one study, which used an intramuscular injection of steroid as the control group. The remaining studies compared epidural steroids versus other substances (mostly local anesthetics) injected epidurally.

The literature regarding the treatment of acute and chronic pain conditions is increasingly focused on multimodal therapies. Patients who undergo treatment with multiple modalities or combinations of pharmaceutical and

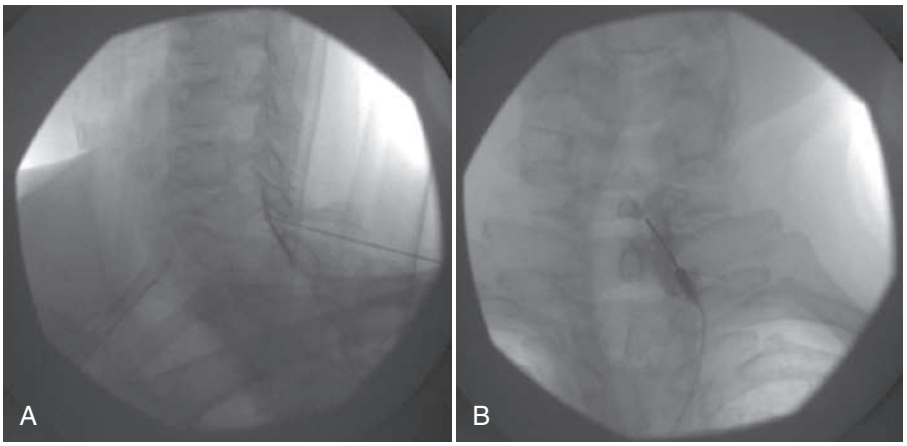

FIG. 22.1 Cervical epidural steroid injection. (A) Contralateral oblique view showing contrast medium in the cervical epidural space. (B) Anteroposterior view showing contrast medium highlighting epidural fat with needle entry at the right C7–T1 level.

nonpharmaceutical treatments fare better than those receiving a single-modality treatment. A recent multicenter RCT of cervical epidural steroid injections (CESIs) for the treatment of cervical radiculopathy showed greater benefits for multimodal therapy over more limited therapy.[36] A total of 169 subjects were randomized to physical therapy plus gabapentin, cervical epidural steroid injections alone, or a combination of physical therapy, gabapentin, and CESIs. All three groups showed significant improvement in arm pain at follow-up. However, the magnitude of improvement was significantly greater for the multimodal group than the physical therapy or epidural-alone groups. The conservative therapy group fared the worst.

Procedure: Cervical Interlaminar Epidural Steroid Injection

The patient is placed in a prone position. The patient is prepped and draped in the usual sterile fashion. A fluoroscopic image is taken in the anteroposterior (AP) direction and a 5- to 10-degree cephalad tilt of the C-arm may be required to open the C7–T1 space. The C7–T1 level is selected because the epidural space is widest and there is a higher chance of an intact ligament, both making a safer injection. The C6–C7 space may be occasionally used, but it is not recommended that the injection be performed above C6 as the cervical enlargement of the spinal cord, thin ligament, and small epidural space increase risk of injury. A pointer is then placed over the superior edge of the lamina of the inferior vertebral level of the target, at the ipsilateral side of the pain complaint for a paramedian approach. (An alternative method is the trajectory view, to follow.) A skin wheal is performed and the area is anesthetized with lidocaine 1%. A Tuohy needle is then inserted coaxial to the radiographic beam and advanced until contacting the lamina. The needle is then walked off the lamina superiorly and advanced into the ligamentum flavum. The stylet is removed, and a loss of resistance (LOR) syringe is then placed on the hub of the needle. At this stage, a contralateral oblique 50-degree C-arm view is recommended to watch needle depth. Continuous light pressure is applied with one hand to the LOR syringe, and the needle is advanced with the other hand. Once LOR is obtained, the LOR syringe is removed. In the contralateral oblique view, the needle tip should be advanced just ventral to the spinolaminar line. When using a paramedian approach, a lateral view is not appropriate, as it will not give an adequate view of needle depth just below the ipsilateral lamina. Iohexol (Omnipaque 240) is injected slowly to confirm proper spread of the contrast medium within the epidural space, also confirming that there is no evidence of intrathecal spread or intravascular runoff. About 3 mL of injectate mix of steroid, and normal saline with or without anesthetic is then performed.[37–39] An alternative method is the trajectory view, in which the needle trajectory is directed toward the interlaminar space without any intent of contacting lamina; a 50-degree contralateral oblique C-arm view is required to watch needle depth, prior to advancing the needle into the epidural space[38] (Fig. 22.1).

Transforaminal epidural steroid injections (TFESIs) and selective nerve root blocks have been promoted as a more targeted modality for treatment or diagnostic purposes. However, there are no randomized, double-blind trials of cervical transforaminal ESIs or comparative studies between transforaminal and interlaminar ESIs. In a review of fluoroscopically guided transforaminal CESIs, Engel et al.[40] reported on six observational studies totaling 357 patients who underwent fluoroscopically guided cervical TFESIs for radicular pain. Of these subjects, 180 (50%) obtained at least a 50% reduction of arm pain. Of the six studies, four had a positive outcome—at least 50% of subjects achieving significant improvement. One of these studies was halted early due to published reports of complications with cervical TFESI.[41] Two of the six studies of cervical TFESIs also reported on progression to surgery. In a study of 70 subjects by Lin in 2006, 44 of the 70 subjects had significant and sustained improvement such that they did not proceed to surgery.[42] However, in a study of 21 subjects with cervical radiculopathy by Kolstad in 2005, only 5 of the 21 had improvement sufficient to prevent progression to surgery.[41]

There have been at least 23 reports of serious complications after cervical TFESI.[36] These have included cerebral injuries with cortical blindness, spinal cord infarcts, vertebral artery occlusion, cerebral and cerebellar infarcts, spinal cord injury, grand mal seizure, and epidural hematomas, among others. There are also reports of adverse events following cervical interlaminar ESIs, but many of these are minor and transient.[32] There have been a small number of direct spinal cord injuries, but in all of these cases, the injections were performed in heavily sedated patients.[32] The use of heavy sedation for spinal injection procedures, especially in the cervical region, is discouraged for this reason.[43] There is growing consensus that transforaminal injections in the cervical region pose a significantly higher risk than interlaminar epidurals and perhaps should be avoided.[2,44]

Cervical selective nerve root blocks have been promoted as a diagnostic test to aid in planning surgical treatment of cervical radiculopathy. However, scant evidence exists for the diagnostic utility of cervical selective nerve root blocks. In a review of the literature on selective nerve root blocks, only one study was found that evaluated cervical injections.[45] In this study, 30 patients with unilateral cervical radiculopathy and more than one level of pathology on magnetic resonance imaging (MRI) underwent diagnostic selective nerve blocks.[46] Correlation between positive selective nerve block and clinical determination of nerve root level from neurologic deficits was only 28%. Correlation with the most severe pathology on MRI was 60%. Given the limited evidence and potential risks, there is little to support the use of cervical diagnostic nerve root blocks for surgical planning.

Procedure: Cervical Transforaminal Epidural Steroid Injection

The patient is placed in a supine position. The appropriate vertebral level is identified under the posteroanterior (PA) view, and the C-arm is tilted until the superior endplate is squared, and the spinous process is midline to the level that is targeted. The fluoroscope is then tilted ipsilaterally to about 45 degrees or until the targeted foramen comes into complete view. A pointer is then placed over the intervertebral foramen at the dorsal and posterior aspect. The skin is anesthetized. A straight short-bevel needle is then advanced toward the target. A PA view is then obtained, and the needle can be advanced, but not past the midline of the lateral mass in order to minimize the potential for dural or spinal cord puncture. Iohexol (Omnipaque 240) is then injected under live fluoroscopy to confirm contrast spread medially around the pedicle, and inferiolaterally along the exiting spinal nerve, without vascular runoff. It has been suggested that use of digital subtraction angiography (DSA) has a greater accuracy in detecting intravascular injection. Lee et al.[47] showed that, of 87 lumbar TFESIs, 20 cases of intravascular injection were detected with DSA. Only 12 of these cases were detected with contrast injection under standard fluoroscopy. In a study of 177 cervical TFESIs in 134 patients, Mclean et al.[48] detected intravascular injection in 18% with real-time fluoroscopy versus 32.8% with DSA. About 1 to 2 mL of injectate mix of dexamethasone and normal saline with or without anesthetic is then performed.[49,50] All other steroids should be avoided due to the risk of neurologic damage. In a rat study of four different steroid preparations (both soluble and nonsoluble), dexamethasone was the only one that did not result in serious neurologic injury after carotid artery injection.[51] The general consensus is that DSA is not required when using dexamethasone. However, DSA should be strongly considered if a particulate steroid is used under special circumstances (Fig. 22.2).

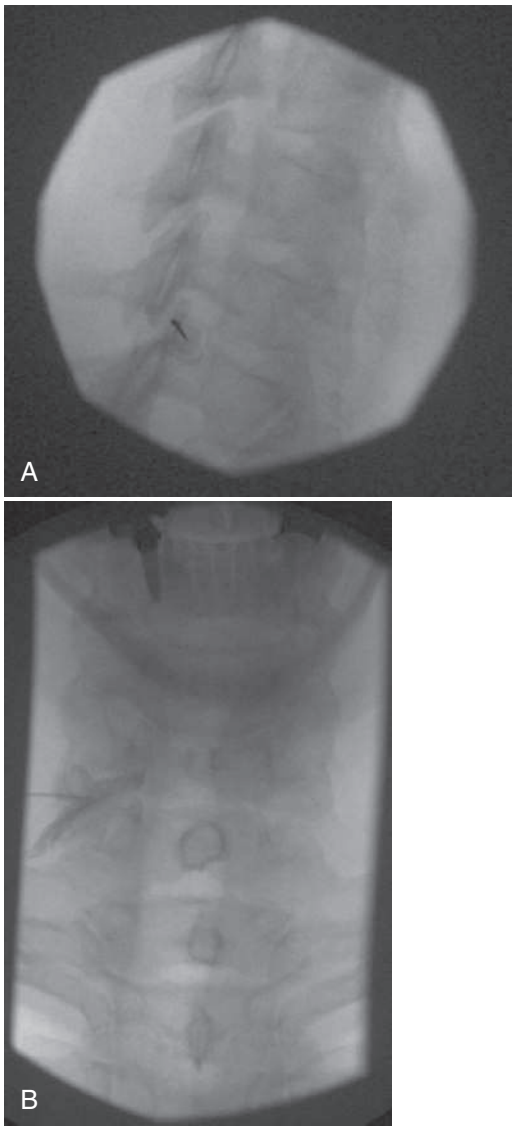

FIG. 22.2 Cervical transforaminal epidural steroid injection. (A) Oblique view of a C6–C7 intervertebral foramen aligned with the needle coaxial to the target point. (B) Posteroanterior view showing the contrast medium filling the foramen, extending peripherally along the ventral ramus, and to the epidural space.

Pain from the cervical facet joints has been reported to account for between 36% and 67% of patients with chronic neck pain.[52,53] Cervical facet–mediated pain is routinely treated with ablation of the medial branch nerves. Unlike in the lumbar region, there is limited literature on the use of intraarticular steroid injections into the cervical facet joints. Only one randomized trial exists that compared intraarticular

injection of steroid to local anesthetic.[54] Both groups obtained relief lasting only days, with no difference between groups. Two observational studies of cervical facet intraarticular steroid injections showed short-term benefit.[55,56]

There is one high-quality RCT of cervical medial branch radiofrequency ablation (RFA) after controlled diagnostic blocks.[57] In this small study by Lord, 24 patients were randomized to sham or RFA. The median time to return of pain was 284 days in the treatment group and 8 days in the sham group. Nonrandomized prospective studies have also found both short-term and long-term benefit from cervical RFA of the medial branch nerves, while two larger retrospective studies found no benefit.[52,53]

Procedure: Cervical Medial Branch Blocks and Radiofrequency Ablation

Cervical medial branch blocks (MBB) are typically performed as a diagnostic technique to determine whether the patient's neck pain is secondary to a facet joint pathology and to determine if the patient is a candidate for RFA. Prior to considering MBB and RFA the pain should have been present for at least 3 months, and the patient needs to have not responded to conservative therapy. The goal of the procedure is to inject anesthetic at the paravertebral facet joint nerves or the medial branches.

Each facet joint is supplied by two medial branches of the dorsal rami. In the cervical spine, two levels must be anesthetized for each joint. For example, the C3 and C4 MBB is performed to obtain information about the C3–C4 facet joint, and the C4 and C5 MBB is performed to obtain information regarding the C4–C5 facet joint.

For the diagnostic cervical MBB, the patient is usually placed in a prone position. The patient is prepped and draped in the usual sterile fashion. The skin and soft tissues are anesthetized with lidocaine 1%. At each level from a lateral direction, a 1.25- to 1.5-inch needle—or from a posterior position, a spinal needle—is inserted under frontal, lateral, and oblique fluoroscopic projections with the needle tip advanced to contact the centroid of the lateral articular pillar at each respective level. Aspiration of each needle must be negative for blood, cerebrospinal fluid, or paresthesia prior to injection. The nerve blocks are then performed by injecting bupivacaine 0.5%, 0.25 mL through each needle.

If the patient exhibits greater than 50% improvement of index pain with 0.25 mL of local anesthetic for at least 3 hours, this is considered a positive diagnostic block. The patient may then proceed to a therapeutic procedure, such as RFA.

RFA is performed with the same set-up and targets as the MBB, except the needle tip should be placed parallel to the nerve. The RF lesion is an oval-shaped lesion that is circumferentially around the shaft of the active tip; thus, an ideal position of the tip is parallel to the targeted nerve.[58]

From a posterior approach at each level, a 22-gauge, 100-mm RF cannula needle with a 10-mm active tip is inserted percutaneously to the radiographic target with the needle tip parallel to the periosteum of the lateral articular pillar. Alternatively, from a lateral approach, a 20-gauge, 50-mm RF cannula needle with a 5-mm active tip is inserted percutaneously to the radiographic target at the center of the lateral mass. The RF probes are then placed through the cannula. Needle placement is confirmed radiographically and with neurologic stimulation. Axial sensory perception threshold using 50-Hz sensory stimulation is achieved at 0.5 V or less at each level. Extremity motor stimulation at 2 Hz is negative at a minimum of 1.5 V, or 2 to 3 times the sensory threshold at each level. Motor stimulation is positive for multifidus stimulation. The paravertebral facet joint nerve blockade is performed by injection of lidocaine 2%, 0.5 mL per level prior to treatment. Each nerve is then treated at 80°C in continuous RF mode for 90 seconds. The needle can be rotated and treated again.[57,59,60] Next, paravertebral facet joint nerve blockade is performed by injection of bupivacaine 0.5%, 0.25 mL. If steroid is mixed with the bupivacaine, it is recommended that dexamethasone be used for reasons described earlier under the risk of intraarterial injection of particulate steroid. The deep cervical artery is at risk of penetration and can communicate with the spinal radicular arteries (Fig. 22.3).

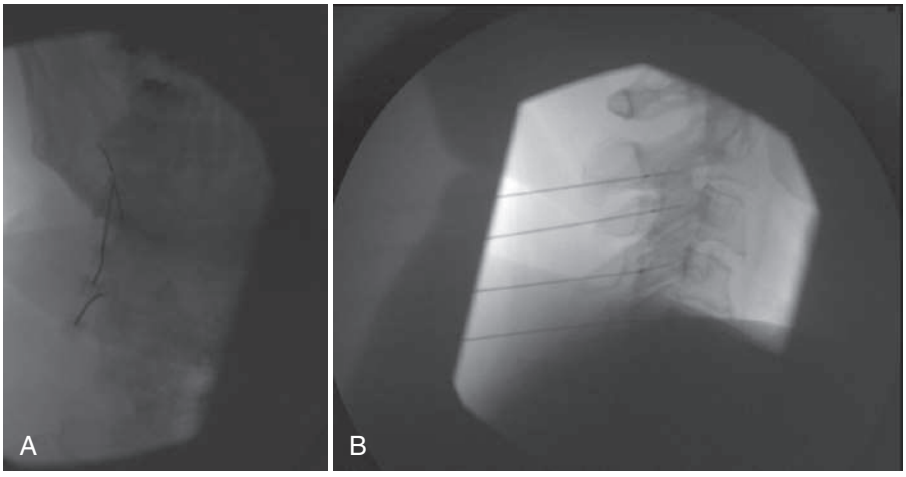

FIG. 22.3 Cervical medial branch block/radiofrequency (RF) ablation. (A) Anteroposterior view showing RF needles placed at the left spine lateral to the articular pillars. (B) Lateral view with the electrodes in the proper position over the left cervical third occipital, third, fourth, and fifth articular pillars.

Lumbar Spine Injections

Lumbar epidural steroid injections have been used for years as a treatment for axial or radicular pain of spinal origin. Lumbar ESIs are often used as an intermediate or conservative treatment measure before considering surgery. In a meta-analysis, Bicket et al. evaluated the effect of lumbar epidural steroid injections for preventing surgery for lumbar radiculopathy.[61] They identified 22 studies of lumbar ESIs that were RCTs and also reported subject progression to surgery. They found that fewer patients in the groups who had received ESIs went on to have surgery in both the short term and long term, but the effect fell short of statistical significance. However, only one of the included studies specifically sought to determine the effect of ESIs on surgery as a primary outcome measure. This study by Riew et al. found that significantly fewer patients who received ESIs (8 out of 28 [28.6%]) compared to epidural bupivacaine alone (18 out of 27 [66.7%]) underwent surgery at 13 to 28 months of follow-up.[62]

Therapeutic epidural steroid injections have been used for the treatment of pain from spinal stenosis, discogenic pain, and lumbar radiculopathy. Radiculopathy from lumbar disc herniation remains the primary indication for ESIs. In a review of fluoroscopically guided lumbar interlaminar ESIs, 5 out of 8 randomized controlled trials showed positive short-term pain relief.[63] In a separate review of 4 randomized trials of transforaminal ESIs for lumbar radiculopathy, all showed positive short-term improvement and 2 of 4 showed longer-term improvement.[64] In his study of 160 patients with unilateral radiculopathy, Karppinen found that, for contained herniations, a transforaminal ESI prevented progression to surgery but provided no relief in herniations with extrusion.[65]

Axial low back and leg pain from lumbar spinal stenosis has also been treated with epidural steroid injections. The use of epidural steroid injections for lumbar stenosis has recently been mired in some controversy. While lumbar decompression is considered the gold standard therapy for lumbar spinal stenosis, not all patients are acceptable surgical candidates. In an RCT that received wide reporting in the lay press, Friedly et al.[66] reported no difference for epidural steroid injections when compared to epidural lidocaine injections at 6 weeks and concluded that ESIs were ineffective for lumbar spinal stenosis. However, this study has been criticized for using relatively low volumes of injectate, inclusion of patients with acute low back pain, and the injection of an active drug, lidocaine, as an inactive control.[67] While the steroid group had significant improvement compared to lidocaine at 3 weeks for both of the primary outcome measures, Roland-Morris Disability Questionnaire (RMDQ) score and leg pain, there was no statistical difference at 6 weeks. However, both the lidocaine and steroid groups had substantial percentages (nearly 50%) of subjects achieving more than 30% relief of leg pain compared to baseline and 38% in both groups reported more than 50% relief of leg pain. In a meta-analysis of epidural steroid injections compared to epidural injections of nonsteroid solutions and injections of solutions outside of the epidural space, Bicket et al.[2] concluded that epidural injections of any solution appear to confer therapeutic benefit and the use of epidural nonsteroid solution injections as a "placebo" control may be misleading. In a systematic review of RCTs of ESIs for lumbar stenosis, Manchikanti[68] concluded that interlaminar and caudal injections of either local anesthetic with steroid or local anesthetic alone provided short- and long-term benefit for back and leg pain.

Procedure: Lumbar Interlaminar Epidural Steroid Injection

For this procedure, the patient is placed in a prone position. The patient is prepped and draped in the usual sterile fashion. A fluoroscopic image is taken in the AP direction and the endplates at the level of planned entry are lined up, most commonly at L5–S1. A pointer is then placed over the superior edge of the lamina of the inferior vertebral level of the target, at the ipsilateral side of the pain for a paramedian approach. (As with a cervical epidural steroid injection, an alternative method for the lumbar epidural steroid injection is the trajectory view, in which the needle trajectory is directly toward the interlaminar space; a 45-degree contralateral oblique C-arm view is required to watch needle depth if the lamina is not going to be contacted prior to advancing the needle into the epidural space). A skin wheal is performed and the area is anesthetized with lidocaine 1%. A Tuohy needle is then inserted coaxial to the radiographic beam and advanced until contacting the lamina. The needle is then walked off the lamina superiorly and advanced anteriorly to the ligamentum flavum. The stylet is removed, and a LOR syringe is then placed on the hub of the needle. Continuous light pressure is applied with one hand to the LOR syringe, and the needle is advanced. At this stage, a contralateral oblique 50-degree C-arm view is recommended to watch needle depth. Once LOR is obtained, the LOR syringe is removed. In the contralateral oblique view, the needle tip should be advanced just ventral to the spinolaminar line. Iohexol (Omnipaque 240) is injected slowly to confirm proper spread of the contrast medium within the epidural space, also confirming that there is no evidence of intrathecal spread or intravascular runoff. When using a paramedian approach, a lateral view is not appropriate, as it will not give an adequate view of needle depth just below the ipsilateral lamina. If using a midline approach, a lateral view is appropriate to monitor needle depth. About 5 mL of injectate mix of steroid and normal saline with or without anesthetic is then performed[38,69,70] (Fig. 22.4).

Procedure: Caudal Epidural Steroid Injection

The patient is placed in a prone position with a pillow under the abdomen, and the legs slightly abducted with internal rotation. The patient is prepped and draped in the usual sterile fashion. The sacral cornu may be palpated to determine the approximation of the sacral hiatus. A pointer is placed over the sacral hiatus at around a 45-degree angle using a lateral fluoroscopic projection to assist in identifying the sacral hiatus. The skin is then anesthetized with lidocaine 1%, and

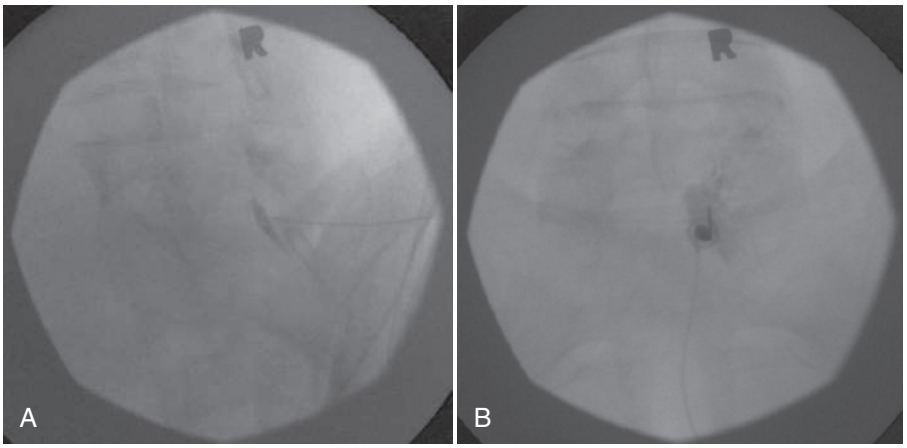

FIG. 22.4 Lumbar epidural steroid injection. (A) Contralateral oblique view showing contrast medium in the lumbar epidural space. (B) Anteroposterior view showing contrast medium highlighting epidural fat with the needle at right L5–S1 level.

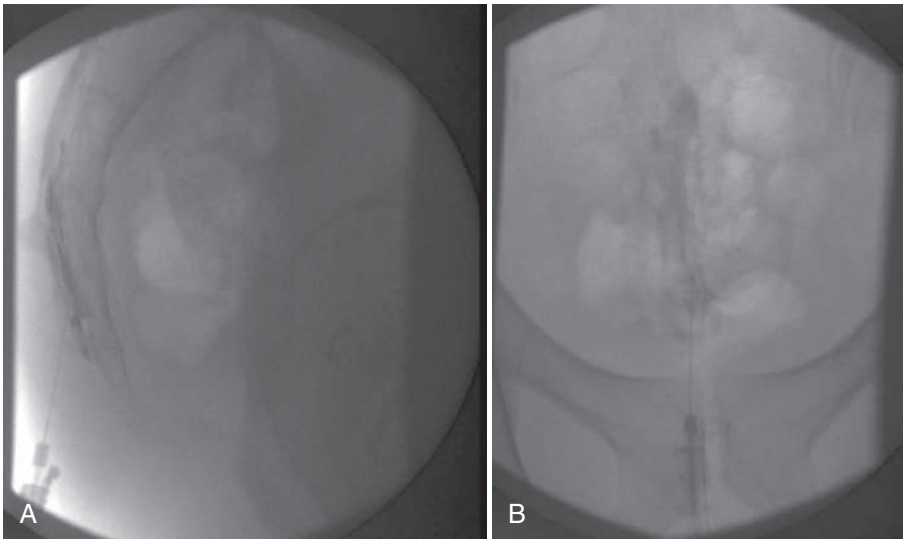

FIG. 22.5 Caudal epidural steroid injection. (A) Lateral view showing a 25-gauge needle in the caudal epidural space with contrast medium flowing superiorly in the epidural space. (B) Anteroposterior view showing contrast medium highlighting caudal epidural fat.

a 27-gauge, 1.25-inch needle, or longer needle if needed, is inserted into position through the sacral hiatus. The needle is advanced midline, and kept inferior to S3 to avoid dural puncture. After negative needle aspiration, contrast is then injected to demonstrate epidural spread in both a lateral and AP projection. Live AP fluoroscopic imaging is then obtained highlighting epidural fat, and cephalad contrast spread without vascular runoff. The usual volume of 5 to 10 mL of injectate mix of steroid and normal saline with or without anesthetic is then performed[71–73] (Fig. 22.5).

The use of diagnostic selective nerve root blocks to identify a particular spinal nerve level in the lumbar region has significantly more evidence than in the cervical region. In his review of these blocks, Datta[45] found moderate evidence for the efficacy of selective nerve blocks as a diagnostic tool in radicular pain. However, there are significant variables that may confound the results of these injections. First, there may be confusion between the interventional pain physician and spine surgeon regarding what type of block is being performed and for what purpose. Some physicians will use the terms *transforaminal* and *selective nerve block* interchangeably. The goal of a truly selective nerve block is to place the needle tip just outside of the foramen and inject a low volume of local anesthetic alone in order to block a single nerve root. Improper placement of the needle tip into the foramen, injection of steroid along with local anesthetic, or use of a larger volume of injectate may negate the diagnostic utility of the injection. In one study, 0.5 mL of local anesthetic and iohexol resulted in epidural spread in 47% of L4 blocks and 28% of L5 blocks.[74] The sensitivity and specificity of nerve root blocks for predicting surgical outcome ranges from 45% to 100% in the various studies. There may be a role for the use of selective nerve blocks when there is clinical evidence of radiculopathy but inconclusive imaging studies. However, surgeons should consider the subjective nature of these blocks as a diagnostic test when evaluating their results.

Procedure: Lumbar Transforaminal Epidural Steroid Injection

There are different approaches for this procedure, including the supraneural (subpedicular) approach and infraneural (retrodiscal) approach. The supraneural approach is the traditional method and most commonly used among pain practitioners, and is described here. All of the risks and precautions described for cervical TFESIs should be considered for lumbar TFESIs.

The patient is placed in a prone position. The appropriate vertebral level is identified, and the fluoroscope is angled cephalocaudad until the superior endplate is squared, and mediolaterally until the spinous process is midline between the pedicles. The C-arm is then tilted ipsilaterally to between 15 and 25 degrees, until the superior articular process projects over the lateral third of the vertebral body. A pointer is then placed under the 6 o'clock position of the pedicle, adjacent to the pars interarticularis. A spinal needle is then advanced coaxial to the fluoroscopic image to the target. A lateral fluoroscopic view is then obtained, and the needle is advanced to the cephalad third of the intervertebral foramen and midway anteriorly into the neural foramen, to potentially avoid vascular structures. At this point, the C-arm is moved to an AP position and the needle position is confirmed to have not passed the midpedicular line to minimize the potential of dural puncture. Iohexol (Omnipaque 240) is then injected under live fluoroscopy. Ideal epidural contrast spread should be medially and cephalad around the pedicle, and inferior along the exiting spinal nerve, without vascular runoff or intrathecal spread. About 1 to 2 mL of an injectate mix of dexamethasone and normal saline with or without preservative-free local anesthetic is then performed.[75,76]

The lumbar TFESI can be performed at the L5–S1 and S1 levels with slight variation. At L5–S1, the iliac crest may obscure the view, and the C-arm may require a larger degree of cephalocaudal tilt.[77] For S1, the C-arm is adjusted to optimize visualization of the dorsal S1 foramen, just inferior to the S1 pedicle, with the target more medial within the foramen. The lateral view is used to confirm needle depth.[78]

The technique for a selective nerve root block is similar to what is described earlier for the TFESI, however, with final needle position more lateral and inferior. As the goal for a selective nerve root block is an anesthetic block to the exiting spinal nerve, ideal contrast spread is inferior along the exiting spinal nerve, without medial epidural spread. To be selective, a nerve root block should be performed extraforaminally, distal to the division of the ventral and dorsal rami and with low volumes of local anesthetic—no more than 0.5 mL[79] (Fig. 22.6).

In the lumbar region, the facet joints have been implicated as a source of axial low back pain in 15% to 45% of patients.[52] Diagnostic physical examination maneuvers and radiographic studies are unreliable in diagnosing facet-mediated pain. The use of controlled diagnostic medial branch nerve blocks is considered the most reliable means of diagnosing pain arising from the facet joints. Additionally, a positive response to two comparative local anesthetic diagnostic blocks significantly increases the likelihood of a robust response to radiofrequency ablation treatments compared to a single diagnostic block.[52] In their review of RFA for lumbar facet pain, Manchekanti et al. evaluated four randomized, sham controlled trials of RFA for lumbar facet mediated pain.[80] Three showed positive results for both short-term (<6 months) and long-term (>6 months) pain relief. Additionally, they found three other randomized, active controlled trials and 10 observational studies with positive results. In one representative study by van Kleef, success was defined as a more than 2-point reduction in visual analogue pain scale and more than 50% reduction in Oswestry Disability Index.[81] Patients were assessed at

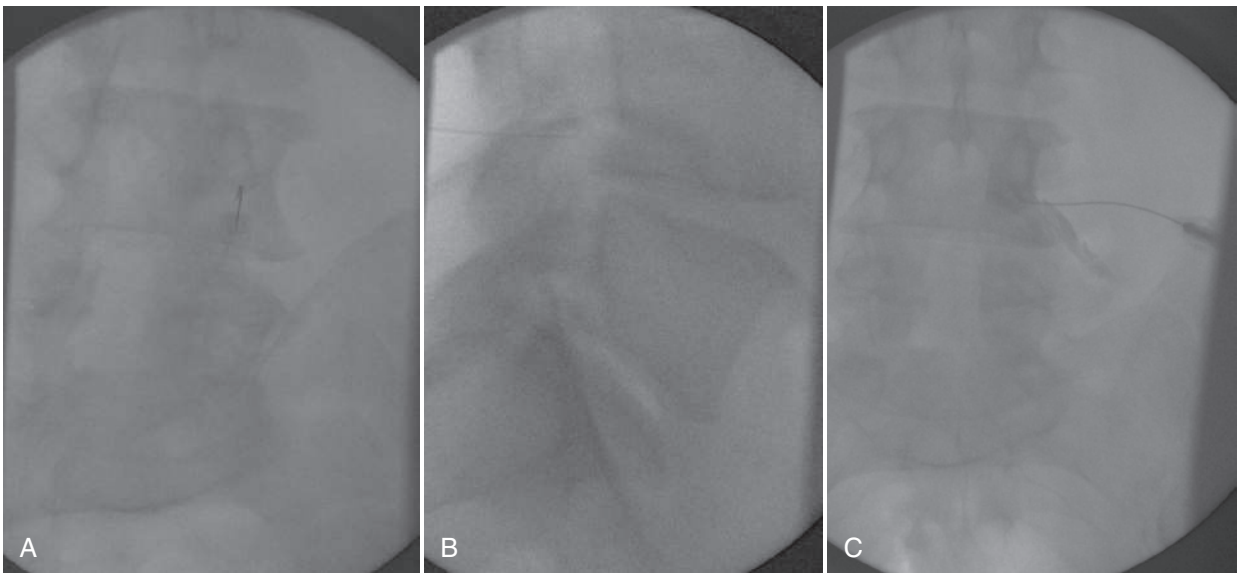

FIG. 22.6 Lumbar transforaminal epidural steroid injection. (A) Oblique radiograph of the spinal needle placed below the L5 pedicle. (B) Lateral radiograph showing the spinal needle in the upper third of the L5–S1 neural foramen. (C) Anteroposterior radiograph showing contrast medium highlighting the exiting nerve root.

2, 3, 6, and 12 months; the treatment group had significantly greater improvement at all time points.

There have been a handful of observational and retrospective studies of intraarticular injection of local anesthetic and steroids.[82] Most of the studies found greater than 50% of patients obtained initial and immediate relief and some short-term but not long-term benefit. There is no well-done, randomized, placebo-controlled trial of intraarticular facet injections.

Procedure: Lumbar Zygapophyseal Joint Injections (Facet Joint)

The patient is placed in a prone position. The patient is prepped and draped in the usual sterile fashion. The C-arm is positioned in the AP direction, and is given a 5- to 15-degree ipsilateral tilt until the facet joint space is identified clearly. The target is the middle to upper half of the joint space at the medial or lateral side of the joint. Osteophytic formation may affect the superior articular process more than the inferior articular process, making the lateral portion of the joint more difficult to enter. The medial border of the joint may be better suited in these cases. Special attention is paid to the L5–S1 facet joint, as the iliac crest can be superimposed, and may require more cephalad tilt. The skin is then anesthetized, and a spinal needle is then inserted and advanced coaxial to the radiographic beam until it enters the joint. At this point, more than one oblique angle, or lateral image, can be checked to confirm the needle tip within the joint space. Injection of iohexol (Omnipaque 240) shows joint space and capsular spread. Due to the small volume of the facet joint, a volume of no more than 1 to 1.5 mL per level of injectate mix of steroid and anesthetic is then performed[83–85] (Fig. 22.7).

Procedure: Lumbar Medial Branch Blocks and Radiofrequency Ablation

Lumbar MBBs are typically performed for two reasons. The first is to obtain diagnostic information as to whether the patient's axial back pain is secondary to facet-mediated pain from lumbar spondylosis. The second reason is to determine if the patient is a candidate for RFA. Prior to considering MBB and RFA, the pain should have been present for at least 3 months, and the patient needs to have not responded to conservative therapy. The goal of the procedure is to inject anesthetic at the paravertebral facet joint nerves or the medial branches.

Each facet joint is supplied by two medial branches of the dorsal rami. In the lumbar spine, two levels must be anesthetized for each joint. At the lowest joint, L5–S1, the L4 medial branch and the L5 dorsal ramus must be blocked. As the most common severe lumbar spondylosis occurs at the L4–L5 and L5–S1 joints, the most common MBB procedures are performed at the L3, L4, and L5 medial branches.

For the diagnostic lumbar MBB, the patient is placed in a prone position. The patient is prepped and draped in the usual sterile fashion. A fluoroscopic image is taken in the AP direction and the endplates at the level of proposed entry are lined up. Next, the fluoroscope is rotated ipsilaterally 10 to 20 degrees until the junction of the superior articular process and transverse process is clearly visible, with the circular projection of the pedicle outlining this junction. The skin and soft tissues are anesthetized with lidocaine 1% at each site.

To block the lumbar medial branch nerves, a spinal needle is inserted percutaneously and advanced under fluoroscopic guidance using dorsal, lateral, and oblique projections to its radiographic target. For each of the lumbar levels, the tip of the needle should be placed at the junction of the superior articular process and the transverse process. The L5 posterior

rami are blocked at the junction of the sacral ala just lateral to the articular process. At the sacral levels, the needle is placed at the lateral border of the respective sacral foramen. Next, paravertebral facet joint nerve blockade is performed by injection of bupivacaine 0.5% or lidocaine 2%, 0.5 mL of anesthetic at each level.

A patient exhibiting greater than 50% improvement of axial low back pain with 0.5 mL of local anesthetic for at least 3 hours may be a candidate for RFA. The purpose of RFA of the paravertebral facet joint nerves is to provide prolonged symptomatic pain relief.

For lumbar RFA, the patient is once again placed in the prone position, and prepped and draped in the usual sterile fashion. A fluoroscopic image is taken in the AP direction and the endplates at the level of proposed entry are lined up. The skin and soft tissues are anesthetized with lidocaine 1% at each site.

A 20- or 22-gauge, 10-cm RFA needle is inserted percutaneously and advanced under fluoroscopic guidance using dorsal, lateral, and oblique projections to its radiographic target, as described earlier in the MBB section. The difference in technique is that the needle tip should be placed parallel to the nerve. As described in the cervical section, the RF causes an oval circumferential shaped lesion around the shaft of the active tip; thus, an ideal position of the tip is parallel to the targeted nerve.[58] The RF probes are then placed through the cannula. In addition to fluoroscopic confirmation, neurologic stimulation is undertaken with both motor and sensory testing. Axial sensory perception threshold using 50-Hz sensory stimulation is achieved at 0.5 V or less at each level. Extremity motor stimulation at 2 Hz is shown to be negative at a minimum of 1.5 V, or 2 to 3 times the sensory threshold at each level, and motor stimulation is positive for multifidus stimulation, without movement of the buttock or leg muscles. Paravertebral facet joint nerve blockade is performed by injection of lidocaine 2%, 0.5 mL per level before treatment. After nerve block is achieved, each nerve is then treated at 80°C in continuous RF mode, for 90 seconds. The needle can be rotated and treated again.[86–90] Finally, paravertebral facet joint nerve blockade is performed by injection of bupivacaine 0.5%, 0.5 mL at each level (Fig. 22.8).

The SI joint has long been an acknowledged source of low back pain. Diagnosis of the SI joint as the source of pain remains a challenge as the diagnostic examination maneuvers for SI joint pain lack specificity. Based on a combination of multiple examination maneuvers and diagnostic nerve blocks, the prevalence of SI joint dysfunction in unilateral low back pain has been estimated at 15% to 25%.[91] There are many physical examination tests that have been advocated for diagnosing SI joint pain. Two of the most common are the Patrick's (FABERS) test and Gaenslen's test. Two studies have shown an improvement in specificity to 79% and 85% when three or more examination tests are positive.[92,93] Imaging study findings are poorly correlated with injection-confirmed SI joint pain.[91,94] The International Association for the Study of Pain (IASP) criteria for diagnosing SI joint pain mandates that the pain should be alleviated by the intraarticular injection of local anesthetics.[95] However, even this diagnostic technique has its limits. Intraarticular injection of the SI joint is one of the most challenging spinal injection procedures. There are several factors that may confound the diagnostic utility of an SI joint injection. The SI joint space is small; thus, local anesthetics injected may extravasate and block other anatomic structures such as muscles, ligaments, or lumbosacral nerve roots, resulting in false positives. Failure to get local anesthetic spread within the joint may result in a false negative.[91,94] All of these factors require consideration while attempting to diagnose pain from the SI joint.

Nonsurgical SI joint pain procedural interventions are limited to the injection of steroids and local anesthetics or

radiofrequency treatment of the nerves supplying the joint. The injection of steroids and local anesthetics for treatment of SI joint pain has often been assumed to require the intraarticular injection of the medication. However, the periarticular muscular and ligamentous connections are complex, and may also be a source of pain.[96] A retrospective study of 120 patients found that the combination of intraarticular and extraarticular injection provided better pain relief than intraarticular alone.[97] In randomized controlled studies, the periarticular injection of local anesthetic and steroids has provided short-term relief. There have been several studies of intraarticular injection of steroids, most of which have found at least short-term benefit.[91] However, two separate systematic reviews of SI joint pain found that the quality of these studies was too poor to grade the evidence or assessed the evidence to be limited.[96,98] A more recent systematic review of SI joint diagnosis and treatment graded the evidence as moderate.[99]

The treatment of SI joint pain with radiofrequency ablation has limited evidence through mostly observational studies, with pain improvement lasting up to a year.[96,98] In a small randomized, placebo-controlled trial of cooled-radiofrequency (cooled-RF) ablation versus sham ablation, the treatment group had significant relief compared to baseline at 1, 3, and 6 months.[100] Additionally, 11 of those who received the sham treatment crossed over to cooled-RF treatment and exhibited similar pain relief results to the initial treatment group. An additional sham-controlled study of cooled-RF found similar results.[101] Studies for conventional radiofrequency have been more limited and mostly observational, with a couple of randomized studies comparing cooled-RF to conventional RF. In one of those studies, Cheng et al. found that both provided greater than 50% pain relief for 3 to 6 months, with no significant difference between the treatments.[102] Last, there is one study of pulsed-radiofrequency neuromodulation of the lateral branch nerves for SI joint pain. In this study by Vallejo et al., 22 patients with SI joint pain confirmed with diagnostic blocks underwent pulsed-radiofrequency of the L4 medial branch, L5 posterior rami, and S1 and S2 lateral branch nerves; 73% achieved at least 50% pain relief at 6 to 9 weeks.[103] The percentage with significant improvement dropped to 32% at 17 to 32 weeks.

Procedure: Sacroiliac Joint Injection

The patient is placed in a prone position, and prepped and draped in the usual sterile fashion. The C-arm is positioned in the AP direction, and the posterior inferior SI joint is identified. At this point, the practitioner may use a combination of either cephalad versus caudal or ipsilateral versus contralateral oblique to increase the lucency of the target, which is located about 1 to 2 cm superior to the inferior aspect to the joint, at the medial side of the joint. The skin is then anesthetized with lidocaine 1%; a spinal needle is then directly coaxial to target. The needle is then walked into the joint, with a medial to lateral trajectory. Iohexol (Omnipaque 240) is injected to confirm proper spread of the contrast medium within the joint space, also confirming that there is no intravascular runoff. A lateral view should be checked to confirm that needle placement is ventral to the posterior sacrum but is not advanced too far ventrally through the joint into the viscera. No more than 1.5 to 2 mL of injectate mix of steroid and local anesthetic is then performed.[15,98,104] (Fig. 22.9).

Summary

This chapter has discussed the etiology of joint, disc, ligamentous, and nerve root pain and how each contributes to the complexity of the pain experience. In general, evidence for spinal injections is rather limited and high-quality gold standard studies are few. Diagnostic and therapeutic spinal injections must be performed in conjunction with a good history, physical examination, and appropriate diagnostic workup. There are complications with any procedure, and the risks and benefits must be weighed before proceeding. Given reports of serious complications in the cervical spine with spinal cord injury and vascular infarcts, cervical TFESI should be avoided, and cervical interlaminar epidurals performed instead. There is also an increased risk from transforaminal epidural steroid injections in the lumbar spine, but significantly lower than seen in the cervical spine. Therefore, TFESI, lumbar interlaminar epidural steroid injection, and CESI

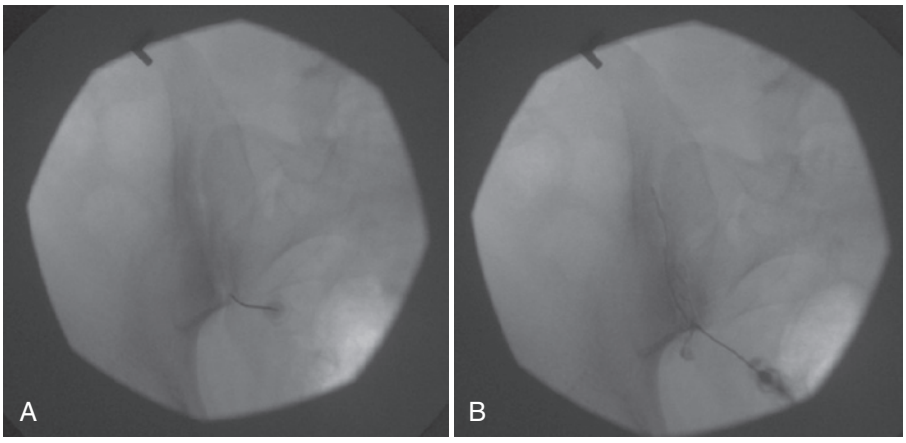

FIG. 22.9 Sacroiliac joint injection. (A) Anteroposterior radiograph showing the left sacroiliac joint. (B) Anteroposterior radiograph showing contrast spread in the left sacroiliac joint with superior and lateral flow, highlighting the joint space.

are routinely performed to help treat radicular symptoms or symptoms of central stenosis. For axial pain, diagnostic medial branch blocks must be performed before treating with RFA. In the lumbar spine, there is also the option of direct zygapophyseal joint or facet joint injections. Finally, the SI joint should also be considered as a common reason for low back pain, and SI joint injections or RFA may be considered.

23 CHAPTER Sacroiliac Joint Pain: Pathophysiology and Diagnosis

Alexandra Schwartz
Vinko Zlomislic
W. Carlton Reckling*
Daniel Cher*

Introduction

Low back pain remains a significant burden on the health care system, representing a source of approximately 12 million physician office visits per year in the United States. It is among the leading causes of disability, accounting for expenditures in excess of $80 billion every year.[1–3] Surgical management of low back pain is known to result in variable success rates, suggesting that the etiology of back pain is complex, often multifactorial, and frequently not clearly known or that treatments provided (or their execution) inadequately address pain generators.

Sacroiliac joint (SIJ) pain is a difficult problem with marked impact on quality of life[4] that is becoming increasingly recognized for its contribution to low back pain. In certain circumstances, SIJ pain may present as an isolated condition. However, in many scenarios, the SIJ represents one of many factors contributing to axial back pain and its various referral patterns. Studies have shown that sacroiliac pathology may either present in association with, or contribute directly to, the etiology of back pain in 15% to 30% of cases.[5–9] The SIJ is often overlooked as a contributing source of back pain. Maintaining an index of suspicion—and a thorough understanding of the relevant anatomy, biomechanics, and clinical presentation involved in SIJ-mediated pain—are required for accurate diagnosis. This chapter presents a comprehensive review of SIJ pathology and diagnostic algorithms as well as current surgical and nonsurgical treatment options and techniques.

Background

Successful management of low back pain requires recognition and appropriate management of the pain source. Studies have shown that the cause of low back pain may not only have variable lumbar origins but may also be a manifestation of hip or SIJ etiology. In a review of over 1200 cases, 44% of individuals presenting with low back pain had findings consistent with lesser-recognized diagnoses such as SIJ and posterior facet syndromes.[6] An additional 33% of patients in their cohort had concordant SIJ symptoms in addition to lumbar stenosis or spondylolisthesis. Further work has shown that of patients presenting to spine clinics for back pain, only 65% have a singular pain generator localized to the spine and 15% to 30% have pain that involves the SIJ to some degree.[5–9]

Adjacent-segment degeneration in instrumented lumbar or lumbosacral fusion is well documented. Not surprisingly, adjacent-segment degeneration of the SIJ also occurs. In a prospective cohort, the rate of radiographic findings consistent with SIJ degeneration was nearly double in patients who had undergone posterior spinal fusion compared to age-matched nonfusion controls followed over a 5-year period.[10] Finite element analysis simulating the effects of lumbar fusion has demonstrated increased forces transmitted across the SIJ that could precipitate degeneration[11]; angular motion and stress were increased along the articular surface following a lumbosacral fusion. A three-level lumbar fusion may result in up to 30% incidence of SIJ degeneration over about 4 years.[12]

Anatomy

The SIJ is the largest axial joint in the human body, with an average surface area of approximately 17.5 cm^2.[13–15] Appreciation of the complex anatomy is critical to making a diagnosis of SIJ dysfunction. As first described in 1864, the SIJ is characterized as a true synovial joint[16] despite the fact that over 70% of its surface area is comprised of capsular and ligamentous structures. A thick layer of hyaline cartilage covers the sacral side of the SIJ. The thinner covering of the iliac surface, though commonly described as fibrocartilage, contains chondrocytes with type II collagen, making this surface a variant of hyaline cartilage.[17] These surface differences may increase the likelihood of SIJ degeneration.[18]

The SIJ undergoes significant morphologic changes throughout life. Development is complete by early adulthood, with formation of an auricular or C-shaped articular joint

*Dr. Reckling and Dr. Cher are employees of SI-Bone, a medical device company.

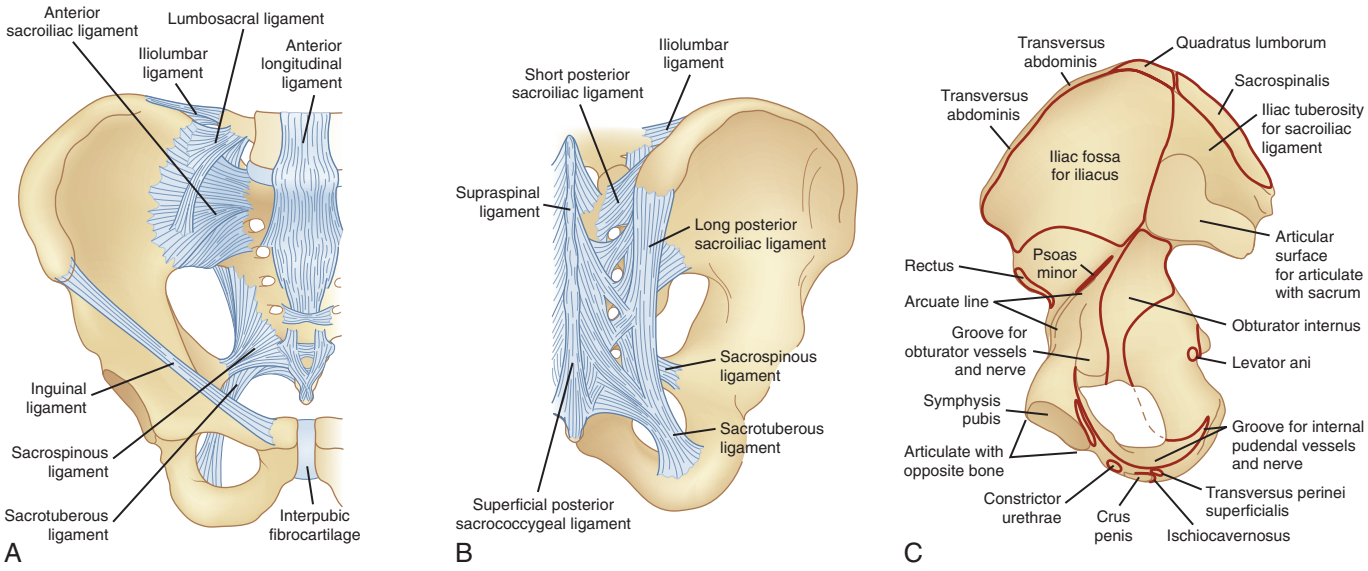

FIG. 23.1 Anatomy of the sacroiliac joint. (A) Anterior ligamentous and capsular structures. (B) Posterior ligamentous and capsular structures. (C) En face view of ilium depicting auricular nature of sacral articulation.

whose final anatomic orientation varies substantially across individuals (Fig. 23.1). Degenerative changes are common over the course of adulthood and have a predilection for the iliac side of the joint first, followed by sacral involvement. It should be stressed, however, that nonspecific degeneration is common, with more than two-thirds of asymptomatic older adults showing radiographic changes consistent with SIJ degeneration.[19]

The SIJ capsule is primarily located in the anterior third of the joint and has a distinct synovial membrane, lined by a thin capsule and overlying ligament that are confluent with the iliolumbar ligament. There is no synovial membrane posteriorly. The interosseous ligament and the dorsal ligaments, which function as a tension band, form a functional dorsal capsule of the SIJ. The sacrospinous and sacrotuberous ligaments contribute to this dorsal capsule (see Fig. 23.1). Additional stabilization is provided by the dynamic function of the gluteus maximus and gluteus medius, erector spinae, biceps femoris, psoas, and piriformis muscles, as well as the lumbodorsal fascia.[14] These structures allow indirect transfer of regional muscle forces to the SIJ and, in many cases, have expansions that invest with the posterior sacroiliac ligament structures. The structural integrity of the capsular and ligamentous structures is at least partly gender specific, with hormonally induced increased laxity in females, allowing for additional necessary motion during parturition.[20–22]

The sacrum is considered the keystone of the pelvis. It is the most caudal component of the vertebral column and provides the transition from the spinal axis to the pelvis. It is critical in the transfer of load from the lower extremities and pelvis to the lumbar spine. The SIJ is six times stronger in lateral compression than the lumbar spine, but fails at one-twentieth the axial load and one-half the shear force.[23] A common misconception is that the SIJ is static. However, current research has shown an average of 2 to 4 degrees of motion in the sagittal plane and smaller amounts of motion in the other planes.[24–26] The primary joint motion is nutation, which refers to a rocking forward of the sacrum relative to the ilium, and counternutation (rocking backward). With nutation of the sacrum, there is concurrent lateral translation of the ilium. Interestingly, the degree of SIJ motion does not correlate with the presence of SIJ pain.[20]

In a series of lectures from 1860 through 1862, John Hilton observed that a nerve that both crosses a joint and innervates the muscles crossing and acting on a joint also innervates the joint.[27] The complexity and ambiguity of SIJ innervation is in part based on Hilton's law. Various macroscopic, histologic, and immunohistochemical studies have demonstrated that the SIJ is highly innervated, with multiple nociceptors and mechanoreceptors present.[28] The synovium and capsule contain unmyelinated nerve endings for pain and temperature. The nerve supply to the posterior joint originates from either L4 to S3 root dorsal rami branches or independent contributions from the L3 and S4 nerve roots.[29,30] The anterior joint similarly has significant variability, with innervation supplied by the ventral rami from L2 to S2 roots.[13] Additional animal studies have evaluated the various pain thresholds of the nociceptive fields involving innervations of the lumbar facet articulations, SIJs, and lumbar disc. Pain sensitivity measured as mechanical threshold was 70 g for the SIJ, which was significantly greater than the lumbar facet (6 g), and less than the lumbar disc (241 g).[31,32]

Relevant surrounding neurologic anatomy consists of the L5 ventral ramus and lumbosacral plexus, which cross the cephalad portion of the SIJ approximately 2 cm distal to the pelvic brim.[33] The L5 root then courses along the anterior aspect of the sacral ala. The S1 ventral ramus crosses the SIJ more caudally, near the inferior aspect of the joint.

Pathology

SIJ dysfunction, a term commonly used to describe pain and disability related to poor functioning of the SIJ, has multiple

FIG. 23.2 (A) Degenerative changes within the sacroiliac joint (SIJ) with dense sclerosis and osteophytes. (B) Inflammatory changes in the SIJ with bilateral erosive sacroiliitis. (C) Complete fusion of the SIJ.

etiologies. SIJ dysfunction may result from capsular or synovial disruption, ligamentous tension, altered joint mobility and stress, microfracture, or disruption in the myofascial kinetic chain. Pathology may be categorized as either intra- or extraarticular. Common causes of intraarticular pathology include infection, inflammation, and degenerative or inflammatory arthritis. The most common infectious organisms include *Staphylococcus*, *Pseudomonas*, *Cryptococcus*, and *Mycobacterium* and should be suspected in intravenous drug use, endocarditis, or posttraumatic situations.[14] Degenerative changes occur over the course of decades and are related to repeated microtrauma, ultimately presenting as a progression of joint sclerosis on imaging studies (Fig. 23.2). Far more rarely, unilateral or bilateral sacroiliitis can be an early symptom in the seronegative and HLA-B27–associated spondyloarthropathies, occurring in individuals diagnosed with ankylosing spondylitis. There is a strong male predilection for the inflammatory spondyloarthropathies and the association with HLA-B27 supports an immune-mediated etiology that is characterized by more erosive changes on radiographs (see Fig. 23.2). These cases must be identified and distinguished from degenerative changes so that they can be referred for the appropriate nonsurgical management.[34]

Extraarticular pathology, often posttraumatic, may be attributable to ligamentous injury, myofascial pain, and fractures. The underlying causes are myriad, including leg-length discrepancy, gait abnormalities, prolonged exercise, athletic injuries, and prolonged lifting and bending.[13] In a retrospective study of 54 patients with injection-confirmed SIJ pain, trauma was the cause in 44% of cases, 35% were idiopathic, and 21% were due to repeated stress.[35] The most common traumatic events were categorized as motor vehicle accidents followed by falls. In young adults, major trauma resulting in SIJ disruption is most common, with lateral compression injuries more likely to result in later development of SIJ dysfunction.[36] Cumulative microtrauma from overzealous activity and repetitive loading, microfracture, and ligamentous or capsular injuries may also commonly cause insidious onset of SIJ pain.

Additional common causes of SIJ pathology may arise from iatrogenic injury due to overaggressive iliac crest graft harvest that inadvertently violates the SIJ or damages the iliolumbar ligament.[37] Increasingly recognized in females, hormonal changes during the final trimester of pregnancy may induce hypermobility of the SIJ that predisposes it and surrounding ligaments to additional injury, resulting in chronic pain and instability. There is evidence that a prior history of lumbar fusion contributes to biomechanical and anatomic alteration of the SIJ.[10,11] Metabolic diseases such as calcium pyrophosphate crystal deposition disease, gout, hyperparathyroidism, and renal osteodystrophy may potentiate early inflammation and degeneration.[14] Although primary sacroiliac tumors are rare, bony metastasis to the pelvis ranks second only behind spinal metastasis and must be ruled out.

Diagnosis

Although often perceived as challenging, diagnosis of the SIJ as a pain generator is possible through a combination of history, physical examination, and diagnostic SIJ block. The importance of the clinical examination may be a "paradigm shift" for surgeons who rely primarily on imaging for orthopedic diagnoses, as imaging plays little role in the diagnosis of SIJ pain. Because SIJ pain referral patterns vary and can overlap with those of other pathologic conditions, the SIJ should be kept in mind when evaluating patients with chronic low back, buttocks, and hip pain.

Clinical History

Patients with SIJ complaints may present with a constellation of variable, and sometimes inconsistent, pain complaints in the lumbosacral region. Pain is usually off-center below L5 in the area of the posterior superior iliac spine (PSIS), with radiation into the buttocks, or, less commonly, into the groin. Pain in the legs above the knee is relatively common; pain below the knee is less commonly reported. Patients with SIJ dysfunction commonly point to an area just medial to and inferior to the PSIS (the insertion of the long dorsal ligament), which is deemed a positive Fortin finger test.[38]

Patients frequently report pseudoradicular pain, numbness, tingling, and weakness in the distribution of the L5 and S1 nerve roots. However, physical examination typically demonstrates no true neurologic deficit. SIJ arthrography has

shown a high proportion of patients with anatomic connections along the dorsum of the SIJ underneath the ligaments between the SIJ and the S1 neuroforamen or S1 nerve root.[39] Likewise, an anatomic connection is frequently demonstrated between the anterior SIJ capsule and the L5 nerve root/lumbar plexus. Finally, the same segmental spinal nerves innervate a variety of structures in the low back, pelvis, and proximal legs, and potentially can cause pain referral patterns from these structures due to convergent sensory pathways. Together, these anatomic findings may explain pseudoradicular pain in patients with SIJ dysfunction.

Typical complaints include pain with activities that preferentially load the involved SIJ, most commonly sitting for prolonged periods, rolling over in bed, sleeping on the affected side, passing over road bumps while driving, or getting in and out of a car or chair. Activities that offload the affected SIJ typically lessen SIJ pain. In prospective studies of patients undergoing surgical intervention, subjects reported the common occurrence of radiating leg pain, groin pain, pain worse with sitting (especially on the affected side), rising, walking, and climbing stairs. Pain occurs during the stance phase of gait. However, no specific aspect of the patient history is considered diagnostic of SIJ pain.

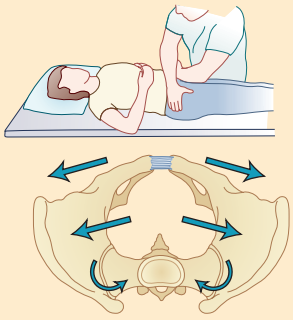
Physical Examination

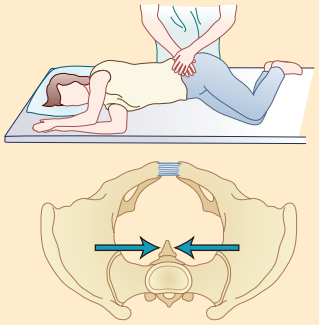
Physical examination of the SIJ focuses on provocative maneuvers (Table 23.1) that stress the SIJ. A maneuver is considered positive if the test reproduces the patient's pain. Interrater reliability of physical examination maneuvers is high for most tests.[40] No single test is perfectly correlated with results from diagnostic SIJ block (considered the reference standard); however, meta-analysis has shown that the occurrence of three or more positive physical examination tests has a high predictive value for a positive diagnostic SIJ block.[41] Another test, used more commonly in Europe, is the active straight-leg raise test. In this test, the supine patient is asked to rate the difficulty of actively raising the leg 20 cm off the examining table. This test is commonly positive in women with peripartum pelvic pain attributed to the SIJ.[42] In one study of minimally invasive SIJ fusion (SIJF), the active straight-leg raise test improved in patients undergoing fusion but remained at baseline levels in patients undergoing nonsurgical treatment.[43]

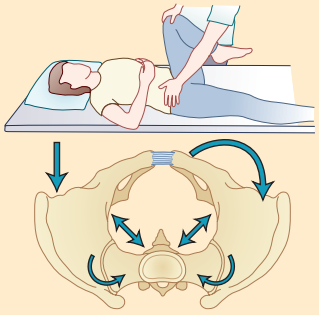
Role of Imaging

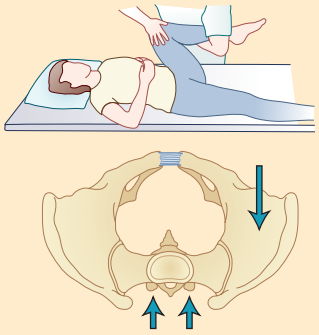
Imaging is considered an important part of diagnosis of autoimmune sacroiliitis, being part of the New York Criteria for this condition.[44] Whether MRI is best for detecting early autoimmune disease is still being debated.[45] However, in the more common setting of suspected SIJ dysfunction due to osteoarthritis or joint disruption, imaging—including plain radiography and scintigraphic scans—has not been found to be useful.[46] Signs of osteoarthritis degeneration (sclerosis, osteophytes, vacuum phenomenon, subchondral cysts) on CT scan are common in patients without suspected SIJ pain.[19] While findings suggestive of osteoarthritis have been reported as somewhat more common in patients with suspected SIJ pain than an age-matched cohort, sensitivity and specificity of CT findings were low.[47] In summary, no finding on radiography or CT scan has been shown to be diagnostic of SIJ pain. Imaging, especially plain radiographs and cross-sectional imaging, is therefore primarily used during diagnosis to rule out inflammatory SIJ arthropathy or other hip or spine conditions.

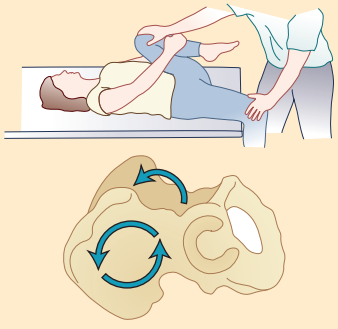
Diagnostic Injection











As in most pain conditions, there is no gold standard for diagnosis of SIJ pain. The accepted reference standard for diagnosis of SIJ pain is an acute reduction in typical pain in response to a fluoroscopically or CT-guided diagnostic intraarticular joint injection with a combination of radiographic contrast and local anesthetic, that is, an SIJ block (Fig. 23.3). Several aspects of SIJ block remain to be optimized: Are one or two blocks required? Which anesthetic should be used? Should nonresponse to a control injection (e.g., saline) be required? What threshold for acute decrease in pain is most appropriate? While steroids are commonly used in combination with local anesthetic, does subacute response to steroids aid in diagnosis? Despite these questions, it is well accepted that blind SIJ injections are unacceptable; SIJ injections must be performed under imaging guidance in order to confirm intraarticular entry and spread in the anterior and lower two-thirds of the SIJ.[15] Extravasation outside the joint suggests the potential for nonspecific responses, though this has not been proven. Injection volumes are typically about 1 to 2 mL; larger volumes may promote leakage and nonspecificity. Even with image guidance, various studies have demonstrated a significant number of false-positive and false-negative results,[48] though one study suggests that SIJ block is more accurate than previously reported.[49] False-positives may result from placebo effect, extravasation of local anesthetic to surrounding structures, or convergence of pain referral patterns. Conversely, false-negative results may be attributed to failure of local anesthetic to reach symptomatic regions of the SIJ, particularly the most anterior and cephalad areas or in the presence of extraarticular pain sources. In the absence of a gold standard for diagnosis, all such injection studies remain of questionable validity.

Extraarticular SIJ blocks, which focus on anesthetizing lateral branches of sacral nerve roots, are often used to screen for SIJ-mediated pain potentially responsive to radiofrequency ablation. In one study, extraarticular blocks at multiple depths were able to mask pain due to probing the interosseous and posterior sacroiliac ligaments but not pain elicited by distending the joint itself.[50] The study suggests not only dual innervation of the SIJ complex but also the probability of extraarticular pain generators.

Summary

SIJ pain is a common but often overlooked cause of low back pain. Diagnosis is based on a combination of history, physical examination tests that stress the SIJ and reproduce typical pain,

TABLE 23.1 Physical Examination Tests for Sacroiliac Joint Pain

Test	Description	Example
Distraction	The patient lies supine and is asked to place the forearm behind the lumbar spine to support the natural lordosis. A pillow is placed under the patient's knees. The examiner places his or her hands on the anterior and medial aspects of both of the patient's anterior superior iliac spines (ASISs) with arms crossed. A slow and steady increasing pressure is placed through the arms and held.	
Compression	The patient is placed in a side-lying position, facing away from the examiner, with a pillow between the knees. The examiner places a downward pressure through the lateral aspect of the patient's top-side ASIS and pelvis, anterior to the greater trochanter.	
FABER (Patrick test)	The patient lies supine as the examiner crosses the same-side foot over the opposite-side thigh. A force is steadily increased through the knee of the patient, exaggerating the motion of hip *f*lexion, *ab*duction, and *e*xternal *r*otation (FABER). The pelvis is stabilized at the opposite ASIS with the hand of the examiner.	
Thigh thrust	The patient lies supine, with one hip flexed to 90 degrees. The examiner stands on the same side as the flexed leg. The examiner provides either a quick thrust or a steady increasing pressure through the line of the femur. The pelvis is stabilized at the opposite ASIS with the hand of the examiner.	
Gaenslen's	The patient lies supine with the near-side leg hanging off the table. The patient is asked to hold the opposite-side knee into flexion. The examiner applies an extension force to the near-side thigh and a flexion force to the opposite knee. The patient assists with opposite-side hip flexion. This is performed bilaterally.	

A combination of three positive tests has a high predictive value for a positive sacroiliac joint block.

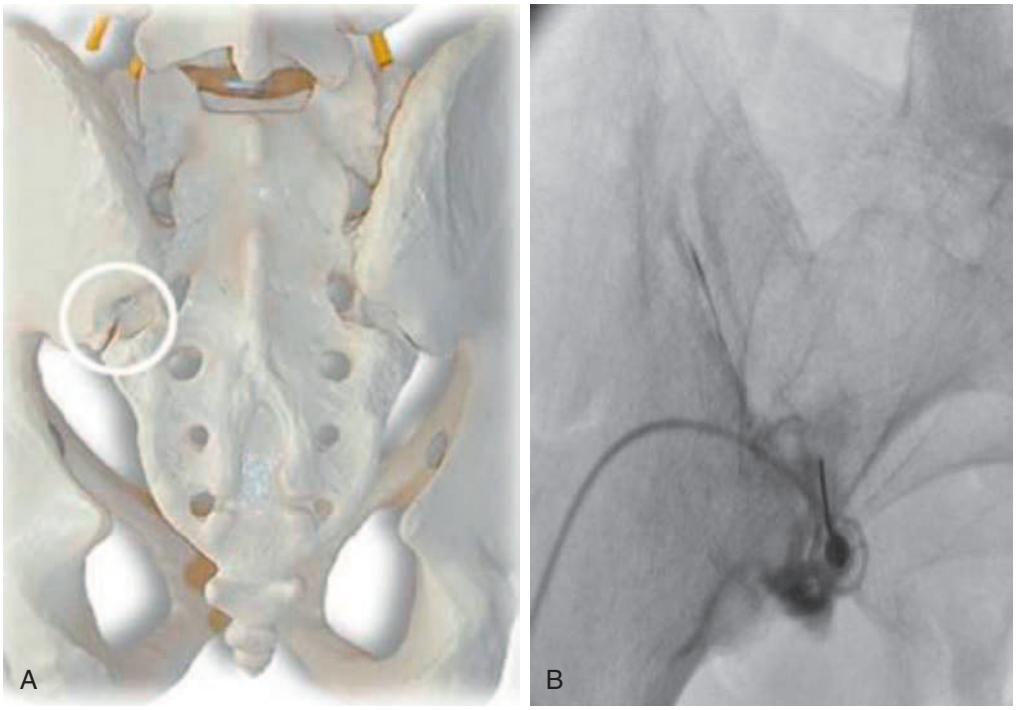


FIG. 23.3 (A) Inferior pole of sacroiliac joint (SIJ), entry point for an intraarticular SIJ injection. (B) Fluoroscopic view of SIJ injection with contrast in joint.

SIJ anesthetic block, and imaging to rule out other conditions. Understanding the anatomy and function of the SIJ and its surrounding structures aids in the diagnosis of the condition.

24 CHAPTER Outcomes of Nonsurgical and Surgical Treatment of Chronic Sacroiliac Joint Pain

Alexandra Schwartz
Vinko Zlomislic
W. Carlton Reckling*
Daniel Cher*

Nonsurgical and surgical treatments for sacroiliac joint (SIJ) pain have been the subject of intermittent study since the early 1900s. Multiple treatments of several modalities are commonly provided, although published high-quality studies supporting safety and efficacy are often lacking. Published high-quality literature on minimally invasive SIJ fusion is growing.

Nonsurgical Treatment

Multiple nonsurgical treatment options exist for the management of SIJ pain, with limited evidence to support successful treatment.

Medication Management

Medications such as opioids and nonsteroidal anti-inflammatory drugs may be useful for acute pain control. Newer agents, including immunomodulators and protease inhibitors, have shown success in management of inflammatory spondyloarthropathy but play no role in the more common degenerative and disruption-based SIJ syndromes. Moreover, no medical treatment has been shown to alter the course of SIJ pain due to degenerative sacroiliitis or SIJ disruption. As with other chronic pain syndromes, opioid abuse remains a significant concern.

Physical Therapy

Physical therapy for nonautoimmune SIJ pain is commonly employed. The goals of therapy are to identify underlying functional deficits and provide improved flexibility and strengthening of stabilizing trunk muscles, often in combination with direct joint manipulation, while also training the patient to avoid activities that exacerbate symptoms. In spite of trials that have shown some benefit with manual therapy and stabilizing exercises,[1–3] no high-quality studies determining the impact of physical therapy on SIJ pain related to osteoarthritic degeneration or SIJ disruption have been published. While physical therapy remains a reasonable nonsurgical option and is used as part of the standard management algorithm, evidence of effectiveness is modest at best and whether it is cost-effective is not known. Anecdotally, failure of physical therapy in treatment of SIJ pain is common.

Pelvic Bracing

Bracing with a pelvic belt, used in pregnancy-related pelvic pain,[4,5] has also been described in the nonsurgical treatment of SIJ dysfunction,[6,7] but no high-quality evidence exists to support its use.

Sacroiliac Joint Injection

Intraarticular and periarticular injections have been employed in the treatment of SIJ pain, with therapeutic effects related to the (as yet undocumented) anesthetic and steroid phases of relief. Intraarticular SI injections are increasingly performed in the United States,[8] but there is no high-quality evidence to support their use. In a blinded randomized trial of periarticular steroid injections, women with pelvic pain after pregnancy attributed to SIJ pain had improved pain levels, disability, 6-minute walk test, and isometric trunk extensor test results at 4 weeks after infiltration of 20 mg of triamcinolone around (but not into) the SIJ compared to after saline placebo.[9] Two small blinded randomized trials from a single group in Finland showed improvement in SIJ symptoms at 1 month after periarticular steroid infiltration compared to lidocaine injections.[10,11] No high-quality study has shown long-term benefit from periarticular steroids.

Radiofrequency Ablation

Radiofrequency (RF) ablation has also been employed to provide pain relief through denervation of the SIJ. Two high-quality blinded trials have shown short-term (1 or 3 months)

*Dr. Reckling and Dr. Cher are employees of SI-Bone, a medical device company.

pain relief after RF ablation of lateral branches of sacral nerve roots.[12,13] In these trials, patients were screened using diagnostic periarticular local anesthetic blocks. A 12-month follow-up in one randomized trial showed moderate pain relief.[14,14a,14b] No high-quality evidence demonstrates long-term pain relief after RF ablation of the lateral branches of sacral nerve roots. The major shortcoming involving percutaneous RF ablation is that the ventral aspect of the joint cannot be addressed. Furthermore, due to complex innervation patterns, many of the nerves ablated during these procedures target other surrounding structures. Finally, much of the innervation of the SIJ is inaccessible to the RF probe. This may contribute to the relatively high rates of return of SIJ pain following RF ablation.

Surgical Treatment

In appropriately selected patients who have failed nonsurgical treatment, surgical management may be considered, with the treatment of choice being SIJ arthrodesis. Goals of SIJF are acute stabilization of the SIJ with hardware and long-term stabilization via biologic fusion. Stabilization and fusion of the SIJ may allow the spine-pelvis-hip complex to function more normally, which can contribute to reduction in pain and improvement of overall function.

Open Surgery

Initially described with a dorsal approach in 1908,[15] subsequent detailed descriptions of lateral-based SIJF were described in the 1920s.[16,17] Since then, scattered case series have demonstrated variably successful results following open SIJF.[18–26]

Access to the SIJ may involve either an anterior, posterior, or lateral approach. The anterior surgical technique utilizes a standard ilioinguinal approach during which the interval between the external oblique and gluteal fascia is developed and the iliacus is elevated from the iliac fossa allowing exposure of the SIJ. The joint is then curetted and fusion is achieved with placement of bone graft, with plate and screw fixation (Fig. 24.1A). The anterior approach affords access to the articular SIJ, especially to the anterior and cranial aspects, as well as preservation of the primary posterior ligamentous stabilizers.[21]

Several posterior-based SIJF techniques have been described, though the posterior approach offers only limited access to the SIJ articular surfaces. Posterior approaches range from simple onlay grafting of the dorsal sacrum and adjacent ilium followed by cast immobilization,[27] debridement and grafting of the dorsal ligamentous portion of the SIJ,[26,28] and debridement and grafting of the articular SIJ, which requires removal of a portion of the overlying posterior iliac crest.[29] Various types of fixation have been described in conjunction with posterior SIJ fusion, including screws placed laterally from ilium to sacrum,[30] screws in the ilium and sacrum dorsally with a rod spanning the SIJ,[23] and hybrid fixation with a plate dorsally and screws laterally.[20,31] Alternatively, a modified Smith-Petersen approach may be carried out to access the SIJ from a lateral approach.[16] This involves removing a rectangular or cylindrical core of ilium (across the joint), allowing exposure, decortication, and grafting of the SIJ. The bony core is then impacted back in so that the thicker iliac component sits across the joint for a fusion, which may or may not include supplemental screw fixation (Fig. 24.1B).[32,33]

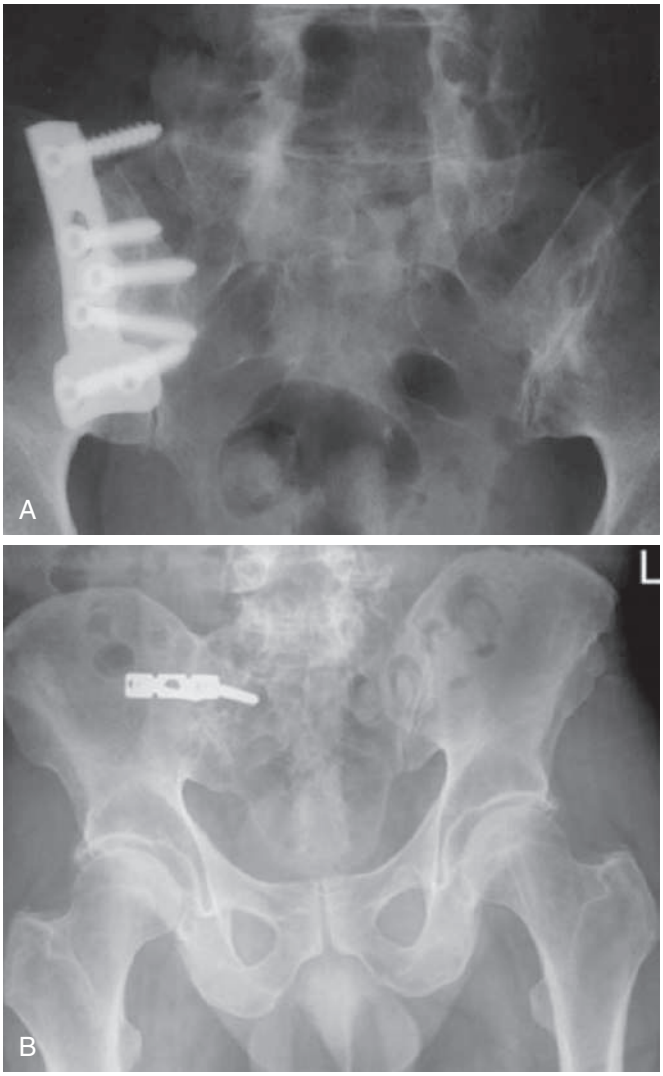

FIG. 24.1 Anteroposterior plain radiographs of the pelvis. (A) Use of T-plate to achieve arthrodesis of the sacroiliac joint using a modified Smith-Petersen approach. (B) Three-hole reconstruction plate spanning the sacroiliac joint following anterior ilioinguinal approach.

Open SIJF is marred by long operative times, high blood loss, long hospital stays, and significant patient morbidity—including infection, prolonged recovery times, and pseudarthrosis.[34] In addition, numerous complications have been reported for open approaches, including injury to the erector spinae muscle insertions, iatrogenic injury to the dorsal sensory nerve roots, sacral plexus, and internal iliac vessels. The most effective method for open SIJF remains unknown, as no comparative studies have been published. Nonetheless, given the historical context of limited surgical technology in use at the time, open SIJF resulted in modest rates of patient improvement along with radiographic fusion rates near 70%. Overall, approximately 60% of patients have indicated they

would choose to have the surgery again.[21] However, with the advent of minimally invasive approaches, interest in open fusion has waned and the open technique is now used primarily in the setting of acute trauma or revision surgery.[35]

Minimally Invasive Surgery

Recent advances in surgical technology, along with a progression toward minimally invasive surgical (MIS) techniques, have resulted in the development and commercial availability of several devices used in MIS SIJF. Minimally invasive SIJF is predicated on a thorough understanding of the anatomy of the pelvis, including bony architecture as well as the position of the neurovascular structures. Appropriate imaging (including pelvic anteroposterior, inlet, and outlet views, and, if possible, computed tomography [CT] scan) must be obtained and studied preoperatively. Images should be reviewed, with particular attention paid to the possibility of a dysmorphic sacrum, which may significantly alter, or decrease, the safe zone for implant placement.

Three approaches similar to those used in open SIJF have been described for MIS SIJF. First, an *anterior approach* with endoscopic placement of a fusion cage has been described.[25] Second, two reports describe a *dorsal approach* with placement of fusion cages into the ligamentous portion of the joint. In one report, a hollow threaded fusion cage was used, with modest improvements.[36] In a second report, a fusion cage filled with recombinant human bone morphogenetic protein-2 was used, with somewhat larger improvements.[31] As of late 2016, no devices placed via the posterior approach are US Food and Drug Administration cleared/approved for SIJF.

The most commonly reported technique for MIS SIJF is the *lateral transarticular approach*, which was derived in part from modifications of the Smith-Petersen technique.[16] In this approach, devices are placed across the SIJ from lateral to medial under fluoroscopic guidance or navigational control.

Outcomes From Minimally Invasive Sacroiliac Joint Fusion

Although several devices are cleared by the Food and Drug Administration for lateral transarticular SIJF, the majority of the published clinical literature for this approach reports use of porous triangular titanium implants (iFuse Implant System, SI-Bone). Three prospective multicenter clinical trials, including two randomized clinical trials, report successful outcomes with use of these implants. A US prospective, multicenter randomized controlled trial (INSITE; n = 148) compared minimally invasive SIJF using triangular titanium implants to nonoperative care.[37] Nonsurgical care consisted of medication management, physical therapy, SIJ steroid injections and RF ablation of lateral branches of sacral nerve roots, administered according to patient needs. Success—a composite of pain reduction, absence of serious adverse events or neurologic worsening, and absence of repeat surgery—occurred in 82% in the SIJF group and 26% of in the nonsurgical group ($P <$ .0001). By month 24, 82% received substantial clinical benefit (Glassman criteria[38]) in visual analog scale SIJ pain score and 66% had received substantial clinical benefit in Oswestry Disability Index (ODI) score. In the nonsurgical group, these proportions were less than 10% with nonsurgical treatment only. Parallel changes were seen for EuroQOL-5D and Short Form-36 quality-of-life surveys, with larger changes in the surgery group at 6 months compared to nonsurgical treatment. The rate of adverse events related to SIJF was low. Three subjects assigned to SIJF underwent revision surgery within the 24-month follow-up period.

In a second prospective, multicenter randomized controlled trial conducted in Europe (iMIA; n = 103), patients with SIJ dysfunction were assigned to either MIS SIJF using titanium implants or conservative management.[39] At 6 months, mean low back pain improved by 43.3 points in the SIJF group and 5.7 points in the conservative management group (difference of 38.1 points; $P <$ .0001). Mean ODI improved by 26 points in the SIJF group and 6 points in the nonsurgical group ($P <$ .0001). Other outcomes, such as active straight leg raise test,[40] EuroQOL-5D-3L, walking distance and satisfaction, were statistically superior in the fusion group. The frequency of adverse events did not differ between groups. One case of postoperative nerve impingement occurred in the surgical group. Twelve-month outcomes were sustained.[41]

Positive results from both randomized trials are supported by a large prospective, multicenter, single-arm clinical trial conducted in the United States (SIFI; n = 172).[42] In this study, patients (mean age, 51 years; 70% women) had SIJ pain for 5 years prior to SIJF, on average. Visual analog scale SIJ pain levels improved from close to 80 at baseline (0–100 scale) to 31 at 24 months. Large improvements were seen in ODI and two quality-of-life measures (SF-36 and EuroQOL-5D). Also observed was a decrease in opioid use for back pain from 76% at baseline to 55% at 24 months. A total of 4.7% of subjects underwent a revision surgery during follow-up. The study showed a high rate of bony apposition to implants on both sides of the SIJ, with modest 1-year fusion rates.

A pooled analysis of all three prospective porous triangular titanium implant studies (Fig. 24.2) showed high degrees of homogeneity across trials and statistically significant but clinically unimportant predictors of success (smoking and baseline opioid use).[43]

In addition to prospective studies, retrospective case series show positive outcomes after SIJF with porous titanium implants.[44–53] Of these case series, notable studies include those with 3-year,[53] 4-year,[52] and 5-year[44] follow-up. In the latter study, 5-year joint fusion rates were high.[44] Three studies[34,54,55] comparing open and MIS SIJF substantiated the potential benefits of the MIS approach, including one study[55] showing less blood loss, shorter operative times, and shorter hospital stays as well as improved pain levels at 1 and 2 years in the MIS approach.

In a comparative long-term case series from Spain, a minority of patients with diagnosed SIJ dysfunction were able to undergo MIS SIJF using triangular titanium implants or RF ablation; the remainder were, due to insurance noncoverage, forced to undergo continued conservative management. Patients in the SIJF group showed marked, immediate, and sustained reductions in SIJ pain and disability scores (ODI), along with a profound decrease in opioid use (63% at baseline

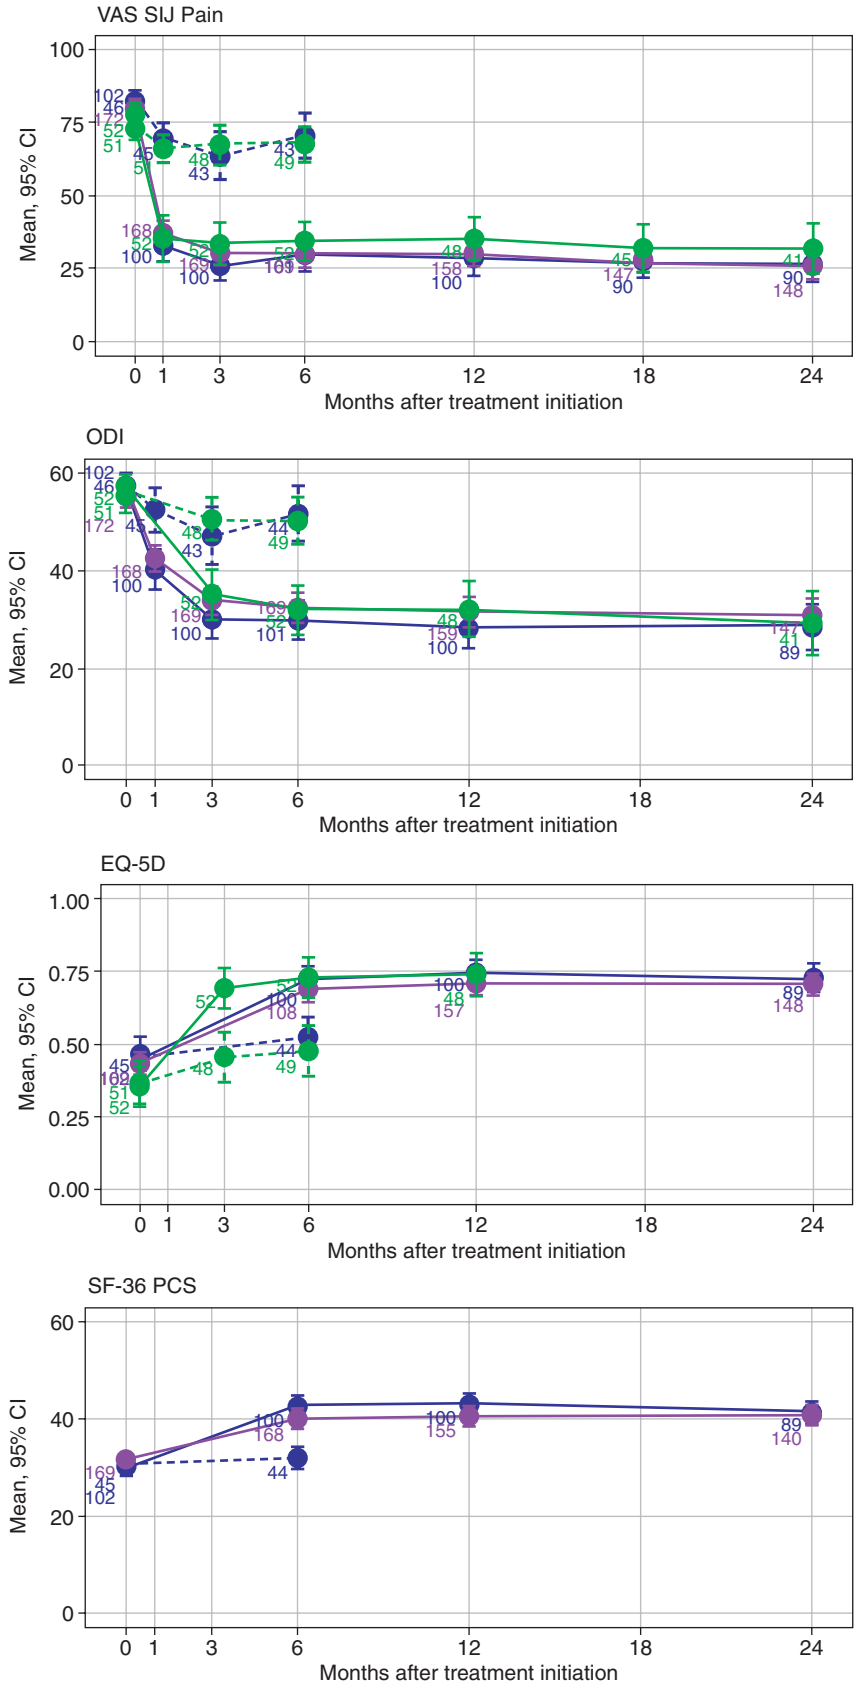

FIG. 24.2 Improvement in sacroiliac joint (SIJ) pain as measured using a visual analog scale (VAS), Oswestry Disability Index (ODI), EQ-5D time tradeoff index, and Short Form-36 physical component summary (PCS) in three prospective trials, including two randomized trials, of sacroiliac joint (SIJ) fusion. CI, confidence interval.

to 7% at last follow-up). In contrast, patients who underwent either RF ablation or conservative management showed worsening of pain and disability scores, increased opioid use, and worsened job status at last follow-up.[56] CT scans in one study showed a modest rate of bridging bone at 1 year[42] and a high rate at 5 years.[44]

Data supporting other commercially available SIJF systems include two small retrospective case series using hollow modular anchor screws,[57,58] one case series in which a minority of patients were treated with the Samba screw,[59] one case series with the Zyga screw,[60] and one single-center prospective study using SI-LOK (Globus).[61] These studies were neither blinded nor randomized; the degree to which outcomes from randomized trials of the triangular titanium implant pertain to screw-based systems is not known and no ongoing comparative studies are in progress. A comparative case series suggests that screw loosening may be more common than loosening of triangular titanium implants.[62]

Complications From Minimally Invasive Surgical Sacroiliac Joint Fusion

Complications of MIS SIJF fall into four categories: (1) device breakage, which has been reported with some systems, but not iFuse implants; (2) standard local operative complications; (3) implant malposition resulting in neuropathic pain due to irritation of the L5 or S1 nerve roots by the distal tip of the misplaced implant; and (4) implants placed insufficiently into the sacrum, resulting in continued or recurrent pain. In prospective trials, local surgical complications did not appear to occur more commonly than after other procedures. Implant malposition causing acute neuropathic pain occurred in about 1% of subjects in prospective clinical trials of triangular titanium implants and at a similar rate in a postmarket surveillance study.[63] In most cases with implant malposition causing new-onset neuropathic pain, pain resolves with repositioning of the implant(s). Failure to place devices sufficiently into the sacrum causes inadequate SIJ stabilization, which may result in either lack of improvement of SIJ pain or pain recurrence. Long-term revision rates after SIJF with triangular titanium implants appear to be low,[64] especially in comparison to some lumbar spine surgeries.[65,66] In some cases, such failures are associated with radiolucencies around the implants due presumably to persistent micromotion. Though not documented, placement of implants under CT guidance may help to improve implant placement accuracy.

Minimally Invasive Surgical Fusion Technique

MIS sacroiliac fusion is done with the patient in the prone position on a radiolucent table. Rolls are placed under the patient's chest. Care is taken to pad all bony prominences, and sequential compression devices are placed on both lower extremities. The arms are placed in an abducted and externally rotated position, rather than adducted at the patient's side, to allow for lateral fluoroscopic imaging. Biplanar fluoroscopy may be used. If two C-arms are used, one is positioned in the anteroposterior plane and one is placed in the lateral plane. If one C-arm is used, it is helpful to mark both positions of the C-arm base on the floor, as well as the various angles of inlet and outlet positions on the machine with tape. Adjust the table height such that no changes need to be made intraoperatively to obtain a good lateral sacral view. When using a single C-arm, it is positioned opposite the surgical site.

The ability to obtain proper imaging views must be ensured before initiation of surgery and should be performed before prepping and draping the patient. Several factors can interfere with the ability to visualize appropriate bony landmarks, including bowel gas, patient habitus, and prior lumbosacral instrumentation. Consideration of preoperative bowel prep should be given to improve visualization if needed. The inlet view is deemed ideal when all sacral bodies are overlapped. The outlet view is best when the S2 foramina are seen immediately cephalad and adjacent to the superior aspect of the superior pubic rami. The ideal sacral lateral view is seen when the greater sciatic notches are perfectly overlapped. The sacral lateral view is critical to understanding the sacral alar slope. The alar slope is best estimated by the iliac cortical density (ICD) and delineates the anterior extent of the "safe zone" if the implant is posterior and caudal to it.[67] Care must be taken in patients with a dysmorphic sacrum (Fig. 24.3), in which the sacral alar cortical bone limit is not represented by the ICD. Due to the more acute slope of the sacral ala, the sacral alar cortical line is cephalad and anterior to the ICD.

The affected gluteal region is prepped and draped in the usual sterile fashion. Draping should extend from midline to the greater trochanter, and from the gluteal crease to proximal to the iliac crest. A timeout procedure is performed.

Various methods have been described to place percutaneous fusion devices. Depending on the system chosen by the surgeon, this may involve a cannula through which one

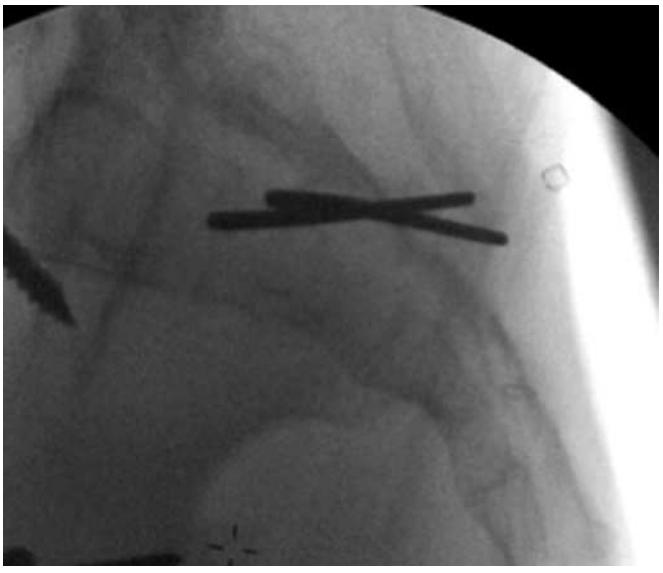

FIG. 24.3 The greater sciatic notches are overlapped, indicating an adequate lateral view. The sacral alar cortical bone limit is not represented by the iliac cortical density, due to the more acute slope of the sacral ala. The sacral alar cortical line is cephalad and anterior to the iliac cortical density.

can accomplish a technique to debride the sacroiliac joint (SImmetry; Zyga Technology), or a percutaneous technique using cannulated wires, broaches, and triangular titanium-coated implants without debriding the chondral surfaces (iFuse Implant System; SI-Bone). The goal of the latter is to create stability by bony growth onto the implant, not necessarily bone growth across the SI joint, though anecdotally this has been observed. Various reports describe other implants used for such minimally invasive, fluoroscopically placed implants.

For the triangular titanium-coated implant system, typically three implants are inserted. A 2-cm incision is first made in line with the midsagittal sacrum. Blunt percutaneous dissection is then carried out to the lateral ilium. The first cannulated guide wire placed should be the most cephalad wire. The goal is to center the guide pin between the S1 foramen and superior endplate of the sacrum on the outlet view while maintaining the guide pin parallel to the superior endplate of S1 (Fig. 24.4). On the inlet view, the guide pin should be aimed from slightly posterior to anterior, care being taken not to violate the sacral canal or exit the front of the sacrum (Fig. 24.5). To avoid the L5 nerve root, which drapes across the anterior sacrum just medial to the sacroiliac joint, the guide pin should be distal to the ICD. The pin should be parallel to the S1 endplate and aim from posterior to anterior on the lateral view (Fig. 24.6). Sequential drilling, broaching, measuring, and ultimately placing the implant are then carried out. Care should be taken to avoid migration of the guide pin. A parallel drill guide is then used to facilitate placement of additional caudal implants, in similar fashion, ensuring that each ends lateral to the sacral foramina (Figs. 24.7 and 24.8).

Summary

SIJ pathology is a common cause of low back pain and often presents in the setting of degenerative lumbar disease. Accurate diagnosis seems limited by lack of interest in the

FIG. 24.5 On this inlet view, the guide pin is aimed from slightly posterior to anterior with care being taken not to violate the sacral canal or exit the front of the sacrum.

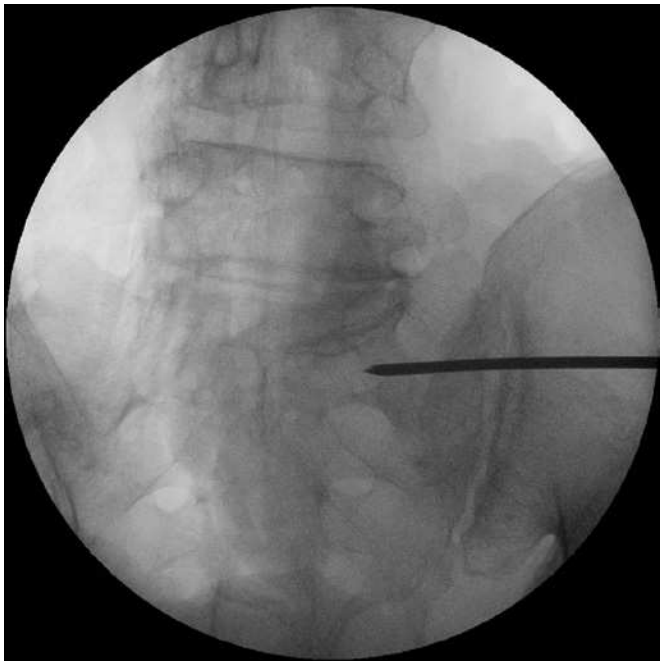

FIG. 24.4 In this outlet view, the guide pin is located between the S1 foramen and superior endplate of the sacrum and is parallel to the superior endplate of S1.

condition as well as the perceived unreliability of diagnosis. The fact that high-quality randomized trials have shown that patients with this condition can be diagnosed and treated with high levels of efficacy using multiple endpoint types argues against diagnostic unreliability. Provocative examination of the SIJ and positive responses to image-guided injections are necessary to confirm the SIJ as the pain source. Once SIJ etiology is established, multiple modes of treatment exist. While evidence for nonsurgical treatment is limited, conservative management with physical therapy and/or injections may be effective for many patients. For those who remain symptomatic, MIS SIJF is an effective option in reducing pain and disability and improving quality of life. Currently, strong literature support is available only for porous triangular titanium implants. The clinical utility of other devices available for MIS SIJF, which have different designs, placement, and fusion strategies, is less well understood and the applicability of evidence from published randomized trials of triangular titanium implants to these other devices is unclear. Procedure success requires careful attention to technical and anatomic factors, including sacral bony and neurovascular anatomy. The likelihood of positive outcomes is increased with careful patient selection and accurate device placement fully across the SIJ.

25 CHAPTER Back Pain in Children and Adolescents

Lori A. Karol
Lauren LaMont
Megan Mignemi

Introduction

The prevalence of back pain in children and adolescents is rising.[1-3] While it is assumed that pediatric back pain is rare, more than 50% of children note episodes of back pain by 15 years of age.[4-7] In 2001, it was reported that, although 39% of teenagers complain of low back pain, few actually present for medical evaluation.[8] While the incidence of back pain in adolescents was previously reported to be around 18% to 30%,[9-11] a recent Danish study reported an 86% incidence of self-reported back pain in a prospective cohort study of 1348 students ages 11 to 13 years, which increased to 89% at 2-year follow-up.[12]

As complaints of back pain in young adults continue to rise, the classically held belief that back pain in children and adolescents is due to serious pathology is no longer thought to be true.[13] In 1985, Hensinger found a specific diagnosis in 84% of children presenting for treatment of back pain.[14] In a more recent analysis, however, Yang and colleagues found that over 80% of adolescents had no identifiable etiology for their back pain within 1 year of presenting to a physician.[3] In this cohort, the most common etiology of back pain in ages 10 to 19 years was muscle strain or sprain. A similar study of patients screened by single photon emission computed tomography (SPECT) scans found a cause for back pain in only 22% of 217 children.[15] Based on this, it is up to the evaluating surgeon to identify which children are most likely to have an underlying musculoskeletal condition and require a comprehensive evaluation to identify the etiology of their back pain.

Studies suggest that back pain in younger children is more worrisome, while adolescent pain is more likely to pattern after adult complaints, especially when the complaint is chronic.[16] The thought that a pathologic abnormality can nearly always be identified as the cause of the symptoms is evolving as more studies demonstrate fewer pathologic findings.[16,17] As children reach adolescence, diagnostic imaging is less likely to yield a diagnosis.[18] As the radiologic armamentarium grows, the treating physician has more choices in the evaluation of these patients, yet every child who presents to the physician does not need to undergo a comprehensive workup. Therefore, a complete understanding of the potential causes of back pain will enable treating physicians to properly evaluate the pediatric patient who complains of back pain.

History

The initial step in distinguishing which children require symptomatic treatment from those who merit a complete radiographic evaluation is obtaining a detailed history. The characteristics of the pain are most helpful. Acute pain following trauma is seen with fractures, disc herniations, and apophyseal ring separations. Insidious pain without a specific antecedent event is characteristic of developmental conditions such as Scheuermann kyphosis and benign neoplasms. However, in adolescent patients, pain without a specific event may also be attributable to mechanical back pain, as is seen in adults with similar complaints. Recurrent pain associated with athletics and relieved by rest leads to suspicion of overuse injuries, such as spondylolysis, or may also be mechanical in nature. Unremitting pain, especially if it is worse at night or wakes the child from sleep, is most worrisome, as this type of pain can be seen in malignancies and infection.[19,20]

The location of the pain is very helpful in narrowing down the differential diagnosis. Localized bony pain may indicate either benign or malignant neoplasms. Lumbar pain may be produced by spondylolysis or spondylolisthesis, while pain in the thoracic area may be due to Scheuermann kyphosis. It is important to note whether pain in each region is bony tenderness elicited while palpating spinous processes or paraspinal soreness, which may point more to muscle strain or mechanical pain. When pain radiates into either the buttocks or legs, there is concern for a disc herniation, apophyseal fracture, and spinal cord or vertebral tumors. As with all examinations, when pain radiates down into the leg or groin, it is important to rule out hip pathology, especially in the adolescent female, who may suffer from unrecognized hip dysplasia.

The presence or absence of constitutional symptoms is useful in deciding the potential severity of the underlying condition. Fever in a child with acute back pain points to an

infectious or neoplastic etiology. It is important to question the parents about malaise, anorexia, and the presence of a rash or abnormal bruising, as back pain can be the presenting complaint in children with leukemia. These concerns call for more emergent blood work and imaging to confirm the diagnosis.

Next, a detailed neurologic history must be obtained. The presence of numbness, weakness, decreased ability to walk, and changes in coordination require prompt imaging of the spinal cord. Questioning the patient and parents as to how much these neurologic symptoms have altered activity level can also be helpful to determine their severity. The treating physician should ask specifically about changes in bowel or bladder function, as adolescents are hesitant to admit to these symptoms.

The patient's age is also very helpful in directing the evaluation of back pain. Back pain in children younger than 4 years is usually due to either infection or malignancy. A history of fever, limp, and malaise should be sought, and an immediate diagnostic evaluation should be performed. Children in the first decade of life commonly present with discitis and/or osteomyelitis and malignant neoplasms, but also may present with benign conditions such as eosinophilic granuloma.[20] Patients older than 10 years are most likely to have back pain secondary to trauma or overuse, resulting in spondylolysis, disc herniations, or apophyseal fractures.[21] Scheuermann kyphosis typically presents in adolescence. Patients older than 10 years are also more likely to have pain attributable to overuse, strain, or mechanical low back pain without abnormal imaging.[3] While more common in younger children, teenagers can present with malignancies. Thus, the evaluating physician should weigh the relative frequency of conditions based on age, but always remain cautious.

A family history should be taken regarding back pain. Adolescents with ill-defined pain, no constitutional symptoms, no history of excessive athletic activity, no anatomically consistent neurologic complaints, and a positive family history often do not have a musculoskeletal etiology for their pain.[5,20] Psychosomatic pain does occur in this age group, but remains a diagnosis of exclusion. History of sleep habits, school performance, changes in weight, mood, and mental health problems can also help identify patients in whom pain is associated with a psychiatric diagnosis that at times may require urgent referral.

Finally, a complete review of systems should be obtained. Back pain associated with menses is rarely orthopaedic in nature. Flank pain may be renal in origin. A recent study showed that 5% of children presenting to an emergency department for evaluation of back pain had urinary tract infections.[22]

Physical Examination

The general appearance of the child should be noted. If the child appears systemically ill, immediate evaluation for infection or malignancy is warranted. Whether the child can walk and the characteristics of the child's gait are important, as the inability to walk can be due to infection or spinal cord compromise. Specific gait abnormalities, such as increased posterior pelvic tilt and decreased hip flexion, may be seen in spondylolisthesis. Examination of the skin for dysraphic lesions, such as hairy patches or deep sinuses, as well as for café-au-lait spots, is also required. Palpation of the spine can identify the location of the pathologic abnormality.

The spine should be inspected for sagittal and coronal alignment. The Adams forward bend test identifies patients with scoliosis, but the presence of scoliosis is more likely to be a symptom of underlying pathology rather than a cause of pain. Trunk lean and decompensation may indicate such pathology as benign or malignant neoplasms, or irritating lesions such as herniated discs. Stiffness of the spine should be noted. Thoracic kyphosis typically increases and lumbar lordosis reverses as a child bends forward. In the presence of significant pain, the child will not allow the spine to move, and will bend the knees to touch the floor rather than flex the spine. Pain with hyperextension of the spine is often seen in patients with spondylolysis and is often worsened with one-legged hyperextension on the affected side if unilateral. This can be further exacerbated by twisting during hyperextension. The Lasegue sign is nearly always positive in patients with herniated discs or fractured apophyses. The straight-leg raise is also diminished in patients with tight hamstrings due to spondylolisthesis, and popliteal angles will also be increased.

Next, a thorough neurologic examination is critical in the evaluation of the child with back pain. Motor and sensory function and deep tendon reflexes should be tested. Long tract signs, such as clonus and the Babinski reflex, must be evaluated to rule out spinal cord compression or abnormality. The abdominal reflex is tested by lightly stroking the four quadrants around the umbilicus in the supine child. While an absent abdominal reflex is not abnormal, an asymmetric response may indicate spinal cord abnormalities.

Diagnostic Studies

With the information obtained from the history and physical, a focused approach to diagnostic studies can be taken. If the patient is aged 10 years or younger, has had pain for 2 months or longer, has night pain, had traumatic injury, or if there are constitutional symptoms, standard radiographs of the spine should be obtained at once. If the patient is older, the pain is of short duration with no major traumatic event, and the physical examination is completely normal, the patient may be observed for a short period of time. Most patients fall between these two groups; thus, the extent of the radiographic evaluation should be decided on an individual basis.

Radiographs

Plain radiographs are the best screening examination for the child with back pain.[19,23] Anteroposterior (AP) and lateral views of the spine should be obtained without pelvic shielding, as the shield hides the sacrum, sacroiliac (SI) joints, and pelvis. The physician should carefully examine the films for

alignment, disc space narrowing, endplate irregularities, and lytic or blastic lesions. Each pedicle should be identified on the AP view. If a question of a lesion arises, a focused coned-down view taken with the patient supine provides better bony detail.

The lateral film should be reviewed for the presence of spondylolysis or spondylolisthesis. As on the AP view, if there is a question of lysis on the lateral view, a spot lateral of the lumbosacral junction better visualizes the pars interarticularis. Oblique views of the lumbosacral spine can also show the lysis; however, recent studies demonstrate that, in the majority of cases, oblique films do not improve the rate of diagnosis of spondylolysis.[18]

The identification of scoliosis on screening films of a child with back pain should not lead to the conclusion that the curve is the cause of the pain. Although up to 33% of adolescents diagnosed with scoliosis complain of some back pain, it is usually located over the rib prominence and is rarely a presenting complaint.[23] The apex of the curve should be carefully inspected for bony lesions in the child with painful scoliosis.

Bone Scan

If plain radiographs are normal, the neurologic examination is normal, but the symptoms of the patient are suggestive of bony pathology, a triphasic technetium bone scan is recommended. Scintigraphy is a highly sensitive but nonspecific tool to localize bony processes. Infection, most benign and malignant bony lesions, and stress fractures will have increased bone turnover, which is visualized as increased tracer uptake on scintigraphic images. Pinhole collimation is helpful in localizing the increased uptake. The study should include the SI joints and pelvis, as pathology in these areas often presents as back pain.

SPECT scanning combines the physiology of a bone scan with the ability to precisely localize lesions within the vertebra, similar to a CT scan. Increased uptake can be seen in the posterior elements in stress fractures; therefore, SPECT is particularly helpful in diagnosing spondylolysis.[24–27] A recent study of children younger than 10 years with back pain found SPECT to be highly sensitive for identifying injury to the pars.[28] Another study of 100 patients aged 2 to 18 years presenting with low back pain found that a negative SPECT scan was most helpful in ruling out an organic cause for back pain of less than 6 weeks' duration.[29]

Computed Tomography

Computed tomography (CT) provides the best imaging of the vertebral anatomy. It is not used as a screening tool, but it is useful when a lesion is seen on plain radiography or when plain radiography is negative but bone scintigraphy shows increased uptake. It can be used to assess the status of the pars interarticularis in patients with spondylolysis or to better delineate the extent of bony tumors. Although bone lesions can be seen on magnetic resonance imaging (MRI), surrounding edema may overestimate the extent of skeletal involvement.

Magnetic Resonance Imaging

MRI is used to image the neural axis in all children who have an abnormal neurologic examination. MRI is able to identify spinal neoplasms, cord abnormalities such as syringomyelia and tethers, discitis, and herniated discs, among other conditions. Auerbach and coworkers[29] recommend MRI as the best imaging modality for patients with low back pain of greater than 6 weeks' duration. In support of this, a recent study of pediatric patients found the incidence of abnormal pathology on MRI to be 34% in patients with constant pain, night pain, radicular pain, and abnormal neurologic examination.[30]

Laboratory Tests

Laboratory tests should be obtained at presentation in all young children with back pain and those with night pain, fever, malaise, or easy bruising. A complete blood count with differential should be obtained. The peripheral smear should be ordered to look for abnormal cell lines consistent with leukemia. The erythrocyte sedimentation rate and C-reactive protein should also routinely be studied because they are elevated in infection and malignancy. Urinalysis should be used to screen for renal conditions.

Differential Diagnosis

Muscle Strain

A very common cause of back pain, especially in athletic adolescents, is muscular strain, which can be up to 3 to 5 times more prevalent in elite athletes.[31] Pain can often be attributed to changes in amount and level of training, ill-fitting equipment, or poor technique. Poor strength of the back extensor and abdominal musculature, as well as tight hamstrings and hip flexor muscles, may be found in patients with muscular strain.[32] Absence of concerning history, such as night pain or radicular pain, and relation to activity can be helpful in excluding other more concerning diagnoses.

Treatment consisting of temporary activity modification, application of ice in the acute phase and heat later for spasm, in combination with nonsteroidal antiinflammatory drugs (NSAIDs), is often sufficient for most young adults. In patients who have failed these measures, a home physical therapy program for core and back strengthening, as well as hamstring stretching, may be prescribed. Important in the counseling of these patients is the emphasis that without regularly performing these exercises, there will be no significant improvement in pain. Return to activity is based on resolution of symptoms while continuing a core strengthening program as part of athletic training.

Disc Herniation

Intervertebral disc herniation occasionally occurs in older children and teens. The onset of symptoms is usually related to acute or repetitive trauma.[33] Of affected patients, 82% complain of back pain with radiation into the legs.[34] This radicular

FIG. 25.1 Magnetic resonance image of a 16-year-old female with back and right leg pain demonstrates a herniated L4–L5 disc *(arrowhead)*.

pain is exacerbated by activity and relieved by rest. As in the adult population, the pain is worsened by sneezing, coughing, or straining. Recent studies have demonstrated a higher incidence of disc herniation in female patients and support that leg pain is the most common presenting complaint.[35]
