Significant blood loss and transfusion requirements are associated with adult scoliosis surgery. Elgafy et al.[76] conducted a review of the literature on reduction of blood loss in major spine surgery and found a high level of evidence supporting the use of antifibrinolytics (e.g., tranexamic acid, aprotinin, and epsilon- aminocaproic acid). Intraoperative red blood cell salvage devices are also popular in the field of spinal deformity correction. The potential to reduce or obviate allogeneic blood transfusions, elimination of risk of alloimmunization and viral disease transmission, and preservation of the normal oxygen-carrying capacity of salvaged red blood cells are some of the major advantages of cell salvage techniques.[77] In a prospective randomized study involving 110 scoliosis patients undergoing posterior instrumented spinal fusion, Liang et al.[78] reported reduced mean intraoperative red blood cell transfusion requirement and a lower perioperative allogeneic blood transfusion rate in the cell saver group (14.5% vs. 32.7%; $P = .025$). However, several other studies do not support its efficacy in reducing the requirements of allogeneic blood transfusions in spine surgeries.[79,80]

Operative Decision Making

There exists tremendous variability in the operative management of adult scoliosis, with little consensus on surgical strategy regarding approach and levels.[81–83] Debate between selective decompression versus decompression and fusion versus limited fusion, identification of proximal fusion levels, and choosing distal fusion levels—including fusion to the pelvis—all remain sources of controversy.

Decompression

Selective decompression in the setting of adult scoliosis involves decompression of neurologic compression without fusion or correction of coronal, axial, or sagittal alignment. Radicular pain and neural symptoms are important clinical presentations of adult scoliosis. Limited decompression of stenotic levels may offer significant improvement of clinical symptoms while limiting surgical risks associated with a larger reconstructive operation. The negative of doing only a decompression is that there may be progression of the deformity, possibly requiring a secondary procedure in the future.[84] Indications for a selective decompression operation would include patients who present with primarily radicular pain, patients with a stable deformity with bridging osteophytes or ankylosis, patients with radicular symptoms from compression of nerve roots from the convexity of the curvature as opposed to foraminal stenosis from the concavity of the curve, and patients with central or lateral recess stenosis.

Decompression With Limited Fusion

As with selective decompression alone, selective decompression and limited fusion has a role in a specific patient population. Patients who cannot undergo long thoracic and lumbar fusions may be candidates for limited fusion. The ideal candidate for limited fusion is a patient whom the surgeon desires to treat with decompression only for the reasons stated earlier; however, radiographs reveal apical progression or a symptomatic lumbosacral fractional curve. The lumbosacral or fractional curve in adults with scoliosis may be a localized source of symptomatic neural compression and pain, even in the presence of more generalized deformity. When performing selective decompressions, transforaminal lumbar interbody fusion or posterior lumbar interbody fusion can be used as a posterior-only approach, with the placement of the intervertebral cage on the concavity of the deformity to allow some deformity correction.[85]

There is little consensus on the proximal fusion level in patients with adult scoliosis once the decision has been made to proceed with decompression and fusion. The proximal fusion should not be stopped at the thoracolumbar junction and, at a minimum, the apex of the deformity should be included in the fusion levels.[86] It is important to consider the proximal and distal levels beyond the ending point of the fusion, as the amount of stability and degeneration at an adjacent vertebral segment to the fusion will predict the

stability of the adjacent level after fusion. Intraoperatively, efforts should also be made to preserve the supra-adjacent facet, the intraspinous ligaments, and the supraspinous ligaments, thus preserving the normal intravertebral ligamentous relationships.[87] In thoracic and lumbar double-curve degenerative scoliosis, the proximal construct should include the thoracic curve and should not stop distal to any portion of the curve.[88] Stopping at the physiologic apex of thoracic kyphosis (T5–T6) should be avoided due to the increased risk of proximal junctional kyphosis.[89] Thus constructs typically end either at or below T10 or between T2 and T4.

The decision to continue the distal fusion level from L5 to S1 is controversial and heavily debated. A fusion that extends to the sacrum provides greater stability, but with the increased stability comes increased risks and complications. Stopping the fusion at L5 may reduce the magnitude of the procedure and may limit perioperative complications. However, this advantage may come at the cost of a loss of deformity correction over time and a possible need for future surgery with extension of arthrodesis to the sacrum. When comparing fusion to S1 and fusion to L5, studies have shown increased coronal balance and lateral listhesis with fusion to S1.[90–93]

The biomechanical forces of the sacrum allow for implant prominence, implant loosening, and instrument-related issues when fusing to the pelvis.[94] Common techniques to minimize sacropelvic fixation prominence complications include the use of S2 iliac screws and S2 alar screws, which allows for reduced implant prominence and allows the use of a single rod, reducing the number of required connections. Kebaish et al.[95] prospectively reviewed the use of S2AI screws in 52 consecutive patients with mean 2.5-year follow-up, concluding that the method is easy, safe, and effective for achieving sacropelvic fixation in long posterior constructs, with minimal complications and low revision rate.

Clear indications to extend instrumentation and fusion to the level of the sacrum include a spondylolisthesis at L5–S1, stenosis requiring decompression at L5–S1, fixed obliquity of the L5–S1 motion segment, incomplete correction of global sagittal balance, and symptomatic degenerative changes at L5–S1.

Surgical Approaches in Adult Scoliosis Surgery

The choice of surgical approach to the spine in adult deformity has an important effect on the morbidity of surgery and on the efficacy of deformity correction and clinical outcomes. Spinal reconstruction can be performed via anterior, posterior, and combined approaches, with or without staging of the procedures. The optimal method must take into consideration the patient's sagittal alignment, bone quality, nutritional status, need for fusion across the lumbosacral junction, anterior column mobility, and the surgeon's technical expertise.

Anterior surgery to treat adult thoracolumbar scoliosis was originally described by Dwyer et al. in 1969.[96] These anterior-only reconstructions were typically utilized for thoracolumbar curvature; they were able to achieve effective correction, especially in the sagittal plane, because of the release of the anterior longitudinal ligament. Distal lumbar motion segments were often able to be spared, a distinct advantage in comparison to the posterior approach options. In addition, anterior-only correction maintains the integrity of the posterior ligamentous complex. The major disadvantage of anterior approaches to the spine is the morbidity of the dissection, with risks to the lung, diaphragm, sympathetic chain, and major vascular structures in the thoracic and thoracolumbar spine, as well as the genitofemoral nerve, kidney and ureter, and the peritoneal contents in the lumbar spine. Smith and colleagues[97] reported excellent clinical outcomes with limited complications in a series of 15 consecutive adult patients treated with rigid single-rod anterior surgery for thoracolumbar scoliosis.

Through an anterior approach, stiff spinal deformities caused by degenerative disc collapse via discectomy can be released by sectioning the anterior longitudinal ligament, allowing for significant correction of segmental sagittal malalignment. This is particularly useful in reestablishing lordosis of the lumbar spine. Correction achieved through anterior column reconstruction may eliminate the need for more aggressive posterior-based osteotomies. Anterior approaches also allow for placement of bone graft within the anterior column that is under a compressive load and the large bony surface area leads to higher fusion rates. Especially at the lumbosacral junction, an interbody fusion is important to mitigate the risk of pseudarthrosis.[98]

Bradford et al.[99] demonstrated that a combined anterior and posterior approach to Scheuermann kyphosis resulted in significantly better deformity correction and better fusion rates and maintenance of correction over the instrumented segments than posterior-only surgery with nonsegmental instrumentation. Similarly, in adult scoliosis, a combined anterior and posterior approach has been advocated for improvement of lumbar lordosis and improvement of fusion rates, especially at the lumbosacral junction.[100,101] Berven et al.[102] studied the outcomes of combined anterior and posterior surgery for the management of fixed sagittal plane deformity. They noted that patient satisfaction with surgery and overall clinical outcomes were best in cases that resulted in an increase in lumbar lordosis. Patients with preoperative regional hypolordosis (≥30 degrees) had the most reliable improvement of health status and had better clinical outcomes than those with lumbar lordosis in the physiologic range. The authors noted that 40% of patients in the study had major complications, including pneumonia, dural tears, wound infection, and pseudarthrosis. Relative indications for combined anterior and posterior fusion include planned arthrodesis across the lumbosacral junction, lumbar pseudarthrosis, correction of a fixed lumbosacral obliquity, lumbar hypolordosis, posterior-element deficiency, and osteoporosis. These rates of complications from combined anterior-posterior approaches have been detailed in several studies in the literature.[103–105]

When a decision for a combined approach for treatment of spinal deformity has been made, the options of doing the anterior and posterior surgery on the same day versus on two separate days must be considered. Staged procedures are well tolerated by many patients, but they may be associated with a higher risk of infection and blood transfusion. For fused, rigid deformities, patients may be served better with a two-stage

surgery with two periods of anesthesia. During the first anesthetic, anterior discectomies and interbody placement with temporary fixation may be performed. At the next stage, done approximately 4 to 6 weeks later, posterior releases, instrumentation, and deformity correction can be performed. This allows ample time to recover from the first surgery before undergoing the second.

The role of minimally invasive approaches to the anterior column, including direct lateral approaches, has expanded the indications and use of anterior surgery for adult scoliosis.[106] Although initially used primarily for foraminal stenosis with loss of disc height and for adjacent-segment degeneration in the lumbar spine, more attention has been paid recently to using various forms of the direct lateral retroperitoneal approach for correcting and stabilizing adult deformity cases. The use for lateral interbody fusion in obtaining indirect decompression of neuroforamina and obviating the need for direct decompression has been well documented,[107] and now it has increasing use in deformity correction. A recent review of the literature[108] on using a specific form of lateral interbody fusion indicated that ODI and visual analog scale scores improved comparatively with other forms of lumbar interbody fusion and that coronal alignment and balance were both corrected, but minimal LL and sagittal balance correction was obtained. A more recent innovation involves release of the anterolateral ligament via the minimally invasive lateral approach, allowing for significant segmental correction (in some cases approaching 30 degrees) in an effort to avoid having to perform the more morbid posterior osteotomy. There has been evidence to support the use of minimally invasive surgery techniques in ASD surgery, particularly in symptomatic elderly patients without significant sagittal imbalance.[109]

Posterior-only approaches for the correction of spinal deformity have become increasingly more common. Three-column segmental transpedicular instrumentation and the development of posterior osteotomy techniques enable greater curve correction without the need for anterior apical releases.[110] Posterior-based osteotomies, including posterior column osteotomies (e.g., Ponte osteotomies), pedicle subtraction osteotomies, and vertebral column resections, allow for significant coronal and sagittal deformity correction from the posterior approach. Posterior column osteotomies typically allow 10 degrees of sagittal correction per level or about 1 degree of correction for every millimeter of bone resected. The pedicle subtraction osteotomy, which is a V-shaped wedge resection of the vertebral body including both pedicles and posterior elements, can achieve a correction of between 30 and 40 degrees at a single level.[111] Vertebral column resection can deliver much greater coronal and sagittal plane correction.[112] The use of osteobiologics may improve fusion rates in adult scoliosis surgery and preclude the need for circumferential fusion at the lumbosacral junction.[113]

Kim et al.[114] analyzed the radiographic and functional outcomes after posterior segmental spinal instrumentation and fusion with and without anterior apical release of the lumbar curve in adult scoliosis patients. Their study showed superior clinical outcome scores (SRS) and subscales in self-image and function in the group with posterior-only surgery as compared to the group with the combined approach, without a difference in radiographic parameters. Perioperative morbidity and complications were higher in the group of patients treated with combined anterior and posterior surgery.

Multiple studies[115–117] have compared outcomes and complications in adults with thoracolumbar scoliosis. Overall, the authors demonstrated similar radiographic correction of deformity for each group. However, patients with staged anterior and posterior surgery had significantly more perioperative complications.

One challenge in treating patients with a posterior-only approach is the risk for pseudarthrosis. Kim et al.[118] reported a 17% incidence (nearly 1 in 5) of pseudarthrosis after long primary arthrodesis with the use of modern segmental spinal instrumentation for the treatment of adult idiopathic scoliosis. Some authors contend that risk for pseudarthrosis in the posterior-only approach can be mitigated with recombinant human bone morphogenetic protein-2. Luhmann et al.[119] have reported a high rate of fusion for both anterior-only (96%) and posterior-only (93%) surgery with the use of rhBMP-2 for ASD. A subsequent long-term follow-up study on the same patients showed significant fusion rates for anterior (91%), posterior (97%), and high-dose posterior (100%) spinal fusion.[120]

For severe spinal deformity, vertebral column resection is a useful technique to permit spinal column shortening and trunk translation. O'Neill et al.[121] recently published their 5-year follow-up on 120 patients who underwent three-column osteotomies. They showed radiographic alignment improvement but were negatively affected by prior surgery and complications requiring revision surgeries. Major complications occurred in 27%, with major reoperations in 25%. A posterior-only vertebral column resection may be effective for spinal deformity that is focal and in which the apex of coronal and sagittal deformity is matched. The combined anterior and posterior approach may be more effective in treating the patient with a deformity that extends across multiple segments; deformity that involves multiple apices, including different apices in the coronal and sagittal planes; and in the spine with hypokyphosis or lordosis across the thoracic spine.

Complications of Adult Scoliosis Surgery

Spinal deformity is one of the oldest conditions known to humankind. Its correction is inherently complicated and has certain risks involved. Neurologic injury during spine surgery can have devastating consequences for the patient; the surgeon being aware of the causes of these complications can help dissipate and potentially prevent them from occurring. The risk of neurologic injury depends on the surgical procedure performed, the amount of manipulation of the spinal cord, the use of spinal instrumentation, and the degree of preoperative spinal deformity and stability. The spinal cord is more sensitive to manipulation than the nerve roots. The pathophysiology of spinal cord injury is extremely complex and can involve physiologic processes such as inflammation, edema, hemorrhage, and ischemia.

The SRS used the largest known database of adult scoliosis to determine the rate of complications of adult scoliosis surgery.[122] Looking at their data from 2004 to 2007, complications were identified and analyzed on the type of scoliosis, age, use of osteotomy, revision surgery status, and surgical approach. Each group was stratified to age 60 years or younger versus older than 60 years. Surgical approach was divided into anterior, posterior, or combined anterior/posterior. Looking at a total of 4980 cases, there were 521 patients with complications (10.5%) and a total of 669 complications (13.4%). The most common complications were dural tear, 142 (2.9%); superficial wound infection, 46 (0.9%); deep wound infection, 73 (1.5%); implant complication, 80 (1.6%); acute neurologic deficits, 49 (1.0%); delayed neurologic deficits, 41 (0.5%); epidural hematoma, 12 (0.2%); wound hematoma, 22 (0.4%); pulmonary embolus, 12 (0.2%); and deep venous thrombosis, 9 (0.2%). There were also 17 deaths (0.3%). In their study, age was not associated with complication rate ($P = .32$). Significantly higher complication rates were identified in osteotomies, revision surgery, and combined anterior/posterior surgery.

As noted by Schwab et al.,[6] surgical complications were prevalent in 60% of patients older than 60 years. Surgical complications can be further differentiated into mechanical in nature, such as radiographic complications from proximal junctional kyphosis, and implant-related complications, such as pullout and implant failure. Complications may also be nonmechanical in nature, such as neurologic, dural injury, and wound healing.

Soroceanu et al.[123] recently looked at the radiographic and implant-related complications seen in adults undergoing spinal deformity surgery. With 2-year follow-up, the radiographic and implant complication rate was 31.7%, with half of these patients requiring a revision operation. These mechanical complications affected HRQOL by decreasing the rate of improvement over time after adjacent-segment disease surgery.

Several techniques have been proposed to reduce the risk of proximal junctional kyphosis. These include strategies to reduce the stiffness of the instrumentation, such as selecting rods of smaller diameter, transitional rods, and/or less stiff composite metals, and using hooks[124] or sublaminar wires in place of pedicle screws at the upper instrumented vertebra. Other authors have advocated the use of cement to augment the upper instrumented vertebra.[125,126] Percutaneous placement of pedicle screws in the upper one or two levels of the construct to minimize injury to the facet complex and supporting soft tissue structures is currently being evaluated. The best strategy to prevent proximal junctional kyphosis is the subject of much debate and an area of active research.[127]

The effect of advancing age on postoperative complications and revision surgery following fusion for scoliosis has been investigated recently.[128] In a retrospective cohort study examining 8432 patients with the average age at 53.3 years, there was an increase in risk of hemorrhage, pulmonary embolism, infection, and refusion associated with age.

The impact of obesity on complication rate infection and patient-reported outcomes in patients undergoing surgery for ASD has been examined by the International Spine Study Group.[129] Their retrospective processed active database of patients with ASD who are surgically treated included 2-year follow-up on 241 patients. This study reported that obese patients had higher overall major complications and wound infections. Obesity did not increase the number of minor complications, radiographic complications, neurologic complications, or the need for revision surgery. Despite these increased major complications, obese patients also benefited from surgical intervention; however, their HRQOL is less than that of nonobese patients.

The use of bone morphogenetic protein (BMP)-2 in ASD surgery has been investigated, most recently by a multicenter prospective study by Bess et al.[130] They reviewed a total of 279 patients, with a mean follow-up of 28.8 months. The BMP group had similar age, smoking history, previous spine surgery, total spinal levels fused, estimated blood loss, and duration of hospital stay as the no-BMP group. The BMP group had greater comorbidity, greater scoliosis, longer operative times, osteotomies per patient, and greater percentage of anterior/posterior surgery. The BMP group had more complications per patient and more minor complications per patient than the non-BMP group. The non-BMP group had more complications requiring surgery per patient than the BMP group. Major, neurologic, wound, and infectious complications were similar for both groups. Their conclusion was that BMP use and location did not increase acute major, neurologic, or wound complications.

Summary

Adult scoliosis is characterized by malalignment in the sagittal and/or coronal planes and can present with pain and disability. Clinical evaluation involves a thorough history, a complete physical examination, and radiographic evaluation with a particular focus on overall balance. Nonoperative management is recommended for patients with mild, nonprogressive symptoms. However, the evidence of its efficacy is limited. Operative management seeks to restore spinal alignment, decompress neural elements as indicated, obtain a solid fusion, and to minimize complications. A variety of surgical approaches and techniques are available to achieve these goals. In well-selected patients, surgery yields excellent outcomes in terms of reduction in pain and disability.

Case Studies

Figs. 72.5 through 72.12 provide several case studies for reference.

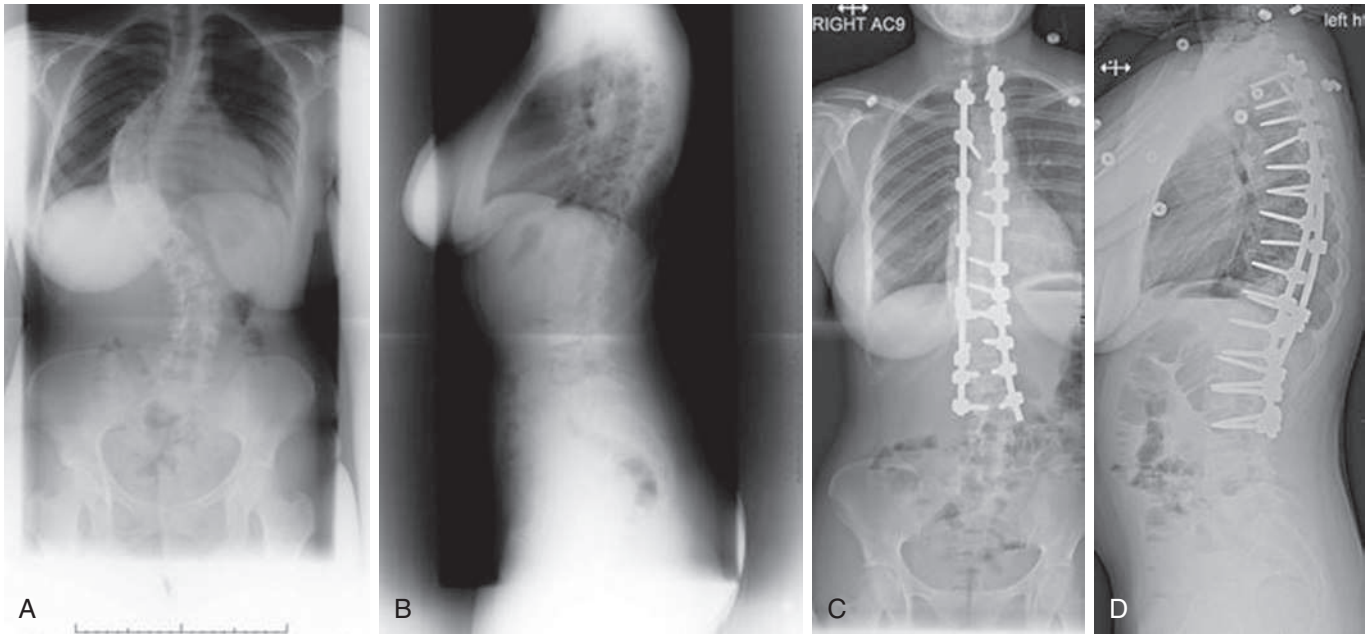

FIG. 72.5 (A–B) Radiographs of a 23-year-old woman with a history of untreated adolescent idiopathic scoliosis. (C–D) The patient underwent posterior spinal fusion of T2–L3 with instrumentation, autograft, and allograft.

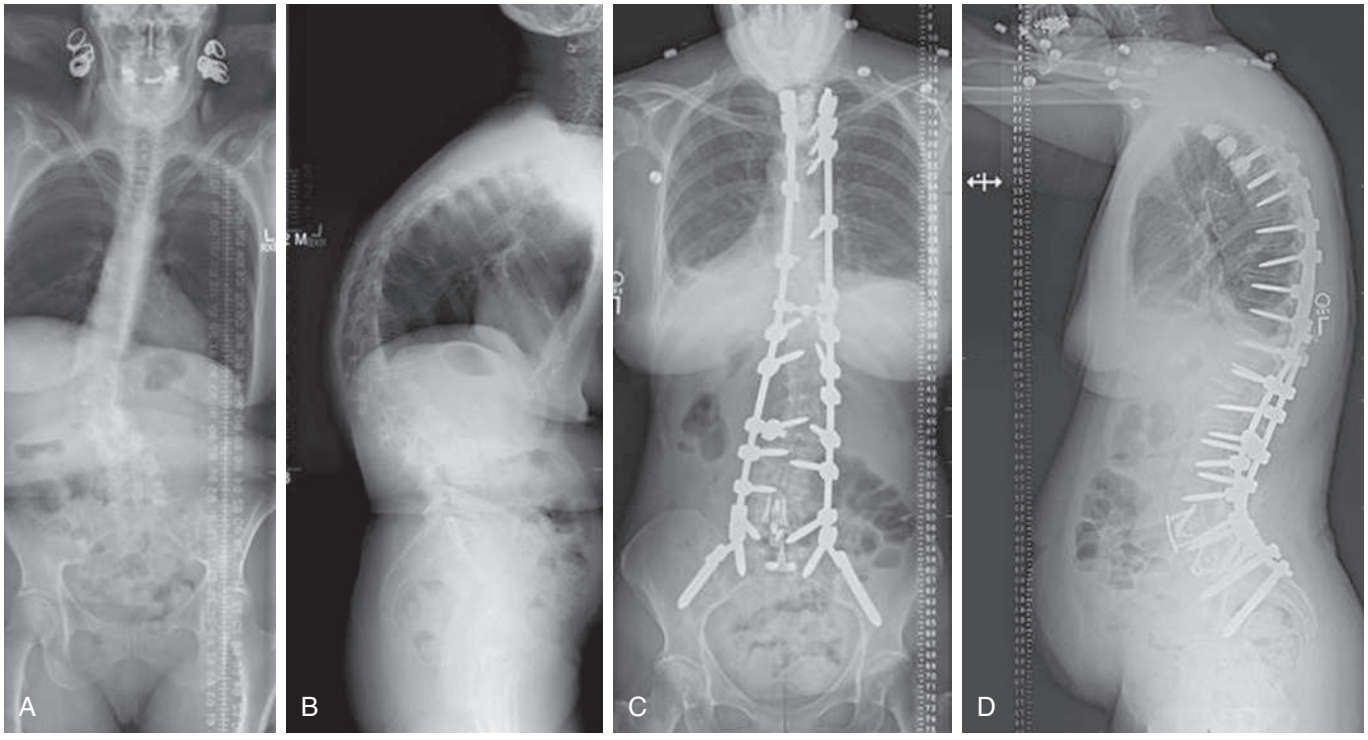

FIG. 72.6 (A–B) Radiographs of a 63-year-old woman with kyphoscoliosis who reported back pain and sagittal alignment issues. (C–D) The patient had an anterior lumbar interbody fusion done at L4–L5 and L5–S1, followed by posterior spinal fusion from T4 to pelvis done about 8 weeks later. At that time, she had Ponte osteotomies done from T9 to L3 to enhance the correction in the sagittal plane.

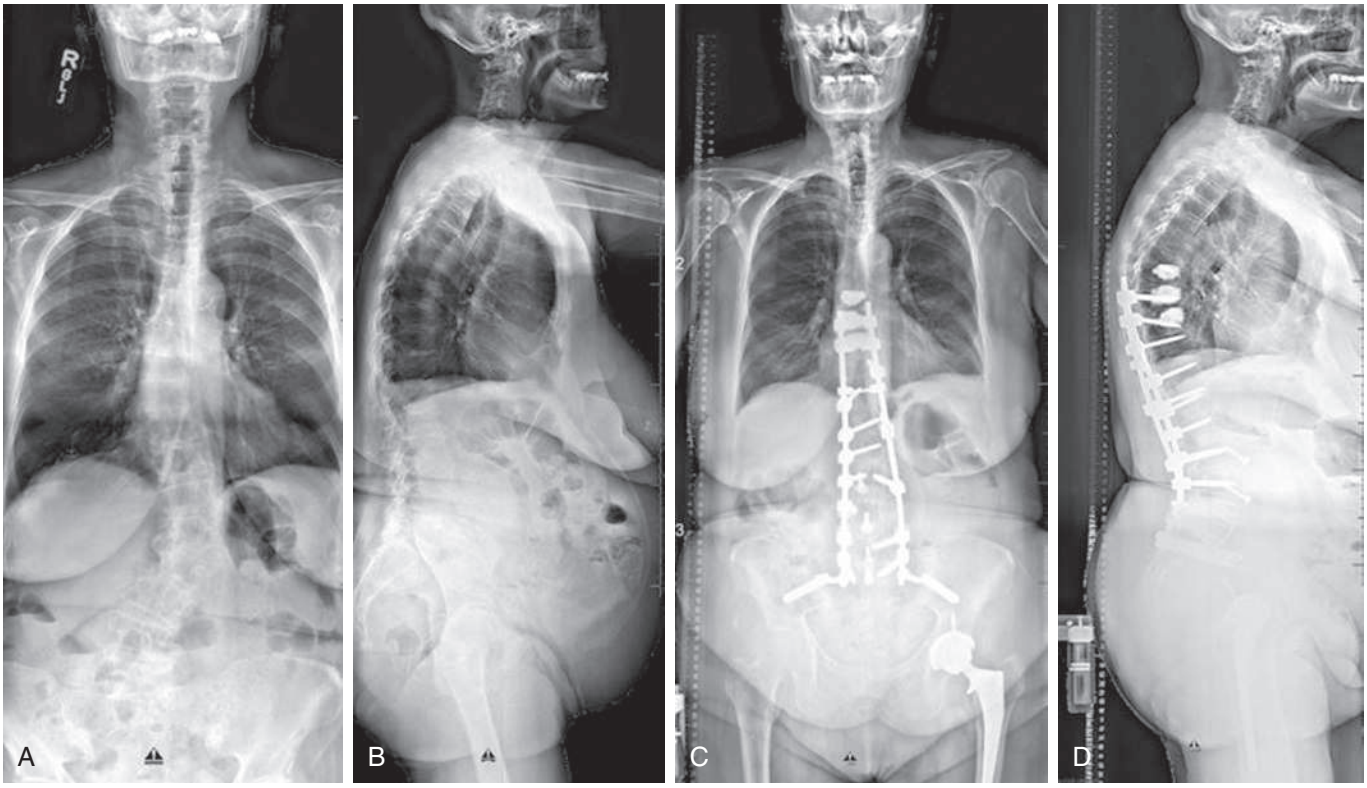

FIG. 72.7 (A–B) Radiographs of a 79-year-old woman with back and leg pain. The patient had an anterior/posterior procedure done at the same setting. (C–D) Anteriorly, she had an anterior lumbar interbody fusion at L3–L4, L4–L5, and L5–S1. Posteriorly, she had a posterior spinal fusion from T9 to S1, with laminectomies at L3–L4 and L4–L5 2/2 lumbar stenosis. Preoperatively, she had vertebroplasties done at three levels at the superior end of the construct, leaving the top level of vertebroplasty uninstrumented.

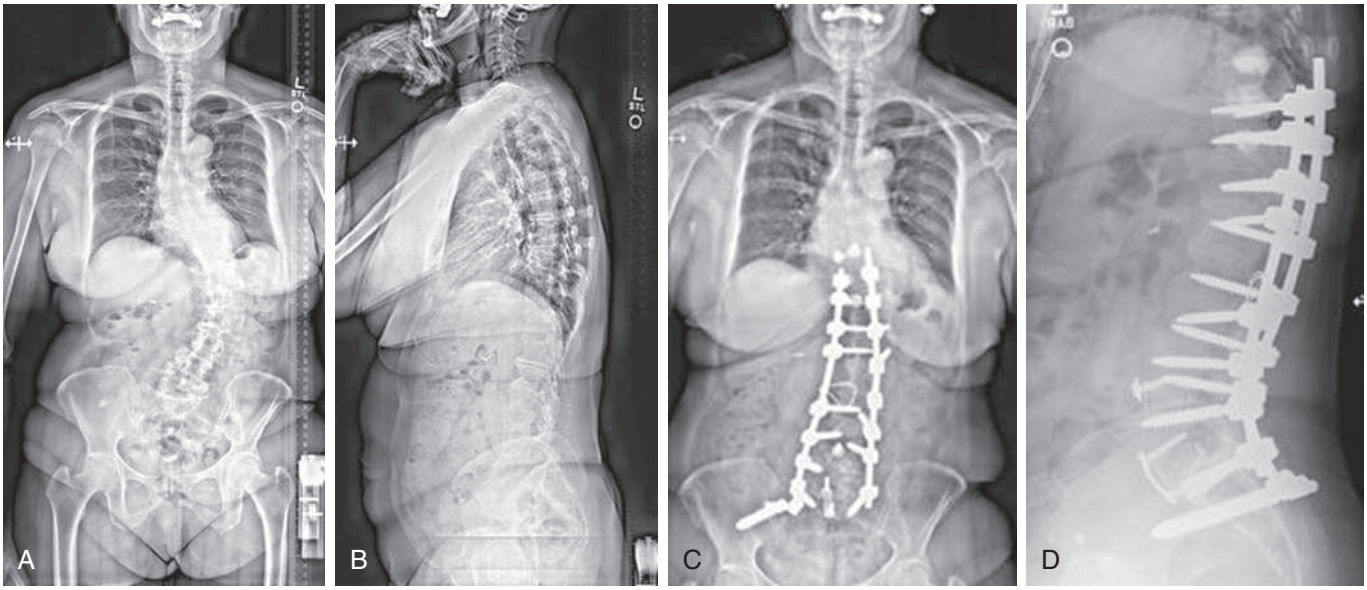

FIG. 72.8 (A–B) Radiographs of a 67-year-old woman who reported back and leg pain as well as issues with coronal imbalance. She had an anterior/posterior procedure done in the same setting. (C–D) She had an anterior lumbar interbody fusion at L4–L5 and L5–S1, followed by a posterior spinal fusion from T10 to pelvis, as well as laminectomies from L1 to L4. Preoperatively, she had vertebroplasties done at three levels at the superior end of the construct, leaving the top level of vertebroplasty uninstrumented.

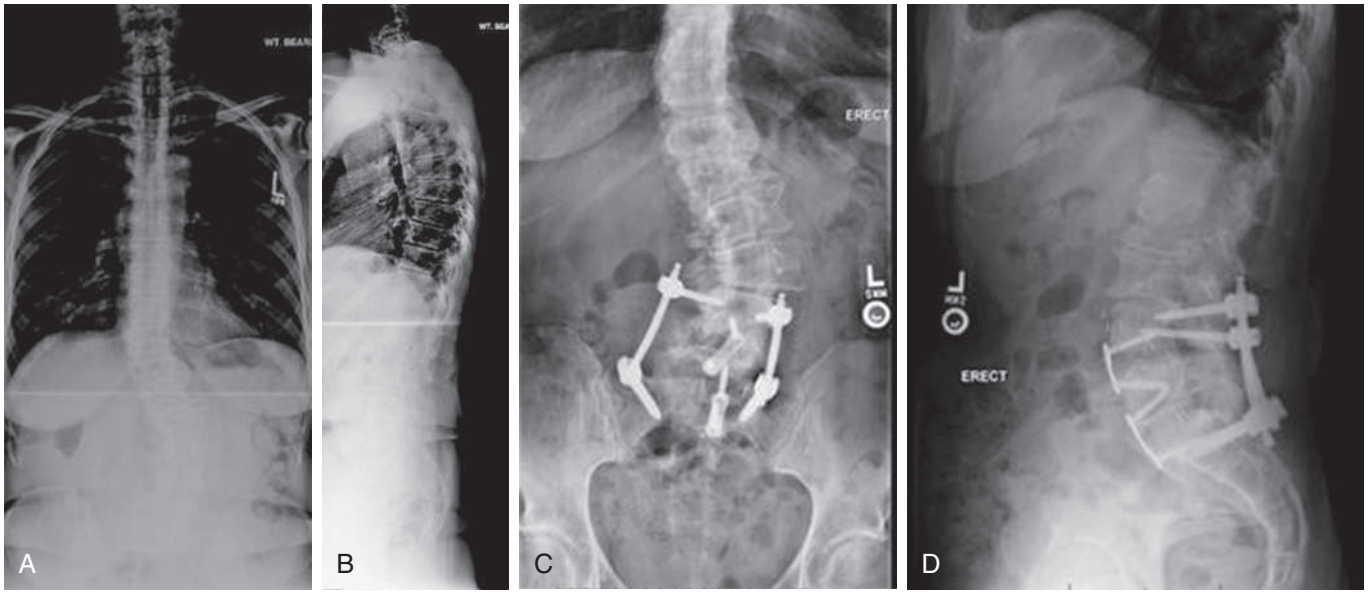

FIG. 72.9 (A–B) Radiographs of a 65-year-old woman with degenerative scoliosis who reported radicular symptoms associated with foraminal stenosis at the L4–L5 and L5–S1 levels. She had an anterior/posterior procedure done at the same setting. (C–D) Anteriorly, she had an anterior lumbar interbody fusion at L4–L5 and L5–S1. Posteriorly, she had percutaneous pedicle screw fixation from L4 to S1.

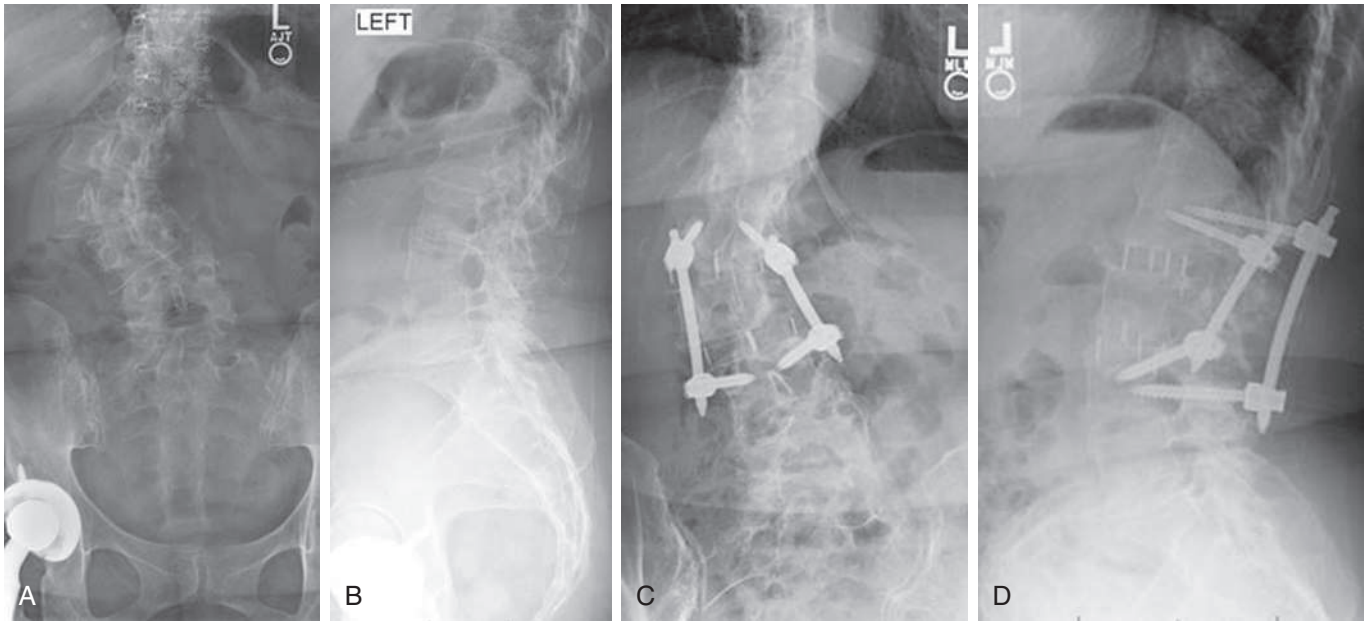

FIG. 72.10 (A–B) Radiographs of a 68-year-old woman with degenerative scoliosis who reported left lower extremity pain in the L2 and L3 distribution. She had minimal back pain and her symptoms improved in a recumbent position. (C–D) The patient had interbody cages placed at L2–L3 and L3–L4 via a direct lateral approach, followed by pedicle screws placed at L2 and L4 percutaneously.

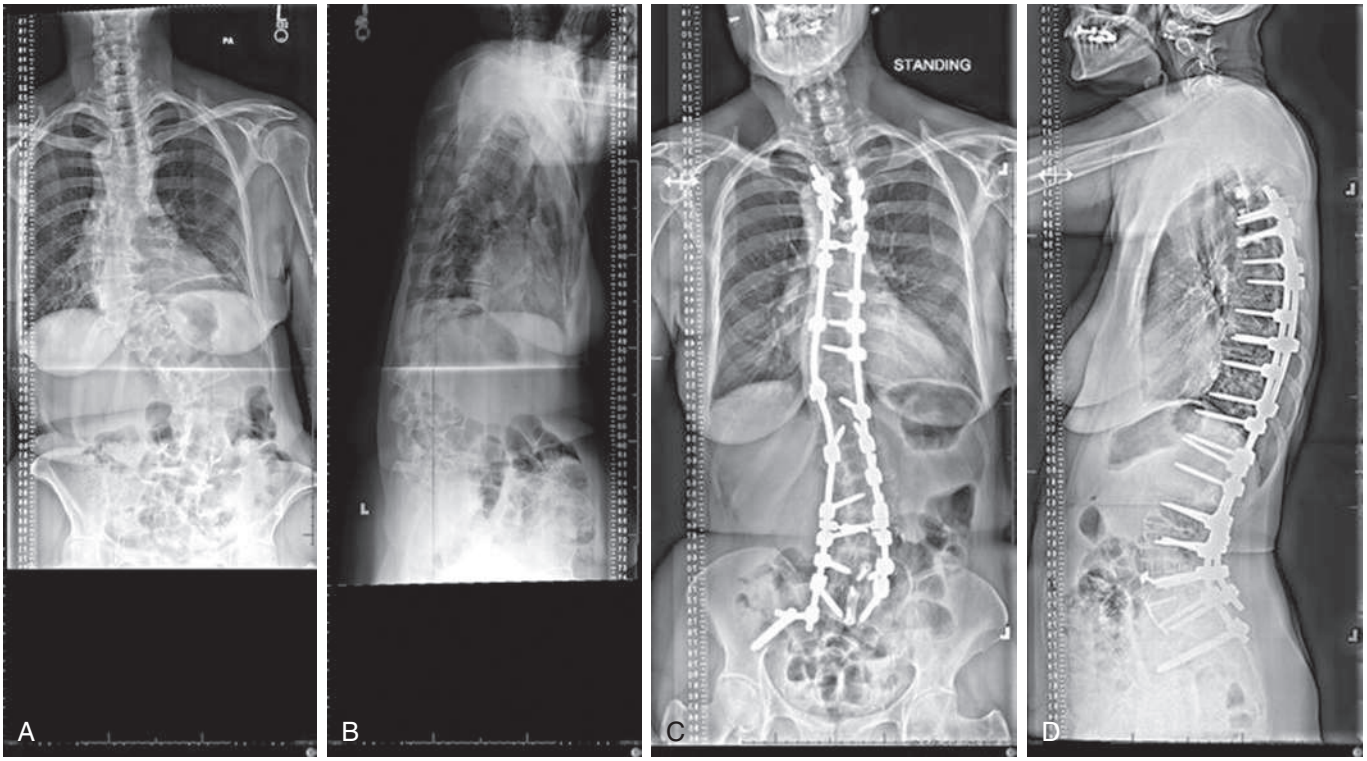

FIG. 72.11 (A–B) Radiographs of a 58-year-old woman with kyphoscoliosis who reported back pain and had sagittal alignment issues. (C–D) The patient had an anterior lumbar interbody fusion done at L4–L5 and L5–S1, followed by a posterior spinal fusion from T4 to pelvis done about 8 weeks later. She underwent preoperative vertebroplasties at the upper end of the construct.

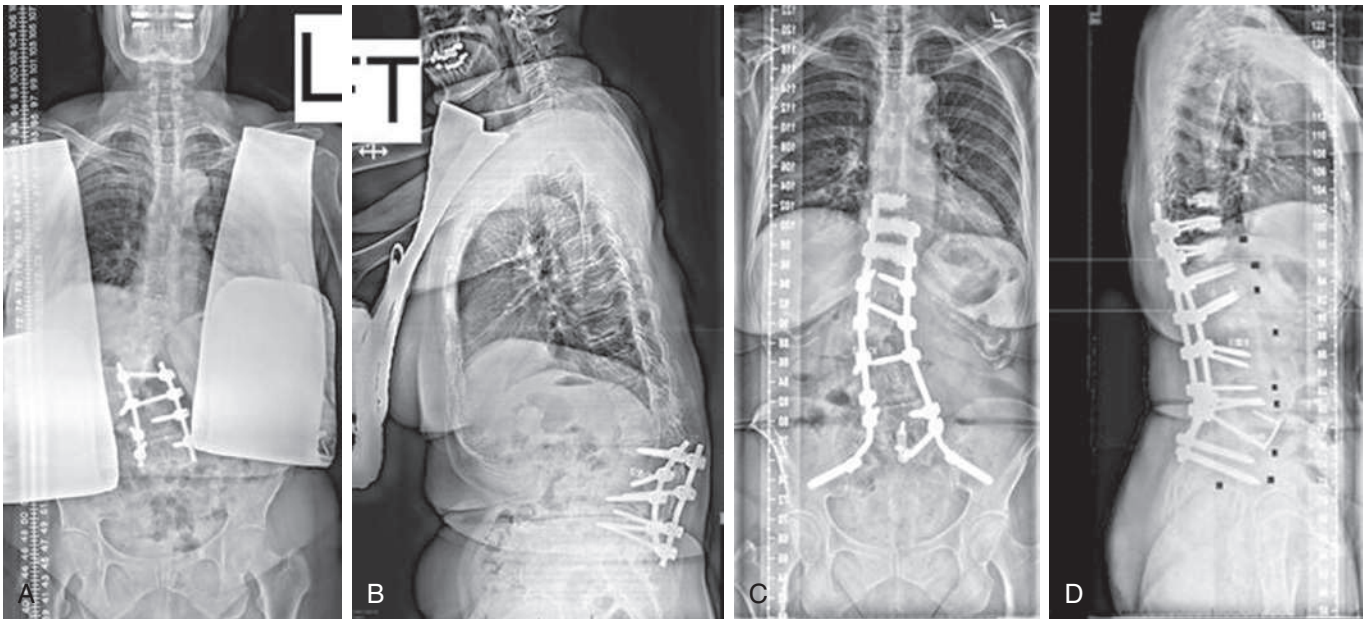

FIG. 72.12 (A–B) Radiographs of a 65-year-old woman with prior L2–L5 fusion who had worsening back and leg pain. She had lumbar lordosis/pelvic incidence mismatch. (C–D) The patient underwent an anterior lumbar interbody fusion at L5–S1 with a 30-degree spacer, anterior instrumentation, spinal implant removal at L3–L5, Smith-Petersen osteotomy at L5–S1, pedicle subtraction osteotomy at L2, transforaminal lumbar interbody fusion at T12–L1 and L1–L2, spinopelvic instrumentation with fixed iliac screws, revision instrumentation at T10–pelvis, and posterior spinal fusion at T10–L2 and L5–S1. She also underwent preoperative T9, T10, and T11 vertebroplasty.

73 CHAPTER Fixed Sagittal Imbalance

Evan J. Smith
Christine Piper
Joseph R. O'Brien

Introduction

Fixed sagittal imbalance refers to the condition in which there is a loss of global spine alignment and an inability to compensate for it through flexibility in the lumbar or thoracic spine. This condition eventually leads to a pitched-forward posture for the patient. The etiology of fixed sagittal imbalance can be diverse, resulting from both natural disease processes, such as ankylosing spondylitis (Fig. 73.1), and iatrogenically after spinal surgery (Fig. 73.2). Fixed imbalance often leads to diminished quality of life and significant patient distress. Patients may experience pain, difficulty with horizontal gaze, difficulty with ambulation, and poor endurance as a result of altered kinematics. Compensation may occur through the hips and knees (increased pelvic tilt), which is a high-energy state leading to rapid fatigue. Treatment of symptomatic sagittal imbalance has traditionally relied on correction of the deformity through spinal osteotomy. Spinal osteotomy may be performed posteriorly or anteriorly; modern spinal fixation is a crucial element of these surgeries.

Etiology

Sagittal imbalance, also known as "flatback syndrome," has a variety of etiologies. The most common presentation is the elderly patient presenting with degenerative imbalance in the setting of previous spine surgery, including lumbar fusion(s). The use of Harrington distraction instrumentation to treat scoliosis deformity in the 1970s to 1980s is often regarded as the main iatrogenic cause of fixed imbalance.[1–4] This surgery involved implanting straight distraction rods posteriorly into the spine, thereby disrupting the normal sagittal curves. When this instrumentation involved the thoracolumbar junction, patients were often left with a proximal lumbar hyperlordosis; the patient would then compensate for this with the remaining lumbar discs.[1-4] Over time and with degeneration, however, the ability to compensate for this imbalance is lost, and deformity ensues (see Fig. 73.2). After prior fusion, there is a progression of degeneration at adjacent levels. The patient progressively loses lumbar lordosis (LL) or increases thoracic kyphosis, making it difficult to stand fully erect.[1] Last, some authors have implicated anterior decompression instrumentation when used with an interbody graft as well as posterior lumbar fusion without structural grafting as a potential cause of sagittal imbalance.[5]

Spinal trauma can also lead to fixed deformity. Any fracture along the length of the spinal column may contribute, but especially those near the thoracolumbar junction can result in a kyphotic deformity, causing pain and loss of natural sagittal curvature.[6] The most commonly encountered example of this would be a compression fracture (Fig. 73.3). Increased stress is then applied to the adjacent segments and their associated discs, transferring load and stress that the fractured level cannot support.

Last, inflammatory and rheumatologic conditions are an often-cited source of sagittal imbalance. Ankylosing spondylitis is a frequently discussed cause of fixed sagittal imbalance. This disease results in a stiffness that allows for little variation in balance before deformity occurs. LL is often greatly decreased in these patients, frequently resulting in a concomitant increase in thoracic and/or cervical kyphosis[7] (see Fig. 73.1). Other disorders leading to flatback deformity include postinfectious kyphosis and congenital kyphosis or scoliosis, the latter being caused by a failure in formation of either the anterior/lateral segments or vertebral segmentation.[8]

Evaluation

The assessment of a patient with sagittal imbalance goes beyond just looking at the spinal deformity—a thorough history is paramount. Patients may present with a variety of symptoms; it is important to understand the etiology of these symptoms. Patients may present with focal back pain around the deformity or neurologic symptoms extending into the lower extremities, suggestive of concomitant stenosis or nerve compression. These patients may require a concurrent revision decompression at the time of corrective surgery, or they may have had previous spine surgeries that will affect future procedures. Others may present with little pain but have significant fatigue, poor endurance, difficulty with horizontal gaze, and

FIG. 73.1 Standing radiograph of a patient with ankylosing spondylitis showing severe loss of natural lordosis in the lumbar spine, leading to a rigid bent-forward posture. This patient also had cervical kyphosis, leading to further deformity and disability.

FIG. 73.2 Standing radiographs of a patient with Harrington rods implanted to treat adolescent scoliosis. The lateral image shows the loss of curvature at the thoracolumbar junction and the general loss of lumbar lordosis and sagittal balance as a result of the combination of the rigid rods and the natural degenerative changes that lead to loss of lumbar lordosis.

FIG. 73.3 Standing lateral radiographs of a patient who had compression fractures at the thoracolumbar levels, leading to significant fixed kyphosis. The patient underwent Smith-Petersen osteotomies at T9, T10, L1, L2, L3, and L4, as well as fusion from T9 to S1. The patient also underwent laminectomy at T12–L1, three-column osteotomy at T12, and vertebroplasty augmentation at T8 and T9.

an inability to perform activities of daily living. It is important to ask about comorbidities in this older population. The effect of osteoporosis, diabetes, congestive heart failure, and chronic obstructive pulmonary disease on the postoperative course should be discussed prior to surgery to establish realistic expectations and understand the significant risks of surgery. The enthusiasm for a technically well-executed surgery must be tempered with the risk of death and disability.

On physical examination, it is important to perform a thorough neurologic exam in addition to an assessment of balance and gait. One must observe the patient with and without assistive devices, such as canes or walkers. As mentioned previously, there are multiple mechanisms to compensate for sagittal imbalance. A patient may be able to maintain an upright posture (i.e., keeping the pelvis under the spine) by extending the hips and flexing at the knees. Because of this compensation mechanism, the examiner should ask the patient to stand erect with the knees straight to truly visualize the patient's posture. Additionally, the examination should be done sitting and supine to isolate the deformity and to assess flexibility of the deformity. A neurologic exam should be done to confirm any nerve compression resulting in sensory or motor deficit. If the deformity is in spinal cord territory

(generally above L1), one should pay particular attention to reflex and pathologic reflex testing.

Radiographic Assessment

Understanding the normal variation in spine alignment allows an individualized appraisal of spinal deformity and the potential for correction in a patient with symptomatic sagittal imbalance. However, many of the radiographic measures have large ranges of normal values; therefore, it can be difficult to reach conclusions about sagittal balance from these measures in isolation. Instead, one must assess these measures in relation to each other. The treating surgeon must understand the idea of spinopelvic harmony, which refers to the interaction of these myriad radiographic measures to assess a patient's pathology. Initial imaging should include standing long cassette radiographs (36 inches) to assess global alignment and to establish the sagittal vertical axis (SVA), as well as regional imaging of the thoracic and lumbar spine and imaging of the pelvis and sacrum to assess thoracic kyphosis (TK) and LL, as well as sacral parameters pelvic incidence (PI), pelvic tilt (PT), and sacral slope (SS), respectively (Fig. 73.4). Flexibility of the deformity can be assessed by comparing standing and supine radiographs. Often, computed tomography (CT) is utilized to assess partial or complete fusion of the spinal deformity. Additionally, magnetic resonance imaging (MRI) is crucial for assessment of neural, vascular, and ligamentous anatomy.

The SVA is the most often cited method to assess sagittal balance. The measurement can be achieved on a standing sagittal cassette of the spine by extending a vertical line from the vertebral body of C7 and measuring its relationship to the vertebral body at S1. In patients with normal sagittal balance, this line should lie within the vertebral body at S1. Negative values indicate an SVA behind the posterior superior edge of S1, while positive values indicate anterior location. Normal ranges for this parameter have varied depending on which study is cited. In a series on asymptomatic patients, Jackson reported that SVA offset greater than 2.5 cm was beyond the normal range. However, generally, a value greater than 5 cm anterior is considered detrimental to quality of life[9] (Table 73.1). It is important to note that SVA has been found to vary with age, with recent studies showing that SVA moves anteriorly as a result of degenerative changes, resulting in loss of LL.[10] Clinically, SVA has shown the strongest correlation with quality-of-life measures.[11]

Regional curvature is also helpful in understanding patient-specific deformity. The normal range of LL varies between studies, and like many of the radiographic measures of the spine, there appears to be a wide range of normal values. Bernhardt and Bridwell found a range of LL of −14 to −69 degrees (standard deviation, ±12 degrees) in a series of 102 asymptomatic adolescent patients.[12] In a series on 100 healthy French volunteers, Stagnara et al. found values ranging from −32 to −84, with an average of −50 degrees of LL.[13] Jackson compared asymptomatic and symptomatic patients, noting a statistical difference in the amount of LL from 60.9 to 56.3, respectively.[9]

FIG. 73.4 Standing lateral radiograph of a patient with a significant fixed kyphotic deformity to the thoracolumbar spine who presented with fatigue, pain, and neurologic symptoms. Radiographic analysis of the sagittal curves found a normal sagittal vertical axis of 1.7 cm, a lumbar lordosis of –48 degrees, and a pelvic incidence of 50 degrees but a pelvic tilt of 29 degrees, suggesting some compensatory posturing in the pelvis.

TABLE 73.1 Radiographic Measurements to Assess Curvature in the Sagittal Plane*

Parameter	Balanced Value
SVA	<5 cm
Cervical SVA	<1.5 cm
T1 tilt	<13 degrees
Pelvic tilt	<25 degrees
Proportional balance	Lumbar lordosis = pelvic incidence ± 9 degrees
Proportional balance	Pelvic incidence + lumbar lordosis + thoracic kyphosis ≤45 degrees

*Based on review of the current literature.
SVA, sagittal vertebral axis.

Pelvic incidence has emerged as an objective measure to better understand ideal LL. Roussouly et al. studied 160 healthy volunteers, demonstrating that the variability seen in LL in normal patients may be the result of natural variations in PI.[14] PI is defined as the angle between a line drawn perpendicular to the surface of the superior endplate of the

sacrum and a line connecting the midpoint of the superior endplate of the sacrum to the center of the femoral head. Often, this angle is used preoperatively to define different pelvic morphologies and understand the ideal LL for a given morphotype.

Last, one can examine at the amount of TK present. TK is defined as the Cobb angle between T1 and T12. These values have been found to range from about 20 to 70 degrees in normal individuals.[14] As with other radiographic parameters, there is a large range of normal values. Ideally, TK values compensate for LL to maintain a normal SVA.

Compensatory mechanisms can develop to maintain a normal SVA despite significant disability. As the spine moves forward with rigid spinal deformity, there is an increased onus on the musculature of the hips and pelvis to compensate to maintain vertical alignment. Much of this compensation can be identified through radiographic measures of the pelvis. The often-studied angles include PT, PI (Fig. 73.5), and SS. The measures are interrelated; the simple formula PI = PT + SS describes their relationship. However, in contrast to the fixed PI, SS and PT are posture-dependent values. SS is defined as the angle between the superior endplate of the sacrum and the horizontal. PT is defined as the angle between a vertical line and a line from the midpoint of the sacral plate and the center of the femoral head. An individual can increase his or her PT to compensate for a rigid deformity by increasing pelvic retroversion, hip hyperextension, and knee flexion, centering the spine over the pelvis and maintaining a normal SVA. These altered postural measures require increased energy for ambulation and limit effective ambulation. Furthermore, there is a positive correlation between PT values and worsening pain and disability scores.[15]

Recent attention has focused on cervical sagittal alignment. The SVA of the cervical spine is measured from the centroid of the dens (C2) to the posterior superior corner of C7. Less than 1.5 cm is desired (see Table 73.1). Additionally, T1 tilt has been examined in cervical deformity. Because T1 is the foundation of the cervical spine, one may consider excessive TK as tantamount to a high pelvic incidence. In cases of cervical deformity, one may have to consider normalization of T1 tilt to correct the deformity and therefore extend surgery into the thoracic spine. In addition to cervical SVA and T1 tilt, the chin-brow angle is used to measure horizontal gaze and deformity in fixed cervical or cervicothoracic deformity.

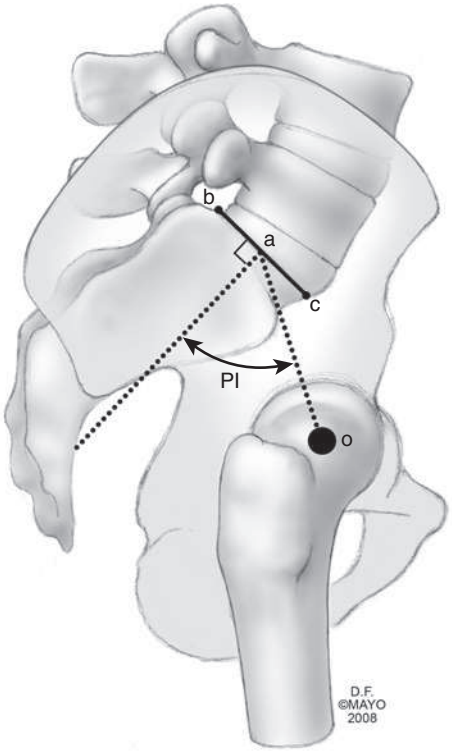

FIG. 73.5 Method of measuring pelvic incidence (PI). PI is the angle subtended by a line perpendicular from the cephalad endplate of S1 and a line connecting the center of the femoral head to the center of the cephalad endplate of S1. (From Rose PS, Bridwell KH, Lenke LG, et al. Role of pelvic incidence, thoracic kyphosis, and patient factors on sagittal plane correction following pedicle subtraction osteotomy. *Spine [Phila Pa 1976].* 2009;34:785–791.)

Surgical Management

The decision to pursue operative versus nonoperative treatment often depends on the severity of symptoms. In patients with mild symptoms or significant comorbidities, undertaking a large corrective procedure with significant morbidity may not be prudent. These individuals can benefit from physical therapy, occupational therapy, antiinflammatory medication, targeted injections for neurologic symptoms, and lifestyle modifications. However, patients with significant distress from debilitating symptoms may be better served by corrective surgery.

The goal of surgery is to restore normal spinal balance and alignment in the sagittal and coronal planes. The surgeon should aim to establish normal spinopelvic harmony. SVA has the strongest correlation with quality-of-life measures.[16] The surgeon should attempt to restore SVA to less than 5 cm.[16] However, one should also examine the PT and PI. Normalized PT (<25 degrees) is crucial for efficient ambulation. Last, the surgeon should assess the LL. The relationship between LL and PI is related to natural spinopelvic morphology. The surgeon must assess these values to establish patient-specific alignment. The formula LL = PI ± 9 degrees allows the surgeon a rough idea of the amount of LL to gain to match the normal patient's spinopelvic morphotype.[17] Rose et al. used TK in conjunction with PI and LL as preoperative measures to determine what amount of LL correction was necessary to provide adequate correction at 2 years in patients undergoing pedicle subtraction osteotomy (PSO).[17] They found that a value of PI + LL + TK less than or equal to 45 (where LL is a negative number) had a 91% specificity for predicting adequate correction at 2 years (see Table 73.1).

Surgical Technique

Open corrective procedures are the workhorse of rigid deformity surgery. These are extensile procedures that aim to

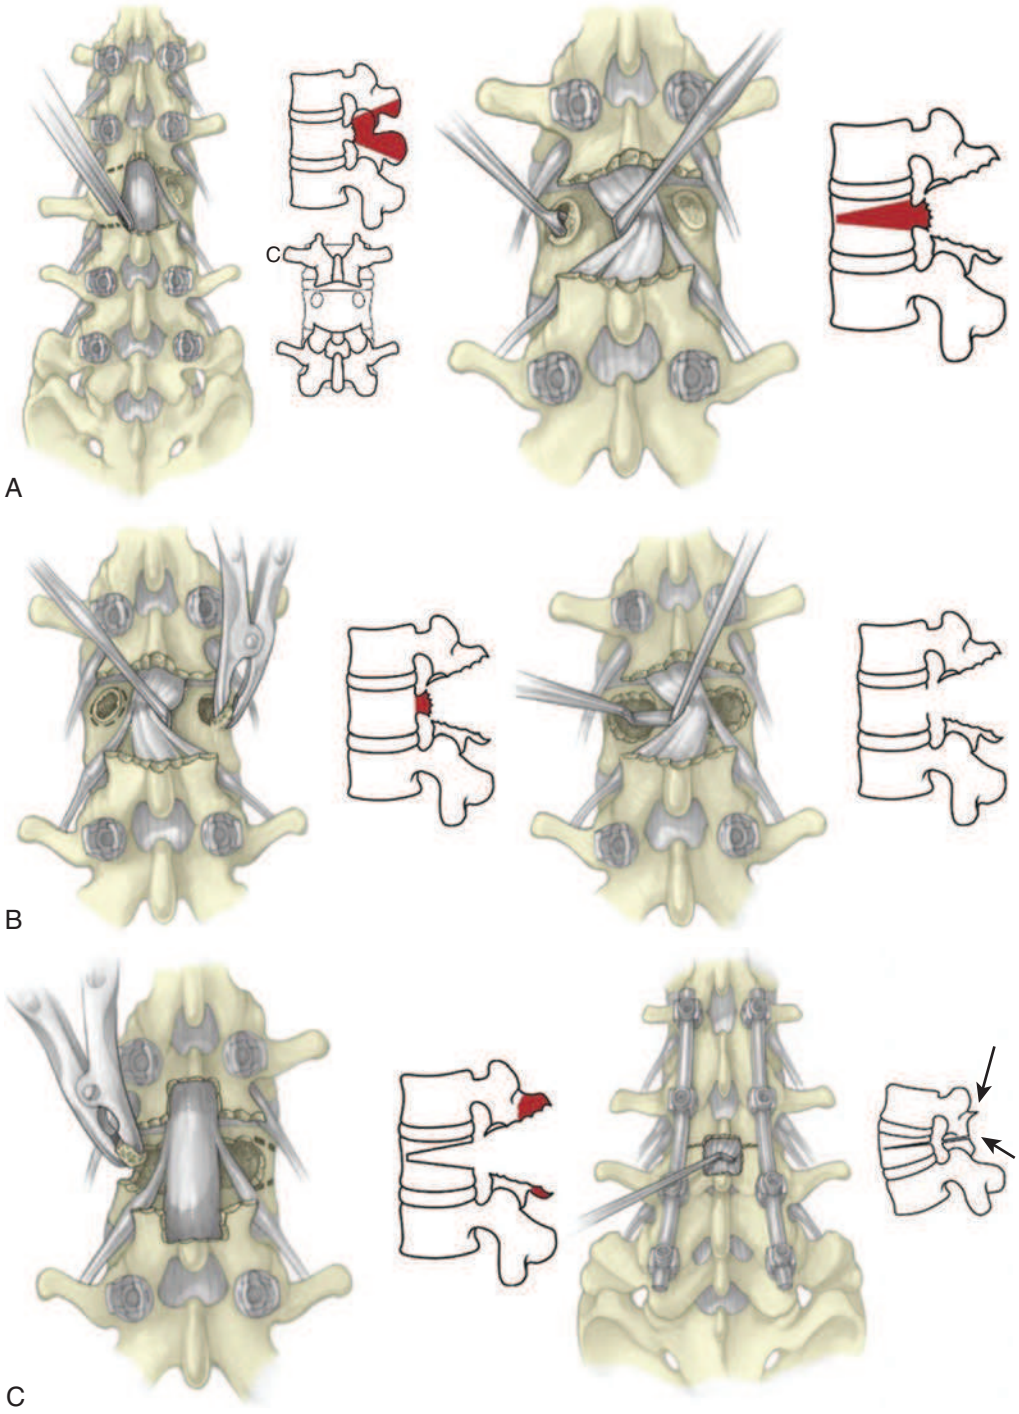

FIG. 73.6 Surgical technique for pedicle subtraction osteotomy. (A) *Left,* Initial resection of the posterior elements and surrounding pedicles. *Right,* Decancellation of the pedicles and the vertebral body. (B) *Left,* Resection of the pedicles flush to the posterior vertebral body. *Right,* Greensticking and resecting of the posterior vertebral cortex. (C) *Left,* Resection of the lateral walls. Note the V-shaped wedge. *Right,* Central canal enlargement. Closure of the osteotomy and final instrumentation. (From Bridwell KH, Lewis SJ, Rinella A, et al. Pedicle subtraction osteotomy for the treatment of fixed sagittal imbalance: Surgical technique. *J Bone Joint Surg Am* 2004;86A:44-50.)

correct deformity primarily by shortening the posterior column. These include the Smith-Petersen osteotomy (SPO), PSO, extensile PSO (Fig. 73.6), and the vertebral column resection (VCR). Invariably, greater correction is gained by removing increasing amounts of posterior bony and ligamentous tissue.

The SPO has evolved to be a corrective procedure for restoring small amounts of LL. The procedure was described in 1945 for the treatment of rigid deformity in ankylosing spondylitis and rheumatoid arthritis.[18] It involves the wedge resection of the posterior components without violation of the posterior longitudinal ligament or vertebral body with posterior closure

by either gravity or posterior fixation. Radiographic studies have shown lordosis correction per level of approximately 10 to 15 degrees and can often be performed in multiple levels in appropriate patients, reaching overall correction as high as 40 degrees.[15,19] It is the recommended procedure when there is a long, smooth deformity.[20] Additionally, because of its relative ease, it has been used as an adjunct with anterior lengthening procedures to provide additional correction.

Technique

The surgeon begins by removing the supraspinous and interspinous ligaments and portions of the spinous processes at the desired level of correction. The ligamentum flavum and the superior and inferior articular processes are then removed. Next, the surgeon provides posterior compression by closing the wedge resection with posterior instrumentation.

Because the SPO hinges on the middle column, it invariably tensions and lengthens the anterior column. This results in anterior structure distraction through the intervertebral disc, anterior longitudinal ligament (ALL), and anterior neurovascular structures. Consequently, the SPO should be avoided in an individual with a calcified, rigid ALL, calcified vessels, or an immobile intervertebral disc. It is recommended that a height of at least 5 mm of disc be present to avoid complications of tensioning an immobile disc.[20] Additionally, the SPO closes the neural foramina, and should be avoided in an individual with concern for nerve root compression or the potential for foraminal stenosis.[20] In cases in which neuroforaminal stenosis is a concern, cantilever transforaminal lumbar interbody fusion (C-TLIF) can be combined with SPO to restore disc height and neuroforaminal height (Fig. 73.7).

The PSO is a more extensive corrective procedure. While incurring more risk, it is a much more versatile procedure for correcting deformity. Studies have shown the PSO to provide lordosis correction of approximately 30 degrees per level.[21,22] It is best performed at the apex of the deformity and is preferred when there is a sharp angle of deformity requiring correction.[20] The procedure involves the wedge resection of the posterior elements extending into the middle column with removal of a portion of the vertebral body as well as posterior instrumentation and closure of the wedge. In contrast to the SPO, the PSO is technically more challenging and incurs more blood loss, as well as neurologic complications.[19,23] However, the PSO does not tension the anterior column, and does not require the same considerations regarding flexible discs and calcified anterior ligaments and vessels (see Fig. 73.6).

Additionally, the PSO does not result in foraminal narrowing, and can be modified to provide coronal plane correction. This can be accomplished by performing asymmetrical resection of the posterior vertebral body. A greater amount of resection should be taken at the convexity of the deformity; this resection often extends into the vertebral discs above and below.[24]

Like the SPO, surgeons have begun to combine anterior and posterior procedures to increase the degree of correction. The combination of anterior ligament releases with interbody cages and posterior osteotomy has shown to improve correction in the sagittal plane. This is discussed further in the section on alternative approaches for correction.

FIG. 73.7 Standing radiograph of a patient who underwent Smith-Petersen osteotomy (SPO) with cantilever transforaminal interbody fusion. There was concern for neuroforaminal narrowing preoperatively; the interbody cage allows distraction across the anterior and middle columns, as opposed to the normal compression seen after SPO.

Surgical Technique

It is useful to break down large surgical procedures into phases. For complex osteotomies, the phases are (1) exposure; (2) removal/(re)instrumentation, which is subdivided to the upper construct with or without cement augmentation and the sacropelvic construct; (3) revision/primary decompression; (4) osteotomy; (5) closure of osteotomy; (6) assessment of spinal balance; (7) bone grafting and closure; and (8) postoperative avoidance of complications.

Exposure

For exposure, it is crucial to limit blood loss. It is also important to keep the dissection close to the old laminectomy sites to facilitate revision decompression. Antifibrinolytic agents, such as tranexamic acid, have proved to be valuable in limiting blood loss in adult spinal deformity surgery.[24–26]

Removal/(Re)Instrumentation

For cases with removal of hardware, it is imperative to have the operative notes of the patient's former surgery and a list of

what hardware is currently present. During (re)instrumentation, one may consider the upper construct and sacropelvic base separately. For lower thoracic stopping points (i.e., T10), we prefer to cement augment the upper screws and the uninstrumented level above. Such methods have been shown biomechanically and clinically to result in less proximal junctional kyphosis.[27,28] After the upper construct is built, the sacropelvic base is built. It has been our preference to utilize pelvic fixation in *all cases* and not choose L5 as a stopping point for lumbar osteotomies. S2AI screws are used preferentially, and show a lower unplanned revision rate as compared to iliac fixation.[29]

Revision/Primary Decompression

This step is often the most onerous phase. Primary decompression is performed as though one would be performing open TLIF two levels above and two levels below the osteotomy site. One seeks to skeletonize the pedicles, and visualize the nerve roots in the extraforaminal zone. Revision decompression can be difficult. It may be approached by doing the following. Identify the margin of the old laminectomy site. Generally, the pars will be present. If transforaminal interbody fusion (TLIF) has been performed previously, consider another level for osteotomy due to extensive anterior scarring. Karlin curettes can be utilized to mobilize above the pedicle, which is a safe neural zone in most cases.

Osteotomy and Closure

Surprisingly, this portion can be as easy as a TLIF once the proper preparation has been completed. A number of manufacturers have supplied osteotomy sets with specialized instruments to facilitate this phase. One should be sure that the exiting and traversing nerve roots are mobile, as is the thecal sac. It is our preference to isolate the pedicle prior to starting removal. This setup requires that the prior posterolateral fusion mass must be fractured and taken down first. The pedicle then is quartered with a 7-mm osteotome. The osteotome is sunk into the pedicle 1 cm and rotated to allow for a controlled fracture. The quarters are then removed. At this point, the pedicle should be flush with the posterior vertebral wall. Conical shavers and wedge paddle shavers are used to remove a wedge of bone. After bilateral pedicle removal, the posterior wall is removed with down-going tamps or a Woodson elevator in osteoporotic bone. A single rod is compressed to close the osteotomy. For cervical cases, the head is moved into lordosis. In cases of pancaking of the vertebra, the osteotomy is opened and a 10- to 20-mm TLIF cage is placed anteriorly in the vertebral body; the osteotomy may be closed over the cage.

Assessment of Spinal Balance and Bone Grafting

At this juncture, a lateral radiograph is taken to determine if the desired correction has been achieved. Instrumentation is visualized at each level to check for proper placement. Intraoperative CT scanning may be considered to check placement as well. The osteotomy site is a potential site for pseudarthrosis. One may consider the use of fusion accelerators, such as recombinant human bone morphogenetic protein, at the site or TLIF at the discs above and below. Lateral surgery and multiple rod use is also a consideration to decrease the incidence of pseudarthrosis at the osteotomy site.

Avoidance of Complications

As with all major blood loss surgeries, management is crucial to success.[30] Intraoperatively, the use of crystalloid should be limited to less than 4 L. Blood products and those that remain intravascular are to be utilized. Use of the intensive care unit should follow the patient's international normalized ratio (INR) and electrolyte levels. Calcium should be replenished. Postoperatively, anticoagulation may be started once the INR is below 1.2 and the platelets are above 100.[31] It is our preference to utilize enoxaparin (Lovenox) 40 mg once daily to avoid deep vein thrombosis. Studies examining postoperative epidural hematoma have shown risk factors to be the following: greater than five-level laminectomy, INR greater than 2.0 in the first 48 hours, and blood loss greater than 1 L. Anticoagulation was not shown to be a risk factor.[31]

Cervical/Cervicothoracic Posterior Osteotomies

While the PSO has a durable track record of providing correction in the lumbar spine, it is also being used to provide correction in the cervical spine outside the territory of the vertebral artery (generally <C6). Initially, attempts to correct rigid deformity in the cervical spine were seen only in patients with ankylosing spondylitis. The techniques used were similar to the SPO, involving removal of the posterior elements at C7 with controlled fracture of the anterior spine and closure of the wedge using a halo orthosis. This procedure has undergone some modifications, as described by Simmons in 1972 and later amended in 2006, including a more extensive bone resection and posterior instrumentation.[32] Recent publications on cervical PSO have shown strong correction potential with an average increase in cervical lordosis of 24 to 50 degrees with no intraoperative or postoperative neurologic complications and improvement in patient outcome measures.[33,34] However, the studies are limited by small patient groups. Reports of long-term outcomes are limited.

Surgical Technique

As with PSO, it is useful to divide the procedure into phases. The setup is quite important in cervical osteotomy cases. We have moved away from the Mayfield holder to a floating setup with traction (Fig. 73.8). This setup is also used for cranial settling cases.[35] For osteotomy closure, we change the traction vector to facilitate the head and neck position. Preoperative planning should consider T1 tilt prior to correction of neck position. For cases with extensive TK, the surgeon should consider extension of the distal aspect of the surgery to T6 or L1. Proximally, one needs to ensure pedicular fixation, and the revision nature of the surgery may limit fixation. Navigation

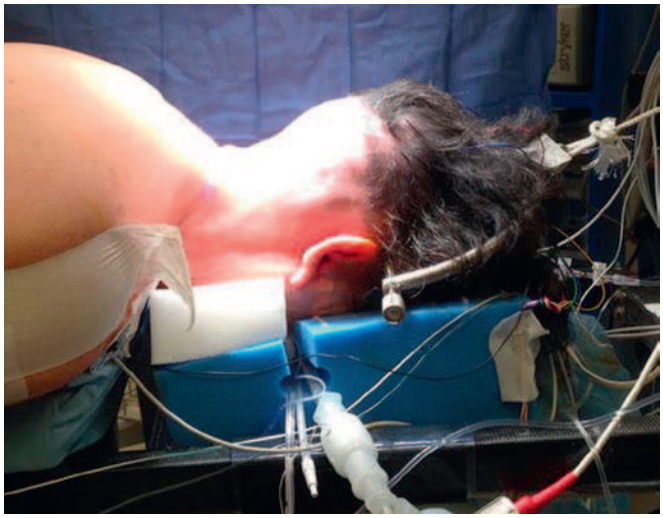

FIG. 73.8 The senior author (J.R.O.), when performing cervical osteotomy, uses the floating setup with traction as pictured.

has been used to safely place midcervical pedicle screws[36]; it is important to consider that one level of pedicle fixation is equivalent to two levels of cervical lateral mass fixation.[37] The C2 level is a reasonable stopping point. In cases of poor bone stock, we have utilized the occiput as a temporary fixation point without bone graft applied to the occipital-cervical junction. The rods may be cut at a later date or pseudarthrosis and rod fracture at the occiput may be expected. The surgeon begins by placing pedicle screws for fusion from the level of C2 to three levels below the osteotomy site: T3. If the patient had a large amount of TK, then the fusion can be extended lower to include the apex of the deformity. Osteotomies begin by removal of the facets and lateral masses at C6–C7 and C7–T1. The nerve roots are then identified and the C7 pedicles are isolated. Next, the pedicles are taken down and the posterior vertebral body is decancellated. The walls of the vertebral body are then removed and the neck is extended to close the osteotomy site. We prefer to use a traction setup to do so.[32]

Midcervical Osteotomy for Fixed Sagittal Imbalance

In some cases, midcervical osteotomy may be required. Generally, in the territory of the vertebral artery (C2–C6), anterior and posterior approaches are utilized. In this segment, our preferred technique will be outlined.

It is our preference to open the posterior portion of the neck only once. As such, our approach begins anteriorly. The anterior cervical spine is exposed broadly. The longus colli is striped laterally, as is done in typical anterior cervical discectomy and fusion. The center of the spine is found either with C-arm fluoroscopy or by placing Penfield dissectors laterally and marking the midline. Corpectomy is performed, as is standard. A width of 16 mm is utilized in all but the smallest-stature patients. The intraoperative use of a ruler from midline facilitates a straight corpectomy trough. After standard corpectomy and spinal decompression, the Penfield retractor is placed laterally around the vertebral body. A burr is then used to remove the lateral wall until the desired cut is obtained. At this point, a cage and plate are placed. If surgical planning does not include returning to the anterior neck, only cephalad screws are placed into the plate spanning the osteotomy site to allow for correction of kyphosis. The patient is then repositioned for posterior surgery. The neck is exposed and decompressed as needed. The fusion mass (if present) is cut and a Cobb elevator or wedge osteotome is placed into the neo-facet joint and twisted until fracture occurs. The neck can then be repositioned into lordosis. Instrumentation is performed as needed. Surgeons may then elect to perform anterior definitive fixation as needed.

Vertebral Column Resection

As the name implies, this procedure removes the posterior elements entirely and all but an anterior cortical shell of the vertebral body. Circumferential removal of the spinal column allows for powerful deformity correction, but is also the most technically demanding. Consideration for robust neuromonitoring must be made. Multimodal neuromonitoring is crucial, as is neurology input at the time of surgery. It is important to realize that both spinal decompression and realignment may impair the function of the spinal cord. As such, when changes in neuromonitoring occur, the context is very important—if a decline in signals occurs just after correction of the spinal alignment, one must reverse the maneuver.

VCR is best used where there is severe malalignment in the thoracolumbar spine, as opposed to focal rigid lumbar deformity. The lumbar deformity is more amenable to PSO. Examples of scenarios in which to use VCR include individuals with sharp, angular kyphosis in the thoracic spine or a severe thoracic or thoracolumbar kyphoscoliosis. During VCR, the surgeon performs complete resection of one or more vertebral levels either from a posterior or combined anteroposterior approach. This is a technically demanding procedure that should be performed by surgeons at centers experienced with deformity surgery. Using this technique, correction can be gained in both the coronal and sagittal plane by a combination of compression and translation of the column. The use of interbody cages and grafts is required, as the spinal column invariably shortens with vertebral body resection. Establishing fusion is critical given the degree of circumferential destabilization.[38]

Surgical Technique

As with pedicle subtraction osteotomy, it is useful to divide the procedure into phases. Once again, for complex osteotomies, the phases are (1) exposure; (2) removal/(re)instrumentation, which is subdivided to the upper construct with or without cement augmentation and the sacropelvic construct; (3) revision/primary decompression; (4) osteotomy; (5) closure of osteotomy; (6) assessment of spinal balance; (7) bone grafting and closure; and (8) postoperative avoidance of

complications. See the earlier section to review the preparatory phases of surgery. Differences are highlighted later in this chapter.

The procedure is centered over the deformity and involves resection of the posterior elements. The adjacent-level laminae and facets are removed as well as the pedicles, vertebral body, and cephalad and caudal discs. Initial efforts to perform VCR may utilize a combined anterior and posterior approach—especially in the lumbar spine, where nerve root sacrifice is not routinely done. Anterior approaches, whether open or minimally invasive, focus on disc removal and mobilization of the great vessels. Alternatively, an osteotomy through the vertebral body in the coronal plane to leave an anterior cortical shell may be performed. A Silastic sheet may be implanted to help find the plane of the cut/mobilization. Posterior instrumentation allows manipulation in the sagittal and coronal planes before final correction. In the thoracic spine, the rib heads may be disarticulated to visualize the vertebral body.

Complication rates increase with the extent of surgery and complexity of the osteotomy. While open procedures have a strong history of providing correction, they may also impart significant morbidity to the patient: blood loss, neurologic complications and postoperative disability, posttraumatic stress disorder, and death.[19,20,39] The Scoliosis Research Society (SRS) in 2011 published results on patients with rigid deformity undergoing corrective surgery. They noted increasing complication rates from SPO (28.1%), to PSO (39.1%), to VCR (61.1%).[23] The complication rates observed in the VCR group were much higher than previously reported rates of 20% to 30%.[38,40] The complications included dural tears, neurologic deficits, deep wound infections, hematomas, pulmonary emboli, and malpositioned implants. Generally, the neurologic deficits were mostly nerve root injuries (82%), while the remaining were incomplete spinal cord injuries. Despite neuromonitoring, only 2 of 18 nerve root injuries were detected. Half of the patients with nerve root injuries had complete recovery, and half had partial recovery at 9 months. Naturally, surgeons have looked for less morbid alternatives to these procedures.

Minimally Invasive Surgery

Minimally invasive approaches to the spine have gained popularity over the last 2 decades. Much of this interest was bolstered by studies demonstrating less morbidity when compared to open posterior procedures.[41–43] These include anterior lumbar interbody fusion (ALIF), TLIF, lateral lumbar interbody fusion (LLIF), direct lateral interbody fusion (DLIF), and extreme lateral interbody fusion (XLIF). The improved complication rates are presumed to be the result of less tissue dissection. Invariably, this improved complication profile has inspired surgeons to apply minimally invasive techniques to treating spinal deformity. In contrast with posterior procedures, these techniques aim to perform primarily anterior elongation through placement of interbody cages and release of anterior restraints.

ALIF has been used with mixed results. Hsieh et al. found that ALIF was superior to TLIF at improving LL.[44] However, the improvement was minimal. This difference may be due to the ALL release required for anterior exposure. There are few studies looking at the stand-alone effect of ALIF on sagittal balance, as it is often combined with posterior osteotomies to provide circumferential correction. In contrast to other minimally invasive approaches, the ALIF procedure allows unimpeded access to the lowest lumbar levels. However, there are significant complications to this technique. These include neurologic complications from injury to hypogastric plexuses, resulting in sexual dysfunction, retrograde ejaculation, and bowel and bladder dysregulation. The most devastating complications include injury to the great vessels, which occur at rates from 1% to 24%.[45] Nevertheless, experienced practitioners have success when combining this approach with posterior osteotomies.[44]

More recently, there has been a progression to using LLIF (DLIF/XLIF) approaches for correcting the anterior column and placement of interbody cages. These approaches utilize a lateral retroperitoneal, transpsoas corridor to access the lateral vertebral body with minimal soft tissue dissection. When compared to ALIF, this approach avoids the need for an access surgeon, and avoids complications related to damage to the anterior neurovascular structures or abdominal or genitourinary viscera. Additionally, this approach avoids the complications frequently seen in posterior procedures: extensive muscle stripping and manipulation of the thecal sac. Preliminary reports have confirmed the lower complication profile when compared to traditional posterior procedures.[46] However, in a systematic review by Phan et al., there was weak and inconsistent correction in the sagittal plane using standard cages with these lateral techniques.[47] XLIF and DLIF have their own set of complications related to psoas muscle injury and genitofemoral nerve injury, including thigh pain, hip flexor weakness, and groin pain.

LLIF has also been used to improve sagittal plane correction. Uribe et al., in an initial cadaveric study, assessed the potential of 20-degree and 30-degree hyperlordotic cages to provide sagittal plane correction with positive results.[48] Subsequently, Marchi et al.[49] examined eight cases using a DLIF approach with 30-degree hyperlordotic cages on patients with sagittal imbalance. These authors noted markedly improved LL with average gains of 10 degrees per level, which was higher than that seen with standard XLIF.[49] They also noted an improvement in SVA from 24 to 9 cm. However, they noted an increase in anterior cage subsidence as well, particularly where there was a tight ALL, making cage placement difficult. As a follow-up, Deukmedjian et al. proposed a minimally invasive technique involving the release of the ALL to decrease tension on the anterior column.[50] Called anterior column release (ACR), this technique allows easier insertion of the hyperlordotic cages, especially where a narrow disc space may result in endplate damage, cage subsidence, and limitation to lordotic correction. In initial follow-up studies, these authors found improvement in sagittal balance by 4.9 cm from 9 to 4.1 cm and a per-level improvement of 17 degrees in segmental LL. They noted that the procedure could be technically challenging, particularly when avoiding sympathetic and neurovascular structures during ALL release, and advocated

for curved retractors to protect these structures. With diligence, they reported no neurovascular complications in their initial cohort.[51]

Other groups have examined the addition of posterior procedures to minimally invasive correction. Manwaring et al., in a follow-up study of early outcomes, studied correction provided by the addition of posterior instrumentation to standard LLIF procedures.[52] These authors found that posterior instrumentation did not provide additional correction with or without the use of hyperlordotic cages or ACR. However, the ACR with hyperlordotic cages did provide a correction similar to that previously seen and similar to the SPO per level, and patients with multilevel procedures had correction similar to that reported for PSO. Berjano et al. examined the effect on sagittal balance with the addition of posterior osteotomies to the ACR.[53] They found that the addition of the SPO provided 24 degrees of correction on average per level. This was similar to correction provided by the PSO in the literature. In a multicenter analysis, Turner et al. confirmed this further improvement offered by posterior SPO. They reported a modest correction of 12 to 15 degrees.[54]

Summary

Fixed sagittal imbalance is a cause of significant disability and distress to patients. It is important for the surgeon to understand the disease process that leads to fixed sagittal imbalance and understand the changes in thoracolumbar and spinopelvic alignment that occur. In patients undergoing surgery, restoring spinopelvic harmony is paramount. Radiographic measures of sagittal balance can be assessed through radiographic measures of the spine. However, surgery to treat this disorder is not without significant morbidity; it is important for the surgeon to understand the risks and benefits of surgery when discussing treatment with patients. Recently, there has been more effort into using minimally invasive approaches for deformity correction with less morbidity when compared to the traditional open posterior osteotomies that have long been the traditional approaches to deformity surgery.

74 CHAPTER Basic Science of Spinal Cord Injury

Alexandre Rasouli

There is still no cure for spinal cord injury (SCI). Recovery in the spinal cord is thwarted by two fundamental obstacles: the inherently weak regenerative ability of central nervous system (CNS) axons and a powerfully inhibitive—and often deleterious—postinjury milieu of physical and chemical factors. These factors are intertwined in a so-called secondary response of tremendous complexity that ironically does more to injure the spinal cord further than to heal it. Years of research have slowly elucidated the pathophysiologic processes that follow a traumatic insult to the spinal cord. This chapter reviews the biochemical and physiologic features of the SCI response and establishes a foundation on which the latest therapeutic strategies can be understood.

The first section discusses the inflammatory cascade that occurs in the moments after an assault to the spinal cord. The second section reviews current understanding of the inhibitory extracellular environment that results from the injury response and that ultimately prevents axonal regeneration. The chapter concludes with a review of the biochemical processes that can be targeted by candidate therapies.

Pathophysiologic Response to Spinal Cord Injury

The acutely traumatized spinal cord is subjected to multiple physical and chemical mediators that cause additional (secondary) injury.[1,2] This concept of secondary injury has been validated in both animal and clinical studies, and secondary injury mechanisms have been the target of the bulk of pharmacologic interventions to date. These processes begin immediately following the injury and continue for weeks (Fig. 74.1).

Hemorrhage and Circulatory Collapse

Upon injury, the blood–spinal cord barrier is disrupted and intraparenchymal hemorrhage occurs, the extent of which depends on the force of the initial trauma. Microcirculatory insufficiency follows.[3,4] Vascular hypoperfusion due to capillary loss, capillary spasm, thrombosis, systemic hypotension, and autonomic regulatory interruption lead to cellular ischemia at the epicenter of cord injury. The neuronal cell bodies in the gray matter are highly vulnerable to ischemia. The resultant shift in pH renders neuronal cell body and axonal membranes highly vulnerable to subsequent injury.

Oxidative Damage

Reperfusion and oxidative stress follow the transient period of hypoperfusion. The introduction of oxygen to the compromised cell membranes produces a highly toxic environment in which the membrane lipid fatty acids undergo oxidation.[5] This membrane lipid peroxidation produces several varieties of free radicals that, in turn, drive even further lipid peroxidation and free radical production. Some of the free radicals accumulate within the cell and denature deoxyribonucleic acid, mitochondrial proteins, and eventually bring energy production to a halt, resulting in irreversible damage and cell death.

Excitotoxicity

Disruption of the neuronal cellular membrane undermines one of the crucial features of cellular equilibrium—ionic regulation.[6] The destabilized neurons undergo an influx of sodium ions that eventually alters cellular pH and leads to cytotoxicity. The ionic balance is perturbed by, and will cause neuronal destruction via, an additional important mechanism: the cellular release of the ubiquitous neurotransmitter glutamate changes the extracellular space into a hostile extracellular milieu.[6] Glutamate activates various cell surface receptors that, in turn, mediate a large variety of intracellular processes. Excessive glutamate will drive these processes to the point of fatal overload to the cell. The most studied of the glutamic receptors is the *N*-methyl-D-aspartate receptor, which mediates entry of Ca^{2+} into cellular cytoplasm from both extracellular and intracellular stores. While calcium in physiologic amounts is the necessary component for many important enzyme-mediated cellular processes, pathophysiologic quantities of calcium lead to the persistent activity of destructive enzymes, including lipoxygenases and phospholipases. These

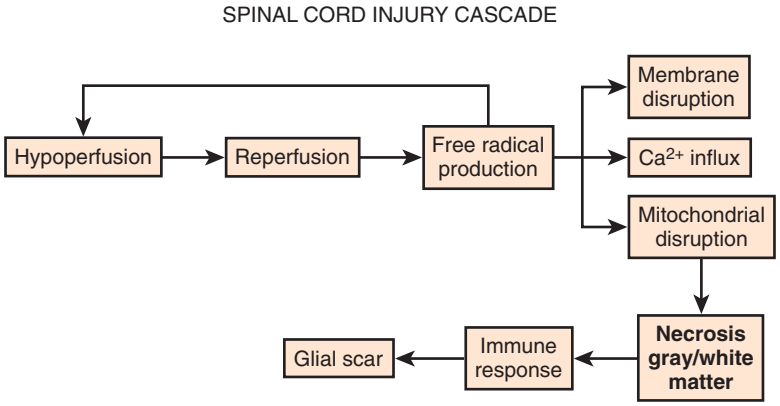

FIG. 74.1 The self-perpetuating injury cascade begins with a sequence of hypoperfusion and reperfusion. The ensuing oxidative damage leads to tissue necrosis and an immune response that culminates in the inhibitory glial scar.

enzymes will target the beleaguered cell membrane again to generate free radicals from lipid oxidation. The radicals will disrupt cellular proteins, in particular, those that mediate the ability of mitochondria, the chief source of cellular energy, to drive oxidative phosphorylation.

Mitochondrial Collapse and Cytotoxicity

The aforementioned free radical formation and glut of Ca^{2+} ions abolish mitochondrial integrity by activating mitochondrial permeability transition pores.[6] The opening of these pores leads to a massive increase in mitochondrial membrane permeability. The organelle loses its electrochemical gradient, adenosine triphosphate production ceases, and the outer membrane swells until it ruptures. The damage is far-reaching. Calcium ions, free radicals, and cytochrome c, once sequestered within the mitochondria, are now free to escape into the neuronal cytoplasm where they immediately activate necrosis and apoptosis.

Neuroimmunologic Response

The cells of the immune system are eventually attracted to the neuronal self-destruction. Over the next hours to weeks, they will lay the foundations for an extracellular environment that will inhibit axonal regeneration. The first of these cells to appear at the site of injury are circulating neutrophils. Once active, neutrophils will secrete cytokines that stimulate production of phospholipases and cyclooxygenase.[7] The former will consume neural membranes to produce arachidonic acid, which the latter (cyclooxygenase) uses to produce prostaglandins and thromboxanes. Prostaglandins (PGE_2, PGD_2, $PGF_{2\alpha}$, PGI_2) serve (1) to amplify the inflammatory response by increasing capillary permeability to allow additional inflammatory cell influx; (2) to increase neuronal calcium concentration, thus promoting excitotoxicity; and (3) to activate other inflammatory cells.[1] Thromboxanes promote platelet aggregation within capillaries and thus worsen local tissue ischemia.

Macrophages, local microglia, and astrocytes eventually appear and begin secreting the two most important factors of the cytotoxic inflammatory response: interleukin-1 and tumor necrosis factor α. Interleukin-1 stimulates the expression of adhesion factors on endothelial cells, which will allow circulating lymphocytes to penetrate the blood–brain barrier. Tumor necrosis factor α serves to recruit activated cytotoxic lymphocytes to first adhere to endothelial cells and then to the site of injury. The recruited lymphocytes, which target myelin basic protein, are particularly adept at causing disruption of the all-important myelin sheath—a critical component of nerve conductivity and axonal regeneration. The epicenter of traumatic injury thus becomes an inflammatory tangle of necrosis, apoptosis, and demyelination. Over the coming weeks, the cellular debris will first liquefy into a posttraumatic cyst and then organize into the notorious astroglial scar, which will inhibit axonal regeneration.

Astroglial Scar

The most significant factor in the inhibition of axonal regeneration after SCI is the glial scar that develops.[8–11] The glial scar is a collection of reactive cells (astrocytes, microglia, oligodendrocyte precursors, meningeal fibroblasts) that express cell-surface and matrix molecules, which surround the area of injury and ultimately repel the advancement of regenerating axons (Fig. 74.2).

The scar features a core zone of meningeal cells and oligodendrocyte precursors, and a lesion-surround zone of astrocytes, oligodendrocyte precursors, and microglia. The core zone is separated from the surround zone by a basement membrane composed mostly of type IV collagen.[12] While some axons may regenerate through the surround zone, no axon can penetrate the core zone without some form of experimental manipulation.[13]

The inhibitory effects of the scar are conferred by three classes of molecules, all of which are expressed by one or more of the reactive cells in the glial scar. These include the chondroitin sulfate proteoglycans (CSPGs; NG2, brevican, phosphacan, neurocan, versican), semaphorin 3 proteins, and eph/ephrin tyrosine kinases. Although the precise mechanisms of their actions are unclear, the molecules exert their inhibitory effects either by directly or indirectly binding to the axon cell

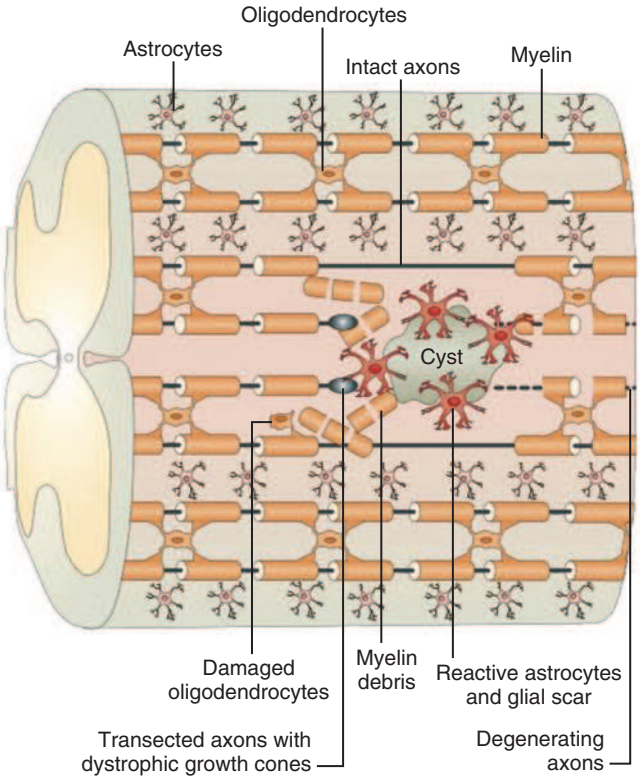

FIG. 74.2 The astroglial scar presents nonpermissive cues to regeneration. These nonpermissive cues include deprivation of trophic support, lack of permissive cues at the axonal growth cones, progressive demyelination, decreased cyclic adenosine monophosphate levels, and a strong inhibitory environment established by extracellular matrix molecules (keratin sulfate proteoglycans and chondroitin sulfate proteoglycans NG2, neurocan, brevican, versican, phosphacan), and by glial and myelin components.

surface or by binding and deactivating trophic factors, cell adhesion molecules, and extracellular matrix molecules that are a requisite for axonal growth and regeneration.[14] The ultimate effect of the gliotic response to injury is the inhibition of successful axonal regeneration and remyelination by both physical and chemical means[15] (Fig. 74.3).

There is tremendous therapeutic potential in the ability to modulate the gliotic scarring response to CNS injury. In vitro and in vivo studies to date, though relatively limited, have demonstrated enhancement of axonal regeneration and functional recovery after inhibition of specific glial scar constituents. Enzymatic digestion of the glycosoaminoglycan chains of CSPGs, for instance, stimulates axonal regeneration through the site of injury.[16] Function-blocking antibodies to semaphorin receptors have allowed sensory axons to regenerate into the formidable core zone of the scar.[17] Chelating agents that prevent collagen IV synthesis around the core zone have also allowed successful axonal regeneration in some animal models.[18] Animals with clonal deletions of a certain eph molecule have almost no astroglial scar response and demonstrate unimpeded regeneration of motor axons through the zone of injury.[19]

Despite its multifaceted inhibitory influence, several recent studies suggest that the glial scar must offer some protective benefit to the injured spinal cord. The role of the gliotic response in mitigating the extension of cord injury beyond the initial site of trauma, for instance, has been proposed.[20] In a study of transgenic mice, selective ablation of reactive astrocytes in the glial scar after both contusion and penetrating spinal cord injury led to markedly increased tissue disruption, cellular degeneration, cystic changes, and profound and persistent motor deficits relative to nonablated controls.[21] It is likely that both the cellular and extracellular matrix elements of the gliotic scar play a critical role in biochemical protection and structural stabilization of cord integrity, and thus function, after SCI.

The duality of the inflammatory response after spinal cord trauma, both inhibitory to axonal regeneration and protective against further injury, is perhaps the most perplexing aspect of SCI and a key reason that a cure has proven so challenging.

BOX 74.1 Classification of Treatment Strategies

Neuroprotective

Methylprednisolone
Ganglioside
Thyrotropin-releasing hormone
Calcium channel blockers

Regenerative

Activated macrophages
Rho antagonists
Anti-Nogo antibodies
Peripheral nerve/Schwann cell transplantation
Olfactory ensheathing
Cell transplantation

Basic Science of a Cure

Consistent with their basic science foundations, the human acute SCI therapies have one of two ambitions: (1) to limit secondary injury (neuroprotection, acute surgical intervention, rehabilitation) and (2) to reverse injury (Box 74.1).

Methylprednisolone

The first randomized, controlled multicenter trial of a neuroprotective agent was the National Acute Spinal Cord Injury (NASCIS) I Study, which attempted to establish the clinical efficacy of methylprednisolone.[22,23] Though its precise mechanism of action is still unclear, methylprednisolone was thought to exert either a cell-stabilizing effect via the glucocorticoid receptor or a cord-stabilizing effect via free-radical inhibition.[24–26] The trial was based on several animal studies that suggested improved neurologic recovery when the corticosteroid was administered promptly after experimental injury.[27] Published in 1984, NASCIS I included 330 patients with acute SCI (defined as any loss of sensation or motor function below the level of injury), who were randomized into two groups within 48 hours of injury: a "low-dose group" receiving 100 mg IV methylprednisolone bolus and then 25 mg every 6 hours for 10 days; and a "high-dose" group receiving bolus and maintenance doses 10 times those of the low-dose group every 6 hours for 10 days. Outcome measures consisted of motor

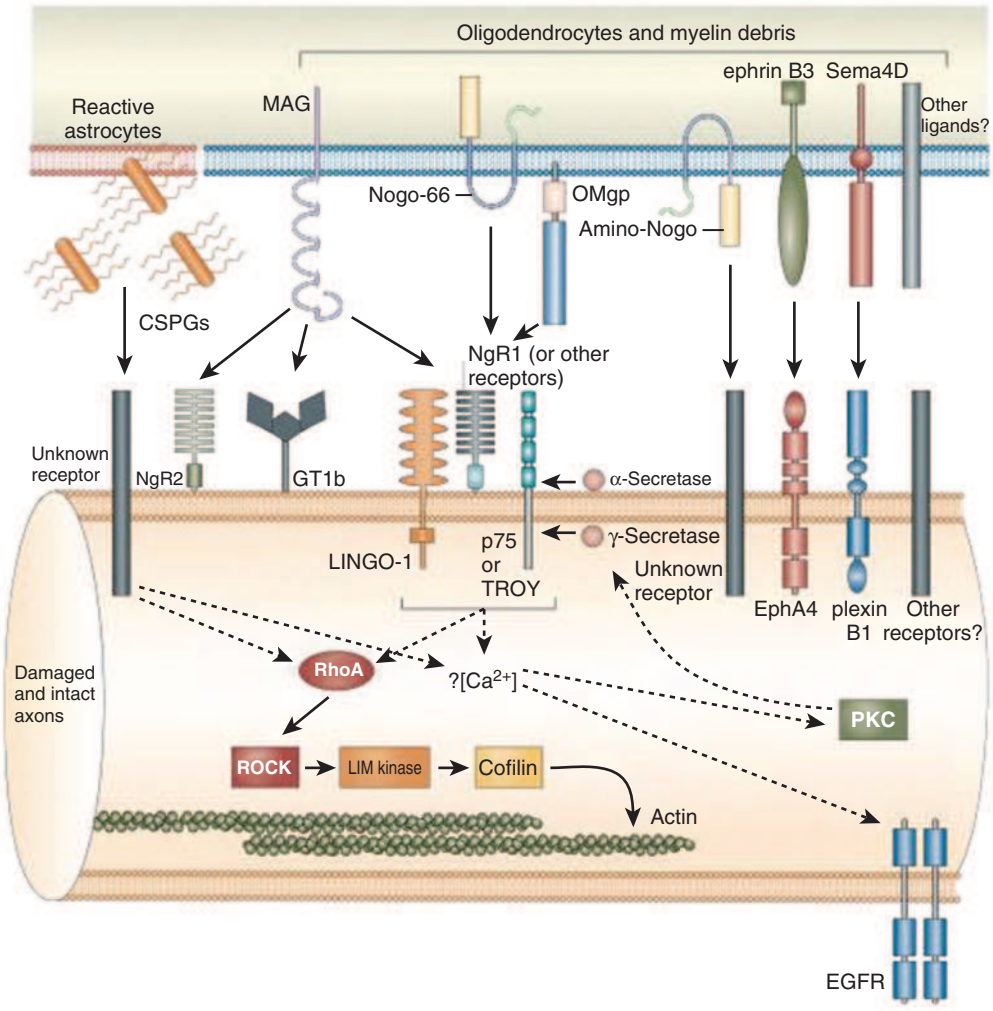

FIG. 74.3 Although the precise mechanisms of their actions are unclear, the molecules of the glial scar exert their inhibitory effects either by directly or indirectly binding to the axon cell surface or by binding and deactivating trophic factors, cell adhesion molecules, and extracellular matrix molecules that are requisite for axonal growth and regeneration. The ultimate effect of the gliotic response to injury is an embarrassment of axonal regeneration *and* remyelination by both physical and chemical means. CSPGs, chondroitin sulfate proteoglycans; EGFR, epidermal growth factor receptor; LINGO1, Nogo receptor-interacting protein; MAG, myelin-associated glycoprotein; NgR1, Nogo-66 receptor 1; NgR2, Nogo-66 receptor 2; Nogo, neurite outgrowth inhibitor; OMgp, oligodendrocyte myelin glycoprotein; PKC, protein kinase C; ROCK, rho-associated kinase; sema4D, semaphorin-4D.

and sensory indices of 14 muscle groups and 29 dermatomes. The follow-up periods were 6 weeks and 6 months. Though there was no difference between the two groups in terms of neurologic outcome, there was an increased incidence of wound infection and even fatality in the higher-dose group, with the former achieving statistical significance.

One year later, NASCIS II was launched as the first randomized, prospective, placebo-controlled trial of a candidate therapy for SCI.[28,29] It was devised to address the lack of a placebo control in NASCIS I and to incorporate new basic-science findings regarding effective methylprednisolone dosing and mechanisms of action. The study involved 487 patients who were randomized into three groups within 12 hours of sustaining either complete or incomplete SCI: a methylprednisolone group receiving an unprecedented 30 mg/kg IV bolus, followed by a maintenance infusion of 5.4 mg/kg/h over 23 hours; a placebo group; and a third group consisting of a 5.4 mg/kg bolus and 4.0 mg/kg/h maintenance infusion of the opioid antagonist naloxone, whose neuroprotective effects had also been suggested by animal studies.[30] The outcome methodology was similar to that in NASCIS I.

When all members of the methylprednisolone group were compared to placebo, there were no statistically significant improvements in sensory or motor function at 6 weeks. However, when the steroid group was stratified according to timing of administration, patients receiving treatment within 8 hours of injury demonstrated a significant improvement in sensory and motor function by 6 weeks versus placebo. The relative improvement was sustained through the 6-month follow-up point. Within the steroid group treated within 8 hours, further subgroup analysis with respect to ASIA scale injury severity revealed that class A patients had the greatest statistically significant improvement in motor and sensory measures versus placebo. Additionally, American Spinal

Injury Association (ASIA) class C and D patients had only motor improvement, whereas class B patients had neither sensory nor motor improvement that reached statistical significance.[28,31] The complication of wound infection was more frequent but statistically insignificant in the steroid group despite the heavy dosing. There were no differences in motor or sensory outcomes between the naloxone and placebo group at either of the follow-up points. NASCIS II established the now ubiquitous "steroid protocol," despite controversies regarding possible nontransparency, data misinterpretation, and near-normal function of some participants.

The objective of the third and final NASCIS was to investigate the interplay between timing of steroid administration and duration of therapy and to evaluate the efficacy of the 21-aminosteroid tirilazad mesylate, which purportedly had a better safety profile than methylprednisolone. A total of 499 patients were randomized into three treatment groups within 6 hours of injury: the first group received methylprednisolone according to the NASCIS II dosing for 24 hours, the second group received this dosing for 48 hours, and the third group received a methylprednisolone bolus of 5.4 mg/kg/h followed by a maintenance infusion of tirilazad at 2.5 mg/kg IV every 6 hours for 48 hours.[32] With outcome measures including motor function, sensory function, and functional independence, the NASCIS III revealed that increased duration of steroid administration (48 hours) resulted in statistically significant benefit only if treatment was initiated between 3 and 8 hours of injury. Infectious complications were more common in the 48-hour corticosteroid group but were statistically insignificant. There were no differences between the tirilazad group and the 24-hour methylprednisolone group.

Ganglioside GM-1

Trials of the glycosphingolipid ganglioside GM-1 followed closely on the heels of the methylprednisolone studies. Gangliosides are mammalian neuronal cell membrane constituents and play a substantial role in neuronal plasticity, axonal recovery after experimental SCI, and cell preservation after ischemia.[33–36] The Maryland GM-1 ganglioside trial was a prospective, randomized, placebo-controlled pilot study of 37 patients with SCI who were assigned to one of two groups: GM-1 100 mg IV per day for 30 days versus placebo.[35] Outcome measures were in terms of motor scores and Frankel grades, and the follow-up point was at 6 months. By 6 months, the authors demonstrated a 2-grade improvement on the Frankel scale in 50% of patients receiving GM-1 but only in 7% of patients receiving placebo, a difference that was statistically significant. The pilot study was then expanded into the largest clinical trial of SCI therapy, known as the Sygen Multicenter Acute Spinal Cord Injury Study (SMASCIS).[37] SMASCIS randomized 797 patients with SCI into two groups receiving GM-1 (300 mg IV bolus + 100 mg IV daily for 56 days versus 600 mg IV bolus + 200 mg IV daily for 56 days) and NASCIS II protocol. Outcome measures included ASIA sensory and motor scores and the ASIA impairment scale rating. At 8 weeks, patients exhibited dose-related, statistically significant improvements in impairment scale ratings relative to placebo; but by the 6-month endpoint, there were no differences in the number of patients achieving improvement (defined as at least a 2-grade improvement in the impairment index) between any of the groups. SMASCIS had revealed that GM-1 ganglioside was ultimately no better than placebo in the setting of acute SCI.

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone (TRH) and its analogs have been shown in multiple animal models of acute SCI to improve functional recovery by acting as a neuroprotective partial opioid antagonist.[29,38–40] The prospective trial evaluating its efficacy in human subjects involved 20 patients with acute SCI who were randomly assigned within 12 hours of injury into one of two groups: a TRH group receiving 0.2 mg/kg bolus IV dose followed by 0.2 mg/kg/h infusion for 6 hours and a placebo group.[41] NASCIS motor and sensory indices and the Sunnybrook system were used as outcome measures. Follow-up time points were at 24 hours, 72 hours, 7 days, 1 month, and 4 months, and 1 year after injury. Patients with complete injuries did not demonstrate a benefit from TRH administration relative to placebo group patients; patients with incomplete injuries did show statistically significant improvement in outcome measure after TRH treatment versus placebo. However, the authors were cautious with their conclusions due to sample size issues and the number of patients lost to follow-up. A larger clinical trial of the hormone has not been completed.

Nimodipine and Gacyclidine

In a number of animal models of SCI, the calcium channel blocker nimodipine has been reported to improve neurologic recovery by increasing spinal cord blood flow and limiting vasospasm, ischemia, and secondary infarction.[42,43] The prospective clinical trial of the antihypertensive involved 106 patients with complete or incomplete SCI who were randomized to one of four groups: nimodipine 0.015 mg/kg/h IV loading dose for 2 hours + 0.03 mg/kg/h infusion for 7 days, methylprednisolone according to NASCIS II protocol, both agents, and placebo.[43] Outcome was measured with the ASIA grade and ASIA motor and sensory scores. At 1 year follow-up, none of the treatment groups demonstrated efficacy over placebo. Interestingly, 80 of the 106 patients were surgically treated within 24 hours of injury; a subgroup analysis revealed that surgery within 8 hours of injury and between 8 to 24 hours of injury yielded identical outcomes.

Posttraumatic glutamate toxicity is the target of the novel *N*-methyl-D-aspartate receptor antagonist gacyclidine, which has been shown to enhance recovery after contusive SCI in rat models.[44] In a prospective, controlled clinical trial, 272 patients were randomized to one of four groups within 2 hours of SCI: gacyclidine at 0.005 mg/kg IV within 2 hours of trauma and once again at 6 hours after trauma, gacyclidine at 0.001 mg/kg IV × 2 doses, gacyclidine at 0.02 mg/kg × 2 doses, and placebo. Outcome measures included the ASIA motor and sensory scores. At 1 year follow-up, there were no statistical differences in outcomes between any of the groups.

Regeneration Strategies

While neuroprotective strategies are directed primarily at limiting secondary neural injury, regeneration strategies involve repair of the damaged tissues. The prerequisite for these therapeutic strategies is the modification of the nonideal local milieu of the injured cord as biochemical, cellular, and extracellular matrix perturbations may limit the potential for axonal repair.[6,45,46]

Rho Antagonist

Several inhibitors of nerve regeneration have been identified, including Nogo, myelin-associated glycoprotein, and myelin-oligodendrocyte glycoprotein. These factors act commonly through the GTPase Rho, an enzyme that orchestrates a potent inhibitory cascade after injury that culminates in growth cone disintegration, neurite sprouting inhibition, and neuronal and glial cell apoptosis.[47,48] The naturally occurring inhibitor of the Rho enzyme, C3 transferase from *Clostridium botulinum*, has been shown to effect remarkably rapid functional recovery in hemisection SCI rats.[49] Histologic analysis of C3-treated rats treated within 24 hours of injury showed increased neuronal sprouting and functional analysis revealed enhanced locomotor recovery and limb coordination.

A recombinant pharmaceutical version of C3 transferase known as Cethrin, in which the enzyme is linked to a protein that facilitates blood-brain barrier penetration, has undergone phase I/IIa trials at nine North American centers to establish safety and efficacy. Preliminary results of this trial have been discussed at scientific meetings and published in abstract form.[50] The study included 37 patients with complete (ASIA class A) SCI at either the cervical or thoracic level who were given increasing doses of extradurally applied Cethrin (0.3, 1.0, 3.0, and 6.0 mg). Outcome measures (ASIA International Standards) were collected at 1.5, 3, 6, and 12 months. The investigators documented no adverse effects of the treatment and by the 1.5-month follow-up period observed improvement of at least one ASIA Impairment Scale grade in 30% of patients. Initial data from the 6-month follow-up period suggest similar rates of recovery.

A phase II/III multicenter clinical trial of the drug Cethrin is planned. The study is anticipating enrollment of complete SCI (ASIA class A) patients to undergo surgery for epidural application of the soluble enzyme antagonist at the time of early surgical decompression.[24] Study enrollment will incorporate a Bayesian trial design in an effort to determine optimal dosing while keeping sample numbers to a minimum.

Anti-Nogo Antibody

Nogo is an oligodendrocyte-expressed soluble factor that is potent in its ability to inhibit axonal regeneration. Investigators have been able to restore corticospinal axonal regeneration and locomotion in rat and primate SCI models in which Nogo was neutralized with the monoclonal antibody IN-1.[51,52] A phase I clinical trial of intrathecally administered Nogo-A antibody in acute, complete (ASIA class A) SCI is currently underway in European SCI centers with expansion of the trial to Canadian centers anticipated.

Peripheral Nerve and Schwann Cell Transplantation

Inducing the CNS to mimic the natural regenerative ability of the peripheral nervous system is a pillar of current SCI research. The injured peripheral nerve expresses a permissive environment for axonal regrowth that is engendered primarily by its myelin-forming cell, the Schwann cell and its basal lamina. Schwann cells secrete trophic factors, express cell adhesion molecules, and produce extracellular matrix molecules that are requisite for axonal growth and regeneration.[53,54] The permissive features of Schwann cells may prove valuable in the treatment of SCI. Several groups have demonstrated improved axonal regeneration and functional recovery after Schwann cell transplantation to the site of SCI in rats.[55] Furthermore, the grafting of peripheral nerves with varying combinations of growth factors in SCI rats has resulted in significant axonal and functional recovery.[56] Most of the ongoing clinical studies involving peripheral nerve grafts that are used to bridge lesional sites in the spinal cord are phase 1 trials and currently involve very few patients. Some have shown neurologic improvement while others have not; none of these yet are prospective, randomized trials.[57] Other studies have involved the injection of Schwann cells and oligodendrocyte precursor cells to the area of cord lesion.[4]

Olfactory Ensheathing Glial Cell Transplantation

The olfactory ensheathing glial (OEG) cell spans both the peripheral nervous system and CNS and thus has a unique role in regenerative SCI therapy; several preclinical studies have shown the OEG to have permissive capabilities similar to that of the Schwann cell.[58] A nonrandomized, noncontrolled clinical trial of OEG transplantation in 171 patients with SCI showed modest improvement in ASIA motor and sensory scores after 8 weeks.[59] The study was criticized for its short duration, potential for bias, and lack of control. Neurologic outcomes in the first seven chronic (> 6 months postinjury) SCI patients treated with surgical implantation of olfactory mucosal autograft in an ongoing surgical case series in Lisbon, Portugal were recently published.[60] The investigators claimed to show a modest improvement in ASIA motor and sensory scores in the treated patients. Preliminary safety results of a small Australian controlled clinical trial of surgical implantation of cultured autologous olfactory cells in patients with chronic SCI has recently been published.[61] The investigators report no significant safety concerns at 1 year postimplant and plan to report efficacy outcomes.

Stem Cell Strategies

The ability of stem cells to differentiate into spinal cord tissue carries significant implications for SCI repair. The classic study by Keirstead et al. involved the use of human embryonic stem cell–derived oligodendrocyte progenitor cells to remyelinate

the area of contusion injury.[62] In the study, human embryonic stem cells were differentiated in vitro into oligodendrocyte progenitor cells which, in turn, were injected onto rat thoracic cord contusion sites both acutely (7 days) and latently (10 months after injury). The oligodendroglial cells that were acutely transplanted led to enhanced remyelination of axons and to enhanced hindlimb locomotor recovery, whereas latent transplants and control groups did not. There have been at least two attempts to translate these findings into human subjects with some preliminary success.

Genetic Modification Strategies

Despite the promising results of Schwann cell transplantation, the strategy is limited by the fact the regenerated axons do not leave the graft to incorporate with the contiguous native tissue rostral and caudal to the graft. The ability of regenerated axons to migrate out of the graft and into surrounding tissue would improve both locomotor and sensory recovery after injury.[62] The main barrier to axonal incorporation is, of course, the astroglial scar. Golden et al.[63] devised a model in which transplanted Schwann cells are first transduced with lentiviral vectors containing deoxyribonucleic acid encoding for chondroitinase ABC, which degrades CSPGs, the previously discussed component of glial scars, and for D15A, a powerful neurotrophic factor. The modified cells were then transplanted into the site of contusion injury. Relative to previous models with nonmodified Schwann cells, this led to (1) enhanced regeneration of axons both within the graft and into the surrounding tissue, (2) enhanced locomotor recovery in subjects, and (3) enhanced recovery of allodynia. This therapy combines strategies for defeating both of the chief obstacles in SCI recovery: the weak CNS reparative capacity and the stultifying effects of the glial scar. It will likely hold great promise.

As the cellular and molecular components of the injury response continue to be characterized, it will be possible to specifically neutralize the inhibitory constituents while preserving its proregenerative protective elements. The ability to modulate the behavior of the inflammatory response can enhance almost every existing modality of SCI treatment, from transplantation to gene therapy. SCI remains a challenging clinical problem. Ultimately, the plethora of promising interventions being studied in the laboratory will have to be validated in the clinical setting; thus, the creation of a streamlined and financially feasible mechanism for clinical trials will be necessary. Ultimately, combination therapies incorporating interventions to limit secondary injury, surgical treatment, regenerative therapies, and rehabilitation will likely be necessary to impact the outcome of this devastating disease.

KEY POINTS

1. A cascade of events following spinal cord injury can both inhibit recovery and cause additional neural damage.
2. The glial scar is a product of the inflammatory response to injury. It is a collection of reactive cells (astrocytes, microglia, oligodendrocyte precursors, meningeal fibroblasts) that express cell-surface and matrix molecules, which surround the area of injury and ultimately repel the advancement of regenerating axons.
3. Future treatment strategies are based on either neuroprotective or regenerative modalities that capitalize on our current understanding of the biochemical processes after injury.

PEARLS AND PITFALLS

1. There is currently no cure for SCI in human beings.
2. Some of the same processes that are involved in wound healing elsewhere in the body prevent healing of SCI.
3. NASCIS II/III results must be interpreted and applied with caution.

CHAPTER 75

Injuries of the Upper Cervical Spine

SECTION XI

Bobby K.-B. Tay
Frank J. Eismont

The upper cervical spine consists of the occiput, atlas, and axis. These three structures, along with their strong ligamentous attachments, are often referred to as the craniocervical junction (CCJ). This osseoligamentous complex that surrounds and protects the upper cervical spinal cord, the brain stem, and lower cranial nerves is anatomically and functionally distinct from the motion segments in the subaxial cervical spine (C3–C7). These differences also are responsible for the distinct patterns of injury that occur at the CCJ. The prevalence of injuries to the upper cervical spine has a bimodal distribution—they are most often encountered in children and in those older than 60 years of age. In the pediatric population, motor vehicle accidents and pedestrians hit by cars are the predominant mechanisms of injury. In the elderly, falls are the most common mechanism. Adults between these two age groups tend to suffer more injuries to the subaxial cervical spine. Upper cervical injuries occurring in these pediatric and intermediate age groups are often caused by high-energy trauma (vehicular accidents and falls) and are associated with a high rate of neurologic injury and mortality. Improvements in emergency medical care, trauma care, and imaging modalities have been beneficial in reducing both the mortality and morbidity of these injuries. Early detection and treatment significantly decreases mortality and improves overall outcomes.

As with internal fixation of extremity fractures, internal fixation of spine fractures has allowed early mobilization and rehabilitation of the patient, resulting in improved overall functional outcomes. The stability of internal fixation of the CCJ has also improved significantly over the past 15 years. Early plate/screw designs have evolved to rod/screw designs and plate–rod/screw hybrid designs, providing more versatility and improved fixation to the occiput using multiple points of fixation and the ability to place screws in the midline on the occiput, where the bone is thickest. Methods to obtain segmental fixation of the atlas and axis through the lateral masses, pars, pedicle, and lamina have improved the spinal surgeon's ability to correct deformity and decompress the neural elements without jeopardizing bony fixation and stability. Advances in the rehabilitation of patients with high cervical spinal cord injuries (SCIs) have improved the overall functional abilities of these patients.

Demographics

Traumatic injuries to the upper cervical spine are most often encountered in children and in people older than 60 years of age. Fortunately, they are still rare occurrences in children. Motor vehicle accidents are the cause of pediatric cervical spine trauma in about 38% of cases.[1–3] Cervical spine injuries in children account for 1% to 9% of all reported pediatric spinal trauma.[4,5] Upper cervical spine injuries are responsible for the majority of these, accounting for 56% to 73% of all cervical spine injuries in children.[2,6] Head injury occurs in conjunction with cervical spine injuries in up to 53% of these cases. When these two entities are concurrent, the overall mortality is very high (41%).[7]

Upper cervical spine injuries constitute a large proportion of cervical spine trauma in people older than 60 years of age. Injuries to the C1–C2 complex account for up to 69.8% of all cervical spine trauma in those older than 60 years.[8] Odontoid fractures alone can constitute up to 57% of all cervical spine injuries in this age group. Unlike the pediatric and young adult populations, upper cervical spine trauma in the elderly often occurs from minor trauma. Falls are often the predominant cause of injury. Any fall greater than 3 feet or 5 stairs requires cervical spine clearance with appropriate imaging. Many explanations for this phenomenon include the presence of weakened bone at the CCJ owing to osteoporosis/osteopenia, higher stresses on the upper cervical spine owing to spondylosis and deformity of the lower cervical spine (leading to compensatory hyperextension at the CCJ), and an increased propensity to fall from deterioration in locomotor response and balance control due to age and cervical spinal stenosis. The lower energy of the trauma is directly correlated to the lower rate of neurologic injury seen in this age group after injury as compared with the pediatric and young adult populations. However, when neurologic deficits occur, they can have devastating consequences. A 26% to 28% mortality for upper cervical level SCI has been reported for this population, with a dismal 59% survival at 2 years.[9–12]

In the young adult population, the majority of patients with spinal column injury are young males (up to 30% are males in their 30s).[13] The most common mechanism in this age group is vehicular accidents, followed by falls, gunshot injuries, and

sports injuries. Most of the cervical spine trauma in this age group occurs in the subaxial spine, and is often associated with a high-energy mechanism, severe head injury, or a focal neurologic deficit.[14] Trauma to the CCJ in this population is often associated with severe neurologic injury and head trauma, with relatively high rates of mortality and morbidity.

Anatomy of the Upper Cervical Spine (Craniocervical Junction)

The upper cervical spine is a complex three-unit joint that includes the bones of the occiput, atlas, and axis; their synovial articulations; and the associated ligamentous structures. The six synovial joints in this complex include the paired occipitoatlantal joints, the anterior and posterior median atlantoodontoid joints, and the paired atlantoaxial joints. These joints allow for a significant amount of motion at the CCJ. The occiput–C1 articulation supplies approximately 50% of total cervical flexion and extension, and the C1–C2 articulations supply 50% of total cervical rotation.[15] Corresponding to this, the majority of the mechanical stability at the CCJ is provided by the investing ligamentous structures. An understanding of the anatomy of the CCJ is necessary to appreciate the spectrum of injuries that occur in the upper cervical spine and the strategies that have been devised to treat them. The specific articulations, ligamentous restraints, and neurovascular structures at risk for injury are addressed here in a systematic fashion.

The occiput articulates with the atlas through paired occipitoatlantal joints. The occipital condyle is oval and sloped inferiorly from lateral to medial in the coronal plane, making a 25- to 28-degree angle with the midsagittal plane. The convex occipital condyles articulate with the concave superior articular facets of C1 in a "cup-and-saucer" type fashion. In the coronal plane, the joint slopes medially toward the foramen magnum. The shape of the occipitoatlantal joint allows significant flexion and extension and some lateral bending, but minimal axial rotation. Flexion is limited by the bony impingement of the anterior portion of the foramen magnum on the odontoid process; extension is limited by the posterior arch of the atlas impinging on the posterior aspect of the skull. The anterior atlanto-odontoid joint lies between the anterior arch of the atlas and the anterior aspect of the dens. The posterior atlanto-odontoid articulation lies between the posterior aspect of the dens and the anterior portion of the transverse ligament. The paired atlantoaxial joints are situated between the inferior articular facets of the atlas and the superior articular facets of the axis. These joints are fairly shallow to allow for a significant amount of motion at the CCJ. The ligamentous restraints provide the necessary stability to prevent injury to the enclosed brain stem and spinal cord (Fig. 75.1).

The anterior longitudinal ligament (ALL) attaches to the anterior body of the axis, the anterior arch of the atlas, and the anteroinferior edge of the foramen magnum. The cruciform ligament is composed of vertical and transverse portions. The vertical portion attaches to the anterior edge of the foramen magnum and the posterior aspect of the body of the axis. The transverse component of the cruciform ligament is commonly referred to as the transverse ligament. This important structure is made entirely of relatively nonelastic collagen fibers, and extends between the osseous tubercles on the medial aspects of the lateral masses of the atlas. The tectorial membrane is the broad cephalic extension of the posterior longitudinal ligament (PLL) and runs from the posterior surface of the body and dens of the axis to the anterolateral edge of the foramen magnum. This structure is a primary stabilizer of the occipitoatlantal articulation[15] and helps to limit extension at this joint. The nuchal ligament extends from the posterior border of the occiput to the spinous processes of the cervical vertebrae

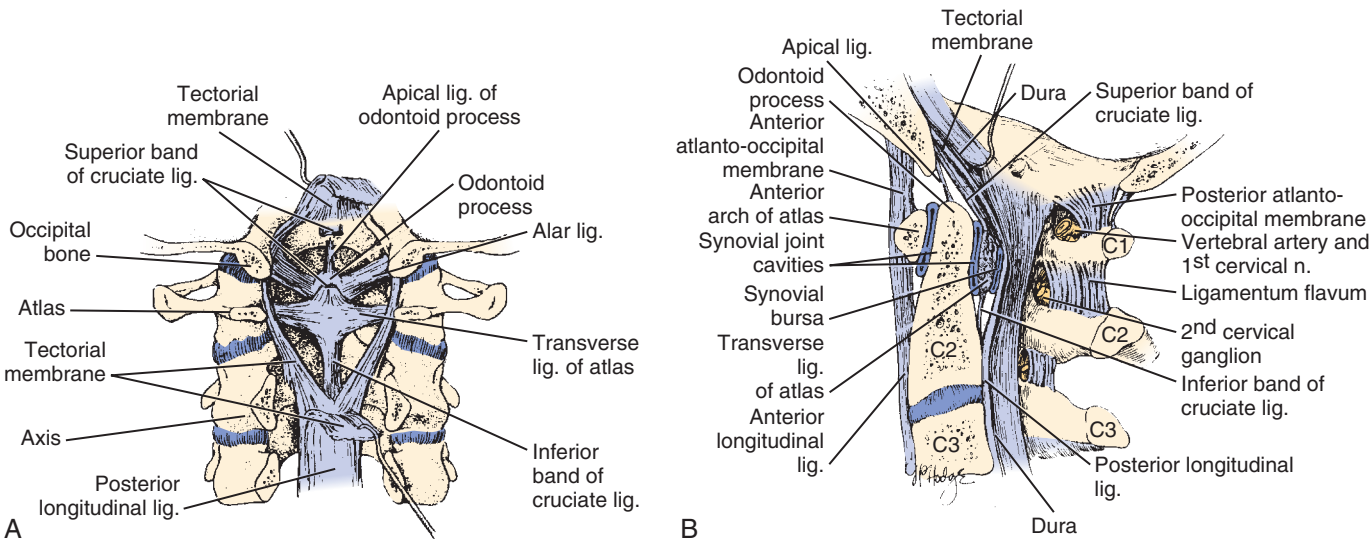

FIG. 75.1 The ligaments at the occipitocervical junction. (A) Coronal view shows the two alar ligaments extending from the superior tip of the odontoid process and extending to the medial aspect of the occipital condyles. (B) Midsagittal view shows the tectorial membrane, which is continuous with the posterior longitudinal ligament. (From Martel W. The occipital-atlanto-axial joints in rheumatoid arthritis and ankylosing spondylitis. *AJR Am J Roentgenol.* 1961;86:223–240.)

to C7 and the intervening interspinous ligaments. The anterior occipitoatlantal membrane, part of the ALL, extends from the cephalad portion of the anterior arch of the atlas to the anterior edge of the foramen magnum. The atlanto-odontoid ligament runs from the anterior surface of the odontoid process and the caudal portion of the anterior arch of the atlas. The apical ligament of the dens lies between the vertical band of the cruciform ligament and the anterior occipitoatlantal ligament. This structure connects the apex of the dens with the anterior edge of the foramen magnum. The alar ligaments are paired structures that arise from the dorsolateral aspect of the dens and run obliquely to connect with the inferomedial aspect of the occipital condyles and the lateral masses of the atlas. These ligaments are very important stabilizers of the occipitoatlantal joint, limiting axial rotation and lateral bending.[16] Like the transverse ligament, the alar ligaments are also made entirely of collagen fibers, and failure occurs at 10% stretch.[17] These ligaments are most vulnerable in whiplash-type injuries.[18] The posterior occipitoatlantal membrane attaches to the posterior margin of the foramen magnum and the posterior arch of the atlas. The posterior atlantoaxial membrane runs between the posterior arches of the atlas and the axis.

The vertebral artery and the internal carotid artery lie in close proximity to the osseous structures of the CCJ. Within the atlas and the axis, the paired vertebral arteries typically lie in the foramen transversarium. At this level, the artery is susceptible to injury by shearing forces with rotation and flexion or extension. At the upper atlantal surface, the artery curves posteriorly into a transverse groove in the atlas behind the superior atlantal articular facet. It then enters the subarachnoid space by piercing the posterior occipitoatlantal membrane and dura mater just medial to the occipital condyle. The vertebral artery can often take an aberrant course around or within the C1 ring. In computed tomography (CT) studies, arcuate foramen was present in 24% of patients and a high-riding vertebral artery, ponticulus posticus, was present in 34% of patients.[19] The internal carotid artery is adjacent to the anterior surface of the lateral mass of C1. This position renders it susceptible to injury by a forward thrust of the lateral mass as the head is forcefully rotated to the contralateral side.[19]

The neurologic structures protected by the osseoligamentous components of the CCJ include the medulla oblongata, lower cranial nerves, upper cervical spinal cord, and the C1 and C2 nerve roots. The medulla oblongata is bounded by the foramen magnum. The hypoglossal nerves (CN XII) traverse through the base of the occipital condyles within the anterior condyloid canals. With these nerves travel a meningeal branch of the ascending pharyngeal artery and an emissary vein. The nerve then descends ventrally and vertically 2 to 3 mm lateral to the center of the lateral mass of C1. At this point, it is at risk for iatrogenic injury by bicortical C1–C2 transarticular screws and C1 lateral mass screws. The jugular foramen (posterior foramen lacerum) is located lateral to the occipital condyle and the hypoglossal canal and posterior to the carotid canal. The glossopharyngeal nerves (CN IX) and the Jacobson nerves (branch of CN IX) pass through the anteromedial portion of the jugular foramen (pars nervosa). The vagus nerves (CN X), the Arnold nerves (branch of CN X), and the spinal accessory nerves (CN XI) pass through the posterolateral portion of the jugular foramen (pars vascularis) along with the internal jugular veins, posterior meningeal arteries, and small meningeal branches of the ascending pharyngeal artery. The proximity of these neurologic structures to the bony anatomy of the CCJ places them at risk for injury in the presence of ligamentous instability or fracture.

Clinical Evaluation

The treatment of a patient with a cervical spine injury regardless of location is initiated at the scene of the injury. Without exception, all victims of trauma are suspected to have a cervical injury until proven otherwise. Cervical spine injury has been closely linked to the presence of severe head injury (odds ratio [OR] = 8.5), a high-energy mechanism (OR = 11.6), or a focal neurologic deficit (OR = 58).[14] In suspected injuries of the upper cervical spine, an adequate airway and ventilation must be established because upper SCI can lead to diaphragmatic and intercostal paralysis with respiratory failure. In addition, large retropharyngeal hematomas can cause upper airway obstruction. Nasotracheal intubation or cricothyroidotomy is safest in the acute setting because it causes less cervical spine motion than direct oral intubation techniques.[19–21] Improvements in fiberoptic imaging have resulted in technologies such as the Glidescope. This videolaryngoscope allows oral–tracheal intubation without the need for significant neck manipulation and is technically easier than the traditional method of fiberoptic-assisted intubation. Once the patient's airway, breathing, and circulation are stabilized, initial stabilization of the cervical spine begins with the application of a rigid cervical collar, a spine board, and sandbags.

In general, noncontiguous spinal injuries can occur in 6% of patients. These fractures can be easily missed in the presence of head injury, upper cervical injury, or cervicothoracic injury. Atlas fractures, specifically, are associated with up to a 50% incidence of concurrent cervical spine fractures.[22] Facial and head injuries are also commonly seen in conjunction with fractures and ligamentous disruptions of the CCJ. Upper cervical injuries are also more frequently seen in patients with trauma to the lower third of the face.[23] In addition, up to 50% of patients with cervical spine injuries, SCIs, or both have associated head trauma. Brain damage is more associated with upper cervical injuries than with injuries to the subaxial spine.[24] Subarachnoid hemorrhages, subdural hemorrhages, and cerebral contusions must be diagnosed and treated expeditiously because they are the most common cause of mortality in these patients.

In addition to spinal trauma, other injuries should be assessed because they may influence the treatment of the spinal lesion and could significantly affect the outcome of the patient. In cervical spine trauma, much attention has been paid to the evaluation of these patients for vertebral artery injury (see Chapter 73). Friedman and colleagues reported a 24% overall incidence of vertebral artery injury in 37 cases of nonpenetrating cervical spine trauma.[25] Vaccaro and associates noted a 19.7% incidence of vertebral artery injury found

by magnetic resonance angiography in 61 patients.[26] In Cothren and coworkers' series, 18% of 69 patients with vertebral artery injury and cervical spine trauma sustained injuries to the CCJ.[27] The incidence of vertebral artery injury increases if the fracture extends into the foramen transversarium.[28] Bilateral or dominant vertebral artery injury can cause fatal ischemic damage to the brain stem and cerebellum.[29] Delayed cortical blindness and recurrent quadriparesis can also occur from occult vertebral artery injury after cervical trauma.[30] Despite the high incidence of vertebral artery injury with cervical trauma as well as the potential morbidity and mortality associated with vertebral artery injury, the great majority of these injuries are clinically silent.

Neurologic evaluation of injuries to the CCJ can be difficult because there is no specific myotomal or dermatomal distributions of motor and sensory loss, and it is further confounded by the frequent coexistence of facial and head trauma. Injuries to the C1 and C2 roots generally result in sensory deficits to the occiput and posterior scalp. A complete SCI at this level can result in ventilator-dependent quadriplegia. Incomplete SCI syndromes can also occur. At the occipitocervical junction, a peculiar syndrome of incomplete paralysis can develop as a result of compression/injury of the pyramidal decussation on the anterior aspect of the brain stem where the corticospinal tracts cross from one side to the other. The tracts to the arms cross cephalad to the tracts to the legs. If the primary injury is to the upper decussation, the arms can be more affected and give the appearance of a central cord syndrome. More caudal injury will affect the legs more than the arms. It is even possible to affect crossed arm fibers and uncrossed leg fibers, the so-called cruciate paralysis as described by Bell.[31] These patients can also have large variations in heart rate, blood pressure, and respiratory rate owing to injuries to the cardiovascular and respiratory centers in the brain stem.[32] Dysfunction of the lower cranial nerves (CN IX, X, XI, XII) is often seen with severe injuries to the occipitoatlantal joint and the skull base.

Imaging

Plain radiography is used as the first imaging modality for the upper cervical spine. The standard series includes anteroposterior (AP), lateral, and open-mouth views. In general, about 85% of all significant injuries to the cervical spine will be detected on the lateral view of the cervical spine. In the upper cervical spine, the lateral view and the open-mouth view are the most useful. Flexion and extension views will be inadequate to assess for ligamentous injury owing to voluntary guarding in 33% of cases.[33]

Evaluation of the lateral cervical view should include assessment for prevertebral soft tissue swelling, sagittal alignment, and instability. The soft tissue shadow should be less than 10 mm at C1, 5 mm at C3, and 15 to 20 mm at C6. Although this measure may be nonspecific for cervical injury, prevertebral soft tissue swelling may be the only evidence of severe ligamentous injury to the upper cervical spine. The sagittal alignment of the spine should be assessed by evaluation of four imaginary lines: (1) a line formed by the anterior margins of the vertebral bodies, (2) a line formed by the posterior margins of the vertebral bodies, (3) a line formed by the anterior cortical margins of the lamina, and (4) a line formed by the tips of the spinous processes. In the upper cervical spine, the relationships of these imaginary lines to the basion and opisthion also should be evaluated.

CT remains the most sensitive imaging modality to evaluate fractures of the upper cervical spine, subaxial spine, and cervicothoracic junction. In a prospective study of polytrauma patients, CT used as a primary screening tool had a sensitivity of 84% in detecting upper cervical injury.[14] CT is also cost-effective as a primary screening tool, especially in high- and moderate-risk patients.[34] With the added benefit of sagittal and coronal reconstructed images, CT has immense power to demonstrate complex fracture patterns not easily seen on standard radiography and on the axial images, especially at the occipitocervical junction.[35]

The availability of intraoperative CT scanning, such as the O-arm (Medtronic) and the Iso-C (Siemens), combined with better image guidance software allows real-time assessment of fracture displacement and reduction. This technology is especially useful in patients who are difficult to image due to size or associated injuries. When combined with intraoperative image guidance software, internal fixation can be more precisely and safely placed than with traditional fluoroscopic imaging.

Magnetic resonance imaging (MRI) is not as good as CT or plain radiographs in the identification and evaluation of cervical fractures. Klein and coworkers showed that MRI had only a 11.5% sensitivity for posterior fractures and a 36.7% sensitivity for anterior fractures.[36] Katzberg and colleagues reported that, for acute fractures, MRI had a weighted average sensitivity of 43%, compared with 48% for conventional radiography.[13] Vaccaro and associates also noted that MRI is not cost-effective as a screening device in patients without a neurologic deficit.[37]

Despite its inadequacies in evaluating bony detail, MRI is unsurpassed for the assessment of the soft tissue elements in the cervical spine. These structures include the intervertebral disc, ligamentous structures, and the spinal cord itself.[13] MRI is much more sensitive and specific than plain radiographs for the evaluation of a prevertebral hematoma. MRI is also useful for the detection of spinal cord hemorrhage, which, if present, carries a poor prognosis for neurologic recovery.[38] Acute hemorrhage has a low signal intensity on T2-weighted images (secondary to intracellular deoxyhemoglobin) and becomes hyperintense over the next several days after it becomes converted to extracellular methemoglobin. MRI diffusion studies allow a more accurate assessment of the degree of spinal stenosis. These diffusion studies assess the flow of cerebrospinal fluid (CSF) around the spinal cord at an area of constriction. If the degree of spinal stenosis is severe, the CSF flow is significantly compromised.[39]

Newer magnets that can produce field strengths over 3 Tesla are able to image individual tracts within the spinal cord itself, providing a more accurate assessment of the neurologic injury after cervical trauma.

MRI neurography provides detailed visualization of individual nerve roots as they exit the brain stem, the CCJ, and the subaxial cervical spine. This MRI modality can help distinguish root-level injuries from more peripheral injuries as well as double-crush-type nerve damage.[40]

Bedside fluoroscopic flexion and extension views have shown some diagnostic value in clearing the cervical spine in obtunded patients. In one report, it was noted that 30% of these patients could not be adequately evaluated by this technique.[41] Other researchers, however, have found this helpful, using a combination of initial inline traction followed by flexion and extension views only if the traction views are normal.[42] Due to the space constraints of most intensive care units and the lack of appropriate built-in shielding for the extensive use of fluoroscopic imaging, bedside fluoroscopy is relatively impractical in most hospitals. In addition, the use of both CT and MRI may provide sufficient information to allow removal of the cervical collar in an obtunded patient without the need for manipulation of the neck.

Initial Stabilization

In general, reduction and stabilization of the cervical spine in the acute setting is usually accomplished by Gardner-Wells tong traction in a rotating bed. The only contraindications to the use of traction in injuries of the CCJ include type II occipitoatlantal dislocations and type IIA hangman's fractures, in which the application of traction can result in significant distraction at the injury site and increased neurologic deficit. The use of a rotating bed minimizes the incidence of pulmonary complications, decubitus ulcers, and deep vein thrombosis. Carbon fiber Gardner-Wells tongs are often sufficient for injuries of the upper cervical spine, because gentle traction is adequate in most cases to achieve and maintain a closed reduction.

Specific Injuries to the Upper Cervical Spine

Occipital Condyle Fractures

Most injuries to the occipital condyles are caused by high-energy trauma to the head and neck. Bell reported the first case of occipital condylar fracture in 1817. The incidence of occipital condyle fractures is reported to range from 3% to 16%.[42,43]

The clinical presentation of these injuries can range from minimal deficits to frank quadriparesis. Patients may complain of high cervical pain, torticollis, headaches, and impaired mobility. The most severe neurologic deficits are often seen with concurrent head injury. Up to 31% of these patients may exhibit acute lower cranial nerve deficits.

Although radiographs may show some abnormal soft tissue swelling in the presence of an occipital condyle fracture, these injuries are often extremely difficult to detect with conventional radiography (Fig. 75.2).[44]

CT with reconstruction is the imaging modality of choice in the diagnosis and classification of these fractures. MRI can be used to assess for damage to the alar and tectorial membranes, but is less useful than CT from a treatment perspective.

The most utilized classification system for occipital condyle injuries was described by Anderson and Montesano (Fig. 75.3).[45] The injuries are categorized into three types according to morphology and mechanism of injury. Type I injuries are impaction fractures of the condyle from axial loading. These fractures tend to be comminuted. The tectorial membrane and the alar ligaments are usually intact. Unilateral type I lesions are stable, but bilateral lesions may be unstable. Type II injuries are part of a more extensive basioccipital fracture that involves one or both occipital condyles. The common mechanism of injury is a direct blow to the skull. The tectorial and alar ligaments are intact, and the fracture is usually stable. Type III

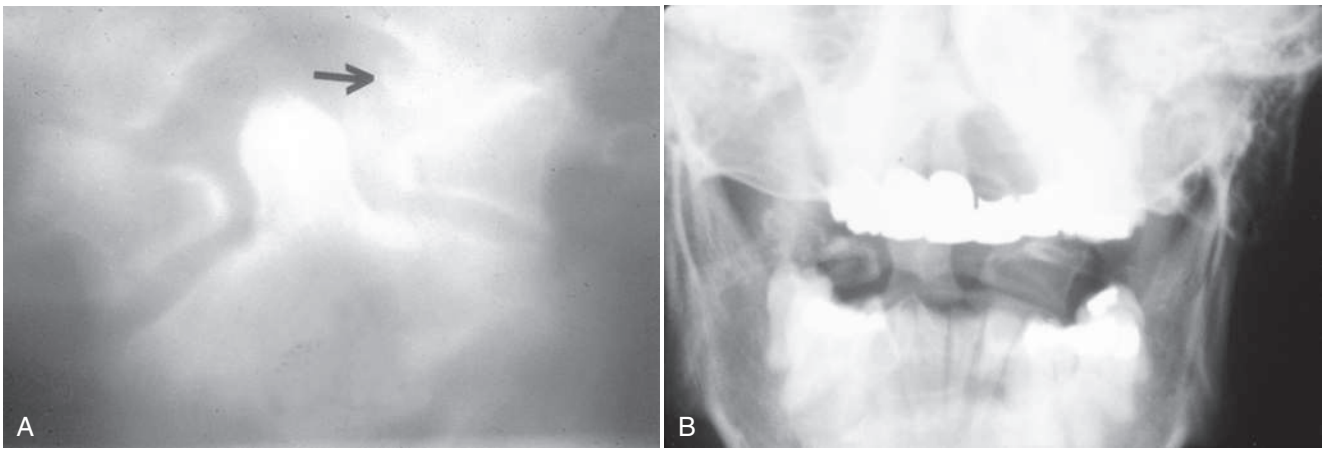

FIG. 75.2 Images of a patient who had fallen on his head and complained of a persistent pain in his upper neck as well as persistent headaches. (A) Open-mouth view shows an asymmetry between the plane of the skull and the plane of the C2 vertebra (*arrow*). The head appears tipped to one side. (B) Anteroposterior tomogram of the occipitocervical junction shows that the patient had sustained a type I impaction fracture of the occipital condyle. This would be expected to cause laxity of the alar ligament on that side. He was treated with a rigid cervical collar for 8 weeks, with gradual improvement of his pain. (From Eismont FJ, Frazier DD. Cranial cervical trauma. In: Levine AM, Eismont FJ, Garfin SR, Zigler JE [eds]. *Spine Trauma*. Philadelphia: WB Saunders; 1998:207.)

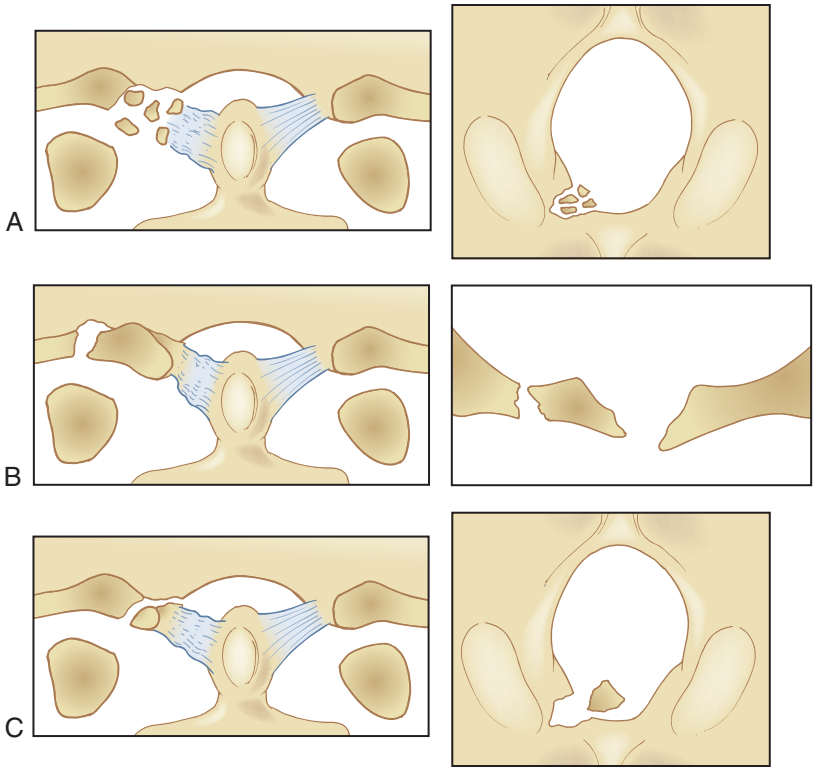

FIG. 75.3 The best available classification for fractures involving the occipital condyles. (A) Impacted occipital condyle fracture. In most cases, this would be a stable injury and can be treated with a collar. (B) This occipital condyle fracture is associated with a basilar skull fracture. In most cases, this would be stable. (C) This condyle fracture destabilizes the origin of the alar ligament, and may be associated with significant occipitocervical instability. (From Anderson PA, Montesano PX. Morphology and treatment of occipital condyle fractures. *Spine*. 1988;13:731–736.)

injuries are avulsion fractures near the alar ligament insertion that result in medial displacement of the condylar fracture fragment from the inferomedial aspect of the occipital condyle into the foramen magnum. The mechanism of injury is a forced rotation of the head combined with lateral bending. Type III fractures are potentially unstable injuries owing to avulsion of the alar ligaments.

Type I and type II fractures can be treated with a rigid cervical orthosis. Type III injuries can be treated initially with an orthosis or halo vest. However, posterior occipitocervical fusion may be necessary for chronic pain, neurologic deficit, or instability.

Atlanto-Occipital Injuries

The incidence of injuries to the atlanto-occipital joint is estimated to be between 5% and 8% of fatal traffic injuries.[46] These injuries account for 19% to 35% of all deaths from cervical spine trauma. More than 80% of cases of occiput-C1 dislocations were reported after 1975. Improvements in on-site resuscitation and emergency transportation have increased the number of patients who survive this catastrophic injury, which is typically the result of a motor vehicle accident. In a review of 146 traffic fatalities, Alker and associates found a 5% incidence of occipitoatlantal dislocations.[47] Children younger than 12 years of age are uniquely predisposed to this injury because their occipitoatlantal joints are flatter and because their head weight to body weight ratio is significantly greater than in adults.

Radiographically, significant retropharyngeal soft tissue swelling at C3 will be seen (Fig. 75.4). Multiple anatomic lines mark the normal relationship of occiput to C1. A line drawn down the cranial aspect of the clivus should be tangential to the dens (the Wackenheim line). Distance greater than 10 mm between the basion and the dens is considered abnormal.[48] The sensitivity of this method is about 50%. An interval greater than 13 mm between the posterior mandible and the anterior atlas or 20 mm between the posterior mandible and the dens is abnormal (Fig. 75.5).[49] The sensitivity of this method is 25%. Failure of a line drawn from the basion to the axis spinolaminar junction to intersect C2 or failure of a line from the opisthion to the posterior inferior corner of the body of the axis to intersect C1 is abnormal.[50] The sensitivity of this method ranges from 20% to 75%. The Powers ratio, the ratio of the distance from the basion to the posterior arch of the atlas divided by the distance from the opisthion to the anterior arch of the atlas, should be 1.0 or less in the absence of anterior occipitoatlantal dislocation (Fig. 75.6).[51] Another method to diagnose occipitoatlantal subluxation or dislocation on plain radiographs was described by Harris and colleagues.[52,53] They described a posterior axial line as the cranial extent of the posterior cortex of the axis body. If the distance between the basion and the posterior axial line (the basion–axial interval) is greater than 12 mm, or if the basion-dental interval is greater

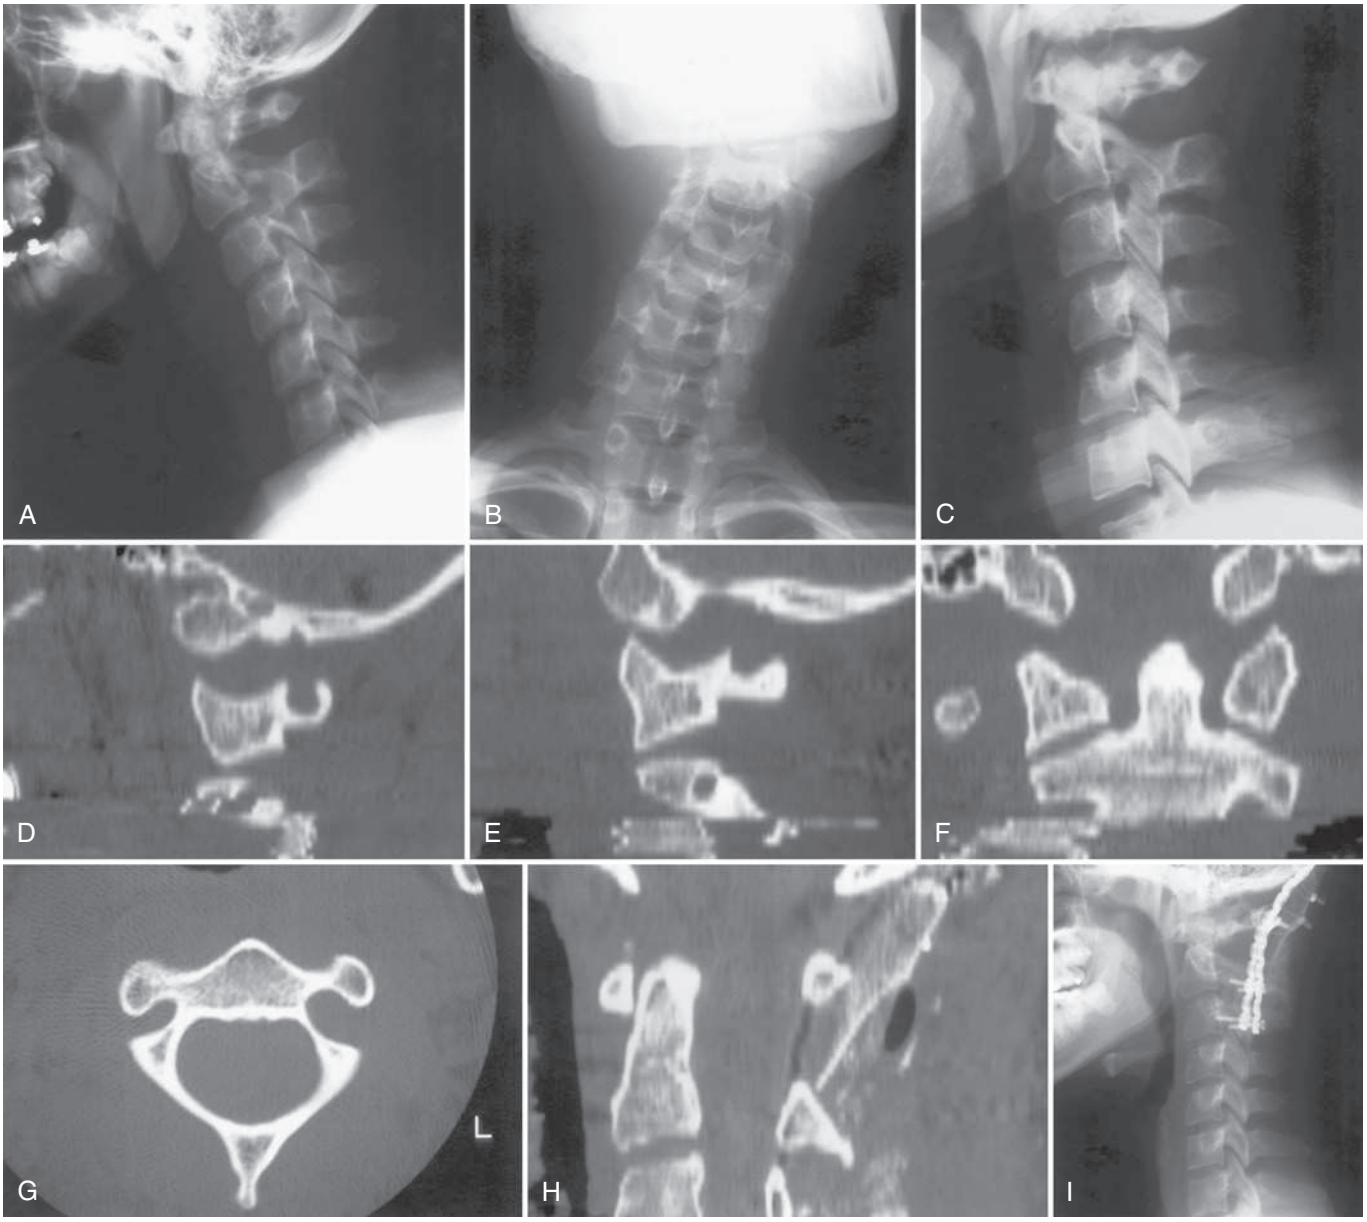

FIG. 75.4 This patient was involved in a motor vehicle accident with an unrecognized occipitocervical injury. (A) Radiograph taken when the patient originally presented to the emergency department shows more than 2 cm of soft tissue swelling in front of C3. His injury was not recognized and he was discharged from the hospital. He was neurologically normal. (B) Ten days later, when the patient returned to the emergency department, he had an obvious occipitocervical deformity. He was still neurologically normal. (C) When the patient was placed in 5 lb of traction, it was apparent that he had separation between his occiput and C1 vertebra. (D) Computed tomography (CT) shows that he has anterior displacement of his occipital condyle in relation to his C1 lateral mass as well as approximately 1 cm distraction of his occipitocervical joint. At the C2 level, he also has a fracture extending into the lateral mass of C2. (E) On the opposite side, the same type of anterior subluxation of the occiput on C1 can be seen as well as separation of the occipitocervical joint. (F) Coronal reconstructed CT scan shows the pathologic distraction between the occiput and C1. Only a 2-mm joint space would be expected at this level. (G) Transverse CT scan shows that the patient has a vertebral artery course that is more medial than usual on each side and prohibited passage of C1–C2 transarticular screws. (H) Midsagittal reconstructed CT scan shortly after surgery shows the large structural bone graft placed centrally between the occiput and C2. This was wired independently to the skull and spine, and is necessary in addition to the plates and screws to ensure adequate healing and stability. (I) Lateral radiograph of the spine taken approximately 2 years after the patient's injury. His spine has maintained normal alignment at the occipitocervical junction and stability has been restored. (From Eismont FJ, Frazier DD. Cranial cervical trauma. In: Levine AM, Eismont FJ, Garfin SR, Zigler JE [eds]. *Spine Trauma*. Philadelphia: WB Saunders; 1998: 205-206.)

than 12 mm, then occipitocervical instability is present.[52,53] The sensitivity of this method varies from 76% to 100% (Fig. 75.7).

Because this is a very unstable injury, flexion–extension views are not recommended. However, if they are available, there should be less than 1 mm of translation seen at the occipitoatlantal articulation. In children, more than 5 mm widening of the occipitoatlantal joints should raise the suspicion of this injury.

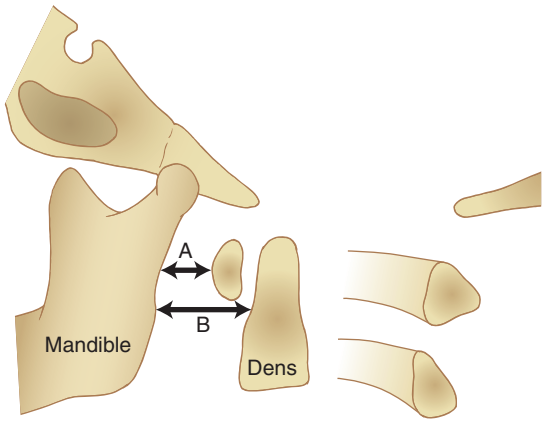

FIG. 75.5 Normal relationship of the posterior ramus of the mandible in relation to the anterior ring of C1 and the dens. Radiographs were taken of 23 normal patients, and distance A averaged 2 mm with a range from −10 to +9 mm. The average for distance B was 10 mm, with a range from 2 to 17 mm. Distances significantly greater than these averages denote anterior occipitocervical dislocation; distances significantly smaller indicate likely posterior occipitocervical dislocation. All radiographs must be done with the patient's mouth closed. (From Dublin AB, Marks WM, Weinstock D, Newton TH. Traumatic dislocation of the atlanto-occipital articulation [AOA] with short-term survival—with a radiographic method of measuring the AOA. *J Neurosurg.* 1980;52:541–546.)

The most commonly employed classification system for occiput-C1 dislocations was described by Traynelis and associates (Fig. 75.8), who categorized these injuries into three types.[54] In type I injuries, there is anterior displacement of the occiput on the atlas. Type II injuries are the result of longitudinal distraction. Any traction applied to a type II injury can result in progression of the existing neurologic deficit. Type III injuries involve a posterior subluxation or dislocation. Very light traction of about 5 pounds applied to type I and type III injuries will help to reduce the dislocation and may improve the neurologic deficit. Radiographs should be taken immediately to ensure that there is no overdistraction.

As noted earlier, the mortality from head-on-neck dislocation is extremely high. Only 20% of patients presenting to the trauma center with acute traumatic atlanto-occipital dislocation will have a normal neurologic examination.[55] The

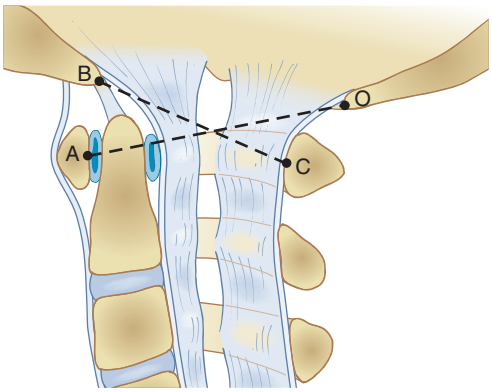

FIG. 75.6 Midsagittal section through the craniocervical junction. B, basion; O, opisthion; A, anterior arch of the atlas; C, posterior arch of the atlas. The ratio of BC/OA should always be ≤1. If it is >1, the patient most likely has an anterior occipitocervical subluxation or dislocation. (From Powers B, Miller MD, Kramer RS, et al. Traumatic anterior atlanto-occipital dislocation. *Neurosurgery.* 1979;4:12–17.)

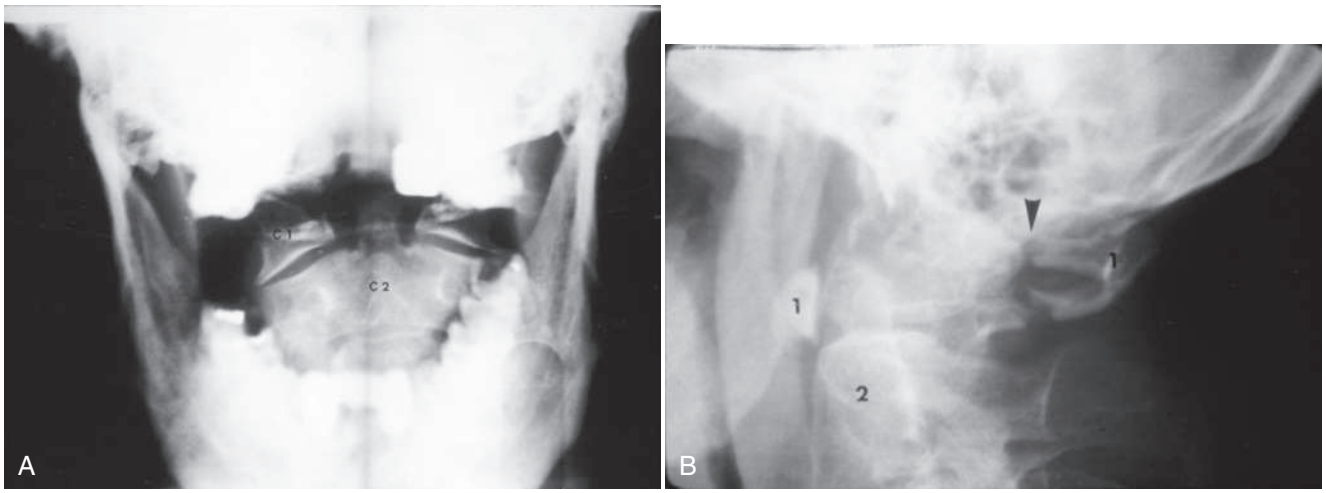

FIG. 75.7 This 68-year-old man was involved in a high-speed motor vehicle accident and was ejected from the vehicle. He complained of neck pain and had a fracture of his femur. He was initially neurologically normal; he was placed in a soft cervical collar and his femur was immobilized. (A) Anteroposterior radiograph of the upper cervical spine looks relatively normal. (B) Cone-down lateral radiograph of the upper cervical spine reveals a fracture of the posterior arch of C1 (*arrowhead*). It also appears that his basion is slightly more posterior than normal. There is significant soft tissue swelling in the retropharyngeal space at C1 and C2.

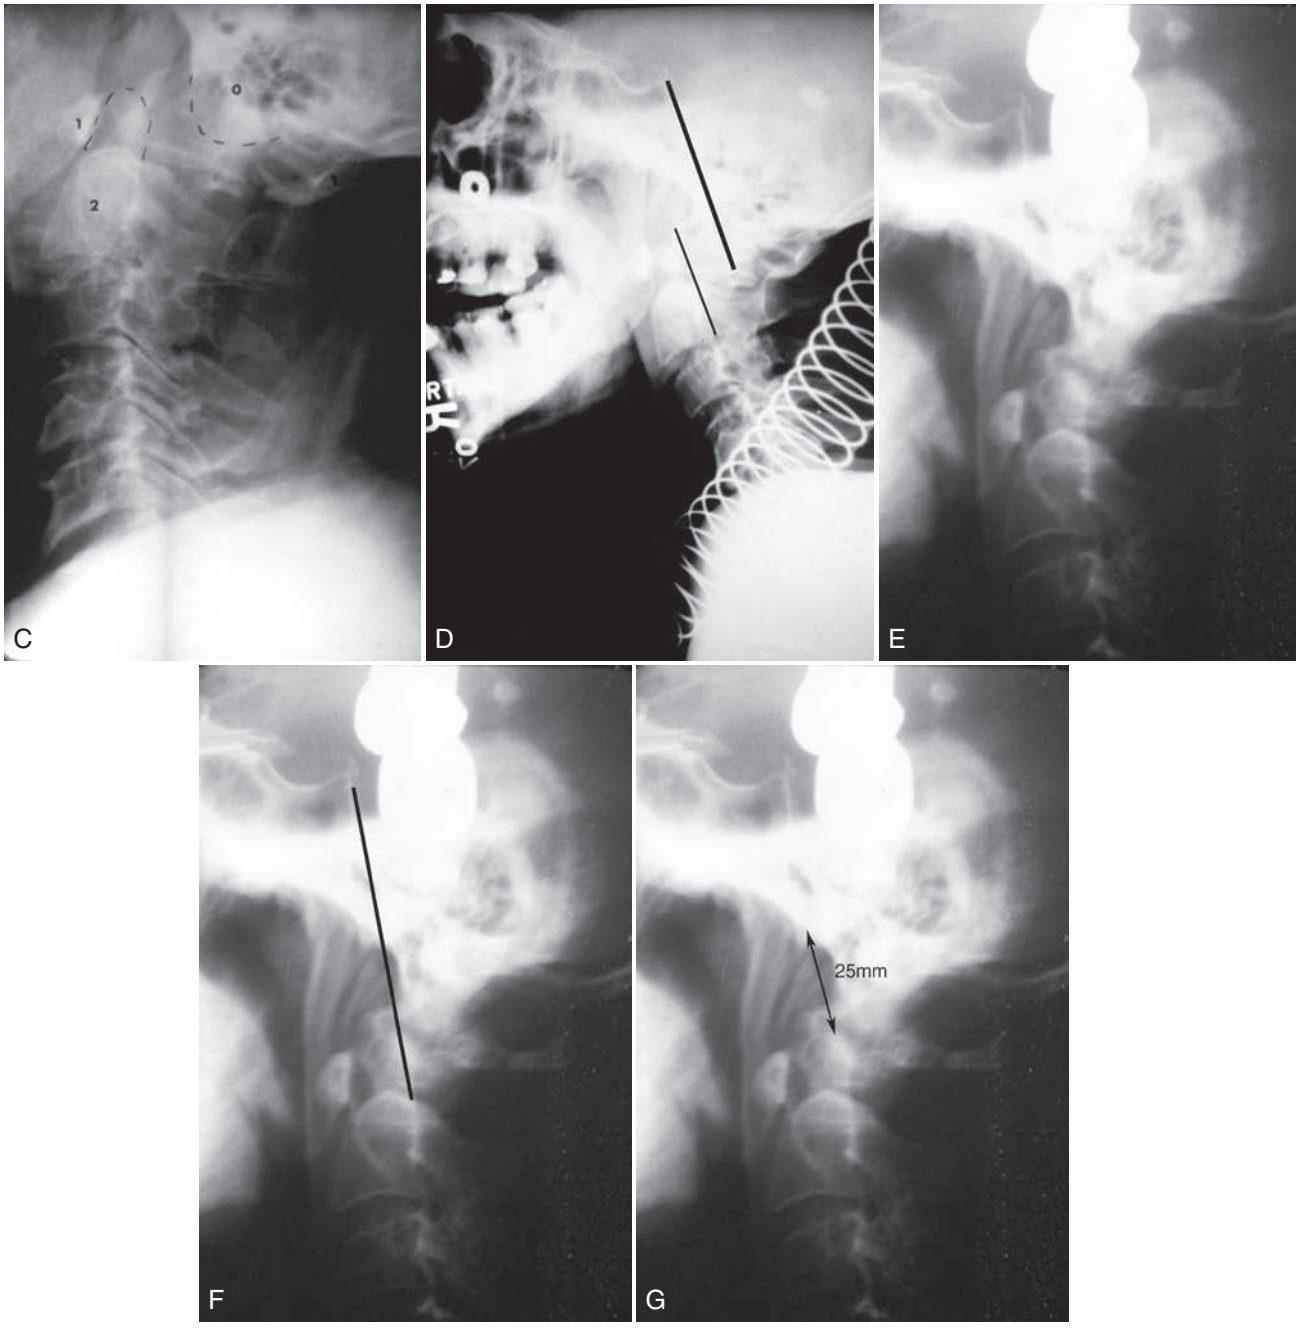

FIG. 75.7, cont'd (C) At 10 days postinjury, the *dotted lines* mark occipital condyles and the odontoid process. It is apparent that his head is posteriorly displaced on the atlas. At this time, he was in a soft cervical collar. He was experiencing problems with hypertension and paroxysmal atrial tachycardia and respiratory distress associated with a spastic quadriparesis. His head-on-neck dislocation was diagnosed at this time, and he was placed in skull tong traction of 4.6 kg. (D) Lateral radiograph shows a posterior dislocation also. The *thick dark line* demonstrates the Wackenheim line extending from the posterior sella turcica down the clivus and over the basion. This line should normally be tangential to the posterior aspect of the odontoid. In this case, there is almost 2 cm of posterior subluxation. It can also be noted that the posterior aspect of the ramus of the mandible also significantly overlaps the anterior arch of the atlas, which, according to Dublin's criteria, denotes posterior occipitocervical dislocation. (E) Lateral radiograph of the upper cervical spine shows that the occiput is correctly located over the atlas and odontoid, but that there is moderate overdistraction. At this time, the weight was reduced to 2.3 kg of traction. The patient's quadriparesis resolved over several hours, and his spasticity subsided over approximately 6 weeks. (F) The Wackenheim line is now drawn and is almost perfectly tangential to the posterior aspect of the odontoid as it would normally be seen. This shows that the posterior occipital subluxation has been corrected. (G) This measurement from the basion to the tip of the odontoid measures 25 mm. This line of Harris should normally be ≤12 mm. Thus, this line demonstrates the overdistraction that is present.

Continued

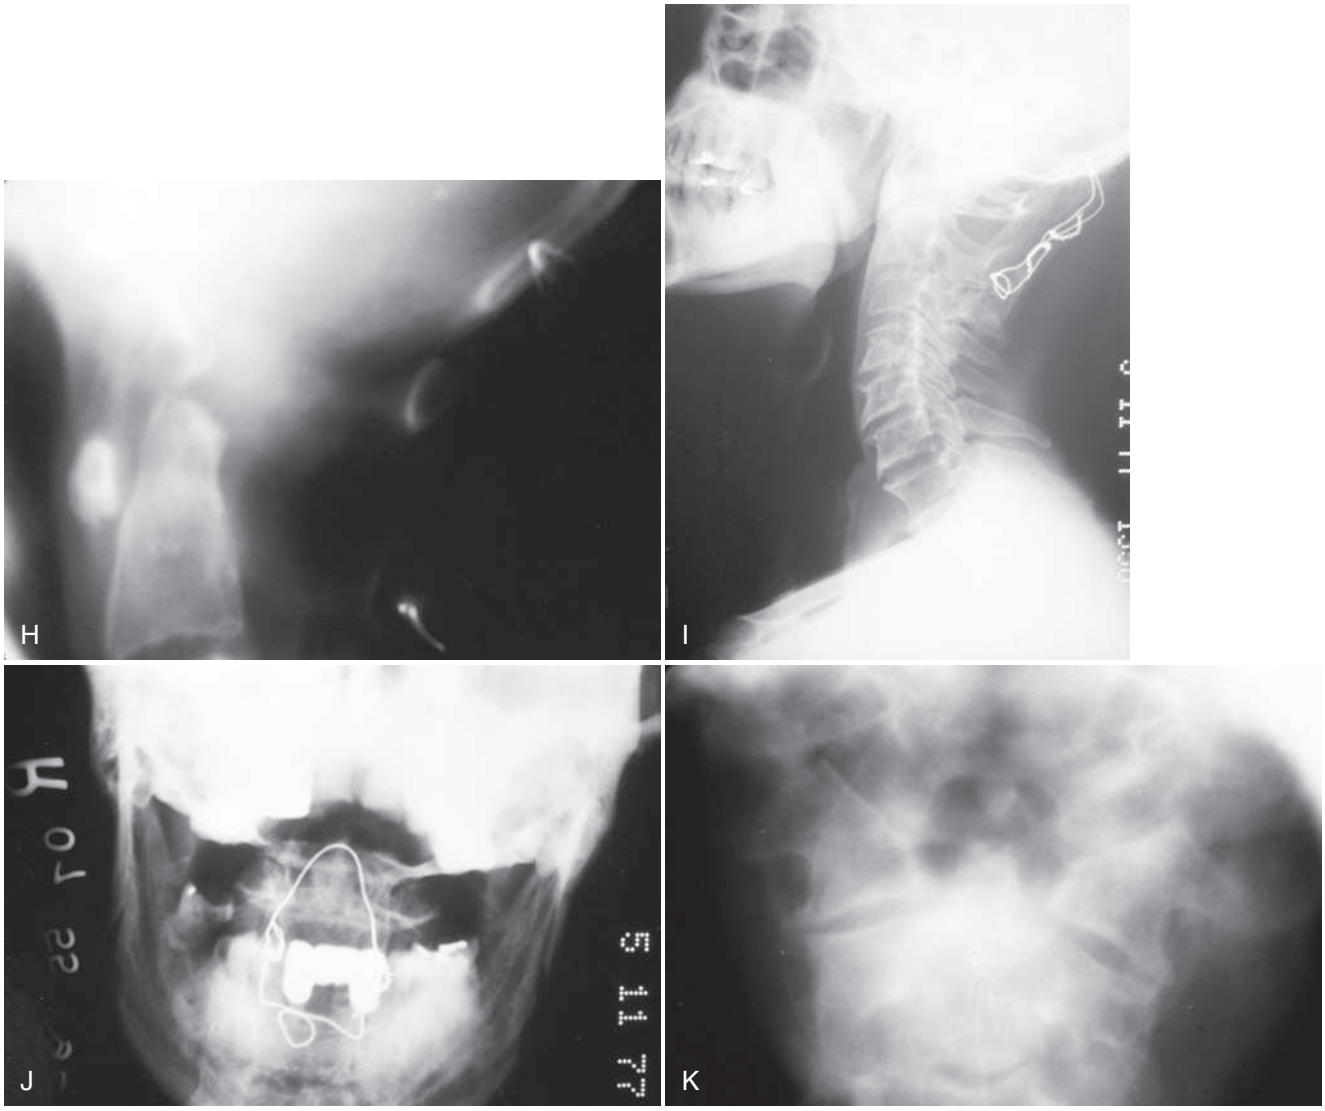

FIG. 75.7, cont'd (H) At 6 weeks after injury, a halo and body cast were applied to immobilize the patient's head on his neck. Twelve weeks after injury, a posterior fusion from the occiput to C3 was performed with iliac crest bone graft wired in place. This lateral tomogram taken 10 weeks after fusion demonstrates avulsion of the apex of the odontoid process, which is a type I odontoid fracture. This probably includes bone attachment of the alar ligaments. This film also shows that the relationship of the basion to the odontoid has been restored to normal and that the posterior laminar line is now again normal. In addition, there is spontaneous fusion anteriorly extending from the basion down to the anterior arch of C1. (I) Anteroposterior tomogram obtained 10 months after fusion reveals that the tip of the odontoid process is avulsed and is a type I odontoid fracture. The occipital condyles are again congruous. (J) Lateral radiograph obtained 14 months after the original injury shows a solid posterior occiput to C3 fusion with good alignment of the occipitocervical junction. (K) Anteroposterior radiograph 14 months after injury shows that normal alignment of the occipitocervical junction has been maintained. (From Eismont FJ, Bohlman HH. Posterior atlanto-occipital dislocation with fractures of the atlas and odontoid process. *J Bone Joint Surg Am.* 1978;60:397–399.)

remainder will suffer deficits of the cranial nerves, brain stem, and upper cervical spinal cord. Vertebral artery injury may accompany the dislocation. The most common mechanism is from an extension-rotation force. Patients with vertebral artery insufficiency at this level may exhibit Wallenberg syndrome, consisting of ipsilateral defects of cranial nerves V, IX, X, and XI; ipsilateral Horner syndrome; dysphagia; and cerebellar dysfunction.

All occipitocervical dislocations should be treated initially by immediate application of a halo vest. Because the majority of these injuries are unstable, posterior occipitocervical fusion is the procedure of choice (Fig. 75.9).[32,56] This can be done using a variety of techniques, including posterior wiring and structural grafting (Fig. 75.10), Ransford loop fixation with wiring, and plate and rod and screw fixation with structural grafting (Fig. 75.11). The first technique will require the use of postoperative halo immobilization; the latter two techniques will usually only need collar immobilization as external support. Improvements in occipital plate designs allow multiple points of fixation in the occiput, especially in the midline,

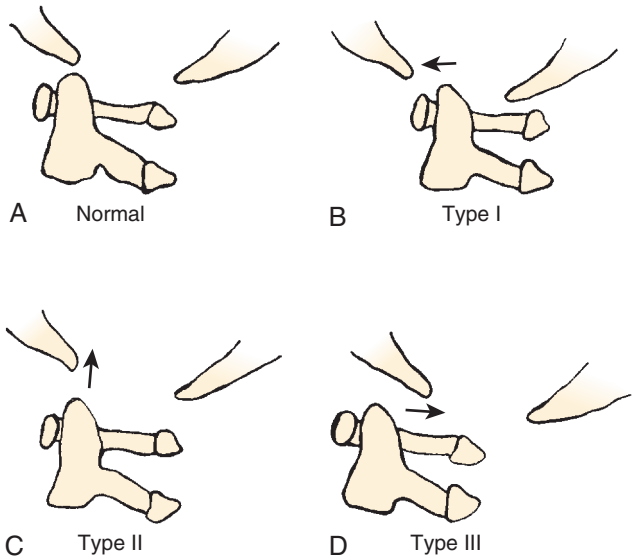

FIG. 75.8 Classification system of Traynelis and coworkers, which describes occipitocervical subluxation and dislocation. (Modified from Traynelis VC, Marano GC, Dunker RO, et al. Traumatic atlanto-occipital dislocation. *J Neurosurg.* 1986;65:863–870.)

where the occipital bone is thicker, providing significantly better initial fixation than off-midline plate-rod constructs.[57]

Fractures of the Atlas

Fractures of the atlas were first described by Jefferson in 1921. They usually occur in the anterior and posterior arches, which are the weakest points on the C1 ring. These injuries comprise 2% to 13% of all cervical spine fractures and approximately 25% of all injuries to the atlantoaxial complex.[22] They are often seen in the younger age groups (mean age, 30 years) and are most commonly the result of vehicular accidents or a fall on the top of the head.

These fractures are caused by axial loading. Because of this mechanism, these fractures commonly accompany head injuries in the polytrauma patient. In addition, there is an extremely high association (up to 50%) of atlas fractures with other cervical spine fractures. These include dens fractures, hangman's fractures, teardrop fractures of C2, cervical burst fractures, and lateral mass fractures.[22]

Patients will often complain of severe suboccipital discomfort and a sense of instability. Neurologic injury is uncommon in the case of isolated fractures of the atlas, but, when it occurs, the greater occipital nerve is most frequently injured, followed by the lower cranial nerves.[58]

Retropharyngeal soft tissue swelling greater than 5 mm at C3 in combination with a fracture of the posterior arch of C1 is highly suggestive of a burst-type injury. A combined lateral mass displacement on the open-mouth AP view exceeding 6.9 mm is indicative of transverse ligament insufficiency (Fig. 75.12),[59] but this measurement may not be sensitive enough to detect all unstable injuries. MRI can be used to help assess the continuity of the transverse ligament in those cases in which ligament status is unclear.[60]

Fine-cut CT in the plane of the axis will clearly delineate the fracture pattern. Common fracture patterns include isolated posterior arch fractures, lateral mass fractures, and burst fractures with combined anterior and posterior arch fractures. Isolated posterior arch fractures (Fig. 75.13) most commonly occur at the vertebral artery groove at the junction of the lateral mass and posterior arch. These are stable fractures that can be treated in a cervical collar for comfort. Lateral mass fractures can be either displaced or nondisplaced. Nondisplaced injuries can be treated with a cervical collar. Fractures that are displaced more than 5 mm can be treated with immediate halo vest application. A variation of the C1 lateral mass fracture, a unilateral C1 lateral mass sagittal split fracture, has a propensity to cause late deformity and pain if not treated with either C1–C2 fusion or direct osteosynthesis.[61] Burst fractures of the C1 ring are often referred to as Jefferson fractures. These injuries have one or two fractures in the posterior arch and one or two fractures in the anterior arch. Minimally displaced fractures (<7 mm) can be treated in a cervical collar.[61,62] Treatment of fractures with a combined diastasis of more than 6.9 mm consists of immobilization in a halo vest for 3 months (Fig. 75.14). After the halo vest is removed, flexion and extension radiographs are taken to test for C1–C2 instability, which, if significant, can be treated by C1–C2 posterior fusion.

Treatment of Jefferson fractures with greater than 6.9 mm of separation is controversial. Levine and Edwards advocate initial reduction of the fracture with skeletal traction for up to 6 to 8 weeks, followed by another 6 weeks of halo vest treatment.[63] Other series have found that immediate treatment with a halo vest can result in an acceptable outcome and avoids the morbidity associated with prolonged bed rest.[64,65] Traction reduction followed by early C1–C2 fusion using C1–C2 transarticular screws has also been described,[66] but intraoperative difficulty may be found owing to gross instability of the C1 lateral masses and the loose C1 posterior arch.

Most surgeons would agree that operative treatment is indicated if more than 5 mm of C1–C2 instability exists on flexion and extension radiographs once the halo is removed. If the posterior arch of C1 is healed, a posterior C1–C2 fusion is indicated. In the case of nonunion of the posterior arch of C1 or significant injury to the occipital condyles, occiput–C2 fusion can be performed. Another indication for surgery is neck and/or occipital nerve pain in a patient with a nonunion of the atlas ring fractures. The recommended treatment would then be a posterior occiput–C2 fusion.[67]

Atlantoaxial Subluxation and Dislocation

Conservative care of atlantoaxial rotatory subluxation in children, also known as Grisel syndrome, is most effective when treatment is instituted early. Most children who have had symptoms for less than 1 week will improve with a soft cervical collar and close observation. When symptoms have been present for 2 to 4 weeks, hospital admission and head-halter traction is usually successful in achieving reduction. For patients who present 1 month after the subluxation occurs, skull traction can be instituted and continued for up to 3

FIG. 75.9 This man was injured when his car struck a tree. He had an immediate onset of pain in his upper cervical spine, with radiation to the back of his head. (A) Lateral radiograph shows normal alignment of the upper cervical spine and the occipitocervical junction. There is no abnormal soft tissue swelling. The basion appears to be directly over the tip of the odontoid and is less than 1 cm from the tip. The Wackenheim line is not drawn here, but the bony line down the clivus and the posterior aspect of the basion appears to be tangential to the posterior aspect of the odontoid. (B) Open-mouth view of the odontoid is abnormal. The patient's right lateral mass of C1 appears smaller than the lateral mass of C1 on the left side. There is also some asymmetry, with the distance from the lateral mass of C1 to the odontoid being shorter on the right side than on the left side. (C) Parasagittal CT reconstruction shows that his occipital condyle on the right side is posterior to the lateral mass of C1. (D) This computed tomographic (CT) image is slightly more medial than that in (C) and shows that the occipital condyle is impacted into the posterior aspect of the posterior lip of the right lateral mass of C1. (E) This view is even more medial, and again shows the occipital condyle to be posteriorly displaced and impacted into the posterior lip of the lateral mass of C1. (F) Coronal reconstruction of the CT scan shows that the left-sided occipitoatlantal joint is normal. On the right side, the occipital condyle is posterior to the lateral mass of C1; thus, it is not seen on this view. (G) This transverse axial image shows the abnormal appearance of the right-sided occipitoatlantal joint. (H) The patient was initially placed in skull tong traction, but the occipitoatlantal dislocation could not be reduced. The patient was then taken to surgery. At the time of surgery, with a combination of skull tong traction and manual manipulation with a cable passed under the posterior arch of C1, the occiput–C1 dislocation was reduced with an audible "clunk." Fusion was performed using titanium cables to fasten autograft bone to the base of the skull posteriorly and to the posterior arch of C1. This postoperative coronal CT reconstruction shows complete reduction of the occipitoatlantal joints bilaterally. (I) Lateral radiograph shows the bone graft and cables in place. Because rigid internal fixation was not utilized, the patient was immobilized in a halo vest postoperatively. (J) Midsagittal reconstructed CT scan shows the bone graft healing at 3 months from the time of surgery.

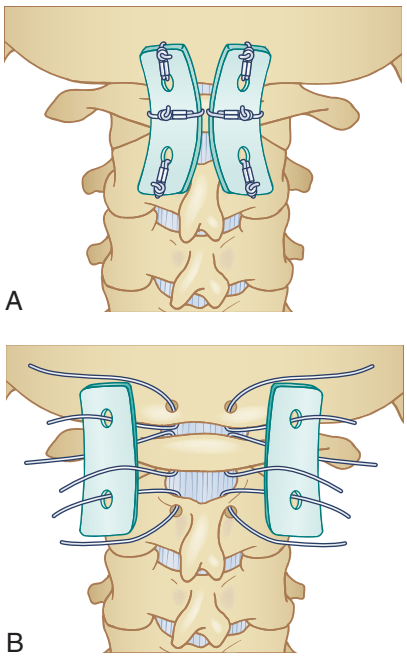

FIG. 75.10 Classic wiring technique for occipitocervical fusion. The titanium cables fastening the bone graft to the skull are passed through two burr holes just posterior to the foramen magnum. The cables are also passed bilaterally under the posterior arch of C1 and under the lamina of C2. Drill holes are made in the iliac crest bone graft to allow passage of the wires as shown. The cables under C2 are passed all the way around the graft. It is imperative that the graft be a thick structural iliac bone graft. If the bone graft is not solid enough, a combination of cortical structural allograft bone graft superficially and the patient's autogenous iliac bone graft beneath this would be used to provide a combination of structural stability and autogenous factors to promote bone healing. If rigid instrumentation (plates or rods combined with screws) is not used, then the patient would be placed in a halo vest until the construct was completely healed. This would usually require a period of 3 months. (From Eismont FJ, Frazier DD. Cranial cervical trauma. In: Levine AM, Eismont FJ, Garfin SR, Zigler JE [eds]. *Spine Trauma*. Philadelphia: WB Saunders; 1998:203.)

weeks. Initial traction should be 7 pounds and gradually increased to 15 pounds. If traction fails to reduce the deformity, open reduction and C1–C2 fusion is recommended.[68]

Traumatic rotatory subluxation or dislocation in adults is most commonly caused by vehicular trauma. Like children, adults will present with a "cock robin" appearance with the head tilted toward and rotated away from the side of the dislocation.

Radiographs will show asymmetry of the lateral masses on the open-mouth view. A "wink sign" may be appreciated; it is caused by overriding of the C1–C2 joint on one side with a normally aligned joint on the contralateral side. Dynamic CT is the best means of demonstrating the condition. Cervical spine CT scans are done in a neutral position and then repeated with the head maximally rotated to one side and then the other side.

Fielding and Hawkins presented the most commonly used classification scheme for these injuries (Fig. 75.15).[69] Type I dislocations are pure rotational injuries. Type II injuries have both rotatory malalignment with anterior displacement of the atlas less than 3 to 5 mm, suggesting only a mild deficiency of the transverse ligament. Type III injuries combine rotatory subluxation with greater than 5 mm of displacement, suggesting complete deficiency of the transverse ligament. Type IV injuries have both rotational malalignment and posterior displacement.

In adults, reduction of the rotational deformity can usually be achieved by skull tong traction. Topical anesthetic in the posterior pharynx may be helpful. The reduction can be palpated through the mouth. If it was difficult to obtain the reduction, then halo vest immobilization may be needed. For most cases, a rigid cervical collar is adequate.

If closed reduction fails, open reduction is performed and a posterior C1–C2 fusion is used to stabilize the reduction. Many methods to achieve fusion of the C1–C2 complex have

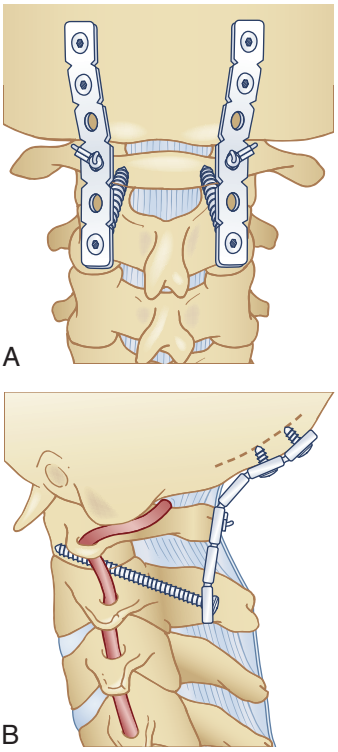

FIG. 75.11 (A) Anteroposterior and (B) lateral views of the occipital cervical plating technique using C1–C2 transarticular screws and titanium reconstruction plates with bicortical skull screws. Because the transarticular C1–C2 screw is the most critical in terms of its positioning, the C1–C2 transarticular screw is always the first screw to be placed in this construct. The path would initially be drilled and tapped. A plate would then be bent to accommodate the local anatomy. The plate must fit flush against the skull, fit against the posterior arch of C1, and fit the contour of the posterior arch of C2. The C1–C2 transarticular screw is then placed through the plate and tightened to within two turns of its final position. The plate is then held against the skull, and two or three screws are placed into the skull. The screws in the skull are always bicortical. The thickness in this area of the bone ranges from 4 to 6 mm. A cable is also usually passed under the posterior arch of C1 and around the plate, then tightened. These cables contribute significantly to the rigidity of the construct. After one side is secured, the second side is similarly instrumented. The C1–C2 screws are placed under lateral fluoroscopic guidance. The pedicle of C2 is dissected so that it can be visualized directly during screw insertion. The starting point for the C1–C2 screw is usually 3 to 4 mm cephalad to the C2–C3 facet joint. The distal tip of the screw should be just to the anterior cortex of C1. It can also protrude slightly through the anterior cortex, but it should be kept in mind that the internal carotid artery lies within a few millimeters of the usual anterior exit point for these screws. (From Eismont FJ, Frazier DD. Cranial cervical trauma. In: Levine AM, Eismont FJ, Garfin SR, Zigler JE [eds]. *Spine Trauma*. Philadelphia: WB Saunders; 1998:204.)

been described, including the Gallie technique, the Brooks technique, C1–C2 transarticular screws supplemented with a posterior fusion, and C1 lateral mass and C2 pedicle (or translaminar) screw construct. The use of transarticular screws and screw–rod constructs provides sufficient fixation to obviate the need for postoperative halo vest immobilization. The other methods of stabilizing C1–C2 may be rigid enough to permit mobilization in a rigid collar or may require use of a halo vest to supplement the fixation, especially if it is difficult to achieve the reduction or if the bone quality is poor.

FIG. 75.12 Transverse computed tomographic scan at the C1 level showing a Jefferson fracture with significant spreading of the lateral masses of C1. This has resulted in the avulsion of the origin of the transverse ligament from the right lateral mass of C1 (*arrow*). The usual treatment for this would be a halo vest and mobilization for 3 months, followed by flexion and extension radiographs to assess C1–C2 stability.

FIG. 75.13 Transverse computed tomographic scan at C1 showing minimally displaced fractures of the posterior arch of C1. This always occurs at the site of the vertebral artery groove. Provided that no other fractures are associated with this, the patient can be immobilized in a cervical collar for a short period of time, for comfort only. By itself, this is a stable injury.

Rupture of the Transverse Ligament

The transverse ligament is the major ligamentous stabilizing structure for the atlantoaxial articulation. It is composed primarily of collagen fibers, which render it stiff and inelastic.[70] When torn or disrupted, it is incapable of repair, and its original strength and function cannot be restored.

Insufficiency of the transverse ligament and subsequent C1–C2 instability is suspected if the atlantodens interval is greater than 3.5 mm in adults and greater than 5 mm in children on lateral radiographs and in atlas fractures when the combined overhang of the C1 lateral masses on C2 is greater than 6.9 mm on an AP open-mouth view of the upper cervical spine.[59,60] Plain radiographs, however, are often inadequate to

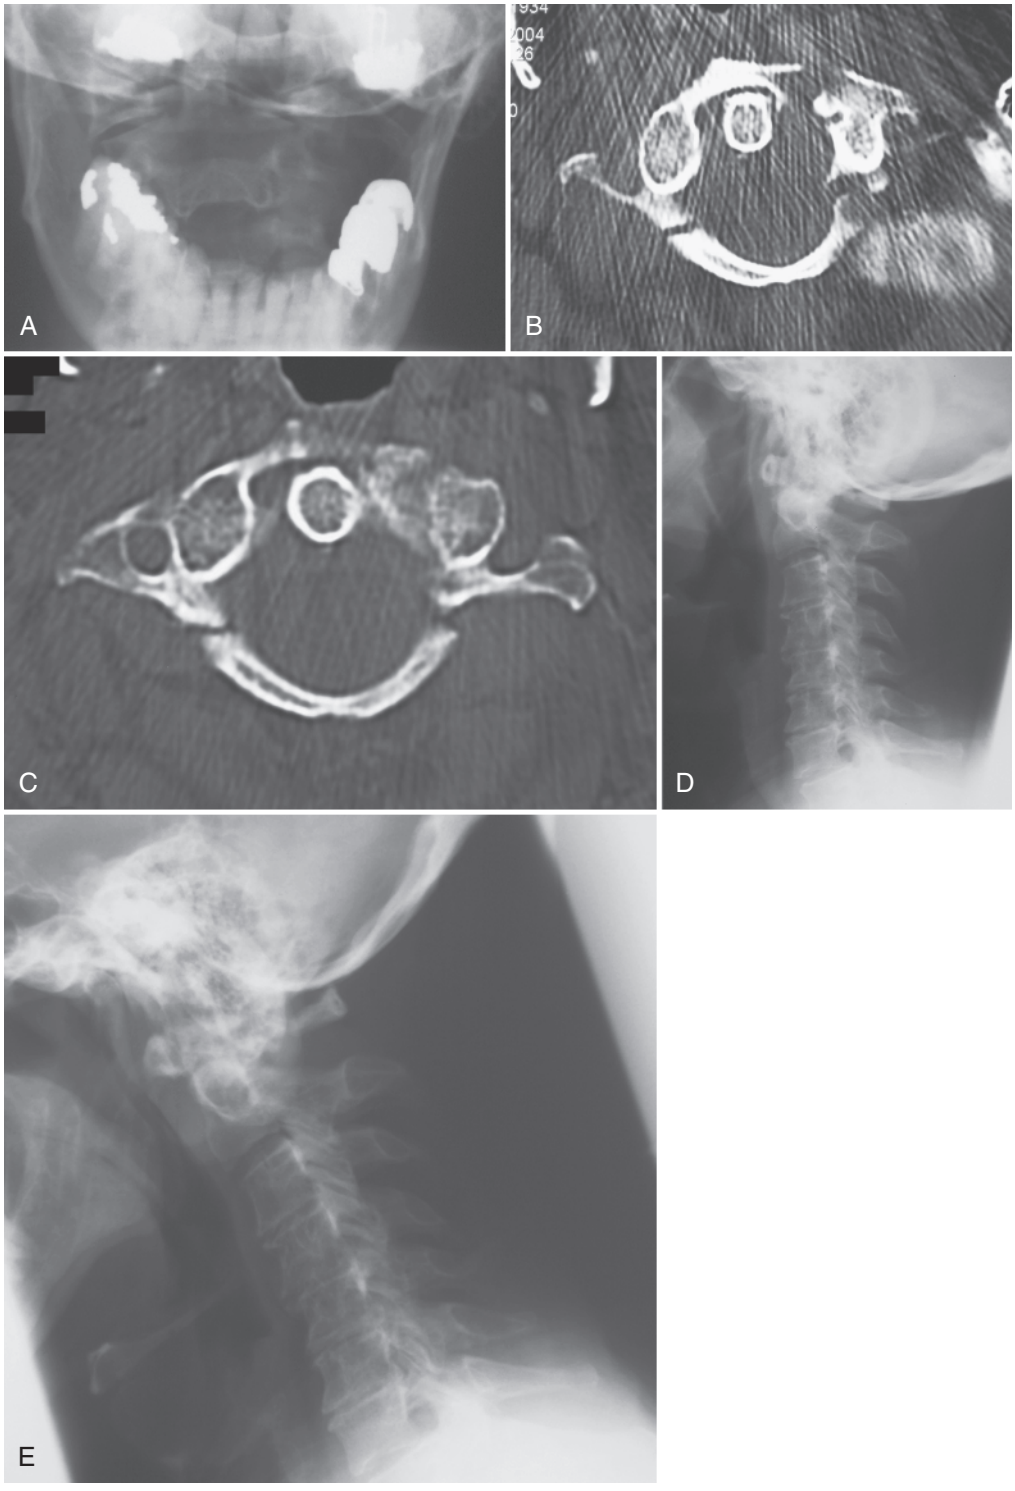

FIG. 75.14 This patient sustained a moderately displaced Jefferson fracture in an accident. He was treated with a halo vest with no initial reduction. (A) Open-mouth view of the C1–C2 joints shows a 2-mm overhang on the right and an 8-mm overhang on the left. (B) Computed tomographic (CT) scan at C1 shows the 8-mm lateral displacement of the left C1 lateral mass. (C) Final CT scan shows that the lateral mass displacement is unchanged, but there is now copious callus anteriorly between the anterior C1 arch, the C1 lateral mass, and the odontoid. (D–E) Flexion and extension radiographs 1 year after the injury show no evidence of instability at C1–C2 or at the occipitocervical joints. He has had no pain since removal of the halo vest and is gradually resuming his preinjury activities with no restrictions.

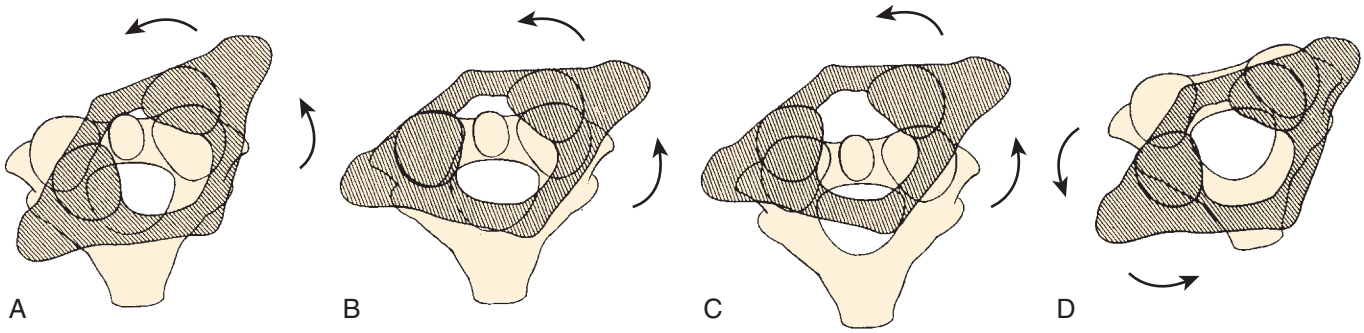

FIG. 75.15 Four types of C1–C2 rotatory fixation. (A) Type I: rotatory fixation with no anterior displacement and the odontoid acting as the pivot. (B) Type II: rotatory fixation with anterior displacement of 3 to 5 mm, with one lateral articular process acting as the pivot. (C) Type III: rotatory fixation with anterior displacement of >5 mm. (D) Type IV: rotatory fixation with posterior displacement. (From Fielding JW, Hawkins RJ. Atlanto-axial rotatory fixation. *J Bone Joint Surg Am.* 1977;59:37–44.)

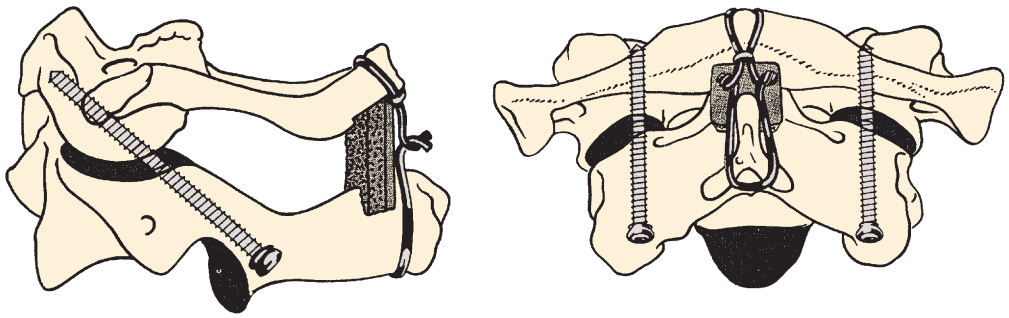

FIG. 75.16 Lateral (*left*) and anteroposterior (*right*) illustrations show the technique described by Grob and associates.[82] They advise having the start point 3 to 4 mm cephalad to the C2–C3 facet joint and having it as medial as possible without penetrating the medial wall of the C2 pedicle. They emphasize seeing the medial and superior aspects of the C2 pedicle as well as the C1–C2 joint. The anterior aspect of the screw should be either to the anterior cortex of C1 or just through it. The internal carotid artery lies just anterior to the usual exit point for the C1–C2 transarticular screw; it is therefore extremely important that the screw tip either not protrude anteriorly at all or only a very minimal distance. The illustration also demonstrates placement of an autogenous bone graft between the arches of C1 and C2 and adequately tightening the wires or cables, which, together with the C1–C2 transarticular screws, makes this an extremely strong construct. Packing bone graft within the C1–C2 joint may be done, but it adds considerably greater risk to the procedure and does not seem to be needed under the usual circumstances. It is necessary to perform fine-cut computed tomographic sagittal reconstruction views of C1 and C2 from side to side to be certain that there is adequate room for placement of a C1–C2 transarticular screw without compromising the vertebral artery. In approximately 15% of cases, local anatomy of the vertebral artery precludes placement of two screws. Placement of one screw in combination with the posterior bone graft seems to be adequate. (From Grob D, Jeanneret B, Aebi M, Markwalder T. Atlanto-axial fusion with transarticular screw fixation. *J Bone Joint Surg Br.* 1991;73:972–981.)

assess suspected transverse ligament injuries; a combination of MRI, CT, and dynamic radiographs is often needed to fully assess the type and extent of injury.[60]

Dickman and colleagues classified transverse ligament injuries into two types.[60] Type I injuries encompass intrasubstance ruptures. Type IA injuries occur in the midportion of the ligament. Type IB injuries occur at the periosteal insertion of the ligament onto the atlas. Type II injuries occur when there is an avulsion of the tubercular insertion of the transverse ligament from the C1 lateral mass. Type IIA injuries occur if the lateral mass is comminuted, and type IIB injuries occur if the lateral mass is intact.

Type I injuries should be treated surgically with C1–C2 fusion. The most common way to achieve this is posteriorly. Wiring techniques, such as Brooks and Gallie fusions, are effective more than 90% of the time,[71] but are the least biomechanically stable,[72] and a rigid cervical collar is usually used for 3 months postoperatively. Transarticular screw fixation (Fig. 75.16) provides sufficient additional stability to allow the immobilization time to be reduced to 6 weeks in a rigid collar or even to allow the patient to be immobilized in a soft cervical collar. There is, however, risk to the vertebral artery when instrumentation is done across the pars interarticularis of C2. C1 lateral mass screw and C2 pedicle screw constructs provide comparable biomechanical rigidity to transarticular screws with less risk to the vertebral artery but with more risk to the internal carotid artery. If necessary, sacrificing the C2 nerve root provides direct visualization of the C1 lateral mass and the C1–C2 joint. The structures can then be instrumented, reduced, and fused under direct visualization. The combination

of C1 lateral mass screws connected to C2 translaminar screws is another alternative fixation option that provides the same degree of stability of the C1–C2 complex. C1–C2 fusion can also be achieved by an anterior approach with anteriorly placed C1–C2 screws.[73] Proponents of this technique note that there is less soft tissue dissection involved as compared with posterior approaches.[74] We, however, recommend the posterior approach in order to provide better supplemental bone grafting and to minimize postoperative swallowing and airway problems.

Type II fractures can be treated with external immobilization for 3 months. Up to 74% of these type II injuries will heal with nonoperative care.[60]

Fractures of the Odontoid

Fractures of the dens constitute 7% to 13% of all cervical spine injuries.[75] They are frequently missed because of the paucity of clinical symptoms other than for neck pain. In addition, if the patient suffers from head trauma and is intoxicated or obtunded, the injury can be easily missed. Both flexion and extension mechanisms can cause fractures of the dens. Hyperflexion results in anterior displacement of the dens fracture; hyperextension results in posterior displacement of the dens fracture.

The fracture can usually be seen on open-mouth and lateral radiographs of the cervical spine, although nondisplaced fractures can easily be missed. Classification of these fractures is based on their location in the odontoid. The most commonly used classification scheme was described by Anderson and D'Alonzo (Fig. 75.17).[76] Type I fractures consist of avulsion injuries at the tip of the dens. Type II fractures occur through the base of the dens at the junction of the dens and the central body of the axis. Type III fractures extend into the body of the axis.

Type I injuries can be treated nonoperatively with a rigid cervical collar, but the possibility of occipital cervical instability must first be ruled out because the bone avulsion always means that at least one alar ligament is incompetent. After 3 months of immobilization, flexion and extension radiographs are taken to assess for healing and residual ligamentous instability.

Type II odontoid fracture is the most problematic type of odontoid fracture. In a prospective study of 144 odontoid fractures reported by the Cervical Spine Research Society[77] there were 96 type II and 48 type III fractures. The incidence of spinal cord–level neurologic deficits was 14 of 96 (14%) of type II fractures and 4 of 48 (8%) of type III fractures. Two of the 14 patients with type II fractures and cord deficits presented with upper extremity monoplegia, which probably represents the cruciate paralysis described earlier in this chapter.

In this same prospective study, of the 38 patients with type II fractures treated primarily in a halo vest, only 66% had a successful result, with seven patients (18%) having nonunions, three having malunions, two having fracture displacement, and one dying before union. Of the 16 patients with type III odontoid fractures treated primarily in a halo vest, 13 (81%) had a successful outcome, with one nonunion, one fracture displacement, and one death, which occurred 1 day after injury due to cardiac arrest. Of the 30 patients (including both type II and type III fractures) treated primarily with a posterior C1–C2 fusion, 96% had a successful outcome, with only one nonunion.

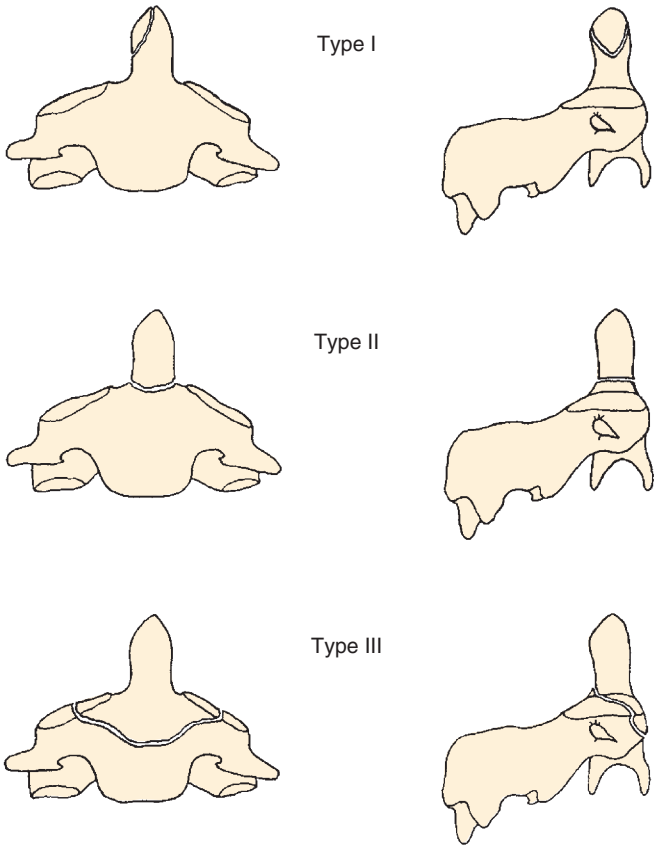

FIG. 75.17 Three types of odontoid fractures. Type I is an oblique fracture at the tip of the odontoid process. It is usually an avulsion of bone at the insertion of the alar ligament. This is normally taught to be a benign injury, but it can be seen in significant occipitocervical injuries. Type II is a fracture at the neck or base of the odontoid, but before it goes down into the body of the axis. This area has a poor blood supply and the smallest cross-sectional area; thus, it has a lower potential for healing. A type III fracture extends down into the body of the axis. It therefore has a larger surface area compared with a type II fracture; in addition, there is a much greater ratio of cancellous bone to cortical bone. Type III fractures have a better healing potential than type II fractures. (From Anderson LD, D'Alonzo RT. Fractures of the odontoid process of the axis. *J Bone Joint Surg Am.* 1974;56:1663–1674.)

In a retrospective review of 322 consecutive patients with type II odontoid fractures treated at three level 1 trauma centers, surgically treated patients had improved 30-day and long-term survival advantage over patients treated nonoperatively even when adjusting for age, sex, and comorbidities.[78] The results of this retrospective review were further supported by a subgroup analysis of a prospective multicenter study. Fifty-eight elderly patients with type II odontoid fractures treated nonoperatively showed worse functional outcomes and higher mortality (14%) at 12 months than their surgically treated cohorts.[79]

The overall nonunion rate for type II odontoid fractures is reported to be about 32%. There is an increased nonunion rate

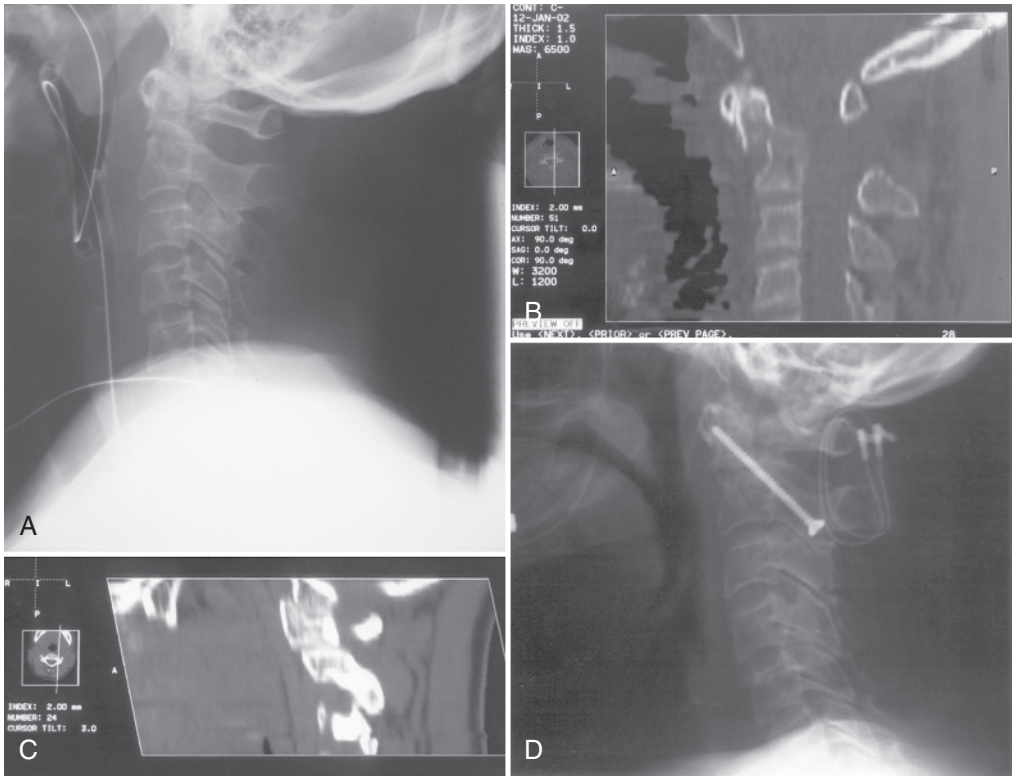

FIG. 75.18 This patient sustained a type II odontoid fracture in a motor vehicle collision. She was neurologically normal, but complained of neck pain. (A) Initial lateral radiograph shows a minimally displaced type II odontoid fracture. There is a slight gap anteriorly at the fracture site. The patient was kept immobilized in a rigid collar and was sent for a computed tomographic (CT) evaluation. (B) Midsagittal reconstruction of the CT scan shows that the fracture has displaced 12 mm anteriorly. This fracture obviously was more unstable than it initially appeared. (C) Parasagittal CT reconstruction is necessary to be certain that there is an adequate path for the C1–C2 transarticular screw. In this patient, the path was adequate on one side, as seen on this image. (D) The patient was placed in skull tong traction and reduced. She was then taken to surgery for fixation using one C1–C2 transarticular screw combined with sublaminar cables from C1 to C2 combined with autogenous structural iliac bone graft. The patient's fracture healed satisfactorily. (From Eismont FJ, Currier BL, McGuire RA Jr. Cervical spine and spinal cord injuries: recognition and treatment. In Helfet DL, Greene WB [eds]. *Instructional Course Lectures, vol 53.* Rosemont, IL: American Academy of Orthopaedic Surgeons; 2003:346.)

associated with fractures with greater than 5 mm of displacement, angulation greater than 10 degrees, age older than 40 years, and posterior displacement.[80] Hadley showed a 78% nonunion rate for type II fractures displaced more than 6 mm in comparison to a 10% nonunion rate when the displacement was less than 6 mm.[81]

Treatment options need to be individualized for each patient. Halo vest treatment may be a good option for a patient with an undisplaced type II odontoid fracture or an undisplaced/minimally displaced type III odontoid fracture in a patient with few or no risk factors for nonunion. The patient needs to understand, however, that even with 3 months of halo vest treatment, there is still a risk of at least 10% that surgery will be needed to treat the fracture. As the amount of displacement and angulation increases and as the number of other risk factors such as more advanced age and smoking increases, then the chance of failing to heal appropriately in a halo vest becomes significantly large.

As the risk factors for nonunion increase, surgical treatment with a C1–C2 fusion or anterior odontoid screw fixation becomes a better option. If primary C1–C2 fusion is selected, the patient should understand that he or she will lose 50% of neck rotation. Many options exist for fixation and fusion of C1–C2. C1–C2 transarticular screws (Fig. 75.18),[82] C1 lateral mass/C2 pedicle screw constructs (Fig. 75.19), and C1 lateral mass/C2 translaminar screw constructs offer a biomechanical advantage over traditional wiring techniques and should minimize the chance of losing the fracture reduction and maximize the chance of having a solid fusion. A fusion rate and fracture union rate of 98% should be expected. If wiring techniques are used, a fusion rate of 94% to 96% can be expected, but there will be a higher chance of losing reduction. Gallie-type constructs are biomechanically advantageous for anteriorly displaced fractures; Brooks constructs are advantageous for posteriorly displaced fractures.

Primary osteosynthesis of the dens (Fig. 75.20) has the theoretical advantage of preserving rotation at the atlantoaxial joint, but the amount of motion that is preserved over a C1–C2 fusion may not be significant.[83] To achieve successful anterior fracture fixation, the fracture needs to be transverse, noncomminuted, and reducible. The patient's chest anatomy and odontoid anatomy must also be amenable to this technique.

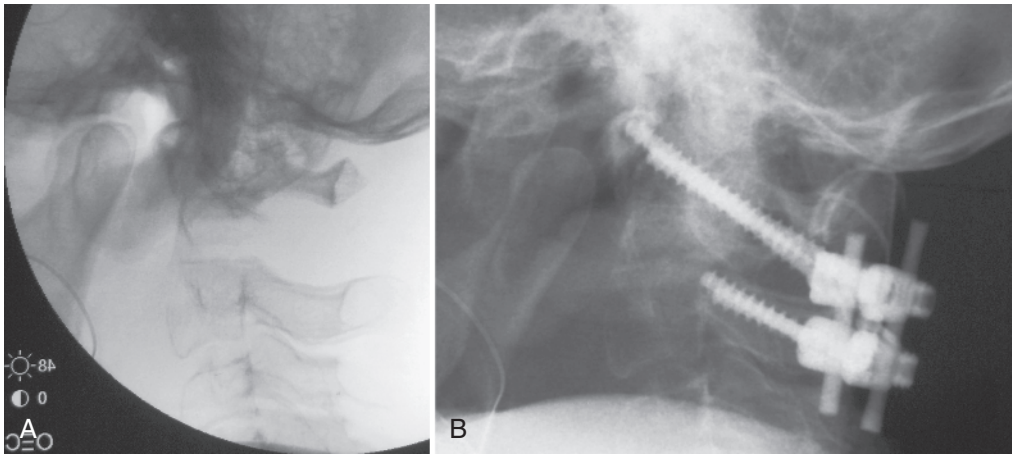

FIG. 75.19 This patient was involved in a motor vehicle collision and sustained multiple trauma with multiple fractures, including this type II odontoid fracture. (A) Postinjury lateral radiograph shows a type II odontoid fracture, which appears well aligned but to have a significant gap in the posterior cortex of the odontoid. With this type of gap present between C1 and C2, it would usually not be possible to insert C1–C2 transarticular screws and obtain adequate purchase. (B) This patient's odontoid fracture was stabilized with C1 lateral mass screws combined with C2 pedicle screws. The starting point for the C1 lateral mass screw is just beneath the posterior arch of C1, and the anterior endpoint is the same as for C1–C2 transarticular screws. This screw-rod construct combined with C1–C2 wiring is able to provide adequate compression across the fracture site to achieve reduction and provide the best opportunity for fracture healing.

In the elderly, the use of odontoid screws is associated with a high complication rate.[84] Two large series of anterior odontoid screw fixation show failure rates of 13% to 17%.[85,86]

Biplanar fluoroscopy or intraoperative CT with image guidance is essential for this technique.

Traumatic Spondylolisthesis of the Axis

Traumatic spondylolisthesis of the axis, also known as a hangman's fracture, can be caused by a variety of mechanisms, including combinations of extension, flexion, distraction, and axial loading of the cervical spine. The fracture line passes through the neural arch of the axis. These fractures are best classified using the modification of the Effendi classification system (Fig. 75.21).[87] Type I fractures occur through the pars interarticularis bilaterally with less than 3 mm translation and no angulation. This fracture usually results from hyperextension and axial load. The neural arch fractures, but the intervertebral disc and anterior longitudinal ligament are still intact (Fig. 75.22). This fracture is associated with other extension-type injuries, including C1 posterior arch fractures and dens fractures.

Type II fractures are bipedicular fractures with greater than 3 mm of displacement and angulation of C2 on C3. This fracture results from an initial axial load, with hyperextension of the neck causing a fracture of the neural arch followed by a flexion moment that results in disruption of the C2–C3 intervertebral disc. This is often accompanied by a compression fracture of the anterosuperior corner of C3 or the posteroinferior body of C2.[87] Two variants of type II fractures have been described. The type IIA fracture shows significant angulation but has minimal (rarely exceeding 2–3 mm) translation and includes significant disruption of the disc and posterior longitudinal ligament. Gross disc space distraction occurs after the application of minimal amounts of traction (Fig. 75.23). This injury usually results from a flexion–distraction injury. In a type II variant described by Starr and Eismont, the fracture line propagates through the posterior aspect of the vertebral body with unilateral or bilateral continuity of the posterior cortex, and is associated with a 33% incidence of neurologic deficit (Fig. 75.24).[88]

Type III hangman's fractures are unstable injuries with severe displacement and angulation, associated with unilateral or bilateral facet dislocations of C2 on C3. Disruption of the posterior longitudinal ligament and the C2–C3 intervertebral disc occurs in these injuries. These injuries are commonly associated with neurologic injuries. Type III injuries occur in three basic patterns: bilateral neural arch fractures anterior to the facet joints with bilateral facet dislocations posterior to it; a rotational injury with fracture of the neural arch on one side anterior to the facet joint and on the second side in the area of the facet joint, causing a unilateral facet dislocation; and a bilateral facet dislocation with fractures of the neural arch just posterior to the facet joints. Type III injuries are usually the result of flexion–distraction followed by hyperextension.

Isolated type I fractures can be treated in a rigid cervical collar for 8 to 12 weeks. Type II fractures are treated with initial traction in extension followed by immobilization in a halo vest. Type IIA fractures are treated with immediate application of a halo vest. Traction is avoided in patients with type IIA injuries because even minimal traction can cause severe overdistraction. All type III fractures should be treated with surgical reduction and posterior C2–C3 fusion. Internal fixation can be achieved with posterior pedicle screws at C2 into the C2 vertebral body and lateral mass screws at C3.

Nonunions of type II or IIA injuries are uncommon,[89] but if they occur and are symptomatic, they can be treated with either a posterior C1–C3 fusion or an anterior C2–C3 fusion.

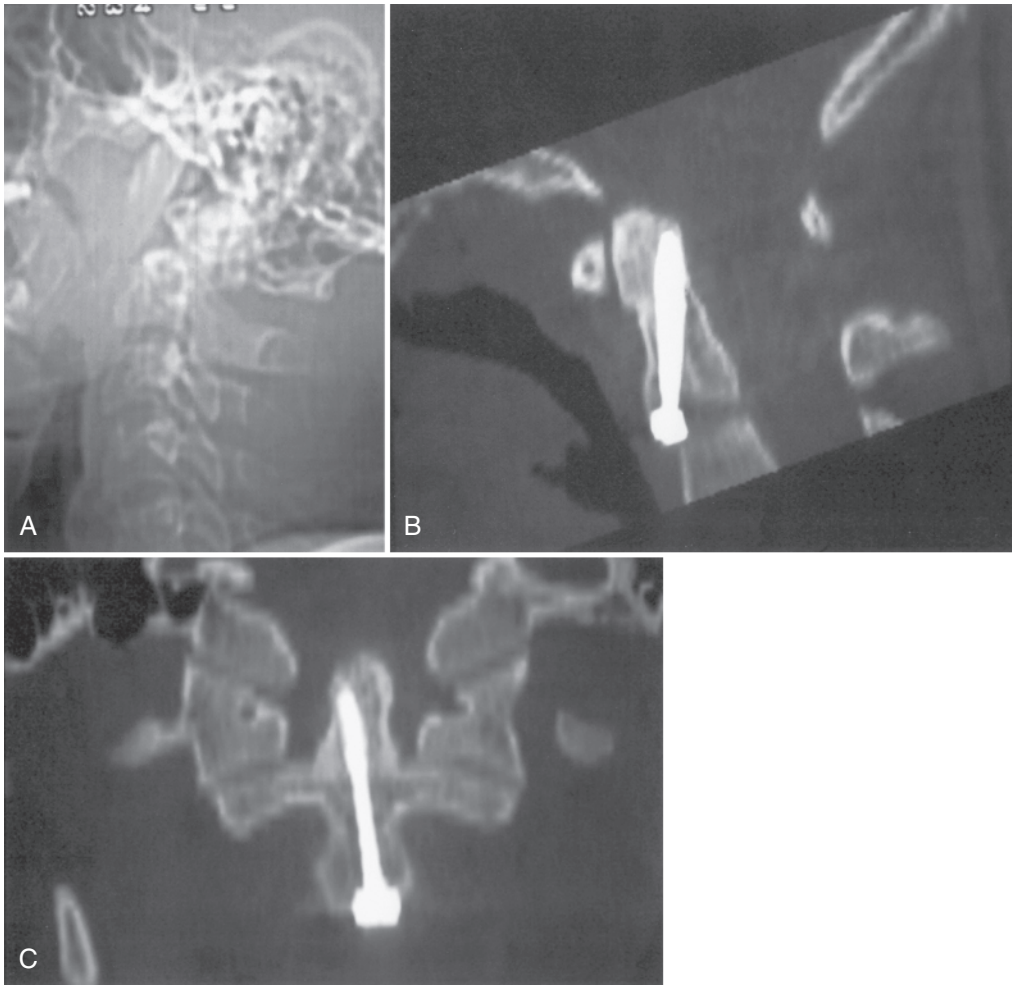

FIG. 75.20 This patient fell from a moving vehicle and sustained a type II odontoid fracture. (A) Scout film from the computed tomographic (CT) scan shows that his odontoid process is displaced posteriorly >1 cm. The patient's young age made anterior odontoid fracture fixation preferable to a posterior C1–C2 fusion. (B–C) Midsagittal and coronal CT reconstruction images were taken at 3 months from the time of surgery. It can be seen that the fracture was well reduced and is now well healed. It is important that the cephalad portion of the screw penetrates through the cortex to gain optimal fixation.

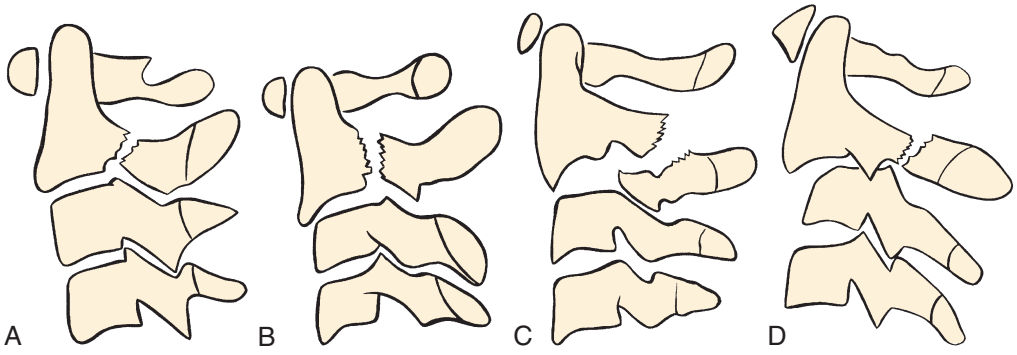

FIG. 75.21 Classification of traumatic spondylolisthesis of the axis. (A) Type I hangman's fracture has fractures of the C2 pedicles bilaterally with no angulation and with as much as 3 mm of displacement. (B) Type II fractures have both significant angulation and significant displacement. (C) Type IIA fractures show minimum displacement, but there is severe angulation, apparently hinging from the anterior longitudinal ligament. These fractures have disruption through the disc space and are easily overdistracted with even small amounts of traction. (D) Type III hangman's fracture combines bilateral facet dislocations between the second and third cervical vertebra with the fracture of the neural arch. This group of patients will always require surgery to reduce the dislocated facets. (From Levine AM, Edwards CC. The management of traumatic spondylolisthesis of the axis. *J Bone Joint Surg Am.* 1985;67:217–226.)

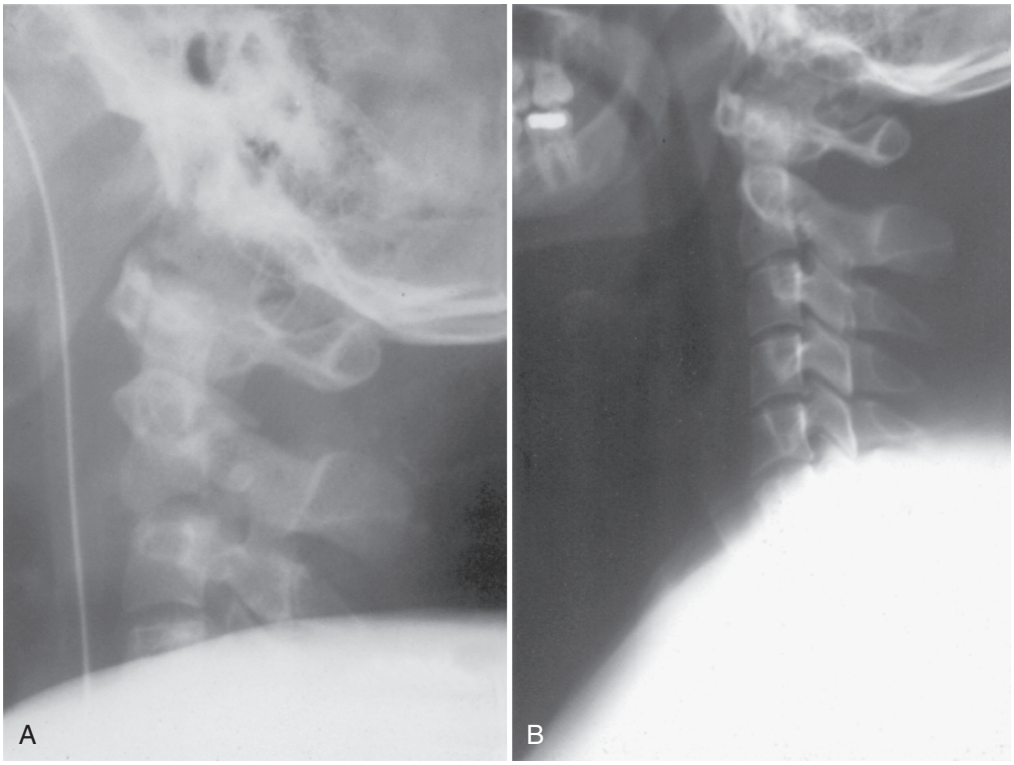

FIG. 75.22 This patient was involved in a motor vehicle accident and sustained a type I fracture of the pedicles of C2. He had no other injuries. (A) Lateral radiograph taken immediately after injury shows minimal angulation and no significant displacement at the fracture site. The patient was treated in a rigid cervical collar for 8 weeks. (B) There is adequate healing of the C2 fracture with good alignment of the spine. (From Eismont FJ, Currier BL, McGuire RA Jr. Cervical spine and spinal cord injuries: recognition and treatment. In Helfet DL, Greene WB [eds]. *Instructional Course Lectures, vol. 53.* Rosemont, IL: American Academy of Orthopedic Surgeons; 2003:343.)

Summary

The unique anatomy of the craniocervical junction results in unique patterns of injuries from typical mechanisms of trauma. In this area, ligamentous structures are as important as or more important than the bony constraints in providing stability and mobility. Luckily, the majority of trauma to the upper cervical spine does not result in neurologic deficit. However, unrecognized injuries may result in severe and permanent injury to the brain stem, upper spinal cord, and lower cranial nerves. A high index of suspicion and meticulous evaluation of the patient, mechanism of injury, and imaging studies will allow early diagnosis and proper treatment of these potentially devastating injuries.

PEARLS AND PITFALLS

1. Use of traction in type IIA hangman's fractures and in occipitoatlantal dislocations can lead to worsening neurologic deficit. In these cases, a small amount of traction can be applied during radiographic imaging under direct supervision to detect the presence of gross longitudinal instability. These patients are best managed with immediate application of a halo vest in compression.
2. Odontoid screw fixation is best accomplished in patients with good bone stock and fractures that reduce in neck extension. Beware of patients with a large chest, as this will compromise the angulation necessary for accurate placement of the odontoid screw. Biplanar fluoroscopy or intraoperative CT scanning is important for safe and accurate placement of internal fixation.
3. Beware of associated injuries and noncontiguous spinal injuries. Patients with multiple bony cervical injuries without neurologic deficit can be managed initially with application of a halo vest to allow the majority of the bony injuries to heal, then with delayed surgical stabilization and fusion of the remaining unstable areas.
4. Prior to placing a halo on patients with head and facial injuries, evaluate the head CT scan to rule out potential skull fractures that may lie in an area of halo pin placement.
5. If the C2 nerve root needs to be sacrificed for exposure of the C1–C2 joint, make sure that it is ligated proximal to the spinal ganglion. Failure to do so can result in severe occipital neuritis.
6. Assess preoperative imaging carefully in placement of any screw fixation into C1 and C2, especially looking for aberrant courses of the vertebral artery.

KEY POINTS

1. Patients who have sustained severe trauma to the head or face caused by a high-energy mechanism have a high incidence of upper cervical spine injuries.
2. Brain damage is more associated with upper cervical injuries than with injuries to the subaxial spine. These intracranial injuries must be diagnosed and treated expeditiously because they are the most common cause of mortality in these patients.

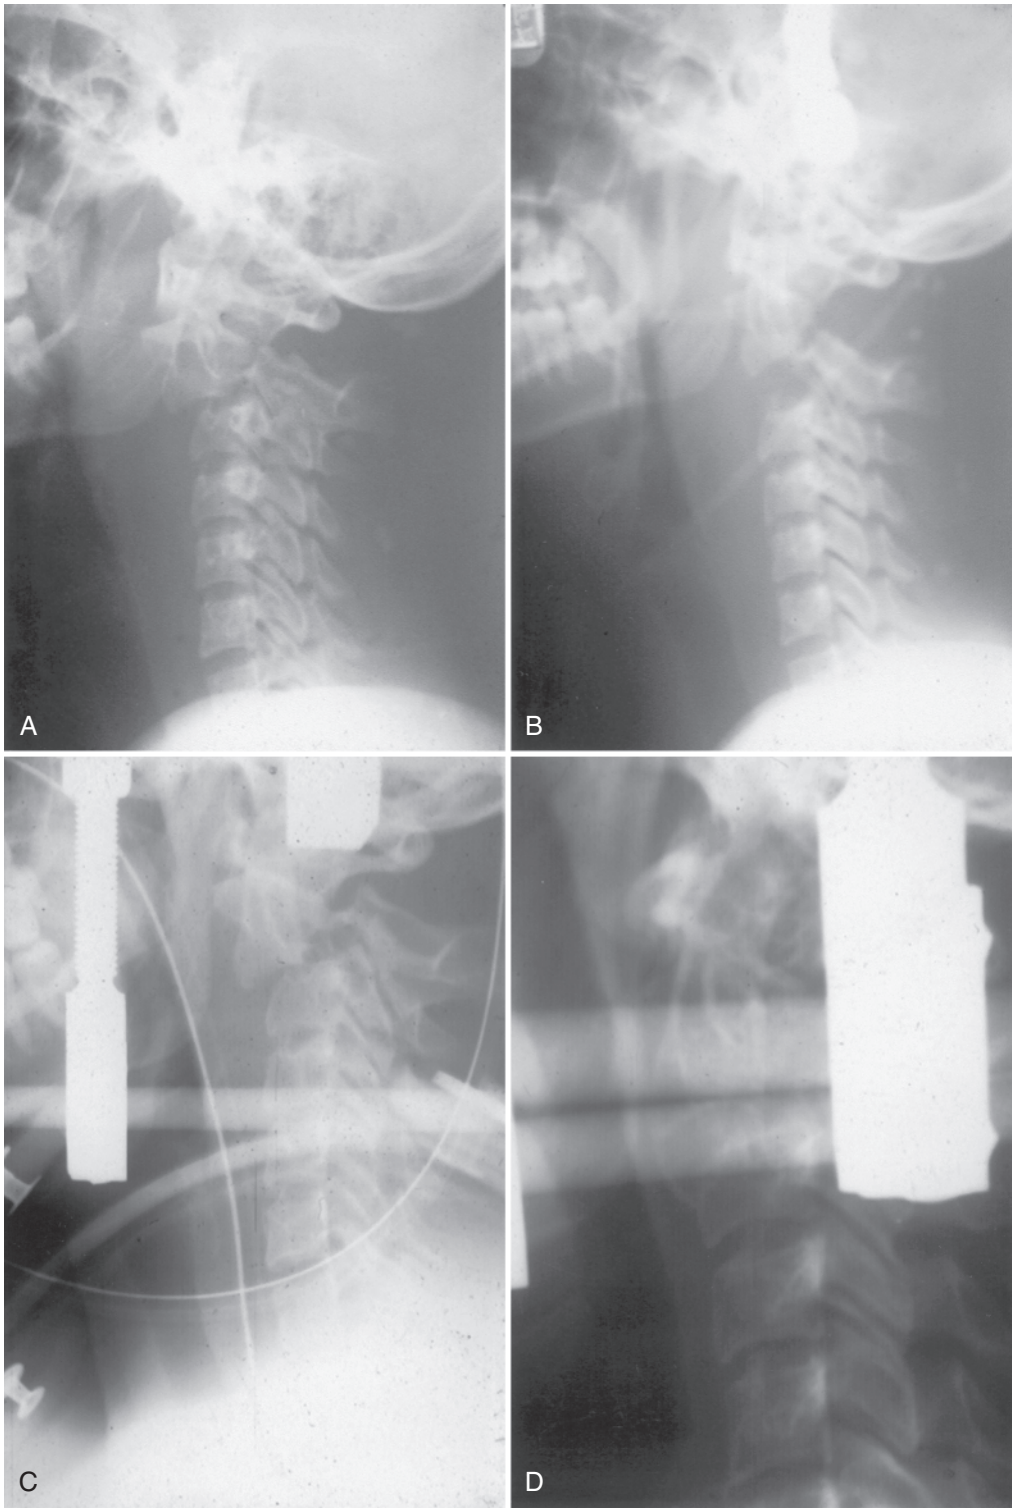

FIG. 75.23 This patient was involved in a motor vehicle collision and sustained a fracture of the pedicles of C2. She had no other significant injuries and was neurologically intact. (A) Lateral radiograph shows approximately 8 mm anterior subluxation with C2 anteriorly displaced on C3. The angulation of C2 on C3 is quite minimal. One would suspect that the disc at C2–C3 is completely disrupted, however, because of the severe degree of displacement. This is also consistent with the very large amount of anterior soft tissue swelling in front of C3, which measures 40 mm. (B) The patient was placed in 5 lb of traction. Overdistraction at the C2–C3 disc space is apparent. The patient remained neurologically intact. (C) The patient's traction was discontinued, and a halo vest was applied. Reduction was achieved under fluoroscopy. The patient remained neurologically normal. She was mobilized more slowly than most patients because of the instability that was present. (D) Lateral radiograph taken 3 months after her injury shows that the soft tissue swelling is completely resolved. There is calcification anteriorly at the C2–C3 disc space. This is often seen with these injuries owing to the significant amount of anterior striping of the anterior longitudinal ligament from the anterior aspect of the C3 vertebral body. With an anterior C2–C3 spontaneous fusion, posterior healing at the pedicles is unimportant.

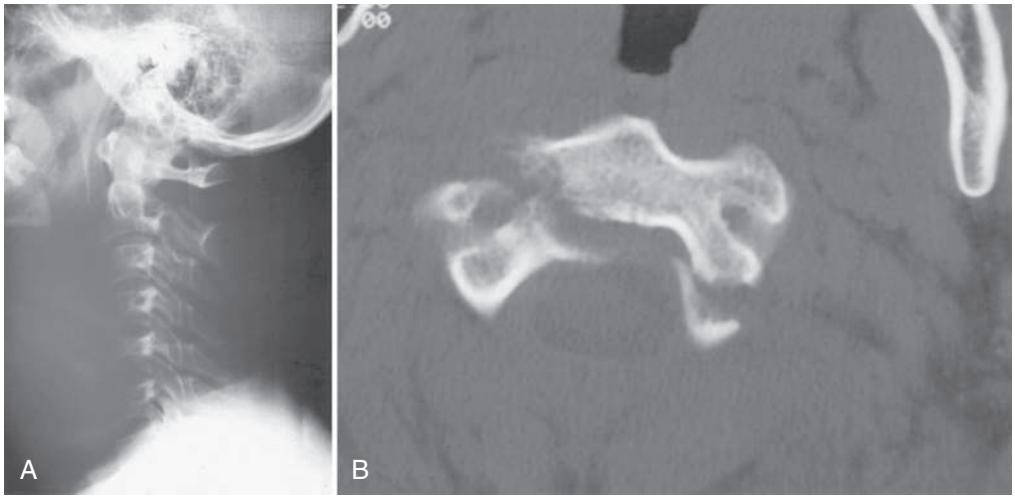

FIG. 75.24 This patient sustained a C2 pedicle fracture as a pedestrian when struck by a car. He had sustained an incomplete quadriplegia noted at the time of the accident. (A) Lateral radiograph shows mild to moderate anterior displacement of C2 on C3. By looking at the posterior aspect of the C2 vertebral body, it is apparent that there is a fracture with part of the C2 vertebral body staying in line with the C3 vertebral body, but there is also a fracture line just above this showing anterior displacement of the more cephalad aspect of the axis. (B) Computed tomography scan shows that the fracture line involved the posterior aspect of the vertebral body on the right side. This patient was treated in a halo vest and had complete resolution of his paralysis, and his C2 fractures healed. His spine was stable when seen at follow-up.

3. Dysfunction of the lower cranial nerves (CN IX, X, XI, XII) implicates severe injuries to the occipitoatlantal joint and the skull base.
4. CT remains the most sensitive imaging modality to evaluate fractures of the upper cervical spine, subaxial spine, and the cervicothoracic junction. CT is also cost effective as a primary screening tool, especially in high- and moderate-risk patients.[11]
5. Reduction and stabilization of the cervical spine is usually accomplished by Gardner-Wells tong traction in a rotating bed. The only contraindications to the use of traction in injuries of the CCJ are occipitoatlantal dislocations and type IIA hangman's fractures in which the application of traction can result in pathologic distraction and increased neurologic deficit.

   This classic article provides the most useful classification scheme for transverse ligament injuries based on CT and MRI evaluation. Evaluation and classification of specific injury types allows the practitioner to predict with high probability the likelihood of late instability. Treatment recommendations are also provided.

76 CHAPTER Lower Cervical Spine Injuries

Paul A. Anderson

Introduction

Cervical spine injuries occur in 3% to 6% of patients presenting for evaluation and should be considered in all blunt trauma patients.[1–3] The subaxial spine from C3 to C7 accounts for two-thirds of all cervical injuries.[4] Spinal cord injuries are present in 0.8% to 1.2% of cases.[1,5] The incidence increases in patients over the age of 65 years and is less common in children. Males predominate and are twice as likely as females to sustain cervical spine injury. The mechanism of injury is from vehicular trauma in up to 50%, while falls account for 40% of injuries, especially in the elderly.[6] Over the past 15 years, the incidence of spinal cord injury and death associated with cervical spine injury has decreased by more than half due to a lower incidence of vehicular trauma.[1]

This chapter reviews the evaluation and management of subaxial trauma patients, focusing on using new classification systems to aid the decision treatment process.

Anatomy

Bony Anatomy

The lower cervical spine normally has a lordotic alignment, which decreases with age. Vertebrae from C3 to T1 have similar shapes, but are increasingly larger caudally, with C7 and T1 having large spinous processes due to attachments of the nuchal ligaments. On the superior surface of each vertebral body, a bony protrusion extends laterally and cranially, called the uncinate process. With age, these may hypertrophy and cause foraminal stenosis. Short pedicles connect the body with the lateral masses. The pedicles are oriented outward relative to the body from 10 to 45 degrees. The lateral masses viewed laterally are rhomboid in shape. Each lateral mass has cranial and caudal articular surfaces; the superior and inferior facet joints form the zygoapophyseal joints. The articular surfaces are flat in the coronal plane and are oriented upward 30 to 45 degrees. The laminae are bony plates connecting the lateral masses posteriorly. The spinous processes are dorsal midline projections from the lamina. From C2 to C5 or C6, the spinous process is bifid. The transverse process extends from the anterior body and connects with bony projections from the lateral masses to form the foramen transversarium.

The subaxial vertebrae articulate with each other through the intervertebral disc and the paired facet joints. The disc is composed of the anulus fibrosus, nucleus, and vertebral endplates. The anulus has approximately 20 layers of type I collagen fibers. The collagen layers are alternatively oriented 40 degrees from the long axis and insert in the outer ring of the endplate. The vertebral endplates are thickened bony plate structures lined with cartilage. The nucleus is a viscoelastic cartilaginous structure containing cells, water, type II collagen, and proteoglycans. The normal disc has 70% to 80% water content, which is bound by the proteoglycans, giving the disc its mechanical properties.

Ligamentous Anatomy

The spinal ligaments are essential to function; assessment of their integrity is critical when evaluating injuries. The anterior longitudinal ligaments (ALL) and posterior longitudinal ligaments (PLL) are continuous, broad, bandlike structures extending from C2 to the sacrum along the anterior and posterior vertebral surfaces, respectively. At each disc, the ALL and PLL can blend with the anulus and span each intervertebral disc. The ALL ends at C2; the PLL continues above C2 as the tectorial membrane, which attaches at the basion at the foramen magnum. Posterior ligaments are essential to stability and include the ligamenta flava, facet joint capsules, and the nuchal ligaments. The ligamentum flavum is largely composed of elastin and spans between laminae. It is not continuous and is elastic, and rupture of it indicates that significant displacement has occurred. The facet capsules are redundant to allow motion of zygapophyseal joints. The nuchal ligaments include the ligamentum nuchae, supraspinous, and interspinous ligaments. The nuchal ligament is strongly attached at C7, T1, and C2 and is essential to maintaining an upright head position.

Neurovascular Anatomy

The spinal cord lies within the spinal canal. It is remarkably similar in dimensions among humans, with an average of about an 8-mm midsagittal diameter in adults. The spinal canal diameter should be a minimum of 13 mm; when less than 10 mm, spinal stenosis is present. Smaller spinal canals correlate with increased risk and severity of spinal cord injury.[7]

At each level, the dorsal and ventral rootlets form a spinal nerve in the neuroforamina. The spinal nerve root lies above each pedicle, behind the disc and posterolateral body, and in front of the lateral masses.

The spinal cord blood supply is from the two posterior and single ventral spinal arteries. In addition, there are several radicular arteries that provide important segmental blood flow, which are variable in number and location. The second part of the vertebral artery passes into the foramen transversarium between C6 and C7 and ascends to C2. Fractures of the transverse processes or lateral masses or subluxations may injure these vessels.

Mechanism of Injury

The cervical spine supports the cranium and is rigidly attached to the thoracic cavity at the cervicothoracic junction; thus, any forces applied to the cranium will be transmitted to the cervical spine. In addition to downward or axially directed forces, bending moments can lead to combinations of compression and distraction injuries. An example is the flexion–axial loading injury or teardrop fracture, in which comminution of the body occurs from compression and tensile failure of the posterior osteoligamentous complex from distraction. Finally, less common, but often the most severe, are injuries from acceleration-deceleration forces. Because the bone and ligamentous tissues have viscoelastic properties, short loading times on the order of 5 to 8 ms create large accelerations/decelerations (which occur during vehicular trauma) and cause proportionally greater damage, especially to ligamentous tissues.

Compression forces are generally downward, centrally, onto the vertebral bodies, but also can be projected laterally onto the lateral masses or posteriorly to the spinous processes. The injury type will be determined by the location of the axial load relative to the vertebrae and the position of the vertebrae at the time of impact. Since the cranium is mobile and may be relatively flexed or extended, the same force can produce a variety of fracture types.[8] In addition, during loading from the cranium, segmental motion occurs, known as snaking, so that one vertebra may be subject to direct compressive forces while another level is subject to distractive forces.

Distraction forces occur from bending moments or from rapid head acceleration-deceleration. Ligamentous injuries with or without bony avulsions can result. This is most commonly seen in hyperflexion, in which facet dislocations and posterior ligamentous injuries occur. Extension-distraction is being seen more commonly, especially in geriatric patients who fall onto their heads or faces. These injuries can result in discoligamentous injuries combined with posterior element fractures.

Increasingly seen as the population ages are patients who have hyperextension injuries and sustain spinal cord injury without significant bony abnormalities. The spinal column may have subtle signs of injury, such as a discoligamentous injury, gaps in the facet joints, or isolated spinous process or laminar fracture. The spinal cord injury occurs due to transient compression of the spinal cord between bulging discs and an infolded ligamentum flavum. The patient will usually have a narrow spinal canal and have ongoing spinal cord compression.

Assessment of the Spine-Injured Patient

Initial Evaluation

Patients sustaining blunt trauma should be assumed to have a potential spinal column injury. During transport, patients are placed on a backboard and immobilized in a hard extraction collar. The immediate primary care is to evaluate airway, breathing, and cardiovascular functions, and begin resuscitation. The secondary exam includes visual examination of the spinal column by log rolling the patient and palpation to determine tenderness, crepitus, and gaps or step-offs between spinous processes. Hemorrhage, contusion, and abrasion on the face, head, or dorsal spine should raise suspicion of spinal injury. The goal of spinal evaluation is to identify patients who require further imaging and to critically measure neurologic function.

Clearing the Cervical Spine

The goal of this evaluation is to identify patients who have significant cervical injury after trauma. Patients can be divided into four categories: asymptomatic, temporarily not evaluable, symptomatic, and obtunded. Asymptomatic patients are those who have no pain, tenderness to palpation, normal cognitive function, and no distracting injuries. Distracting injuries are other sources of trauma that may decrease or eliminate cervical spine signs or symptoms. Examples of distracting injuries are fracture-dislocations, long-bone fractures, burns, shock, chest trauma, and craniofacial trauma.

Asymptomatic Patients

Asymptomatic adult patients can be cleared of cervical spine injury without any radiologic imaging. The National Emergency X-Radiography Utilization Study (NEXUS) screened 34,068 patients using the criteria and identified 99.8% of all injuries.[9] Six of the eight missed cases were trivial fractures and two were significant (odontoid fractures) that did not develop a neurologic injury. The specificity was low (12.8%), indicating that many patients still required imaging, which was negative. A simple modification is the Canadian Cervical Spine Rule (CCR), which adds 45 degrees of pain-free rotation of the head to the examination.[10] Stiell reported a 100% sensitivity using this method and improved specificity over the NEXUS method.[10] Both of these protocols are not applicable to children and are less accurate in geriatric patients.[11]

Temporarily Not Evaluable

These patients are less well defined. However, they could be cleared using the asymptomatic criteria, but have distracting

injuries or impaired cognitive function, such as intoxication, that will clear or be corrected within 24 to 48 hours.[12] Initially, they are immobilized in an orthosis, then later reevaluated based on NEXUS or CCR criteria. If negative at that time, they may be cleared with further imaging. If clearance is required immediately, then they should be evaluated as described later for obtunded patients.

Symptomatic Patients

All symptomatic patients following blunt trauma are at high risk for cervical spine injury, thus require radiologic imaging.[9] Computed tomography (CT) in adults is highly sensitive and preferred over plain radiography.[13] Magnetic resonance imaging (MRI) is not recommended as a screening examination due to its cost and high rate of false positives.[14] MRI is indicated in patients who have unexplained neurologic deficits (such as central cord syndrome), for patients for whom there is suspected ligamentous injury, in patients with significant degenerative or postsurgical changes, as well as to aid surgical decision making. A negative MRI, however, does accurately exclude the presence of a cervical spine injury.[14]

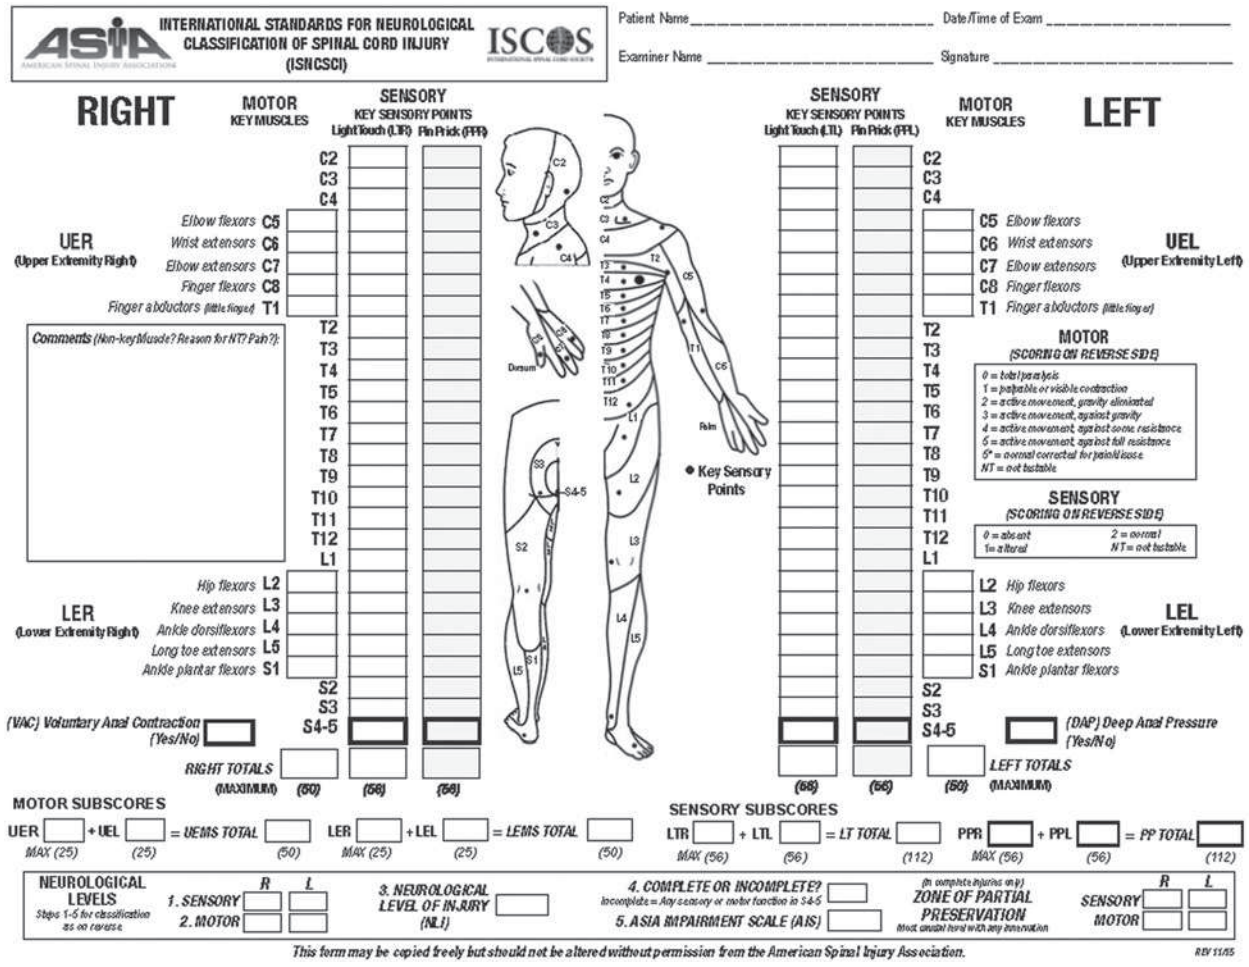
Obtunded Patients

The clearance of obtunded patients remains controversial. Maintaining spine precautions and cervical immobilization in this patient population is associated with reduced pulmonary function, increased intracranial pressure, and risk of skin decubitus. Thus, timely clearance is important. Two options are available in obtunded patients: utilize results of CT or include MRI.[12] Modern helical CT is highly sensitive and rarely have significant injuries been reported following CT. Most cases are results of misreading by radiologists. MRI, however, has been shown to identify more injuries than CT and, in some studies, resulted in need for surgical treatment. Like investigations regarding CT, these studies are small retrospective studies without adequate statistical power. I recommend that each institution utilize its own protocol and continue to monitor effectiveness.

Neurologic Examination

A complete neurologic examination is performed, including cognitive function, cranial nerve, motor sensory function in the extremities, reflexes, and pathologic reflexes. In addition, in patients with any neurologic deficits, careful evaluation of perineal function is performed. Patients' neurologic function should be reported per American Spinal Injury Association (ASIA) standards (Fig. 76.1).[15] The ASIA motor score is the summation of motor function of 10 key muscle groups, five in the upper and five in the lower extremities, bilaterally; each is graded from 0 to 5. Summation of these scores defines the ASIA motor score and the total ranges from 0 to 100. Sensory examination of each dermatome is recorded as intact, hypoesthesia, or absent. Perianal examination is essential, as patients may have only sacral root sparing, which can dramatically change the prognosis.

Perianal rectal function is determined by digital rectal examination, assessing the initial tone and asking the patient to perform voluntary rectal contractions. The bulbocavernosus reflex and the anal wink are spinal cord–mediated reflexes at the level of the conus medullaris. The anal wink is obtained by brushing the paraspinal area with a pin and observing for an anal contraction. The bulbocavernosus reflex is best obtained during digital rectal examination by placing tension on a Foley catheter and observing for a rectal contraction. These reflexes are present in intact patients. Although they are typically absent in acute spinal cord–injured patients, they may return early (within 7 to 10 days after spinal cord injury). Intact perianal function in injuries at the conus medullaris, such as L1 or T12 fractures, or for cauda equina injuries is a good prognostic sign, as it indicates that the afferent and efferent neurons and the conus are functional.



Deep tendon reflexes, including biceps, triceps, patella, and Achilles, are assessed. In acute spinal cord injuries, the reflexes below the level of injury are usually absent due to spinal shock, but will return in 10 to 21 days when they will become hyperreflexic. In addition, pathologic reflexes—such as Hoffman, Babinski, and clonus—should be recorded. Priapism, if present, is a sign of acute spinal cord injury.

Spinal Cord Injury Classification

Spinal cord injuries are classified at the level and extent of injury. ASIA defines the level as the lowest segment with at least antigravity (grade ≥3) motor function.[15] The extent of spinal cord injuries is how much of the cross-sectional area of the cord is injured. Complete cord injuries are defined as complete loss of motor and sensory function; incomplete cord injuries have some retained motor and/or sensory function below the zone of injury. Special attention needs to be focused in the perineal area, as this may be the only area distinguishing complete from incomplete injuries. Incomplete cord injuries are important to recognize and have a much better prognosis. The anterior cord syndrome represents loss of the anterior two-thirds of the spinal cord, where there is paralysis of distal motor function and loss of pain and temperature sensation. These patients have retained dorsal column function, so that they may experience light touch, proprioception, and vibratory sensation, but no pinprick or motor function.

Central cord syndrome is a common cord injury in which there is loss of gray matter and central white matter. The white matter tracts are laminated, with cervical tracts positioned more centrally and lumbar and sacral tracts located toward the periphery. Because of the relative sparing of these laterally located tracts, the central cord syndrome is manifested by greater loss of upper than lower extremity function. The prognosis for central cord syndrome is good, with an expectation for ambulation, but hand function may be chronically impaired. The posterior cord syndrome is the loss of the posterior column with sparing of the anterior cord. These injuries produce loss of vibration, light touch, and position sense, but maintain pain, temperature, and motor functions. Brown-Séquard syndrome is a hemicord injury with ipsilateral motor paralysis and loss of dorsal column function as well as

A

B

ASIA Impairment Scale (AIS)

A = Complete. No sensory or motor function is preserved in the sacral segments S4-5.

B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-5 (light touch or pin prick at S4-5 or deep anal pressure) AND no motor function is preserved more than three levels below the motor level on either side of the body.

C = Motor Incomplete. Motor function is preserved at the most caudal sacral segments for voluntary anal contraction (VAC) OR the patient meets the criteria for sensory incomplete status (sensory function preserved at the most caudal sacral segments (S4-S5) by LT, PP or DAP), and has some sparing of motor function more than three levels below the ipsilateral motor level on either side of the body.
(This includes key or non-key muscle functions to determine motor incomplete status.) For AIS C – less than half of key muscle functions below the single NLI have a muscle grade ≥ 3.

D = Motor Incomplete. Motor incomplete status as defined above, with at least half (half or more) of key muscle functions below the single NLI having a muscle grade ≥ 3.

E = Normal. If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Using ND: To document the sensory, motor and NLI levels, the ASIA Impairment Scale grade, and/or the zone of partial preservation (ZPP) when they are unable to be determined based on the examination results.

contralateral loss of pain and temperature. The prognosis for Brown-Séquard syndrome is excellent.

The ASIA Impairment Scale (AIS) assesses the extent of injury and is highly predictive of outcomes (Fig. 76.1B).[15] Complete cord injuries with absence of distal and sensory motor function are ASIA A. The ASIA B patient has some sensation, but no motor function below the zone of injury. ASIA C patients have both motor and sensory function below the zone of injury, but the motor function is less than grade 3. ASIA D patients, like ASIA C patients, have both motor and sensory function, but motor function is grade 4 or 5. ASIA E patients are intact.

Patients with neurologic deficits should have neurologic exams at least every 2 hours, which are documented in the record. Neurologic function may change in the initial stages after spinal cord injury, which will be an important determinant of treatment. Therefore, accurate reporting of the neurologic exams is essential. The ASIA classification is useful for a comprehensive report of the neurologic examination (see Fig. 76.1A).

Classification of Injuries

Many classification systems of lower cervical spine injuries have been described, with none being universally accepted. These systems are based on fracture morphology, presumed mechanism, force vectors of injury, or ratings of severity, such as stable versus unstable. These all have shortcomings, including poor reliability, high complexity, utilization of out-of-date imaging, lack of inclusion of neurologic deficits, and poor prediction of surgical indications and prognosis. One important determinant of treatment is severity of injury, which is difficult to quantify.

Fracture Stability

Determining fracture stability is essential for determination of the best course of treatment. Stability has been defined as the ability to maintain alignment and protect the neural tissues, resulting in a long-term painless spine under physiologic loads. This simple concept is difficult to apply in individual patients even by experienced practitioners. Stability thus defined is binary: stable or unstable. However, in reality, stability is a continuum. Also, stability may be time dependent, usually worse initially but may recover at later points in time depending on the healing potential of the tissues involved and of the patient. Newer systems apply this concept of assessing stability along a continuing scale rather than present or absent.

Cervical Spine Injury Severity Score

More recent systems have been developed to resolve these shortcomings. The Cervical Spine Injury Severity Score (CSISS) divides the spine into four columns: anterior, each lateral column, and the posterior osteoligamentous complex.[16] The severity of injury to each column is assessed using an analog scale from 0 to 5. A 0 is given for no injury and 5 for the most severe injury possible to that column. The scale is continuous, and each column is graded independently. The scores from each of the four columns are summed, resulting in the CSISS, and ranges from 0 (no injury) to 20 (most severe injury). The reliability of the CSISS is excellent. In one study, a score of 7 or greater was associated with surgery in 100% of cases and a score less than 5 indicated nonoperative treatment.[16]

Subaxial Cervical Injury Classification System

The Subaxial Cervical Injury Classification System (SLIC) was developed to include both severity of injury and the neurologic state to aid in surgical decision making.[17] Three domains are assessed and graded independently: fracture morphology, the osteoligamentous complex, and neurologic function (Table 76.1). The morphology is graded based on a general description of the fracture mechanism: compression, burst, distraction, and translation/rotation. The osteoligamentous complex has long been felt to be essential to maintain spine stability. In the SLIC system, this is assessed as intact, intermediate, and injured. The intermediate grade is allowed, as in many cases it is impossible, even with MRI, to know the state of the osteoligamentous complex. Neurologic function is graded as intact, radiculopathy, complete spinal cord injury, and incomplete spinal cord injury. The incomplete spinal cord injury is given the higher score compared to complete, as the urgency in surgical indications are greater in this injury pattern. Each of the three domains are scored and summed, giving a SLIC score ranging from 0 to 9. Scores of 3 or less are treated nonoperatively, and scores of greater than 5 are treated surgically. Scores of 4 or 5 may be treated either nonoperatively or operatively. In many cases, an orthosis is attempted and upright serial radiographs are obtained to assess maintenance of alignment. If neurologic symptoms or progressive kyphosis or subluxation develops, then surgery is warranted.

AO Cervical Spine Classification

The AO group has been a leader in developing classification systems for all skeletal traumas. Their spine classification system is based on three basic morphologies: compression, distraction, and translation. However, this system lacked reliability and was too complex for clinical use. Recently, an updated AO classification system has been developed.[18] The AO system uses four criteria: injury morphology, facet injury, neurologic status, and case-specific modifiers. When using the system, the user should record level, morphology type, and secondary injuries. In addition, modifiers such as facet injury, neurologic status, and case-specific variants are placed in parentheses.

The modified AO classification system has been updated to simplify its use, promote better direction for treatment, and is based on modern imaging, including MRI.[18] Three basic categories describe the primary injury (Table 76.2). Type A occurs from compressive forces with intact posterior tension band. Type B is distractive injuries of the posterior or anterior tension bands. Type C is injuries in which there is translational displacement in any of the primary axes, including anteroposterior (AP), lateral, rotational, or vertical. If multiple types of injuries are present, then the fracture is graded with its highest score.

AO Type A Injuries

AO type A compressive lesions are vertebral body injuries that occur under axial loading forces with loss of vertical height. Similarly, impaction of the spinous processes can cause fracturing under compression. Compression injuries are subcategorized into five types. Type A0 has no bony or trivial injuries, such as fractures of the spinous process or transverse process and patients who have spinal cord injuries without bony fracture. Type A1 fractures are compression fractures of a single endplate without involvement of the posterior vertebral body wall. Type A2 are fractures that include both superior and inferior endplates without fracture of the posterior vertebral body wall. Type A3 are burst fractures when there is fracture of one endplate and the posterior vertebral body wall with retropulsion of bone into the spinal canal. Type A4 injuries are comminuted burst fractures that involve both superior and inferior endplates and sagittal split fractures that also involve both endplates.

TABLE 76.2 Modified AO Classification Cervical Spine Injuries

Type A	A0	No bony or trivial injury
	A1	Compression fracture of only single endplate
	A2	Compression fracture involving two endplates
	A3	Burst fracture with bone retropulsion involving only single endplate
	A4	Burst fracture with bone retropulsion involving both endplates
Type B	B1	Bony injury of either anterior or posterior tension bands
	B2	Posterior ligamentous distractive injury with or without fracture
	B3	Anterior discoligamentous disruption
Type C	C	Translation or rotational injury along any axis
Facet injuries	F1	Nondisplaced facet injury with low potential for subluxation (<1 cm and <40% facet)
	F2	Nondisplaced facet injury with low potential for subluxation (>1 cm and >40% facet)
	F3	Fracture separation of lateral mass
	F4	Perched facets
Neurologic	N0	Intact
	N1	Transient neurologic deficit
	N2	Root injury or radiculopathy
	N3	Incomplete spinal cord injury
	N4	Complete spinal cord injury
Case-specific modifiers	M1	Possible ligamentous injury
	M2	Traumatic disc herniation
	M3	Fracture in ankylosed spine
	M4	Vertebral artery injury

AO Type B Injuries

The AO type B are distractive lesions and can include disruptions of either the anterior or posterior tension bands. These injuries do not have associated translation. Type B1 are bony injuries of the posterior or the anterior tension band. Type B2 are distractive injuries involving posterior ligaments, with or without fracture. These lesions may include nuchal ligaments, facet capsules, and ligamenta flava. Type B3 are anterior tension band injuries with distraction injuries to the discoligamentous complex and the ALL. The posterior tension band is intact, which acts as a tether or center for rotation. There may be bony avulsion fractures along the bodies.

AO Type C Injuries

Type C are translational injuries along any axis, resulting in displacement of one vertebral body relative to the other.

Facet Fractures

Facet injuries are difficult to classify in traditional systems. The AO system grades each facet independently. For bilateral facet injuries, the right side is annotated before the left. If the type of facet injury is identical between sides, BL is designated. Injuries that are isolated to the facet articulations—without a type A, B, or C injury—are classified as facet injuries. F1 are nondisplaced, inferior, or superior facet fractures that have low potential for displacement (<1 cm, <40% of lateral mass). F2 are inferior and superior facet fractures that involve a larger area of the facet with increased likelihood of displacement (>1 cm, >40% of lateral mass). Type F3 is a fracture separation of the lateral mass, where there is an ipsilateral fracture of the lamina and pedicle, which creates a free-floating lateral mass.[19] If this subluxes or rotates anteriorly, then vertebral subluxation can occur at both the cranial and caudal level. Type F4 are facet injuries, where the inferior edge of the cranial facet lies in the perched position at the tip of the facet. Another pathologic subluxation includes posterior diastasis of the facets.

In the AO system, the neurologic status is graded similarly to the SLIC. N0 is neurologically intact. N1 is a transient

neurologic deficit that has resolved. N2 is a radiculopathy or nerve root injury. N3 is an incomplete spinal cord injury, and N4 is a complete spinal cord injury.

Case-specific modifiers are important, as they can alter treatment. M1 is an incomplete posterior tension band injury. CT or plain radiographs may indicate a possible ligamentous disruption, but MRI shows that the nuchal ligament, interspinous/supraspinous ligaments are intact, although they may have edema. M2 is traumatic herniation of the intervertebral disc behind the vertical line drawn along the posterior wall of the caudal vertebrae. M3 are fractures in patients with ankylosed spine. M4 is an associated vertebral artery injury.

General Approach to Treatment of Injuries

Each patient is assessed clinically for signs of injury by palpation, checking for tenderness, and by a detailed neurologic examination. A patient with tenderness or signs and symptoms of neurologic injury should have a CT to identify injury patterns. If any ligamentous injury is suspected or unexplained neurologic deficits are present, an MRI scan is indicated. At this point, the injury is classified morphologically using the AO system. The severity is then graded using CSISS or SLIC. Patients who have a score greater than 5 SLIC or greater than 7 CSISS are treated surgically. In patients with less severe injuries, nonoperative treatment in orthosis is attempted.

Nonoperative Care of Subaxial Cervical Injuries

Nonoperative care is indicated for those with stable fractures or those who are not otherwise surgical candidates. For most lower cervical spine injuries, patients are managed in an orthosis. Choices include soft collar, hard collar (e.g., Miami J [Össur]; Aspen collar [Aspen Medical Products], or CervMax [PMT Corporation]), cervicothoracic brace, and halo vest. The general approach in all orthotic management is similar (Box 76.1). The orthosis is fitted by a trained orthotist. Pads that wick fluids away from the skin can help to prevent skin breakdown. The brace needs to control head-mandible motion relative to the thorax. No brace, including the halo vest, will completely prevent segmental motion in a fractured cervical spine, as the spinal column can easily assume snakelike intervertebral motions.[20] Twice-daily skin checks are ordered while the patient is hospitalized or in a rehabilitation facility. Training of patients and family is essential to ensure proper use and to avoid complications of the orthosis. In patients older than 65 years, a swallow consult is obtained to assess aspiration risk prior to institution of diet. Occupational therapy trains patients to use the brace and in the activities of daily living while immobilized.

BOX 76.1 Principles of Nonoperative Treatment

Appropriate indication for fracture type and patient condition
Orthotic placement by certified orthotist
In patients >65 years, a swallow study before feeding
Twice-daily skin check
Removable pads
Proper training of patient, family, and nursing staff
Check alignment initially and at regular intervals

Upright radiographs are obtained after brace placement and scrutinized for increasing kyphosis and/or subluxation. Any change in these, or new or worsening neurologic symptoms indicates instability, and surgery is recommended. Follow-up radiographs are obtained at 2, 6, and 10 weeks. In most subaxial injuries, healing will occur by 10 to 12 weeks or earlier. Patients are initially informed that their orthosis is a test of stability and that about 5% to 10% of patients will fail and may require surgery. In patients without clear surgical indication (such as SLIC scores of 4 or 5 and CSISS scores of 5 to 7), either approach can be chosen. In general, I recommend a trial of nonoperative therapy with orthosis in these cases. In such cases, shared decision making should occur, taking into account the patient's preferences.

Soft Collar

Soft collars provide little stability and are used for comfort but also to alert medical personnel that injury is present. These are indicated for frail elderly patients with minimal or stable fractures or in patients who cannot tolerate even a hard collar.

Hard Collar

Many forms of hard collar are available. Use of extraction collars and Philadelphia collars should be avoided, as these fit poorly and can lead to skin breakdown. It does not appear that the stabilization effect among well-fitting hard collars varies by manufacturer. It is best that the orthotist use a single brand so that personnel can become familiar with their use and maintenance. Hard collars do not provide sufficient stability for unstable fractures, but are effective, in my experience, in stable SLIC score less than 3 and CSISS score less than 5.

Cervicothoracic Orthosis

The cervicothoracic orthosis (CTO) has anterior and posterior chest pads that are connected by straps under the axilla and over the shoulder. Vertically, they are connected to occipital and mandibular pads rigidly. The CTO brace provides greater stability than hard collars, especially at the cervicothoracic junction. The CTO places increasing pressure on the occiput and chin, and should be used with caution. I do not recommend its use in spinal cord–injury patients who lack body control or any patient with cognitive impairment due to the risk of skin ulcerations. I recommend the CTO for patients with injuries at the cervicothoracic junction, those with multilevel spine fractures where multilevel fusions might be otherwise utilized, and cervical spine injuries combined with upper thoracic injuries. An alternative treatment for this injury pattern is the thoracolumbosacral orthosis with chin piece (cervical-thoraco-lumbosacral orthosis). I have abandoned its use due to risk for skin ulceration and poor patient acceptance.

Halo Vest

The halo vest is the most rigid external orthosis, although segmental motion can still occur at the fracture site. Anderson reported in patients with unstable fractures treated in the halo vest that 1.8 mm of translation and 7 degrees of angulation fracture site motion occur during position change from supine to upright.[20] The use of the halo vest has declined and is rarely used today in my experience for subaxial injuries. It is indicated for unstable fractures in which fusion is a poor alternative, such as young patients who are neurologically intact or those with multilevel injuries. For these cases, the halo vest may provide the best nonoperative approach, thereby avoiding multilevel fusions.

Treatment of Acute Spinal Cord Injury

The goals of treatment of spinal cord–injury patients are to protect the neural tissues from further injury, reduce and stabilize fracture-dislocations, and provide a stable long-term painless spine.

Transport

Patients presumed to have spinal cord injuries should be transferred to institutions that are experienced in their management, have advanced imaging available, and can provide intensive care and urgent surgical services. Treatment of spinal cord injuries in Level 1 trauma centers is shown to reduce rates of complication as well as shorten the length of hospitalization and rehabilitation time.[21] Spinal cord–injury patients require intensive care to monitor neurologic state and provide hemodynamic support, assess pulmonary function (which often deteriorates over time), and prevent adverse events, such as skin breakdown.

Immediate Care of the Spinal-Injured Patient

Once a subaxial fracture is diagnosed, consideration of immediate treatment is entertained. All patients with spinal cord and nerve root injury as well as those with unstable fractures are candidates for immediate intervention. This includes hemodynamic support, further diagnostic testing, administration of neuroprotective agents, reduction using tong traction, and urgent surgery. While the decision-making process for resuscitation is taking place, patients with subaxial fractures should be immobilized in a hard collar and maintained flat on a bed or stretcher. Although the backboard is an excellent aid for transport to and within the hospital, it should be removed as soon as possible to reduce the risk of skin breakdown. In addition, backboards can be associated with fracture displacement, especially in children or in patients with thoracic kyphosis.

Hemodynamic Support

The injured or compressed spinal cord is ischemic, which can further exacerbate the spinal cord injury. If spinal cord injury is present, there is a loss of vasomotor tone, with resultant hypotension and bradycardia, causing a condition known as neurogenic shock. In addition, the spinal cord, like the traumatized brain, loses its ability to autoregulate blood flow. Therefore, intramedullary blood flow becomes related to the systemic arterial pressure. Any hypotension, either from loss of vasomotor control or from blood loss, can worsen or exacerbate the spinal cord injury. Guidelines recommend resuscitation of a spinal cord–injured patient to a systolic blood pressure greater than 120 mm Hg (usually with pressor agents) and maintaining the mean arterial pressure at 85 mm Hg.[22] A high FiO_2 should be administered to maintain O_2 saturation greater than 95%. Ventilatory failure may be present or develop over time and requires intubation and mechanical support. Intubation needs to be performed carefully so that fracture displacement is minimized. It is best that the surgical team assist in this task by holding the head while maintaining traction.

Magnetic Resonance Imaging in Acute Spinal Cord Injuries

Early treatment decisions may require further imaging by MRI. Urgent MRI is indicated for unexplained neurologic deficits, neurologic deterioration, to evaluate ligamentous structures, or in patients with no or minimal deficits who have facet dislocations to determine the presence of a traumatic disc herniation. In these cases, neurologic worsening has been reported after open reduction when the disc lies behind the vertebral body compressing the spinal cord after reduction. Several case reports have documented that disc herniation behind the vertebral body remains in that location after reduction, causing significant neurologic deficits.[23] In addition, MRI is useful for preoperative planning.

Neuroprotection

To address the secondary spinal cord injury caused by vascular, molecular, biochemical, and/or inflammatory changes, early treatment using neuroprotective agents has been proposed. Many pharmacologic and cellular agents show promise in laboratory animals. However, only methylprednisolone is approved for current use. Methylprednisolone, when given within 8 hours of injury, has an antioxidant effect by reducing lipid peroxidation that occurs as part of the secondary injury pathophysiology. The clinical evidence for use of methylprednisolone is based on the National Acute Spinal Cord Injury Study 2 (NACISC2). In this randomized control trial, 454 patients with blunt traumatic spinal cord injuries were randomized to naloxone, methylprednisolone, and placebo.[24] All patients had randomization and administration of drugs within 8 hours of injury. Naloxone was thought to have neuroprotective properties at the time. Patients receiving methylprednisolone had a statistically significant improvement of 5 points of ASIA motor level. The impact of the NACISC2 study was significant; subsequently, almost all spinal cord injuries were treated using the NACISC2 protocols. However, critical analysis of the statistical methodology, identification of potential harms, including death, and the minimal perceived benefits have led many to abandon or

limit the use of methylprednisolone for spinal cord injury. Recent guidelines by the American Academy of Neurological Surgeons and the Congress of Neurological Surgeons recommend against the use of methylprednisolone in acute spinal cord injury.[25]

Unfortunately, the data from the NACISC2 study included mostly patients who did not have surgery or even reduction of fracture dislocations within 24 hours. Further, hemodynamic support was not utilized routinely at the time of the original study. Thus, there is a knowledge gap as to whether methylprednisolone may have a beneficial effect when combined with other current standard practices in care. My current recommendations are to administer methylprednisolone in select patients with cervical cord injuries, both complete and incomplete, and in incomplete thoracic cord injuries. Methylprednisolone is recommended only in patients without other significant traumatic injuries or comorbidities. I do not recommend its use in geriatric patients with spinal cord injuries. When used, methylprednisolone is administered as a 30-mg/kg loading bolus over 1 hour and a continuous infusion of 5.4 mg/kg per hour for 23 hours.

Fracture-Dislocation Reduction

Early fracture-dislocation reduction is important to remove neural compression and reestablish blood flow to ischemic tissue to prevent deterioration and maximize the chance of neurologic recovery. This can be achieved by two methods: cranial tong traction and surgery. Cranial tong traction is a useful and generally safe method to stabilize the spine and to achieve realignments of fractures and dislocations.[26] Indications for cranial tong traction vary and are being supplanted by immediate surgery where reduction by traction is avoided. In a study to evaluate the timing of surgery on the outcomes of spinal cord injury, the authors found that only one-third of patients were ever treated with tong traction before surgery.[27] Cranial tong traction is a fast method to reestablish spinal cord blood flow through reduction. In low-energy facet dislocations, such as from sporting accidents, early reduction within 4 hours of injury in patients with quadriplegia was shown to have a reversible effect in 80% of cases.[28]

Timing of Surgery

The timing of surgery in humans remains controversial, despite a large volume of animal data that demonstrates early surgery correlates with greater neurologic recovery. Because of difficulties with study design, heterogeneity, and severity of injury, these benefits of early surgery have not been proven in humans. A recent observational study, Surgical Timing in Acute Spinal Cord Injury Study (STASCIS), compared neurologic improvement at 6 months based on ASIA impairment scale between early (≤24 hours) and late (>24 hours).[27] Patients were stratified according to whether surgery was performed before or after 24 hours. There was no difference for the chance of improving one ASIA level; however, there was a statistically significant and better chance of improving 2 ASIA levels if surgery was performed within 24 hours. In patients with spinal cord injuries, the potential for neurologic deterioration caused by early surgery has been a concern. The mechanics of this are unclear, but likely are due to hemodynamic changes that occur during surgery. In the STASCIS study, only one patient deteriorated neurologically; the authors believe that early surgery was feasible and safe in patients treated at centers with experience in managing spinal cord injuries.

Cranial Tong Technique

Cranial tongs have a metal or carbon fiber arc, two pins which are inserted into the skull, and a hook for traction rope. The pins are disposable, and one pin has a compression spring that acts to measure the applied force of the pins into the skull. Both MRI-compatible and non–MRI-compatible devices are available. Unless heavy weights are anticipated, I recommend the use of MRI-compatible devices.

Guidelines for Initial Closed Reduction of Subaxial Cervical Fractures

Gelb reported guidelines based on a systematic review of the use of closed reduction with tong traction in subaxial fractures and dislocations.[26] Based on a retrospective case series, he recommends early reduction with cranial tong traction for subaxial injuries in awake patients without more rostral injuries. Prereduction MRI should be obtained in patients who cannot be examined during closed reduction or if closed reduction fails. MRI will identify disc disruptions in up to 50% of cases, but does not appear to influence outcomes in awake patients; therefore, their utility is questioned.

Cranial Tong Insertion

The location of tong insertion is 1 cm above the pin and in line with the external auditory meatus. Placement more anteriorly or posteriorly can change the force vectors, which may theoretically aid reduction. For consistency, I recommend placement in line with the exterior auditory meatus. The skin is prepared with chlorhexidine and the subcutaneous tissue and periosteum is infiltrated with local anesthetic. No shaving of the scalp is required. The surgeon holds the tongs with pins located just above the correct starting point, which are then symmetrically tightened into the skin and skull. The pin containing the compression spring is scrutinized until it protrudes 1 mm out from the surface of the pin. Jam nuts along the side of the pins are tightened to prevent inadvertent further tightening of the pins. If the traction is to be continued (unusual today), the pins may be retightened one time at 24 hours. The rope is attached to the tongs and connected to weights by a pulley at the head of the bed. I prefer to raise the head of the bed 20 to 30 degrees while keeping the angle of the rope at the same slope.

Reduction Technique

Reduction of fractures and dislocations requires a rigid protocol to maintain safety. The initial weight is selected depending

on many factors, including body weight, level of injury, age, and fracture pattern. For midcervical and lower cervical spine injuries, it is recommended starting with 10 kg (20–25 lb). After the weight has been attached (and after any increase or decrease of weight), a radiograph is obtained and a neurologic examination is performed and documented in the medical record. The radiograph is assessed to determine if reduction has been achieved and for signs of overdistraction. Overdistraction is assessed by examination of the disc space and facet joints. Overdistraction may cause excess traction on the spinal cord and vertebral arteries, which could result in neurologic deterioration. However, to reduce a facet dislocation in the absence of fractures, overdistraction of 3 to 5 mm may be required. The neurologic examination assesses any change in perceived sensations, increasing pain, or paresthesia in the extremities, or deterioration of sensory or motor function.

If reduction is not achieved, 5 to 7 kg of additional weight is added as long as no neurologic deficits or radiologic signs of overdistraction occur. A C-arm with the patient on a stretcher or Jackson-type table can reduce the time required to obtain the reduction. In general, once the reduction is achieved, weights may be decreased. However, for unstable fractures, reducing weight can result in displacement and neurologic injury. Therefore, if weights are decreased, it is essential to repeat the neurologic examination and examine new radiographs. Some manipulation may be required to achieve reduction, which should only be done by experienced surgeons. In facet dislocations, slight flexion may be required to unlock the impacted dislocated facets. This is accomplished by adding bolsters underneath the occiput to create neck flexion. Another method is to manually manipulate the spine while in traction. For bilateral facet dislocations, an attempt to reduce each facet independently is preferred. The tongs are grasped and a lateral bending movement and forward flexion is applied, ideally reducing one facet. The same movements are performed on the contralateral side.

In several conditions, cranial tong traction reduction may lead to neurologic deficits. Distractive lesions, although uncommon in the subaxial cervical spine, lack any longitudinal running ligaments, which provide the potential for ligamentotaxis that controls reductions. Facet dislocations have a disrupted disc complex in almost all cases. In a few cases, however, the intervertebral disc may be herniated behind the cranial vertebral body. The disc may not reduce when the spinal column is realigned and the disc behind the vertebral body may increase compression on the spinal cord, resulting in neurologic deficit. This appears to be a rare condition and almost exclusively occurs during closed reductions with patients under general anesthesia.[23] Most surgeons agree that cervical tong traction in awake patients using the method described earlier is much safer. In patients with significant neurologic deficits, I believe that the benefit of immediate reduction exceeds the potential for worsening due to disc herniation, and I proceed with rapid reduction when indicated. In patients who are intact or have mild deficits, it is usually possible to obtain an MRI scan prior to reduction. If a traumatic disc herniation behind the body of the cranial vertebra is present, the patient should undergo anterior discectomy and then reduction using direct vertebral manipulation or intraoperative tong traction. If reduction is achieved, then anterior interbody fusion with a plate is performed. If reduction is not achieved, the patient is turned prone on a turning frame and open posterior reduction is performed. Lateral mass fixation and bone graft is applied. The wound is closed and the patient is repositioned supine and anterior body fusion performed with or without addition of an anterior plate.

Another contraindication to traction reduction is ankylosing spondylitis. These are highly unstable injuries in which the ALL and PLL are absent and thus do not provide ligamentotaxis. Traction in these cases can lead to loss of alignment, overdistraction, and neurologic deficits.

Surgical Treatment of Subaxial Cervical Spine Injuries

Surgical Goals

The goals of surgery are to decompress neural elements when warranted, realign the spine by reduction and correction of kyphosis, provide stabilization while minimizing the number of segments permanently arthrodesed, minimize orthotic use postoperatively, and to provide a long-term painless spine (Box 76.2). In addition, patients should be able to be mobilized as soon as possible and the surgical procedure should avoid adverse events.

Indications

The indications for surgical treatment are unstable injuries that have poor potential for healing, the need to decompress the neurologic elements in the presence of neurologic deficits, or failure of conservative treatment. In general, injuries that have SLIC scores of 5 or greater and CSISS of 7 or greater are treated with surgery.

Surgical Approach

The subaxial cervical spine can be approached by anterior, posterior, or combined approaches. Many factors determine which approach will be used, but often are related to surgeon preference. I recommend identifying the goals of surgery and choosing an approach that best matches those goals. Surgical fixation should meet the biomechanical requirements of the injured segments.

BOX 76.2 Goals of Surgical Treatment

Decompress spinal cord and nerve roots
Reduce fractures and dislocations, and correct kyphosis
Stabilization
Minimize number of levels fused
Rapid mobilization of the patient
Minimize orthotic use
Avoid adverse events

The advantages of the anterior approach are direct decompression of the spinal cord, ease of positioning, familiarity of the approach by most surgeons, less blood loss, lower risk of infection, and better ability to correct kyphosis, if present. Disadvantages are that biomechanical strength of fixation is less than posterior fixation techniques, higher rates of nonunion, and postoperative dysphagia with aspiration risk and airway compromise. The advantages of a posterior approach are the ability to extend to more cranial and caudal levels, greater ease of reduction, improved biomechanical strength, and avoidance of anterior soft tissue complications. A combined approach provides maximum fixation, the chance for circumferential decompression, and less need for postoperative immobilization. However, the combined approach is associated with more complications and longer operative times.

Anterior Decompression and Fusion

Anterior decompression and fusion is performed using the Smith-Robinson approach. After confirmation of the correct level, the disc anulus is sectioned and discectomy performed. If needed, the canal is decompressed directly. The endplates are prepared by removal of cartilage and flattening. In cases requiring corpectomy, such as burst fracture, the discs cranially and caudally are removed, the vertebral body is removed piecemeal, and the posterior wall is removed with a burr. A trough a minimum of 15 mm wide should be created. Reconstructive options for discectomies include allograft or autograft. After corpectomy, I prefer radius allograft strut graft, although satisfactory results have been obtained using cages filled with autogenous graft material from the corpectomy. Stabilization is achieved with a plate and screws, either static or dynamic. Final radiographs are obtained to assess alignment and instrumentation.

Posterior Approach

The posterior approach requires prone positioning, which is done by either log rolling the patient onto an operating table or use of a turning frame. In the former, the neck can be stabilized with a collar and with the surgeon holding the head. If traction is already applied, I prefer the turning frame, in which traction can be maintained. After positioning and taping the arms caudally, the alignment is confirmed radiographically. A midline incision is used and the spinous processes and laminae out to the edges of the lateral masses are exposed. When dissecting, the nuchal ligamentous complex needs to be preserved to avoid adjacent segment kyphosis.

If reduction of facet dislocation is needed, the spinous processes may be grasped as levers and manipulated to gain realignment. In some cases, an elevator may be placed into the dislocated facet joint and used as a lever to achieve reduction. Alternatively, 3 to 5 mm of the superior facet can be removed with a burr, allowing clearing of the inferior facet into position. Kyphosis can be reduced, if present, by use of an interspinous wire fixation.

Optimal fixation is achieved with lateral mass screw and rod constructs.[29] The borders of the lateral mass are exposed and the center identified. A starting point is placed 2 mm medial to the center of the lateral mass with a burr. A drill or Kirschner wire (K-wire) with a stopped drill guide creates a pilot hole. The screw orientation is upward (parallel to facet joint) and laterally away from the vertebral artery, 15 to 20 degrees. The hole is drilled and checked for far cortex perforation. If not perforated, the drill guide is adjusted to allow 2 mm more length, and the process is repeated. This continues until the far cortex is reached, a length of 16 to 20 mm. Variable head screws are inserted and rods of appropriate length are placed into screw heads, then set screws are tightened. The posterior third of the facet joint is decorticated and packed with bone graft. The nuchal ligaments are reconstructed and vancomycin powder applied to the wound.

Anteroposterior Approach

Combined AP approaches are occasionally needed when injuries have total ligamentous disruption, are highly comminuted, when compression is located both anteriorly and posteriorly, or when reduction cannot be achieved preoperatively or by only one approach. It is best if the patient is hemodynamically stable to accomplish this under one session of anesthesia.

Treatment of Specific Fracture Types

AO Compression Injuries Type A1 and A2

These compression-type injuries rarely require surgical treatment. The important determinate is whether the posterior ligamentous complex is intact. Several authors have noted that compression fractures can be associated with posterior ligamentous injury, resulting in progressive kyphosis, so-called "hidden flexion injury."[30] Careful scrutiny of CT images and plain radiographs for disruption of facet articulations and widening between spinous processes are clues to possible ligamentous injury. Fat-suppressed MRI is the best method to determine the status of those ligaments. If there is associated ligamentous injury, then this is an AO type B injury and treated surgically, as described later.

AO Compression Injuries Type A3 and Type 4

These are burst fractures without disruption of the posterior ligaments and, in the absence of neurologic injury, can be treated nonoperatively. A cervical orthosis for 10 weeks is recommended. These commonly occur at C7, where a CTO should be considered. The posterior ligamentous complex needs to be assessed as described earlier for A1 and A2 injuries. In cases of neurologic injury, reduction using cranial tong traction reduction can be achieved. Surgically, these are best treated by anterior corpectomy and fusion with plate instrumentation. In cases in which reduction has been achieved, posterior fusion is also an option. The type A4 fracture has greater comminution of the vertebral body and, therefore, is more likely to develop progressive kyphosis, which might require surgery.

AO Distractive Injuries Type B1

These are rare bony distractive lesions from either flexion or extension forces that often occur in patients with an ankylosed spine. Nonoperative treatment can be attempted in nonankylosed patients, but any change in alignment should be treated surgically. Patients with ankylosed spines with these injuries are best treated surgically. Posterior lateral mass fixation is the preferred technique, as this provides the best fixation strength and it is easier to include more levels if needed.

AO Distractive Injuries Type B2

This injury is a posterior ligamentous disruption often associated with a minimal compression fracture. These are inherently unstable and have a SLIC score of 5 or greater and, except in the young, are best treated surgically (Fig. 76.2). Either an anterior or posterior approach can be used if bony structures are intact. During surgery, attention to achieving correction of the kyphotic deformity is important. When performing anterior fusion, lordosis is achieved by positioning in extension using blanket rolls placed behind the shoulders and by placing distraction pins, which initially converge and, when distracted, tend to lordose the spine. Posteriorly, if reduction does not reduce kyphosis, either compression of the lateral mass screws or use of an interspinous wire can be performed to correct kyphosis.

Posterior ligamentous injuries are associated with various anterior column injuries, such as compression or burst fractures. These injuries are best treated surgically; I prefer a posterior fusion if reduction is achieved preoperatively. A special case is the flexion–axial loading fracture in which the body splits, leaving a small triangular fragment at the anterior longitudinal ligament, and the remaining body translates posteriorly into the spinal canal (Fig. 76.3). Associated with this injury are varying degrees of posterior ligamentous disruption, facet fracturing, and subluxation. The fracture can be reduced but may require large weight, up to 50% to 70% of body weight. Definitive treatment is by anterior corpectomy and plate fixation. An additional posterior fusion may be indicated in the more displaced and comminuted injuries.

AO Distractive Injuries Type B3

These are discoligamentous injuries resulting from hyperextension and may be associated with central cord syndromes. They often also occur in patients with ankylosed spines. The discoligamentous injury is often not apparent on initial radiographs and may be hard to differentiate from degenerative changes (Fig. 76.4). The potential for late deformity is less than in posterior ligamentous injuries, but these injuries can result in posterior translation (retrolisthesis) of the cranial vertebral body. Discoligamentous injuries without neurologic injury can be treated in a cervical orthosis. When associated with central cord syndrome, early decompression—either by anterior or posterior approach—and fusion is recommended. Discoligamentous injuries in patients with ankylosed spines should be treated surgically, usually with a posterior fusion, although anterior discectomy and fusion in patients with excellent bone quality can be considered.

AO Translational/Rotational Injuries Type C

Many forces can result in translational and rotational deformities in the subaxial spine. Most common are unilateral and bilateral facet dislocations with or without facet fractures. In addition, bilateral pars fractures can result in traumatic spondylolisthesis, which occurs most commonly at C7. Extension forces, when severe, can cause complete disc and facet joint disruptions and posterior translational injuries.

Unilateral Facet Dislocations

Unilateral facet dislocation occurs when the inferior facet is translated over the superior facet, and is often associated with facet fracture. Radiographically, there will be up to 25% vertebral body subluxation. Biomechanical studies suggest that significant posterior ligamentous and disc anulus injury is required for this injury to occur. The ipsilateral neuroforamen is narrowed and may be associated with a radiculopathy. Disc disruptions occur universally and disc herniation is present in 56% of patients.[31]

The treatment of these injuries remains controversial. Most agree that closed reduction should be performed. In the presence of a facet fracture, especially if it involves more than 40% of the facet, displacement may recur.[32] One treatment after reduction is orthotic management with an orthosis or halo vest. Alternatively, surgery, either anterior or posterior, can be performed. When reduction has been achieved, anterior discectomy and fusion is recommended. Posterior fusion is indicated when vertebral body fractures are present and when open reduction is required. Long-term outcomes have been shown to be improved with surgical rather than nonoperative treatment.

Bilateral Facet Dislocations

Bilateral facet dislocations are highly unstable and result in a minimum of 50% vertebral subluxation. Spinal cord injuries occur frequently. In addition to the facet dislocations, the posterior osteoligamentous complex and disc anulus are disrupted. Fractures of the lamina and spinous process also occur frequently, which may affect treatment decisions. Further, the intervertebral disc is always disrupted and may appear displaced into the spinal canal. The disc is located in the normal position relative to the caudal vertebra but posterior to the cranial vertebra. In some cases, free disc fragments are located behind the cranial vertebral body wall and may remain after reduction, causing increased cord compression.[23]

All bilateral facet dislocations should be reduced and undergo spinal fusion (Fig. 76.5). In spinal cord–injured patients, it is urgent that reduction is achieved to allow restitution of vascular supply and is best done by traction or early surgery.

In intact patients, there is a small incidence of neurologic worsening from intervertebral disc herniation behind the vertebral body after reduction. If possible, an MRI before

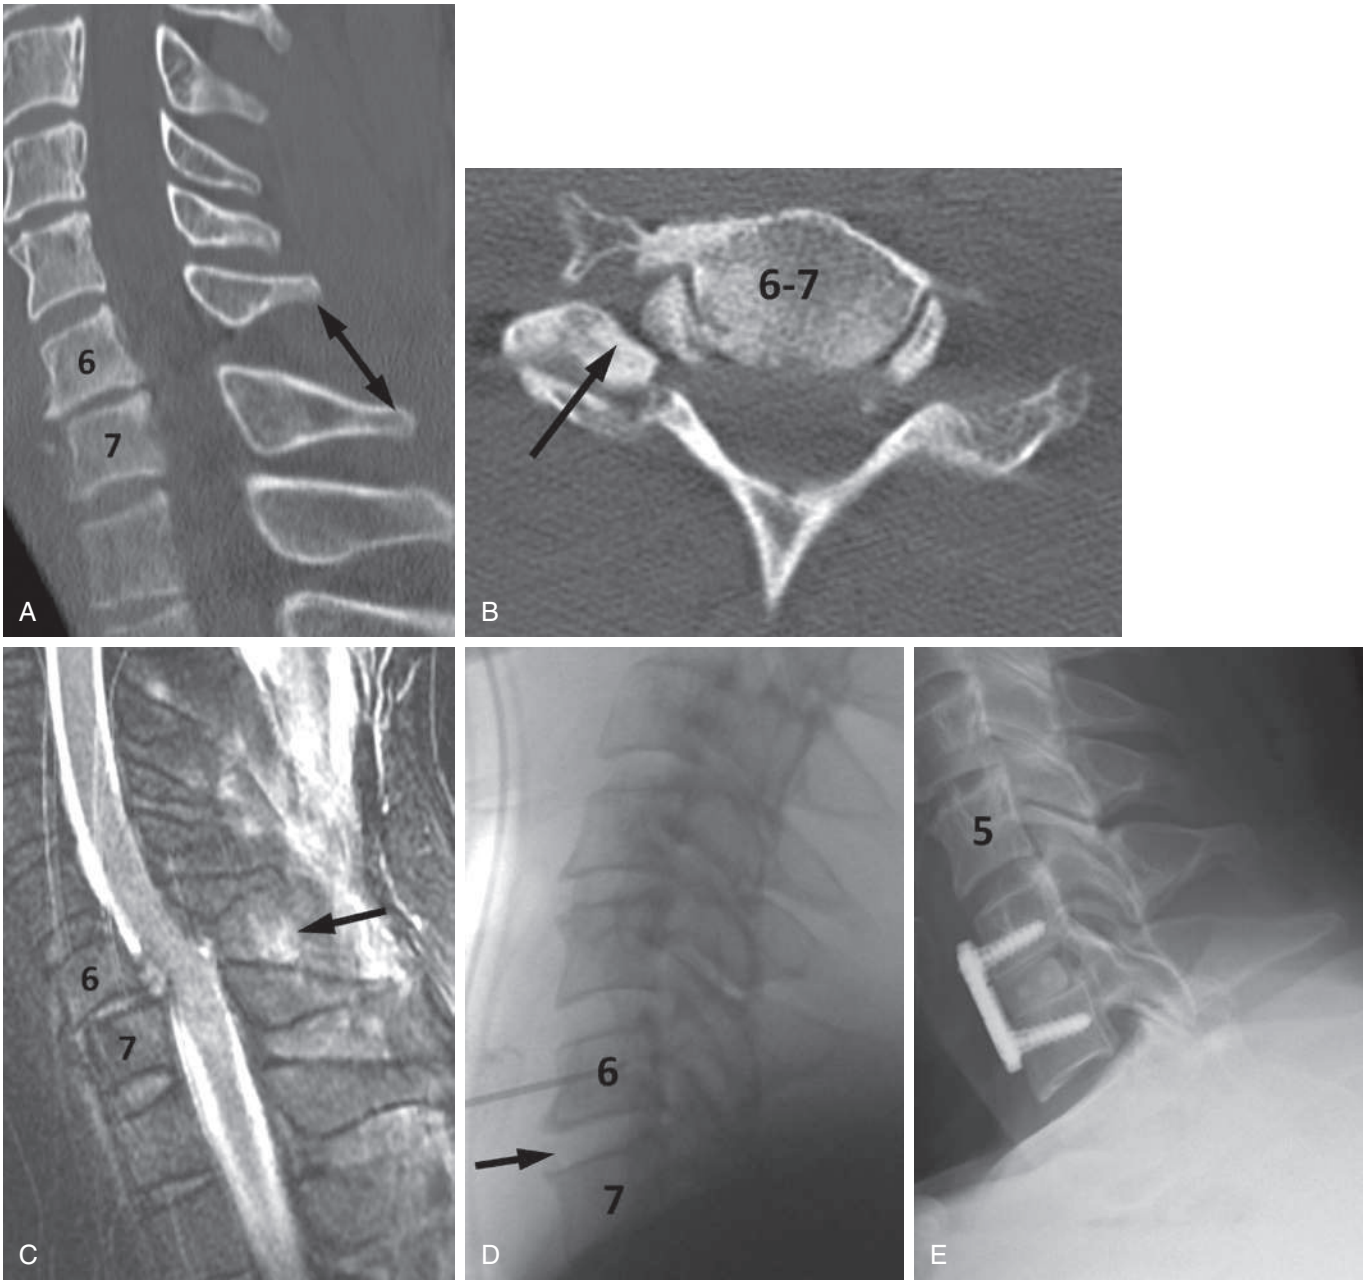

FIG. 76.2 (A) Sagittal computed tomographic (CT) image showing posterior ligamentous injury at C6–C7 in a 52-year-old man who presented with American Spinal Injury Association quadriplegia. Wide separation is noted (*arrow*) between spinous processes. The disc is narrow, with suspicion of herniation into the canal. (B) Axial CT at C6–C7 shows a right facet fracture and a displaced superior facet fracture in the neuroforamina (*arrow*). (C) Magnetic resonance image showing disc herniation with significant cord compression. The spinal cord is deformed and had signal changes within. The arrow points to disrupted posterior ligaments. (D) Intraoperative fluoroscopic image after placement of 20 lb of traction and extension with a roll behind the shoulders. Note overall excellent alignment and disc distraction relative to preoperative CT. At surgery, the anterior and posterior longitudinal ligaments and disc were disrupted. (E) The patient was treated by anterior discectomy and fusion with dynamic plating.

reduction is recommended. If the disc appears behind the body, then anterior discectomy and fusion is performed prior to reduction. Then, reduction can be obtained by manipulation and interbody fusion with placement of bone graft and plate. If reduction cannot be achieved, the patient can be turned prone and an open reduction and posterior fusion performed. Finally, an anterior interbody fusion is performed. Alternatively, a closed reduction can be attempted if the patient is awake and cooperative by carefully monitoring the neurologic function as increasing weight is added. This protocol can be done safely and has not been associated with neurologic deficits in awake patients.[33]

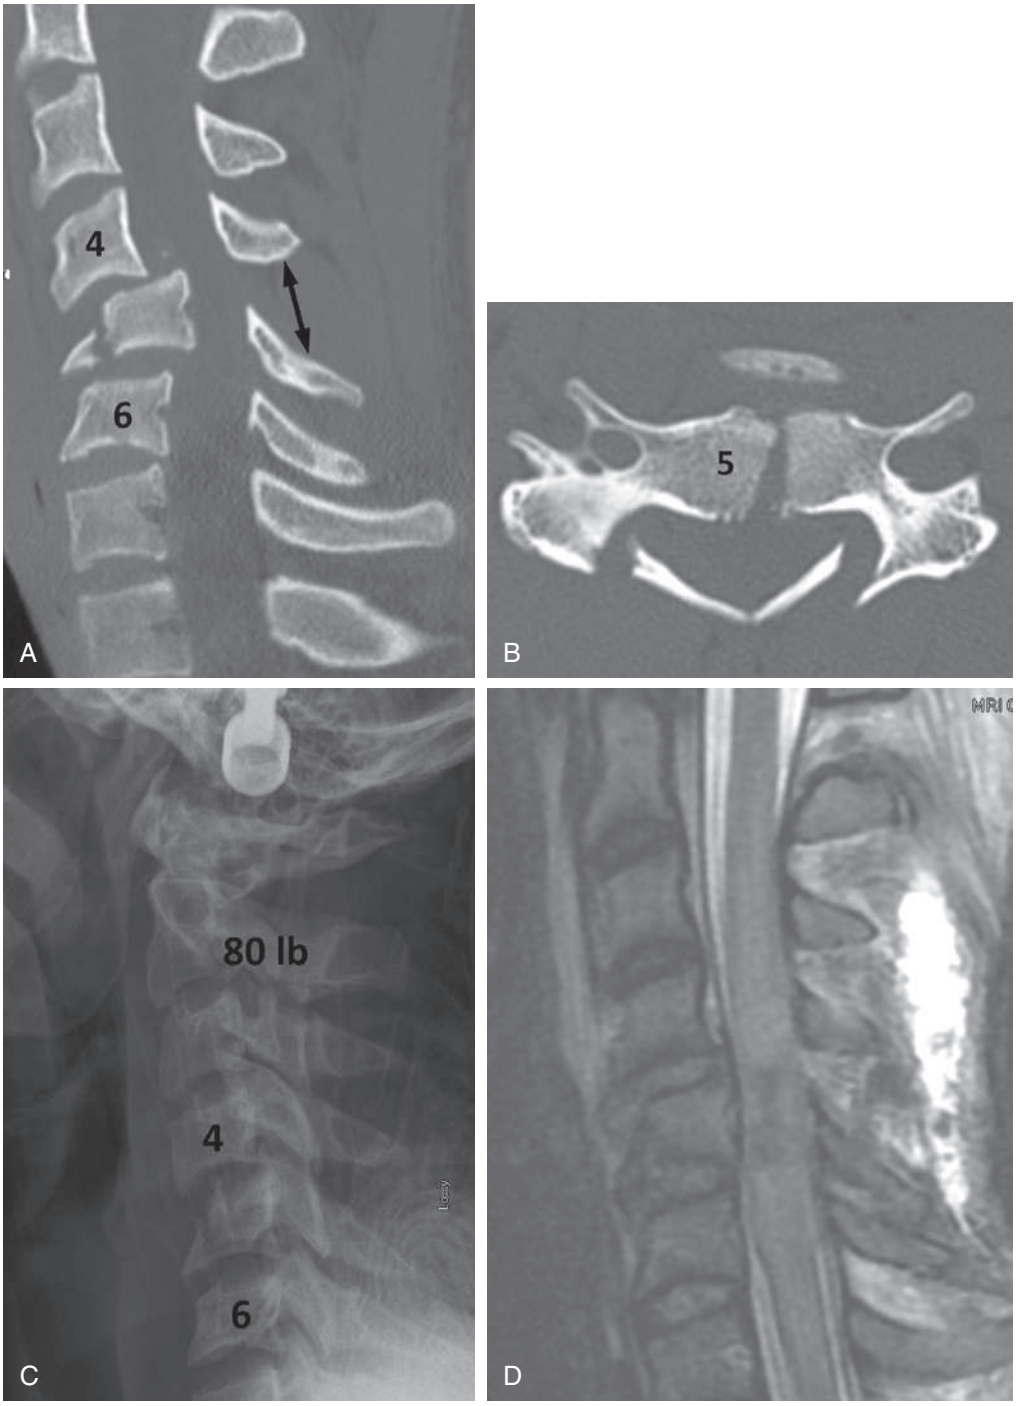

FIG. 76.3 (A) A 20-year-old man was a C5 complete quadriplegic from a diving accident. The sagittal computed tomographic (CT) image shows a flexion–axial loading injury (AO B2). There is a teardrop fracture of the anterior-inferior corner of C5, and the posterior aspect of C5 is rotated into the spinal canal. The posterior osteoligamentous complex is disrupted (*arrow*). The fracture is unstable and has a Subaxial Cervical Injury Classification System score of 9. (B) Axial CT demonstrating comminuted body and posterior element fracture with narrowing of the spinal canal. (C) After application of 80 lb of traction, excellent reduction was achieved. (D) The patient was treated with a posterior fusion of C4–C6. The postoperative magnetic resonance image shows severe cord edema, hematoma at the site of the injury, and posterior ligamentous disruption.

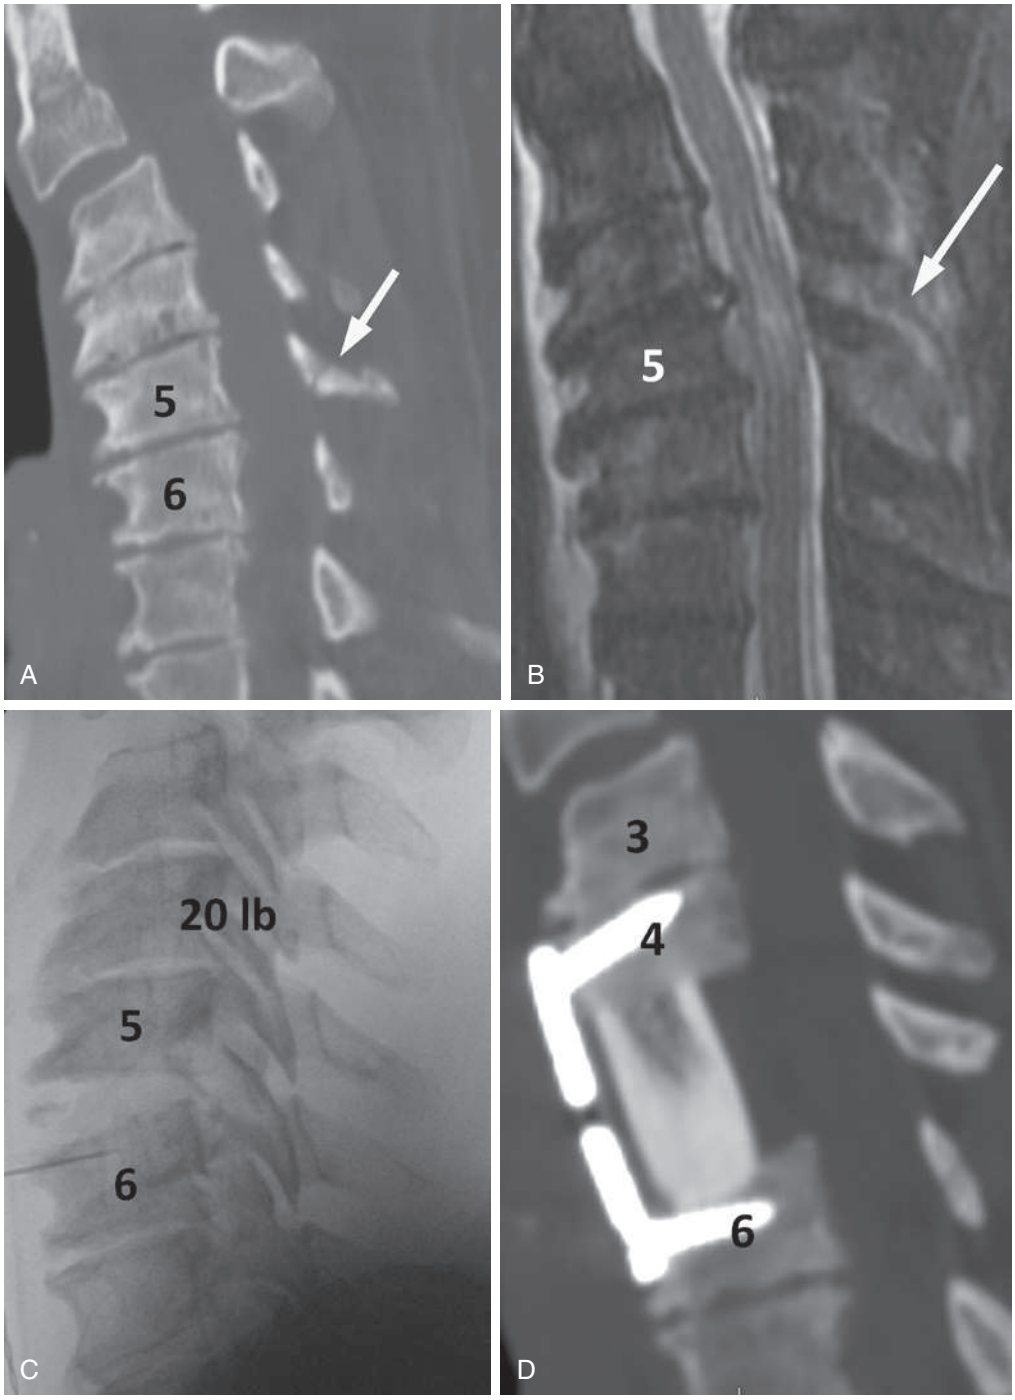

FIG. 76.4 (A) A 56-year woman had a hyperextension injury from a fall. She presented to an outside hospital complaining of weakness in both arms. Twelve hours later, she deteriorated and was transferred with central cord syndrome. Sagittal computed tomography (CT) showed multilevel degenerative disease, cervical kyphosis, and nondisplaced fracture of C5 (*arrow*). (B) Short tau inversion recovery magnetic resonance imaging showed spinal cord edema opposite C5 and edema in posterior osteoligamentous structures (*arrow*). No evidence of discoligamentous injury was present. (C) The patient was positioned in neutral alignment in 20 lb of traction. The lateral radiograph shows significant C5–C6 disc distraction. The traction weight was reduced and an anterior C5 corpectomy was performed. (D) Postoperative CT after corpectomy at C5 and reconstruction with radius allograft and plate.

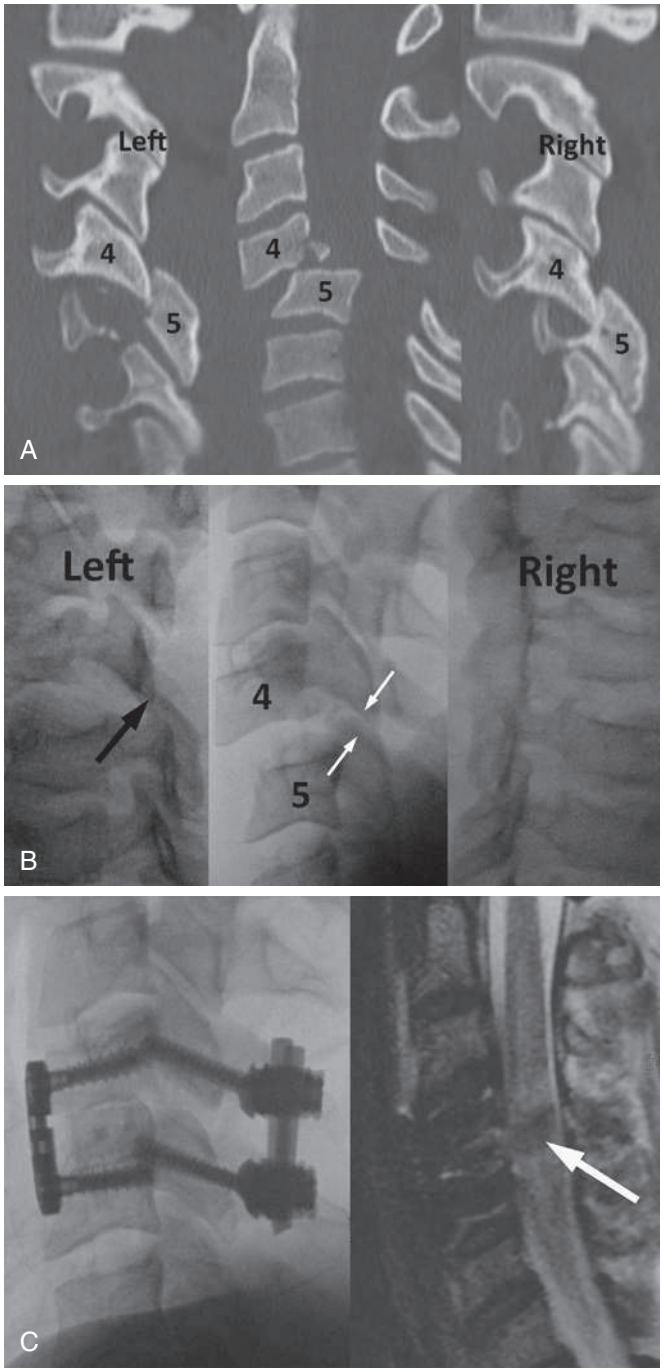

FIG. 76.5 (A) A 22-year-old man rated as a complete quadriplegic sustained bilateral facet dislocations from a diving accident. The left and right sagittal computed tomographic sections show facet dislocations. There is 80% anterior translation of C4 on C5, with a fracture of the posterior inferior corner of C4 displaced into the spinal canal. (B) Cranial tong traction of 50 lb reduced the right facet, but the left facet (*black arrow*) remained dislocated. In the center panel, the vertebral bodies realigned with only 25% residual subluxation, and reduction of one of the facet dislocations is seen (*white arrows*). The patient underwent posterior open reduction and lateral mass fixation. The patient was turned supine, and anterior decompression and fusion were performed. (C) Postoperative lateral radiograph (*left*) demonstrating excellent reduction from combined anterior-posterior fusion. The MRI (*right*) confirms excellent canal decompression. Unfortunately, the cord appears to be transected (*arrow*) and spinal cord edema is seen from C2–C5.

In patients who do not require decompression, either anterior or posterior fusion can be performed.[34] Despite the high degree of instability, anterior fusion with instrumentation provides adequate stability without the need for additional posterior surgery unless vertebral body fractures are present.

Traumatic Spondylolisthesis

Hyperextension forces can result in bilateral pedicle or pars fractures. With continued forces, the disc anulus is disrupted and vertebral subluxation occurs. The spinal canal becomes larger despite subluxation and spinal cord injuries are less frequent. This injury is unstable, requiring reduction and stabilization. Traction reduction is attempted, but complete reduction is difficult to obtain. Either an anterior or posterior approach can be utilized; in some cases, a combined approach is required. Instrumentation of two levels will be required.

Hyperextension Subluxations

Hyperextension forces can cause disruption of the disc anulus, facet capsules, and even posterior ligaments, resulting in posterior vertebral body subluxation. The spinal cord may be compressed and exiting nerve roots are compressed. Treatment may be traction initially but may result in overdistraction, as these injuries may have significant ligamentous disruptions. Definitive treatment is anterior discectomy and fusion.

AO Facet Fractures F1 and F2

The cervical facets are essential to prevent anterior projection translation due to their upward coronal plane orientation. When incompetent from injury, anterior translation may result, with the potential for pain and neurologic injury. Stability models such as the SLIC and CSISS scoring systems often fail to predict behavior.[35]

The treatment goals are to maintain alignment and prevent late instability. Better clinical and radiographic outcomes appear to be associated with surgery.[35] Aarabi studied 25 patients with unilateral nondisplaced facet fractures.[35] In the 10 surgical patients, alignment was maintained and no further treatment was required. Nine of the 15 nonoperatively treated patients developed increased subluxation or kyphosis and needed surgical repair. In a systematic review, Kepler found that 88% of operative compared to 43% of nonoperatively treated patients maintained reduction.[36] Anterior instrumentation had a higher success rate, 92% compared to only 64%, with posterior fusion. However, many posterior fusion patients were treated with outdated wire fixation. Brodke et al.[34] and Kwon et al.[37] noted no difference in results between anterior and posterior fusion.

The treatment of F1 and F2 isolated facet fractures without initial displacement is attempted nonoperatively with a collar or CTO. If subluxation or kyphosis develops, then anterior fusion is recommended. Posterior fusion is an alternative and occasionally needed if there is a displaced facet fracture causing radiculopathy requiring foraminotomy.

AO Facet Fractures F3

This fracture, called "fracture separation of the lateral mass," occurs when the pedicle and lamina are fractured, creating a free-floating lateral mass.[19] The lateral mass can rotate forward and lead to anterior subluxation of both the cranial and caudal vertebral levels. Often, the foramen is narrowed and radiculopathy is present. Sufficient anterior subluxation can cause spinal cord compression. Manoso reviewed 60 cases and found that 38% had radiculopathy and 18% had spinal cord injury.[38]

Nondisplaced F3 injuries can initially be treated nonoperatively with an orthosis. However, fracture separations are likely to develop subluxation, and careful follow-up is required. In Manoso's study, two-thirds of patients treated nonoperatively developed subluxation.[38]

Those patients with initial displacement should be reduced and undergo arthrodesis. An important consideration is whether both segments should undergo fusion or just the level with subluxation. If alignment of the facets can be achieved, then a single-level arthrodesis can be attempted with either the anterior or posterior approach. However, failure can occur when the nonfused segment develops subluxation. Alternatively, a two-level arthrodesis can be performed.

AO Facet Fractures F4

Hyperflexion causes disruption of the posterior osteoligamentous complex from the posterior to the anterior direction. As the vertebra rotates in flexion, the cranial inferior facets slide upward and may become perched in an almost dislocated position. Perched facets indicate substantial injury to the nuchal ligaments, ligamenta flava, and likely the disc anulus, thus should be considered unstable.

Most patients with perched facets should be treated surgically with either anterior or posterior fusion. In younger patients, nonoperative treatment can be attempted with a collar.

Special Cases

Fractures in Patients With Ankylosed Spines

An increasing number of patients who have ankylosed spines due to ankylosing spondylitis, diffuse idiopathic skeletal hyperostosis, severe degenerative disease, or from surgical fusion are sustaining cervical fractures.[39,40] These injuries usually occur from hyperextension and are highly unstable. The most common injury patterns are hyperextension through the disc space.

Displacement, neurologic deterioration, and progressive deformity occur with nonoperative treatment; therefore, surgery is recommended in most cases (Fig. 76.6). Caron et al. reviewed 122 cases and found that delay in diagnosis was common, resulting in neurologic deficits in 81% of those cases.[39] They found that posterior instrumentation three levels above and below was most successful. Fusion of additional levels is immaterial, as these patients are already fused by their disease.

Vertebral Artery Injury

Vertebral artery injuries are common, and may occur in up to 11% of cervical trauma patients.[41] Indications for screening with CT angiography specific to the subaxial cervical spine injury are fractures involving the foramen transversarium, lateral mass fractures, and fracture dislocations. The treatment remains controversial since the majority of patients are asymptomatic. Patients with documented vertebral artery injuries are to be treated with antiplatelet therapy.[21] Symptomatic patients or those who have strokes related to vertebral artery injury may need endovascular repair or revascularization.

Central Cord Syndrome

There is an increasing incidence of patients sustaining hyperextension injuries from falls who present with central cord syndrome. At the time of injury, there is transient compression of the spinal cord, resulting in a central cord injury. Clinically, patients present with worse neurologic deficits in their arms compared to the legs. Bony injury may be absent, but fractures of spinous processes and laminae, disc distraction, and retrolisthesis of vertebral bodies are often present. MRI shows spinal stenosis, often at multiple levels, and spinal cord edema.

The treatment of central cord injuries remains controversial. Nonoperative treatment may be appropriate in patients making rapid recovery. Decompression is warranted in patients with significant deficits, instability, or progressive worsening.

The surgical approach will depend on the degree of skeletal injury, number of levels requiring decompression, and location of cord compression. I often recommend laminoplasty for patients with normal or lordotic alignment and multilevel compression (Fig. 76.7). The timing of decompression of central cord syndrome has been recently evaluated in a systematic review.[42] Anderson reported that patients having decompression within 25 hours of injury had better neurologic outcomes than those decompressed after 72 hours.[42]

Traumatic Disc Herniation

Rarely, a patient with head or neck trauma sustains a traumatic disc herniation with spinal cord compression. These are often the result of sporting accidents in younger patients. Treatment can be nonoperative in the absence of neurologic deficits. Those with spinal cord injury are best treated by early anterior cervical discectomy and fusion.

Adverse Events

Adverse events are common in patients with cervical spine trauma. A commitment to patient safety at all stages of care is required to minimize the chance and severity of complications.

Neurologic Deterioration

Delay in diagnosis and subsequent neurologic deterioration is still frequent, occurring in 0.21% of patients presenting to

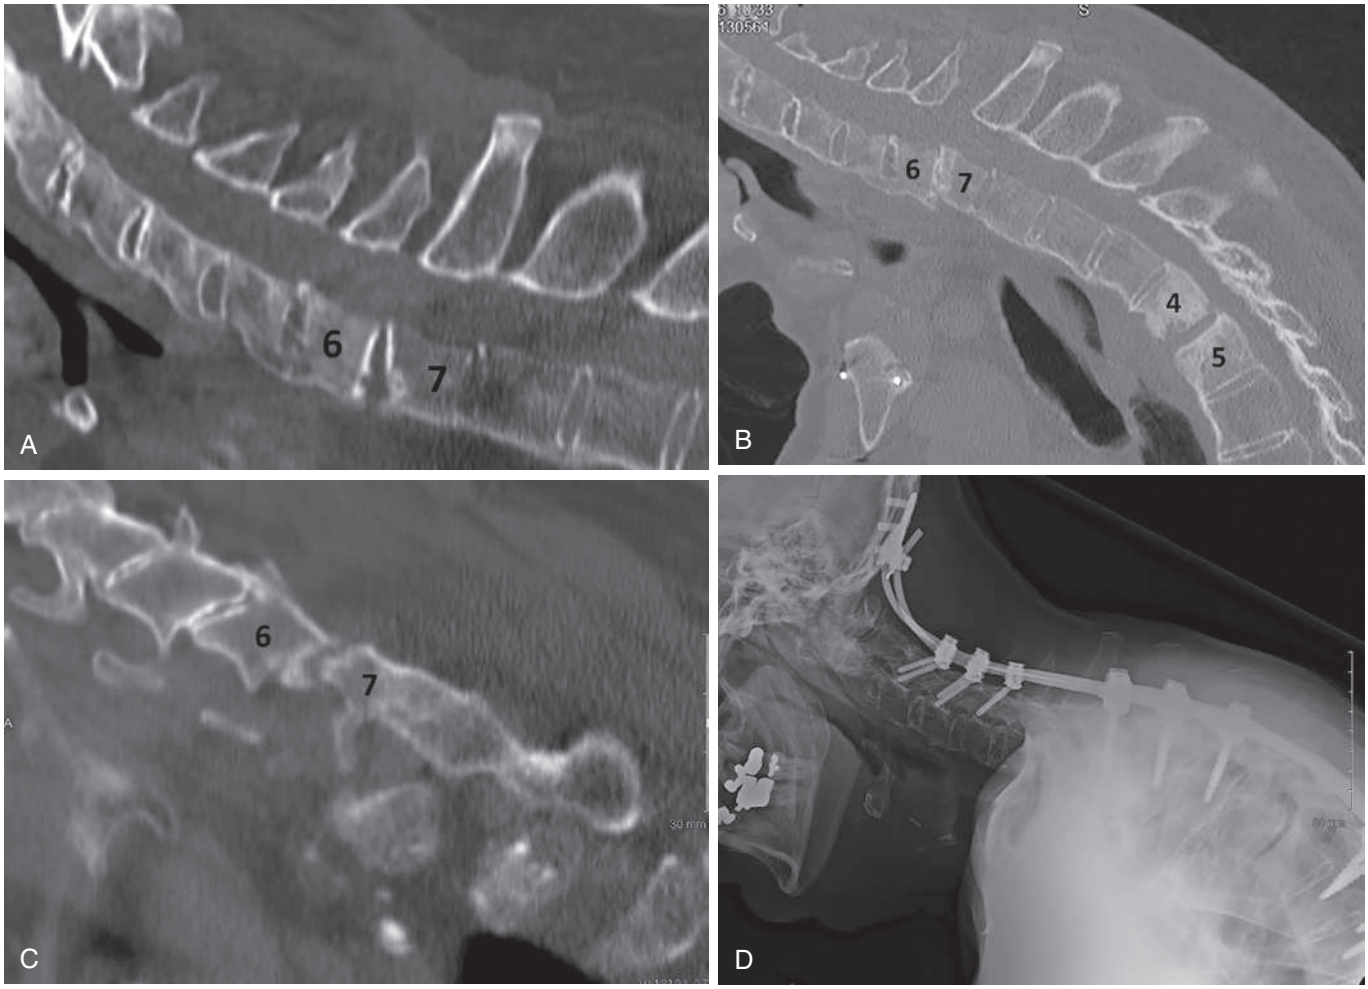

FIG. 76.6 (A) A 58-year-old man with ankylosing spondylitis fell and was seen in an outside hospital complaining of back pain. Computed tomography (CT) showed ankylosing spondylitis with opening across the C6–C7 disc space, indicating hyperextension injury. There is preexisting kyphosis. The diagnosis of injury was missed. (B) Sagittal CT 1 month later showed displacement of the C6–C7 injury, and increased kyphosis (*double arrow*) between the C6–C7 spinous processes. At T4–T5, there is chronic spondylodiscitis (chronic nonfusion). (C) Parasagittal CT demonstrating C6–C7 facet fracture. (D) The patient was treated by posterior instrumentation occiput–T6, as seen on lateral radiograph. His C1–C2 segment was also unstable, requiring extension to the occiput.

trauma centers.[2] The most common cause is insufficient imaging or misreading of images. Careful attention to screening criteria described earlier and critical review of all images by an experienced radiologist can minimize these changes. At-risk groups are the elderly, unconscious, or those with impaired mentation and patients with ankylosed spines.[2]

Neurologic deterioration after hospitalization occurs in 2% to 3% of patients with known spinal fractures.[2] Patients with complete spinal cord injury are at higher risk, reported by Harrop et al. as 6% neurologic deterioration in 186 cord-injured patients.[43] The early cause of deterioration was instability and fracture displacement, deterioration occurring in 2 to 7 days likely being from hypotension, with later deterioration from vertebral artery injury.

Wound Infections

Posterior cervical fusion in trauma patients has a high incidence of surgical site infection (SSI). Cooper reported 4%, while Caroom reported a 15% incidence of SSI. Efforts to minimize these risks include avoiding the use of methylprednisolone and using intrawound vancomycin powder. In studies specific to posterior cervical wound, the use of vancomycin powder can reduce infection by 50% to 75%.[44,45]

Loss of Reduction

The use of modern fixation methods has significantly reduced the cases of loss of reduction. In nonoperatively treated patients, I estimate that 5% of cases will develop increased

FIG. 76.7 (A) A 58-year-old woman sustained central cord syndrome after a ground-level fall. Sagittal computed tomography shows severe degenerative disc disease with larger osteophytes projecting into the spinal canal causing canal narrowing from C4–C7. (B) Sagittal short tau inversion recovery magnetic resonance imaging (MRI) demonstrated severe cord compression at C4–C6 with cord signal changes. There was no evidence of acute ligamentous or disc injury. She was treated by C3–C7 laminoplasty. (C) Axial MRI at C5–C6 showed severe cord compression. (D) Laminoplasty of C3–C7 was performed with reconstruction with laminoplasty plates.

subluxation or kyphosis requiring fusion. Therefore, careful attention to upright radiographs and follow-up is needed to identify these cases and treat them surgically before neurologic changes. Matching the construct to the biomechanical requirements and rigid methods of fixation reduce the risk of loss of reduction.

Venous Thromboembolism

Venous thromboembolism (VTE), including DVT and pulmonary injuries, are known complications associated with spinal cord injury that often result in death. The combination of stasis from muscle paralysis, intimal damage, and hypercoagulable state increases the risk of VTE in patients with spinal cord injury. Guidelines recommended that all spinal cord–injured patients receive anticoagulant prophylaxis, although the optimal method is not clear.[46] Patients treated with fractionated heparin are four times less likely to develop VTE than without prophylaxis. Treatment should start within 72 hours of injury. It is not clear whether the risk of VTE in neurologically intact patients is sufficient to warrant anticoagulation, but, given the risk of epidural hematoma, anticoagulation prophylaxis is not routinely recommended.

Pulmonary Events

Pulmonary adverse events occur frequently in spinal cord–injured patients as a result of impaired ventilation, poor cough, and absence of accessory muscles for respiration, leading to atelectasis and fluid collection. Early surgery reduces pulmonary complications, length of hospitalization, and overall complications.[47] Prolonged traction and bed rest should be avoided. Respiratory therapy and pulmonary toilet should be routine in spinal cord–injured patients. A swallow study should be performed before feeding quadriplegics to assess the risk of aspiration.

Summary

Cervical spine injuries occur in 3% to 5% of all blunt trauma patients. Assessment in all patients must include determination of whether significant cervical spine injury is present utilizing evidence-based protocols. Essential to the determination of treatment is neurologic function and fracture stability. Initially, patients are immobilized in collars; then, injury is classified for stability and fracture type using systems such as SLIC and the modified AO cervical spine system. The more stable injuries are treated nonoperatively with an orthosis. An important component is to critically assess efficacy using upright radiographs to identify maintenance of alignment. Surgical care is warranted for injuries having SLIC grade 5 or greater and most AO types B and C. In addition, surgery is indicated when decompression is required in neurologically impaired patients, for progressive neurologic deterioration, and for failure of nonoperative treatment. Either anterior or posterior approaches may be utilized but depend on the goals of treatment. Rarely is a combined AP approach warranted.

PEARLS

1. Determine stability of injuries based on CT and MRI, then tailor surgery or orthotic management to the biomechanical needs of the injury pattern.
2. Early reduction and surgery is warranted for patients with spinal cord injury or highly unstable fractures.
3. The choice of surgical approach depends on the morphology of injury and should provide excellent stabilization while minimizing the number of spinal segments permanently fused.
4. Decompression is required in neurologically impaired patients when the neural elements are compressed.
5. Early mobilization of spinal-injured patients reduces risk of complications.
6. Regardless of treatment choice, monitor spinal alignment with upright radiographs on a regular basis.

PITFALLS

1. Delay in diagnosis secondary to inadequate interpretation or misinterpretation of radiologic imaging of spinal injury is associated with significant risk for neurologic deterioration.
2. When attempting nonoperative treatment, fracture displacement may occur in 5% to 10% of patients, who may require surgical treatment.
3. Diminish orthosis-related complications with optimal fitting by a certified orthotist and by using the most appropriate orthosis for the patient and the patient's injury pattern.
4. Fracture comminution may weaken the surgical construct. Consider using an alternative approach in areas with adequate bone stock.
5. Avoid posterior cervical surgical wound infections by meticulous aseptic technique, intravenous antibiotics, and possibly by intrawound administration of vancomycin powder.
6. Vertebral artery injuries should be investigated by CT angiography when fractures involve the foramen transversarium, fracture dislocations, and lateral mass fractures. If present, antiplatelet treatment is recommended.

KEY POINTS

1. Critical evaluation by history and physical examination is needed to identify trauma patients with potential cervical injury. Cervical CT is indicated for symptomatic patients, those who cannot be evaluated, and for those who have distracting injuries.
2. Injuries are assessed for stability and classified using the SLIC and updated AO system.
3. Successful nonoperative treatment requires selection of an appropriate orthosis. An upright radiograph is assessed to determine efficacy of treatment. Progressive deformity, translation, or neurologic change warrants surgical consideration.
4. Surgery is indicated for unstable injuries, those with SLIC >4, or for most B and C type AO lesions.
5. Early reduction with tong traction in quadriplegic patients with facet dislocations and burst-type fractures should be considered.
6. Fractures in patients with ankylosed spines should be treated with posterior instrumentation.

CHAPTER 77

Thoracic and Lumbar Spinal Injuries

Joseph P. Gjolaj
Seth K. Williams

The treatment goals for patients with injuries to the thoracic, thoracolumbar, or lumbar spine are primarily to maintain or restore spinal alignment and stability, preserve neurologic function, assist appropriate management of other injuries, and mobilize the patient as soon as possible. Controversy persists over the choice of operative versus nonoperative treatment of certain fractures, but there is agreement on the basic principles in the diagnosis and management of thoracic and lumbar spinal injuries.

Incidence

The thoracolumbar junction is the most common injury site for thoracic and lumbar trauma. Most patients are young males involved in high-energy accidents. More than half of fractures occur between T11 and L1, and another 30% occur between L2 and L5.[1–3] More than 50% of injuries are sustained in motor vehicle accidents, and another 25% are sustained in a fall from greater than 6 feet. Complete neurologic injuries occur in about 20%, and incomplete neurologic injuries occur in about 15% of patients. Associated injuries—including fractures, head trauma, pulmonary injuries, and intraabdominal injuries—occur more than 50% of the time. Noncontiguous spine injuries remote from the site of the primary injury occur in 5% of patients.[1–3]

Anatomic Considerations

Considerable anatomic differences exist throughout the thoracolumbar spine, contributing to the differences in spinal injury patterns in the thoracic spine, thoracolumbar junction (T11–L2), and lower lumbar spine. The thoracic spine is kyphotic and has the greatest amount of intrinsic stability because of the rib cage, but it also has a relatively narrow canal that gives little reserve for neural element protection after spine trauma.[4] Axial rotation is greater in the thoracic spine than the lumbar spine because of the coronal alignment of the facets. The lower lumbar spine is lordotic and has the greatest amount of flexion and extension capabilities due to the sagittal facet joint orientation.[5,6] The human body's center of gravity is anterior to the thoracic and thoracolumbar spine, which places compressive forces on the vertebral bodies and tensile forces on the posterior ligamentous structures in the upright position. The center of gravity is located more posteriorly in the lower lumbar spine, in part due to the greater degree of regional lordosis; the posterior elements, in particular the osseous components, experience significant compressive rather than tensile forces in the upright position.[7–10] The posterior osteoligamentous complex consists of the lamina, facets, facet joint capsules, and interspinous ligaments. These structures are commonly referred to as the posterior ligamentous complex (PLC), reflecting the key role of the ligaments in maintaining spinal stability when there is injury to the vertebral body and intervertebral discs. The lower lumbar spine is inherently stable and somewhat protected from injury due to its lordotic configuration, distribution of compressive forces across the vertebral bodies and posterior elements, and relatively large vertebral bodies. The thoracolumbar junction is the transition zone from the rigid, stable kyphotic thoracic spine to the mobile, lordotic, relatively stable lower lumbar spine. Therefore, it is particularly susceptible to injury.

Mechanisms of Injury

Thoracic and lumbar spinal injury patterns can usually be explained by the application of one or two force vectors. These forces cause relatively consistent injury types that serve as the basis for the main classification schemes, which are described later. The most common primary forces are axial compression, lateral compression, flexion, extension, distraction, shear, and rotation (Fig. 77.1A–E). The most common force combinations are flexion-rotation and flexion-distraction (Fig. 77.1F–G).

Initial Evaluation and Management

Any patient with a known or suspected spine injury should be evaluated in a systematic fashion, starting with assessment of the airway, breathing, and circulation as per standard Acute Trauma Life Support protocol. Spine injury precautions are

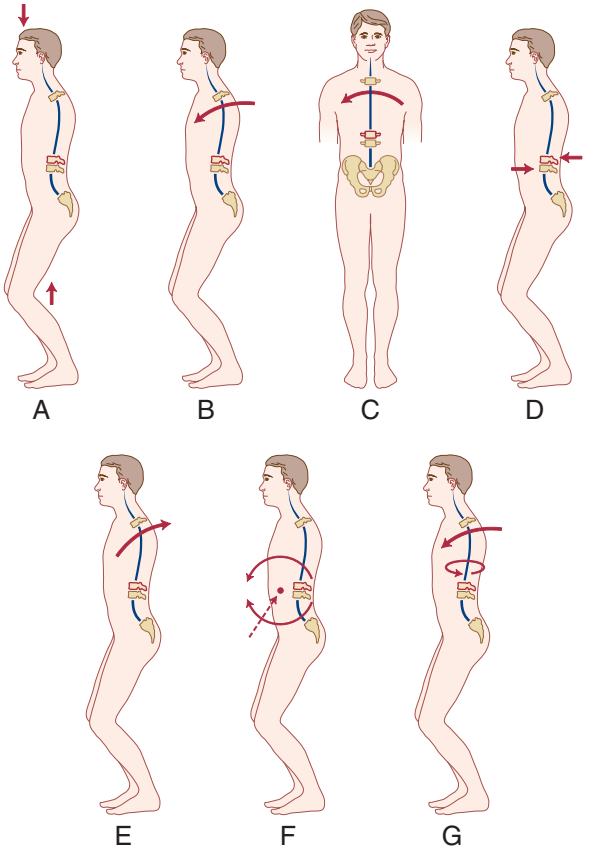

FIG. 77.1 (A) Axial compression forces usually result in compression or burst fractures. (B) Flexion forces may result in compression or burst fractures or, if the force is severe, Chance injuries. (C) Lateral compression forces usually result in lateral wedge fractures, which are asymmetrical compression and burst fractures. (D) Shear forces tend to produce unstable injuries, such as fracture-dislocations. (E) Extension forces usually cause injuries in ankylosed spines, but occasionally may cause injuries in patients with normal spinal anatomy. (F) Flexion-distraction combined forces cause Chance fractures and Chance variant injuries. (G) Flexion-rotation forces cause a variety of fracture patterns involving vertebral body fracture and disruption of the posterior elements. (From Eismont FJ, Garfin SR, Abitbol JJ. Thoracic and upper lumbar spine injuries. In Browner B, Jupiter J, Levine A, et al. [eds]. *Skeletal Trauma: Basic Science, Management, and Reconstruction*. 4th ed. St. Louis: Elsevier; 2009.)

usually instituted in the field by emergency medical personnel and should be continued as long as there is suspicion of spine injury. The patient is maintained in the supine position on a rigid backboard, and the cervical spine is immobilized with a prefabricated collar. The airway is secured, hemodynamic status is addressed, and extremity injuries are splinted. A team of three or more people should roll the patient to the lateral decubitus position, with the lead physician immobilizing the cervical spine and the other two controlling the torso to move the body as a unit to prevent any displacement of the spine injury. The back is then inspected for any signs of trauma such as lacerations, ecchymosis, localized tenderness, swelling, and deformity, such as a step-off between adjacent spinous processes. The patient is then rolled back to the supine position. If additional transfers are necessary for computed tomography (CT) scans or magnetic resonance imaging (MRI) scans, the patient may be left on the backboard until the trauma evaluation is complete. Subsequent spinal immobilization depends on the severity of the spine injury; it may be necessary to place the patient in a rotating bed and institute measures to prevent skin breakdown.

In patients with spinal cord injuries, attention must be made to minimizing the secondary cascade of injury caused by hypoperfusion. Hypotension may occur secondary to hemorrhagic or neurogenic shock. It should be treated aggressively with fluid and blood replacement and vasopressive medication or interventions if necessary.

Associated injuries are common, which can include chest and abdominal injuries, as well as orthopaedic injuries, including pelvis and extremity fractures, head trauma, and contiguous and noncontiguous spine injuries.[11,12] The potential for these injuries must be kept in mind and reassessed periodically, especially in the early stages and in obtunded or severely injured patients who cannot direct attention to their injuries. The initial assessment and subsequent surveys should be systematic and thorough from head to toe, realizing that even in the highest volume and most experienced trauma centers, injuries in the spine and elsewhere sometimes go undetected and can have significant functional consequences.[3,13–15]

The use of pharmacologic agents in spinal cord injury as part of the initial resuscitative protocol has been extensively studied and debated. The rationale is to minimize the harmful secondary cascade of events, such as the inflammatory response and oxidative cell injury that occurs after mechanical injury to the spinal cord. The National Acute Spinal Cord Injury Studies (NASCIS II and III) examined methylprednisolone, naloxone, and tirilazad for this purpose. If administered within 8 hours of injury, there may be improvement in long-term neurologic function with high-dose methylprednisolone. The study dose was a bolus of 30 mg/kg, followed by a 5.4 mg/kg per hour infusion for 23 hours if therapy is initiated within 3 hours of injury or 48 hours if initiated at 3 to 8 hours after injury. There are significant potential complications—such as pneumonia, postoperative wound infection, gastrointestinal bleeding, and sepsis—with the use of steroids.[16–18] Steroids have not been shown to be effective in purely lower motor neuron lesions. GM-1 ganglioside has been studied as well.[19] The use of steroids has not been universally accepted and remains controversial, but can be considered as a treatment option, as can GM-1 ganglioside.[20] There is interest in systemic hypothermia after spinal cord injury, but clinical data are limited.[21]

Initial Neurologic Evaluation

Neurologic injury may have a profound effect on a patient's ultimate function, and the presence or absence of a neurologic deficit often guides subsequent injury management, including operative versus nonoperative treatment. A detailed neurologic examination is therefore critical. It consists of testing both motor and sensory function as well as reflexes in a sequential and systematic manner. Findings should be carefully documented to enable accurate assessment of neurologic

deterioration or recovery. Motor function is assessed in the main muscle groups in the upper and lower extremities, which can sometimes be difficult in an injured extremity, but every attempt should be made under these circumstances. Motor function should be graded on a 0 to 5 scale. A score of 5 is normal, with full range of motion (ROM) against gravity and resistance; 4 is full ROM against gravity and slight resistance; 3 is full ROM against gravity only; 2 is full ROM only with gravity eliminated; 1 is palpable or visible contraction of a muscle without joint motion; and 0 is a muscle without any function. Rectal sphincter tone and volitional control should be tested as well. Sensory function should be assessed in a dermatomal distribution. This should include testing of the perineal region because sparing of the sacral dermatomes may provide an indicator for functional recovery in patients sustaining a spinal cord injury. Temperature, pain, and light touch are spinothalamic tract functions that can be assessed with a sterile needle and an alcohol swab. Vibration and position sense are posterior column functions that can be assessed with a tuning fork and limb or digit positioning. Reflexes include superficial abdominal (stroking of the abdominal skin causes the umbilicus to be drawn toward the stimulated area, above the umbilicus T7–T10, below the umbilicus T11–L1); cremasteric (in males, stroking of the inner thigh causes the scrotum to be drawn upward, T12–L1); patellar tendon (quadriceps reflex or knee jerk, L3–L4); Achilles tendon (ankle jerk, S1); anal wink (anal sphincter contraction with stimulation of the perineal skin, S2–S4); and bulbocavernosus reflex (described later, S2–S4). Pathologic reflexes indicating an upper motor neuron lesion include clonus and an abnormal Babinski test. The Babinski test is normal when a stroke along the lateral plantar aspect of the foot results in down-going toes and is abnormal with up-going toes. Paralysis may be secondary to spinal shock, which is a physiologic disruption of spinal cord–mediated function and is characterized by absence of all motor and sensory function and reflexes below the level of spinal cord injury. It is only after spinal shock has resolved that an accurate neurologic assessment can be made because some patients will have spontaneous recovery of function. Spinal shock resolves within 24 to 48 hours in almost all cases, heralded by the return of spinal cord–mediated reflexes below the level of injury. The bulbocavernosus reflex is the first to return because it is the lowest cord-mediated reflex. Brief traction on the Foley catheter or placing pressure on the clitoris or penis should result in contraction of the anal sphincter around the examiner's gloved finger. When this bulbocavernosus reflex occurs, there is an intact reflex arc, spinal shock is not present, and the degree of neurologic injury can be accurately assessed. If the bulbocavernosus reflex is absent, spinal shock is present and spinal cord injury severity cannot yet be accurately determined.

Spinal shock should not be confused with abolition of the bulbocavernosus reflex with injury at the level of the conus medullaris and cauda equina. These involve injury to the lower motor neurons that are part of the reflex arc; thus, the bulbocavernosus reflex may be permanently extinguished. It is important to recognize that patients in this condition are not in spinal shock.

Neurologic Injury Classification

The most basic delineation of neurologic injury is a complete versus an incomplete lesion. A complete neurologic injury is a total lack of sensory and motor function below the level of injury once spinal shock has resolved. An incomplete neurologic injury means that there is some residual spinal cord and/or nerve root function below the level of injury. Incomplete lesions involving the spinal cord usually manifest in distinct patterns that are a reflection of the specific anatomic region of the spinal cord that is affected and are named accordingly, with one exception (central, anterior, and posterior cord syndromes and Brown-Séquard syndrome). Because the spinal cord typically transitions at the thoracolumbar junction to the lower motor neurons of the cauda equina, these four incomplete injury patterns apply to injuries in the cervical and thoracic spine. Injuries involving the conus medullaris and cauda equina (or lumbosacral nerve roots) may be complete or incomplete, and are usually classified descriptively according to the level of nerve roots involved.

Central cord syndrome usually involves an injury to the cervical spine in older patients. It is characterized by upper extremity weakness, with relative sparing of the lower extremities and sacral nerves. Although this injury pattern usually applies to cervical spine injuries because of the upper extremity involvement, Bohlman described a central cord injury pattern in thoracic spine trauma with a greater degree of muscle weakness in the trunk and proximal muscle groups, with relative sparing of the distal muscle groups and preserved bowel and bladder function.[22] Although central cord syndrome is the most common of the incomplete patterns when considering all spinal cord injuries, it is rare when cervical injuries are excluded and thoracic injuries alone are considered. Anterior cord syndrome is the most common incomplete pattern in thoracic spine injury, characterized by loss of all motor and most sensory function below the level of the lesion, with sparing of the vibratory and position sense via the posterior columns.[22] This has a poor prognosis for recovery and is a debilitating injury pattern. Posterior cord syndrome is rare and involves loss of vibratory and position sense. Patients cannot rely on tactile lower extremity feedback for spatial orientation and must use visual cues when ambulatory. They have preserved bowel and bladder function. Brown-Séquard syndrome is usually a result of cord hemisection by penetrating trauma and is characterized by ipsilateral loss of motor function and contralateral loss of pain, temperature, and light touch sensation. Patients typically have preserved bowel and bladder function, are ambulatory but may require assistive devices, and have the best prognosis for recovery from incomplete spinal cord injury syndromes. The conus medullaris marks the anatomic transition from the upper motor neurons of the spinal cord to the lower motor neurons of the cauda equina, and is usually found at the T12–L1 levels. The conus medullaris injury pattern is characterized by flaccid paralysis, loss of reflexes, and sensory loss of the lower extremities with bowel, bladder, and sexual dysfunction. Injury to the cauda equina below the conus medullaris is a purely lower motor

neuron injury and presents with the same types of findings as with conus medullaris injury, except that there is a higher incidence of asymmetric involvement and can occur at any level below the conus medullaris. These injuries may be complete or incomplete.[23,24]

Radiologic Evaluation

Suspected spine trauma requires radiologic evaluation. The primary goal is to detect a spine injury, with the secondary goal to determine the stability of the injury pattern in order to guide subsequent treatment. The main imaging modalities are conventional radiography, CT, and MRI.

Anteroposterior (AP) and lateral conventional radiographs of the thoracic and lumbar spine are the most basic imaging modalities available. A swimmer's view of the upper thoracic spine may be necessary to visualize the vertebral bodies through the shoulder region. The lateral radiograph is used to examine the height, width, and alignment of the vertebral bodies, pedicles, spinal canal, neural foramina, facets, and spinous processes. The cortical margins of the vertebral bodies should be smooth and contiguous and, when viewed in conjunction with adjacent vertebral bodies, should form a gently arcing line both at the anterior margin (anterior vertebral body line) and posterior margin (posterior vertebral body line). The AP radiograph allows assessment of coronal alignment, interpedicular distance, and alignment of the spinous processes, and best visualizes the ribs and transverse processes. Anterior wedging of the vertebral body with a break in the anterior cortical margin signifies a compression fracture. Loss of posterior vertebral body height, a break in the posterior vertebral body cortical margin, spinal canal narrowing, and widening of the interpedicular distance signifies a burst fracture.[25] The posterior vertebral body angle can also be used to distinguish subtle burst fractures from compression fractures.[26] Facet widening; spinous process splaying or malalignment; fracture lines in the pedicle, lamina, facets, and spinous processes; and vertebral body translation signify injury to the posterior elements, including possible ligamentous injury, and are radiographic markers of potential instability.[27] Conventional radiography of the thoracolumbar spine has technical, logistical, and diagnostic limitations; therefore, CT has become a key modality in evaluating thoracolumbar trauma.

Many trauma centers now use screening spiral CT of the chest, abdomen, and pelvis as part of the standard trauma evaluation. These images include collateral thoracic and lumbar spine information. As a result, some centers are adopting CT protocols as the initial screening radiologic modality for spine trauma.[28–30] Studies have shown that CT scans have a higher sensitivity than conventional radiographs in the detection of thoracic and lumbar spine fractures, although this applies mainly to stable rather than unstable fractures.[31–33] CT is better than conventional radiography at discerning compression fractures from burst fractures; misdiagnosis may occur in up to 25% of injuries when relying on conventional radiography alone.[34–36] Screening CT scans may decrease the incidence of missed, delayed, or incorrect diagnoses of thoracic and lumbar trauma, especially in obtunded and multiply injured patients, but the clinical significance of this has not been determined. Thus, it is not standard in all trauma centers to obtain screening CT scans. The typical protocol for a trauma-screening CT scan consists of sequential 5-mm axial images with or without reconstructions, whereas a dedicated spine CT protocol consists of 2- to 3-mm axial images with sagittal and coronal reconstructions. It may be necessary to obtain a dedicated spine protocol CT scan if it seems that some important detail may not have been imaged during the screening examination. If the thoracic or lumbar spine injury is initially diagnosed on conventional radiographs alone and a high-energy mechanism is known or suspected, a dedicated spine protocol CT scan should be considered. The main limitation of CT is the limited ability to visualize the soft tissues, for which an MRI scan may be useful.

MRI allows for high-resolution imaging of soft tissues, making it particularly important in the evaluation of spinal cord injury because the neural elements can be visualized. This helps to delineate the presence of edema, hemorrhage, hematoma, compression, and transection of the neural elements. MRI findings may contribute to the understanding of injury severity, including the potential for spinal instability and the need for surgical intervention, and may be useful for predicting the potential for neurologic recovery.[37] Hemorrhage within the spinal cord and edema extending over multiple cord levels are correlated with poor prognosis for neurologic recovery.[38–40] The posterior ligamentous structures can be reliably evaluated with MRI.[41–44] Unless contraindicated, MRI should be considered in all cases with neurologic injury and in cases for which further evaluation of the PLC is necessary in deciding between operative versus nonoperative treatment. The main limitations for MRI are logistics, cost, and the inferior visualization of the bony elements; thus, MRI is usually complementary to CT rather than a substitute.

Concept of Spinal Stability and Its Role in Fracture Classification Systems

Spinal mechanical stability refers to the structural integrity of the spinal column. In its simplest form, it is the ability to resist physiologic loads without progressive deformity or damage to the neural elements.[45] Spinal neurologic stability refers to the presence or absence of a neurologic deficit. The concept of mechanical stability serves as the basis for the main recognized fracture classifications; more recently, attempts have been made to incorporate neurologic stability into the classification schema. Classification systems are potentially useful for communication, research, determining prognosis, and guiding treatment. With respect to thoracic and lumbar spine injuries, certain fracture patterns and associated injury mechanisms have been recognized. As a result, terminology has evolved to form a core group of specific injuries with relatively consistent nomenclature, even though there is not a universally accepted classification system. The majority of fractures can be grouped into these main well-recognized categories, but some injuries are of a mixed pattern and are not readily classifiable. The

underlying theme of modern classification systems is to determine whether or not an injury is mechanically stable; the lack of universal acceptance of one classification system reflects the great difficulty in assessing stability in some cases. As the injury severity increases, so does the degree of instability. This occurs along a continuum, however; thus, it is not always possible to determine the point where the transition from a stable injury to an unstable injury occurs. Despite intense work in this area, assessment of mechanical stability remains a judgment call at times. This mainly explains the disparity in treatment approach for certain injuries (especially burst fractures) from one surgeon to the next.

Fracture Classification Systems

Classifications have evolved since their introduction in the mid-twentieth century. Descriptions of thoracic and lumbar injuries first appeared in print publications in the mid-1900s.[46–48] Nicoll[49] credited these early authors and classified injuries as anterior wedge fractures, lateral wedge fractures, fracture-dislocations, and isolated neural arch fractures in 1949. Holdsworth[50] expanded on this classification and detailed the traumatic forces causing distinct fracture patterns, described as flexion, flexion and rotation, extension, and compression. He conceptualized the two-column theory of spinal stability, with the anterior column resisting compressive loads and the posterior ligamentous complex resisting tensile forces. Wedge compression and compression burst fractures were considered stable due to preservation of PLC integrity, whereas dislocations, extension fractures and dislocations, and rotational fracture-dislocations were considered unstable. Kelly and Whitesides[51] built on Holdsworth's work and formally presented the two-column theory as a conceptualization of spinal stability as it relates to spine trauma. These classification systems did not incorporate the extent of neurologic injury; other authors focused on this aspect of the injury.[52,53] The application of CT to spine imaging marked a major change in the understanding of the various fracture patterns, contributing to the evolution of the modern classification systems. Denis[54] analyzed 412 thoracic and lumbar spine injuries with CT scans, classifying major injuries as compression fractures, burst fractures, flexion-distraction injuries, and fracture-dislocations (Figs. 77.2 to 77.5). He proposed a three-column theory of spinal stability and delineated the concepts of mechanical instability and neurologic instability. In this scheme, the anterior column is composed of the anterior longitudinal ligament (ALL), anterior anulus, and the anterior portion of the vertebral body. The middle column is composed of the posterior vertebral body, posterior anulus, and posterior longitudinal ligament. The posterior column is composed of the ligamentum flavum, neural arch, facet joints and facet capsules, and the PLC. Mechanical instability begins to occur with failure of two of the three columns.[54,55] The three-column theory was later validated with biomechanical cadaver studies.[56] Injuries with neurologic deficit were deemed by Denis to have neurologic instability. Neurologic instability was felt to be an important concept because injuries severe enough to cause neurologic injury are usually also mechanically unstable. Subsequent classification systems and current treatment algorithms are based on the perceived mechanical stability of the injured spine and the presence or absence of neurologic injury. Mechanical stability is a continuum—great controversy exists in determining at what point a "stable" injury becomes "unstable." This controversy is most evident with burst fractures.

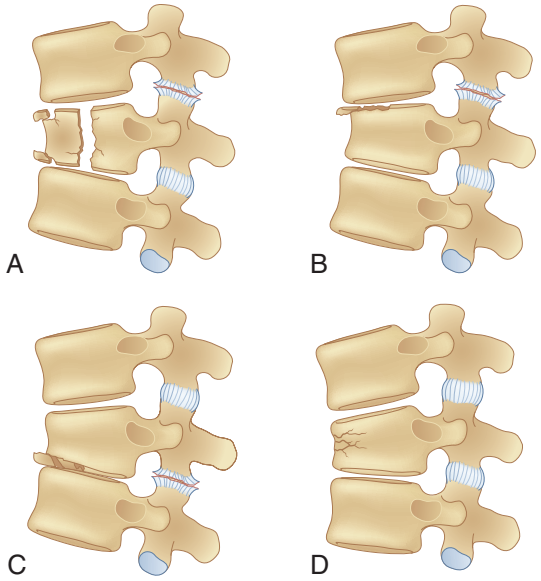

FIG. 77.2 Denis classification of thoracolumbar compression fractures. These injuries may involve (A) both endplates, (B) the superior endplate only, (C) the inferior endplate only, or (D) a buckling of the anterior cortex, with both endplates intact.

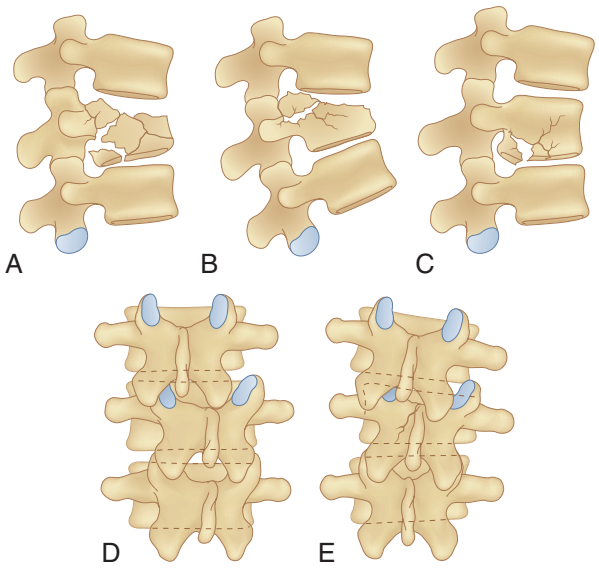

FIG. 77.3 Denis classification of thoracolumbar burst fractures. The fracture may involve (A) both endplates, (B) the superior endplate only, or (C) the inferior endplate only. (D) A combination of a burst fracture with rotational forces, with vertebral body translation best appreciated in the coronal plane. (E) An eccentrically loaded fracture, also best appreciated in the coronal plane.

McAfee described a classification based on analysis of the CT scan appearance of 100 fractures. Six basic injury patterns

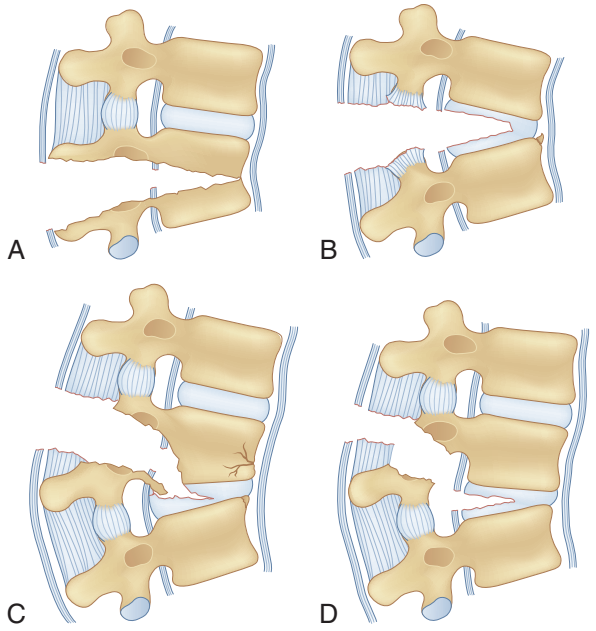

FIG. 77.4 Denis classification of flexion-distraction injuries. These may occur (A) at one level through bone; (B) at one level through ligaments and disc; (C) at two levels, with the middle column injured through bone; or (D) at two levels, with the middle column injured through disc.

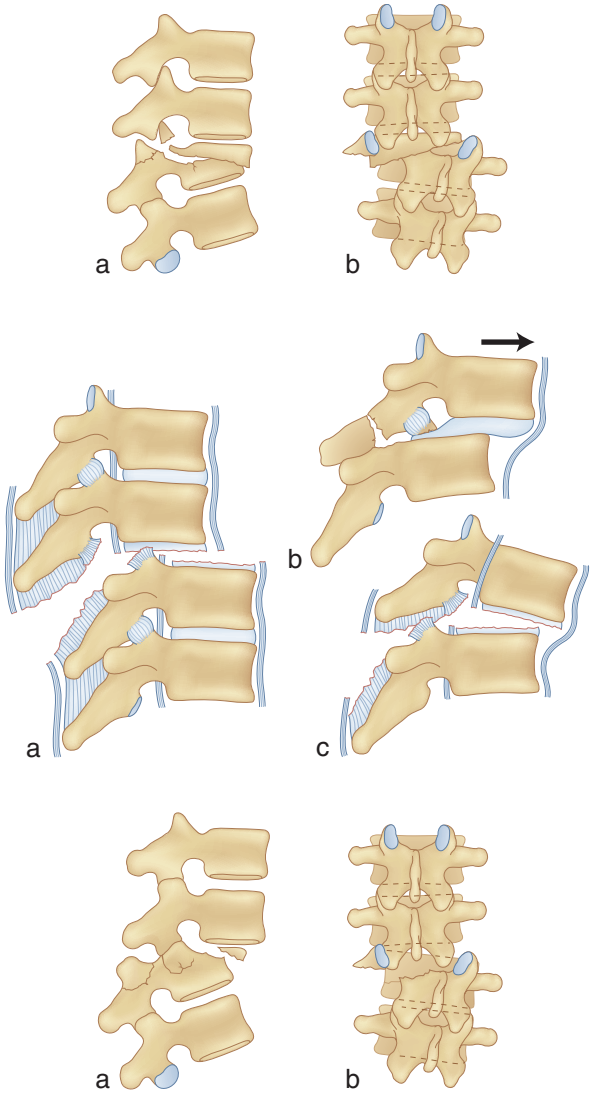

FIG. 77.5 Denis classification of fracture-dislocations. These may occur at one level through bone (*top,* a–b); at one level through ligaments and disc (*middle,* a–c); or at two levels, with the middle column injured through the bone or through the disc (*bottom,* a–b).

were proposed: wedge-compression, stable burst, unstable burst, Chance, flexion-distraction, and translational.[57,58] Ferguson and Allen[59,60] combined the three-column theory with the forces causing the injury and proposed a mechanistic classification. Fracture types included compressive flexion, distractive flexion, lateral flexion, translational, torsional flexion, vertical compression, distractive extension, and isolated transverse process fractures. The Arbeitsgemeinschaft für Osteosynthesefragen (AO) system was an attempt at comprehensively classifying spine injuries. Three main injury types were recognized: vertebral body compression, anterior and posterior element injury with distraction, and anterior and posterior element injury with rotation. Multiple subtypes exist within each group.[61,62] Most recently, the Spine Trauma Study Group has integrated key concepts of these various classification systems to create a more simple and reproducible schema. Neurologic status is included in the classification, with the goal of generating a more standardized thoracic and lumbar spine injury treatment approach. The Thoracolumbar Injury Classification and Severity Score (TLICSS) is based on three categories: injury morphology, integrity of the PLC, and neurologic status. Injuries are analyzed and point values assigned to subgroups within each category. More severe injuries receive higher injury scores; therefore, treatment theoretically may be guided by calculating the injury score.[63–67]

Description and Diagnosis of Specific Fracture Types

There is no universally accepted classification system, but these design efforts over the years have resulted in the development of relatively consistent terminology used in the literature and among spine surgeons to describe the main fracture types. The pathoanatomy and diagnosis of these injury types are described in this section, with treatment described in the following sections.

Sprains

Injuries to the spinal column involving the ligaments and musculotendinous units that do not cause facet joint subluxation, fracture, or listhesis are considered sprains and are stable.[68] This tends to be a diagnosis of exclusion based on the history, physical examination, and imaging studies. With a reliable history, mild physical examination findings, and otherwise normal spine anatomy, plain radiographs may be sufficient to rule out spinal instability and diagnose a sprain. If there

is a high-energy mechanism, unreliable history, significant physical examination findings (such as obvious swelling or neurologic injury), or abnormal anatomy (such as with ankylosing spondylitis or congenital anomaly), advanced imaging studies are warranted. CT followed by MRI are often necessary under these circumstances to diagnose a sprain rather than a more significant injury.

Disc Herniations

Traumatic disc herniations caused by high-energy mechanisms are relatively rare as an isolated injury. Fractures are often associated with disc disruption, and the displaced disc material may contribute to neurologic injury. The category of injury described here, however, refers to an otherwise intact spinal column in association with a disc herniation that appears to be traumatic on the basis of the patient's history, symptoms, and physical examination combined with correlating imaging studies. Disc herniations are commonly associated with minor trauma such as that which occurs with lifting a heavy object, but the disc herniations considered here are due to high-energy trauma such as motor vehicle accidents that also caused or had the potential to cause other significant injuries. Diagnosis is made with MRI. There may be other imaging or clinical evidence of injury to the spinal column, such as a soft tissue injury that would otherwise be called a sprain. However, in order to be considered an isolated disc injury, there must not be any facet subluxation or traumatic listhesis. The classification scheme is anatomically descriptive and identical to that used in atraumatic disc herniations: bulging, protruded, extruded, or sequestered.[69,70] It may be difficult to definitively establish a disc herniation as traumatic rather than preexisting because disc herniations are common in the asymptomatic population and it is a rare luxury to have the availability of preinjury magnetic resonance images. From a clinical perspective, it is not so important to establish a disc herniation as traumatic or preexisting because management of the disc herniation depends primarily on the presence or absence of neurologic symptoms (radicular pain), the physical examination findings (sensory and motor deficits), and the apparent temporal sequence in which these signs and symptoms developed. The spinal column itself is usually stable, with isolated disc injuries.

Minor Fractures

Transverse process fractures and spinous process fractures usually represent an avulsion injury due to indirect trauma, but they are also caused by direct trauma and can occur as a single fracture or as multiple fractures. Transverse process fractures are best visualized on AP radiographs; spinous process fractures are more readily detected on lateral radiographs, though CT will show these fractures clearly. Isolated pars fractures, lamina fractures, and articular process fractures can also be considered minor injuries and are best detected by CT. These fractures are stable provided that they are not associated with significant ligamentous injury. This can be demonstrated by maintenance of spinal alignment on upright radiographs once the patient has mobilized. L5 transverse process fractures may be associated with vertical-shear sacral fractures; CT images should extend through the pelvis when an L5 transverse process fracture is detected.

Compression Fractures

Compression fractures result from axial compression through the vertebral body, with failure through the anterior column. The fracture may involve the superior or inferior endplate alone, both endplates, or buckling of the anterior cortex with endplate preservation. The posterior column is usually not involved, but occasionally is. When this is the case, what appears to be a compression fracture may be a more significant flexion-distraction injury, described later as a Chance fracture (Fig. 77.6). The main distinguishing feature of the compression fracture is predominant failure of the anterior column in compression, whereas the flexion-distraction injury is characterized by predominant failure of the posterior column in tension. Plain radiographs are usually diagnostic, but CT scans may be necessary to confirm the diagnosis because extension into the middle column may be subtle and burst fractures may be misdiagnosed as compression fractures 25% of the time on the basis of plain radiographs alone.[36]

Burst Fractures

Burst fractures, like compression fractures, are caused by axial compression through the vertebral body. The fracture may involve the superior or inferior endplate alone, both endplates, or rarely with preservation of the endplates. Lateral compression forces may cause an injury variant that is asymmetrical in the coronal plane. The posterior column may or may not be involved, though more frequently it is involved when compared with compression fractures. In more severe injuries, the distinction between a burst fracture and a compression fracture is clear, with retropulsion of the fractured middle column fragments into the spinal canal being the hallmark of a burst fracture. In less severe injuries, the distinction between compression and burst fractures is less clear and practically speaking may be in nomenclature alone, such as when the middle column fracture is minimally displaced and barely extends into the posterior cortex and there is minimal retropulsion of the middle column fragments (Fig. 77.7). The generally accepted differentiation between compression and burst fractures occurs at the middle column, which is spared in compression fractures and involved with burst fractures. Practically speaking, the transition from compression fracture to burst fracture represents a continuum of injury rather than distinct injury patterns because the same force vector is responsible. Plain radiographs are often diagnostic, but CT scans are usually necessary to distinguish compression fractures from subtle burst fractures.[36] For classification and descriptive purposes, if CT confirms that the fracture extends into the posterior cortex of the vertebral body, regardless of the degree of displacement, it is referred to as a *burst fracture.*

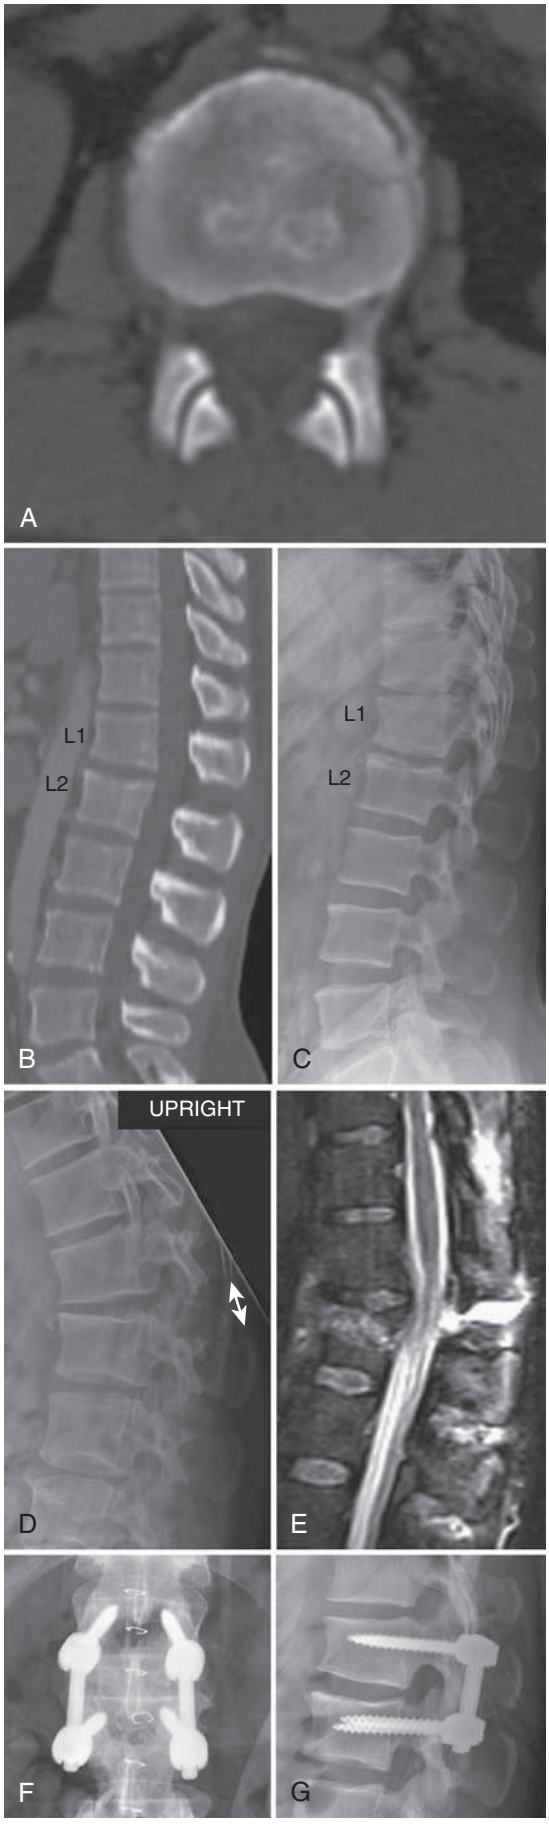

FIG. 77.6 Unstable ligamentous Chance injury variant masquerading as a compression fracture. (A–B) Computed tomography cuts and (C) a lateral radiograph showing what appears to be a compression fracture. There is subtle splaying of the spinous processes of L1 with respect to L2 in (B), but minimal focal kyphosis and L2 height loss. (D) Upright radiograph in a brace shows an obvious increased distance between the spinous processes of L1 and L2 with focal kyphosis. (E) Subsequent magnetic resonance imaging demonstrates the ligamentous injury through L1–L2 posteriorly. (F–G) The deformity was reduced, and the posterior tension band was restored with short-segment posterior instrumented fusion.

Flexion-Distraction Injuries (Chance Fractures and Chance Variants)

Flexion-distraction injuries are characterized by primary distractive forces on the spine, rather than crushing forces as seen with compression and burst fractures. These distractive forces cause tension failure of the PLC and associated injuries to the anterior and middle column, either involving the disc or vertebral body. The axis of rotation is within or just in front of the anterior column, and at times the height of the anterior column can be relatively well maintained. The injury may be entirely osseous or entirely discoligamentous, or a combination of osseous and ligamentous (Fig. 77.8). Chance described the purely osseous lesion as a horizontal fracture extending through the spinous process, through the lamina and pedicles, and into the vertebral body.[57] These injuries are commonly referred to as *Chance fractures.* Variants of this injury involve disc and ligamentous disruption with or without fracture. Anterior column disruption occurs through the disc space, not the vertebral body, and posterior column disruption is manifested as facet dislocation and ligamentous rupture, rather than fracture through the pedicle. These discoligamentous injuries are commonly referred to as *Chance variants.* If the axis of rotation is anterior to the spine, the vertebral body may be completely intact without fracture; if such an injury is severe, all the spine ligaments including the ALL may be disrupted, resulting in a severely unstable injury. If the axis of rotation is within the anterior column, there may be a vertebral body fracture with radiographic findings consistent with a compression or burst fracture If attention is not paid to the posterior elements and the distractive nature of the injury is not appreciated, underdiagnosis as a compression or burst fracture may occur.

The diagnosis of a flexion-distraction injury may be made with plain radiographs, but CT is helpful in defining the precise anatomy of the osseous injury and identifies minimally displaced and nondisplaced injuries. Facet dislocations have a characteristic appearance on axial CT images, known as the "naked facet" or "empty facet" sign.[71] This was first described in Chance variant injuries but is probably seen more commonly with fracture-dislocations.[72] MRI is particularly good at detailing the extent of ligament and disc involvement with Chance fractures and Chance variants.

Fracture-Dislocations

Fracture-dislocations may be caused by a variety of mechanisms, including shear, rotation, distraction, flexion, and

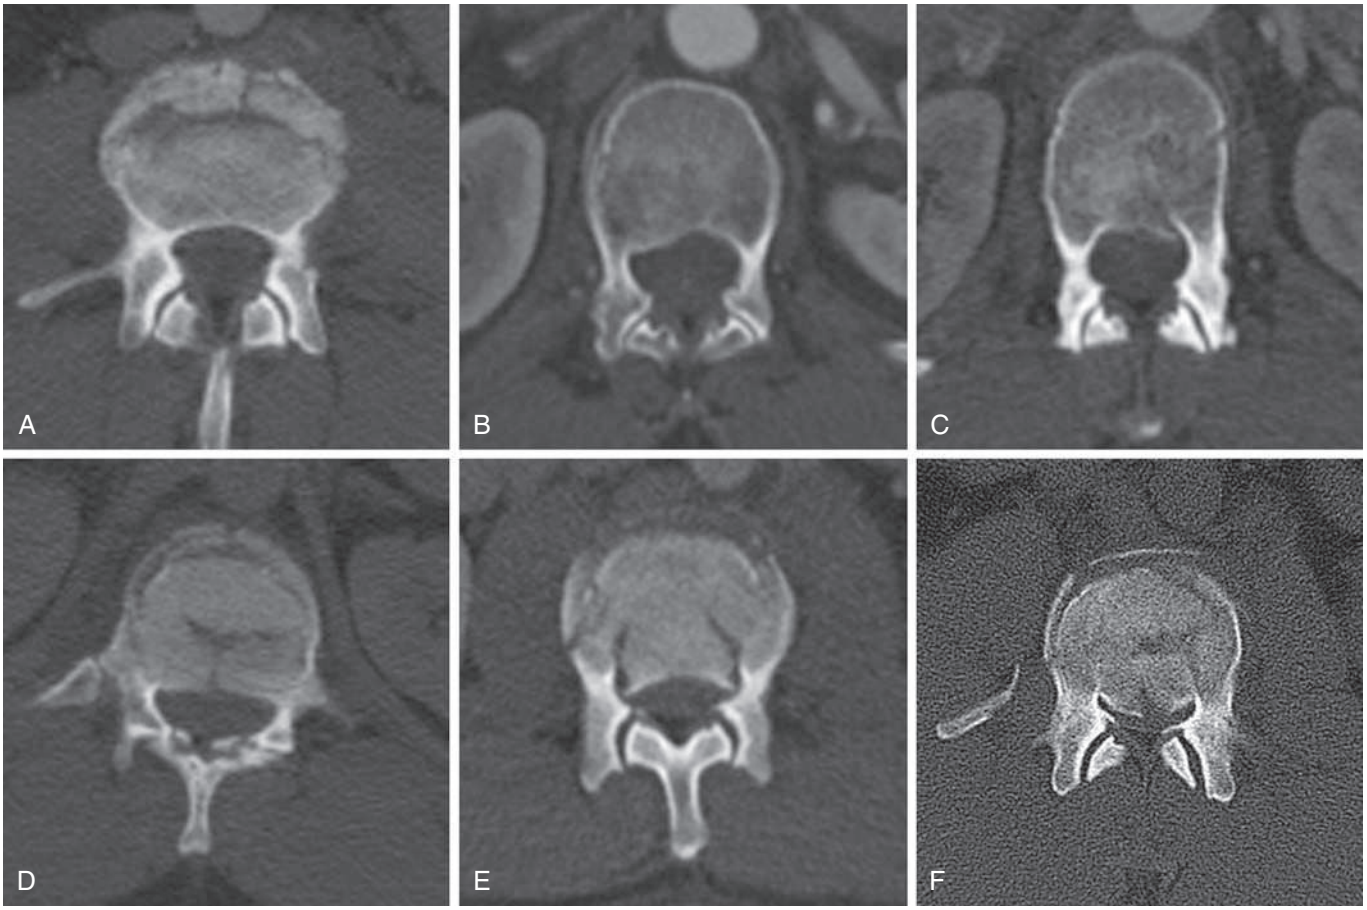

FIG. 77.7 Axial compression injury continuum. These axial computed tomography images show increasing injury severity and the transition from compression fracture to mild burst fracture to severe burst fracture. (A) A compression fracture, with maintained integrity of the posterior wall of the vertebral body. (B–F) Burst fractures. (B) Minimal retropulsion of one side of the posterior vertebral body is seen. (C–F) Increasing retropulsion is apparent, with almost complete obliteration of the spinal canal (F).

extension. Often, the injury mechanism involves a combination of these force vectors; thus, it is difficult—if not impossible—to discern the precise nature of the injury. The unifying theme with this fracture pattern is a high degree of spinal instability. All three spinal columns are disrupted via some combination of fracture, disc disruption, and ligamentous injury. The hallmark is unilateral or bilateral facet disruption due to fracture, subluxation, or dislocation, with anterior, posterior, or lateral translation of the cephalad vertebral body on the adjacent caudal vertebral body. When facet dislocation and vertebral body listhesis are present, this diagnosis may be readily apparent. Sometimes, there has been spontaneous reduction of the listhesis and the main clue to the extent of the injury is subtle facet subluxation. This type of injury is particularly dangerous in a neurologically intact patient because the degree of instability may be overlooked and neurologic deterioration may occur during routine patient care. Any time there is subluxation of one facet or both facets and/or vertebral body translation, this diagnosis must be strongly considered.

Diagnosis can often be made on plain radiographs. The AP view may show lateral translation, whereas the lateral view may show anterior or posterior translation. CT scans will better quantify the bony injury and often demonstrate the "naked facet" or "empty facet" sign (Fig. 77.9).[71,72] MRI should also be performed to assess the degree of disc and ligament injury and to visualize the neural elements.

Extension and Extension-Distraction Injuries

Injuries caused by an extension mechanism are relatively rare and are most commonly seen in patients with an ankylosed spine such as ankylosing spondylitis (AS) or diffuse idiopathic skeletal hyperostosis (DISH). The ankylosed spine is immobile and often demonstrates a kyphotic deformity. The discs and ligaments are ossified; thus, the spine acts as a single contiguous segment. Fractures do not follow typical patterns and come to resemble long-bone fractures more than vertebral fractures (Fig. 77.10). These fractures are usually unstable. Extension injuries can also occur in the otherwise normal spine.

Conventional radiography provides the first clue to the diagnosis, not necessarily because the fracture is readily identified, but because AS and DISH should be readily apparent. If there is displacement, the cephalad segment may be

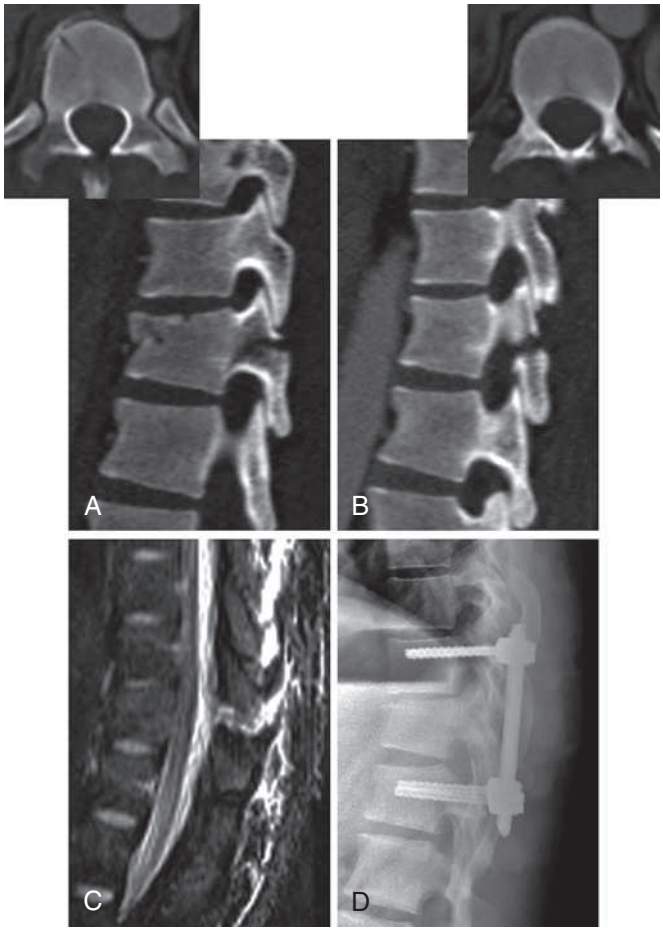

FIG. 77.8 Chance fracture. (A–B) Axial and sagittal computed tomography images of a fracture involving the vertebral body extending through the right pedicle and the left pars interarticularis. (C) Magnetic resonance image showing the increased signal intensity through the posterior ligaments of the involved level. (D) The fracture was stabilized with posterior pedicle screws.

located posterior to the caudal segment due to the extension nature of the injury. Fractures in the AS and DISH population must be treated with caution because of the high degree of instability associated with these injuries, even if there is minimal displacement and the plain radiographs appear relatively innocuous. Therefore, any patient who presents with trauma and the potential for spine injury with evidence of AS or DISH on conventional radiographs must be treated with a high index of suspicion and CT scans must be obtained. CT scans will identify and characterize the injury. Because the discs and ligaments are ossified and this injury is purely osseous in nature, MRI is used primarily to visualize the neural elements. It is also useful for detecting epidural hematomas, which occur more frequently in this group of patients.

In those circumstances in which an extension injury is evident radiographically but AS or DISH is not present and the spine is otherwise normal, MRI is helpful to characterize the disc and ligamentous injury. These injuries are typically due to an extension-distraction mechanism and are rare, identified by gapping in the anterior and middle spinal columns rather than the more typical gapping in the posterior column seen in flexion and axial-load type injuries.[73] The facets may be dislocated with the axial CT images, demonstrating the "naked facet" sign.[72]

Penetrating Injuries

Gunshot injuries to the spine are the most common form of penetrating injury. These injuries are almost always inherently stable. Radiographs and CT scans are usually sufficient to characterize the injury. The use of MRI when the bullet is in the spinal canal is controversial because of the potential risk of neurologic deterioration if the bullet migrates due to the pull of the MRI magnet. Bullet migration has been reported, but appears to be quite rare.[74–77]

General Treatment Principles: Operative and Nonoperative

The decision to treat a fracture surgically with internal fixation with or without neural element decompression, or nonsurgically with a brace, depends on several factors. Indications for surgery are clear in some cases but controversial in others and include spinal mechanical instability, neurologic deficit, significant spinal deformity, and multiple injuries complicating the ability to brace.

A nonoperative treatment option that is less commonly considered in the era of modern spinal fixation systems is prolonged bed rest.[52,78,79] This is a consideration in the setting of a spinal injury that is too mechanically unstable to treat with a brace, but surgery is contraindicated or refused by the patient. This approach is most likely to be successful when the injury is primarily bony in nature and is not associated with significant deformity. However, prolonged bed rest is often associated with complications such as deep vein thrombosis (DVT), pulmonary embolism, pneumonia, and decubitus ulcers. Because this treatment approach is so rarely employed and is usually a result of necessity rather than surgeon preference, the discussion hereafter centers on bracing principles and surgical principles.

Bracing Principles

Fractures that are mechanically stable in neurologically intact patients without significant spinal deformity can usually be treated successfully by bracing. Bracing helps stabilize the spine by providing relative immobilization above and below the level of injury. For upper lumbar and mid-to-low thoracic injuries, a standard thoracolumbar orthosis is appropriate. This may consist of a Jewett-type hyperextension brace for sagittal-plane injuries or a custom-molded, total-contact brace for injuries with coronal or rotational components. Lower lumbar injuries are more difficult to immobilize because the lumbosacral junction must be incorporated in the brace in order to stabilize the spinal segment below the level of injury. Options include a thoracolumbosacral orthosis, possibly with incorporation of one of the thighs to maximize stability in fractures below L3. Similarly, fractures above T6 usually require a cervicothoracic

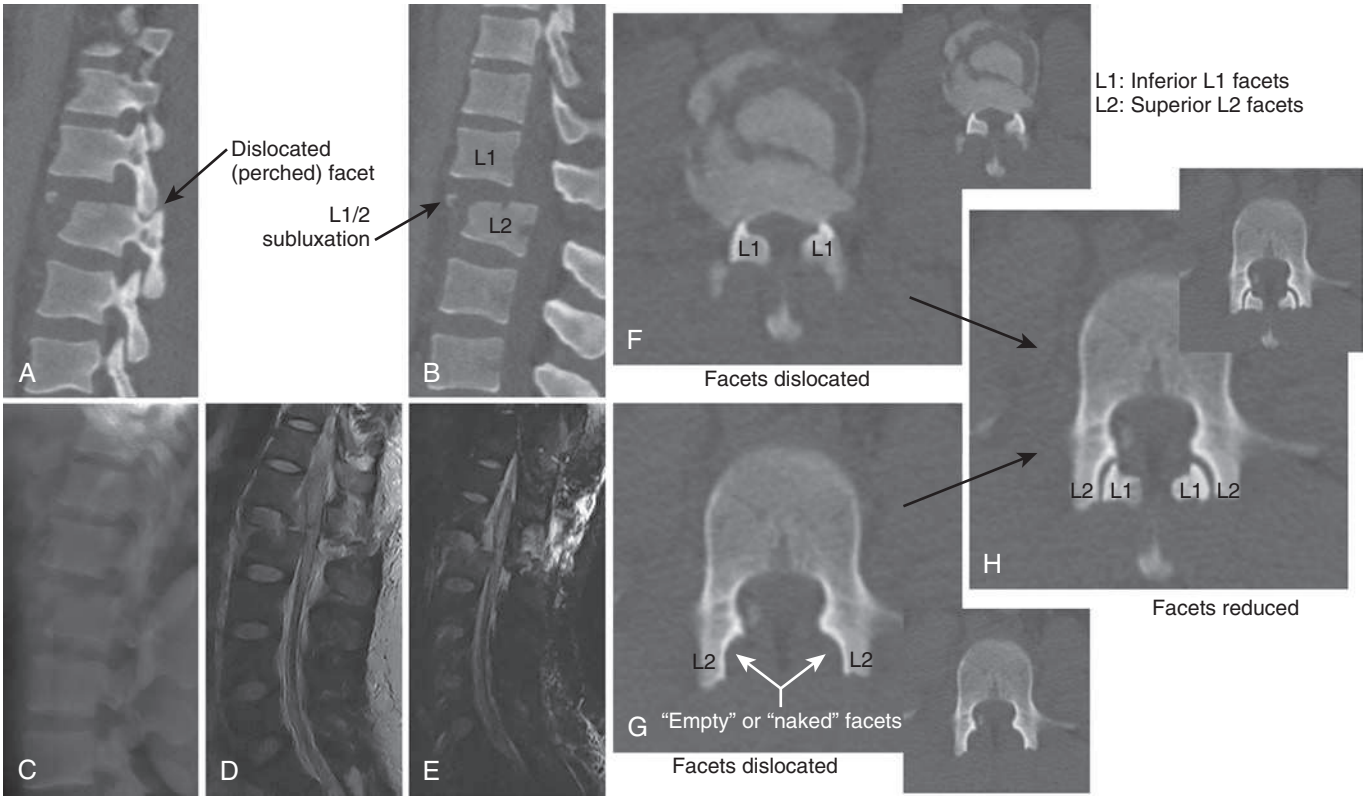

FIG. 77.9 Fracture-dislocation. (A–B) Sagittal computed tomography (CT) images showing listhesis of L1 on L2, with dislocation of the facets. (C) Lateral radiograph showing the listhesis of L1 on L2. (D–E) Sagittal magnetic resonance images (T2-weighted and short tau inversion recovery [STIR], respectively) clearly demonstrate the injury, including the involvement of the posterior ligamentous complex, which is particularly evident on the STIR images. (F–G) Axial CT images showing the dislocated facets, which are shown in their reduced anatomic position (H). (G) "Empty facet" or "naked facet" sign.

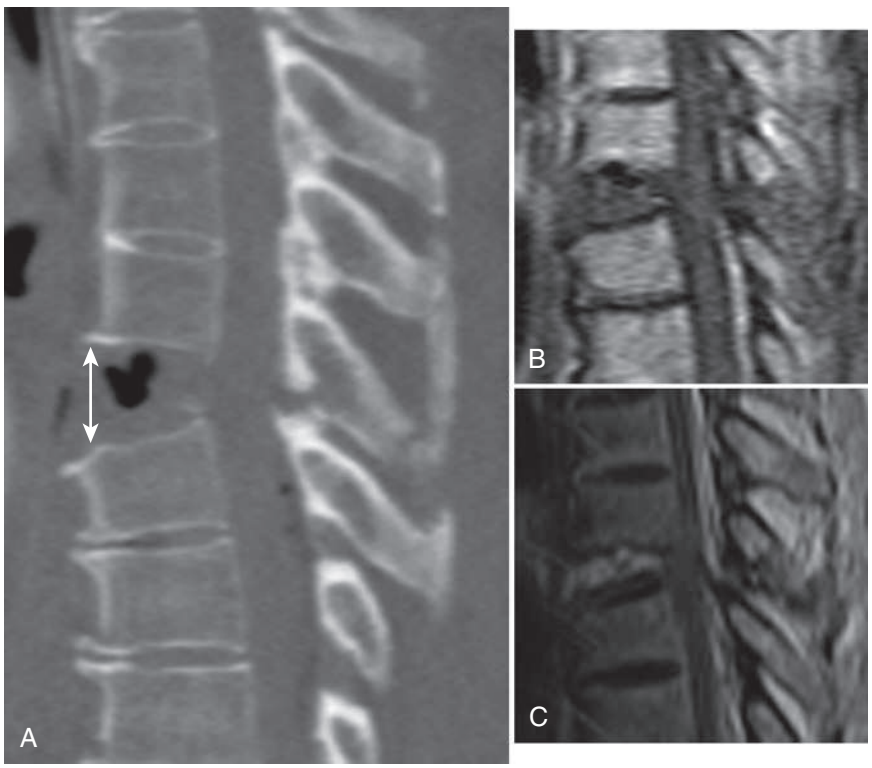

FIG. 77.10 Extension-distraction injury. (A) Sagittal computed tomography image showing an ankylosed spine with distraction across adjacent vertebral bodies (*white arrow*). (B) Sagittal T1-weighted magnetic resonance image through the level of injury. (C) Sagittal T2-weighted magnetic resonance image through the level of injury.

orthosis in order to control the spinal segment above the level of injury. Regardless of the level and type of injury, once the brace is fit, upright radiographs should be obtained to make sure the fracture is stable in the brace.

The brace is worn whenever the patient is out of bed, and the patient should not perform any activities that involve bending or twisting through the spine or lifting more than 10 pounds. This may be a relatively conservative regimen and under certain circumstances may be modified, but only with caution. The typical brace duration is approximately 3 months, perhaps somewhat shorter with mild compression fractures and up to 4 to 6 months for three-column burst fractures. Typically, the patient is evaluated in the brace in the clinic 2 weeks and 6 weeks after injury with upright radiographs, to make sure that the brace is being properly worn and the fracture remains stable. After the second visit, subsequent clinic visits are made at 6- to 8-week intervals. Brace weaning is initiated once there is clinical and radiographic evidence of fracture healing. Once the brace is discontinued, flexion and extension radiographs are obtained. Provided that these show no evidence of instability, the patient can slowly start to resume the usual activities once pain-free motion and strength have been restored.

Surgical Principles

Injuries that are not believed to be amenable to bracing should be treated surgically. The goals of surgery are to achieve and maintain anatomic reduction, minimize construct length while providing sufficient stability to allow for early mobilization, achieve neural element decompression when indicated, avoid complications, and proceed within the most appropriate time frame.

Surgical Principle Number 1: Achieving and Maintaining Anatomic Reduction and Stability—Surgical Approach and Instrumentation Choice

In order to achieve and maintain anatomic reduction, the forces that caused the injury must be counteracted by the instrumentation construct, which should be robust enough to withstand physiologic loads until the injury heals. Posterior pedicle screw and rod constructs are more rigid than anterior constructs, thus have become the mainstay of spinal instrumentation in thoracic and lumbar trauma.[80] The posterior approach is quite versatile, allowing for powerful reduction techniques. However, the anterior spine performs the majority of the axial load bearing, which must be taken into consideration. Anterior approaches are primarily used for neural element decompression and structural restoration of the anterior column. The integrity of the anterior column may be restored by performing a corpectomy of a highly comminuted vertebral body fracture followed by reconstruction with structural bone grafting or a structural device, such as a titanium cage.[81] Anterior internal fixation devices may provide additional stability and may obviate the need for additional posterior instrumentation. This requires further exposure to place the internal fixation device in the intact vertebral bodies above and below the fractured level, which may be difficult and risky anteriorly, especially in the lower lumbar spine and at the thoracolumbar junction.[82–85] In cases in which an anterior approach is performed as the primary component of the fracture treatment, consideration may be given to supplementing the anterior construct with posterior pedicle screw instrumentation. This is especially true if the PLC is disrupted because the combined construct is stronger than either construct alone and more reliably handles the load demands of early mobilization.[86]

Surgical Principle Number 2: Decompression

Neural element decompression is generally reserved for patients with neurologic deficits, irrespective of the degree of spinal canal compromise. Neurologically intact patients with significant canal compromise of 50% or more do not benefit from decompression. It has been shown that resorption of retropulsed bone occurs naturally, and late spinal stenosis has not been shown to be a problem provided that there is maintenance of spinal alignment.[87–90] Patients with neurologic deficit may benefit from decompression, either indirectly or directly. Indirect decompression is best achieved within the first 48 hours after injury and relies on ligamentotaxis to reduce retropulsed fragments as the fracture is reduced and spinal alignment restored.[91–94] Direct decompression may be performed anteriorly or posteriorly. Posterior decompression via laminectomy is useful when a piece of fractured lamina or infolded ligamentum flavum is protruding into the canal or a single nerve root requires decompression. Retropulsed vertebral body fragments in the spinal canal cause most neurologic deficits; these require a direct decompression. Because the compression is anterior to the thecal sac, an anterior approach is the most direct method to effect the decompression. In some instances, the decompression may be achieved via a posterolateral transpedicular approach, especially in the lumbar spine at the nerve root level, where the dural tube may be retracted more safely than at cord level.[95] The offending bone fragments are identified and either removed or tamped anteriorly. Posterior pedicle screw instrumentation is then performed to achieve stability.

Surgical Principle Number 3: Minimization of Construct Length

Minimization of construct length is more important in the mobile lumbar spine than the thoracic spine. Classically, long-segment constructs consisted of instrumentation 2 or 3 levels above and below the injured level.[96,97] With the advent of modern pedicle screw systems, constructs now typically include one or two levels above and below the injured level, provided that the bone quality is normal. The addition of sublaminar hooks at the same level as the terminal screws may improve the biomechanical performance of the construct while minimizing the construct length.[98–100] Short-segment fixation is the term used to describe a construct limited to one level above and below the injury. Initial reports with this technique were disappointing due to relatively high rates of instrumentation

failure and loss of reduction.[101–104] As techniques, implants, and indications have been refined, short-segment fixation may be used with a similar success rate as long-segment fixation in certain injury patterns, which maintains as much native spinal motion as possible.[105,106] Placement of screws in the injured level when technically possible may provide enough additional rigidity to allow for short-segment fixation in cases that would have been traditionally treated with long-segment fixation.[107–109] The surgeon may choose to support the instrumentation construct with an orthosis depending on individual patient factors such as screw purchase and patient compliance.

Surgical Principle Number 4: Appropriate Surgical Timing

The optimal timing for surgical decompression and stabilization in patients with neurologic injury is not well established.[110–112] The potential benefit of early decompression must be weighed against other factors, such as medical optimization, management of coexisting injuries, and operating room conditions, such as availability of neurophysiologic monitoring and the appropriate anesthesia team and operating room personnel. Those patients with a progressive neurologic deficit should certainly be taken to surgery as quickly as possible.

Surgical Principle Number 5: Avoidance of Complications

The main complications associated with surgery include dural tear, iatrogenic neural injury, pseudarthrosis, failure of fixation, iatrogenic flat back, infection, and medical complications. Burst fractures with associated lamina fractures have a high incidence of dural tear, especially in the setting of a neurologic deficit.[113] The surgeon must be aware of the possibility of nerve roots entrapped in the lamina fracture and must be prepared to repair dural tears or place a cerebrospinal fluid drain, if needed. Iatrogenic neural injuries may occur during prone patient positioning or from direct injury during surgery. Great care must be taken when positioning patients with unstable injuries. Consideration should be given to performing awake positioning in patients with severe spinal instability and intact neural function or incomplete neural injuries. The patient may be able to self-protect the spine to some degree with muscle tone, and the surgeon can directly and continuously monitor the patient's neurologic function.

If neurophysiologic monitoring deteriorates during surgery, standard measures—such as the reversal of any recently performed reductions, assessment of potential implant malpositioning, and treatment of hypotension—are employed. If the patient emerges from surgery with a new neurologic deficit, the decision must be made whether to immediately reoperate if the deficit is believed to be a result of hematoma or screw malpositioning or proceed directly to MRI or CT myelography to try to determine the cause.

Infection, pseudarthrosis, instrumentation failure, and iatrogenic flat back are related to patient factors and surgical technique. The surgeon should take the necessary steps to minimize the risk of these complications while achieving the primary goals of reduction, decompression, and stabilization. Medical problems may occur due to unfamiliarity with the patient's medical and social history, associated injuries, and the lack of a preoperative outpatient medical evaluation to identify and optimize any medical conditions. Extra effort must be exerted in ascertaining the patient's history and involving other medical and surgical disciplines to help identify and manage these potential problems.

Contemporary Concepts in Surgical Treatment of Thoracolumbar Spine Injuries

Spinal Stabilization Without Fusion

The concept of spine fracture stabilization without fusion has theoretical advantages, such as the ability to achieve and maintain fracture reduction and healing without permanent stiffening associated with spinal fusion. This technique is most often used with minimally invasive surgery but has its origin in traditional open techniques.[106,114–117] The preservation of joint motion by avoiding fusion is a widely accepted notion in orthopaedic extremity fracture care and increasingly adopted in the treatment of spinal fractures. Before pedicle screw instrumentation, Harrington rods were used to instrument the spine two to three levels above and below the injured segment. To avoid long-segment fusions, the "rod long fuse short" method was utilized, which involved local fusion limited to the injured levels and subsequent rod removal 1 year later.[118] Dekutoski and colleagues retrospectively studied this method, noting that the unfused segments regained 5 to 6 degrees of flexion-extension motion after instrumentation removal, with good-to-excellent overall results in all study patients. However, they noted that kyphosis increased by an average of 9 degrees by final follow-up.[119] Another study by Ko et al.[120] reported on 60 patients who underwent fusionless instrumentation for unstable thoracolumbar burst fractures and noted maintenance of spinal motion and alignment after instrumentation removal. There are select fracture types that have excellent bony healing potential, thus should be considered for fusionless instrumentation. Patients with fractures through an ankylosed spine, most commonly with AS or DISH, have a clear indication for fusionless instrumentation, especially percutaneous pedicle screws and rods, due to the fact that the fracture can be stabilized without concern about the effect on adjacent spine segments because the spine is immobile. Chance variant fractures with the posterior element injury through the spinous process also have excellent primary bony healing potential and are particularly well suited to fusionless techniques. The role of fusionless instrumentation is not as clear in flexion-distraction injuries, burst fractures, compression fractures, and multilevel spine fractures. In the case of AS or DISH, fractures through ankylosed spine segments have been noted to heal rapidly once adequately stabilized.[121,122] If instrumentation is solely performed across ankylosed segments, there is no role for performing a fusion; in actuality, the concept of a fusion does not apply because the spine is already fused. Because of this, there is no need to remove the instrumentation once the fracture has healed unless the instrumentation is prominent, which is unusual.

Flexion-distraction and Chance variant (bony Chance type) fractures also heal rapidly, in particular if the posterior element injury is predominantly bony, thus should be considered for fusionless instrumentation. Grossbach and colleagues found no difference in clinical and radiographic outcomes when treating flexion-distraction injuries with fusionless technique versus open fusion.[133] They identified advantages, including shortened operative time and less blood loss with the fusionless technique. This technique may also have a larger role in pediatric patients who more promptly heal posterior ligamentous complex (PLC) injuries.[122–124] Fusionless instrumentation in adults with flexion-distraction injuries and Chance fractures with a posterior element injury that is predominantly ligamentous depends on ligamentous healing. The role of this technique is still being established.

Regarding burst fractures treated with the fusionless instrumentation technique, Dai and colleagues reported minimal difference in clinical and radiographic outcomes in their randomized trial of short-segment posterior instrumentation with or without fusion for stable burst fractures at the thoracolumbar junction.[106] A meta-analysis by Tian and colleagues[117] comparing fusion to nonfusion for thoracolumbar burst fractures found that patients treated without fusion had shorter operative times and less blood loss, but the second procedure of hardware removal was not included in their analysis. They found no differences in radiographic results besides greater vertebral height loss after instrumentation in the fusion group and no differences in clinical outcomes or instrumentation failure rates.

The disadvantages of fusionless surgery include recurrent kyphosis after instrumentation removal, instrumentation failure (loosening or breakage), possible need for removal of instrumentation, and/or facet arthrosis. Gardner and colleagues found autofusion (facet arthrosis) in only 2 of 75 facet joints traversed by rods but not fused after utilizing "rod long fuse short" treatment of lumbar burst fractures.[124] In contrast, Kahanovitz found that stabilization using Harrington rods across a mobile facet joint might lead to facet arthrosis based on a canine study and biopsy of eight human facet joints obtained during instrumentation removal.[125,126] However, it is not known whether these findings apply to pedicle screw fixation and timely instrumentation removal, nor if the development of facet joint arthrosis is clinically relevant. Additional disadvantages include the theoretical need for hardware removal with fusionless instrumentation treatment and the associated costs of a second procedure. However, some advocate that instrumentation removal is unnecessary in certain circumstances, such as when performed in the thoracic spine across relatively immobile segments, and more obviously in cases of AS or DISH, as discussed previously. Despite these disadvantages, our experience shows that patients tolerate instrumentation removal well with a low complication rate, and that it can usually be performed on an outpatient basis.

Minimally Invasive Stabilization Using Percutaneous Instrumentation

The concept of fusionless spine surgery for thoracolumbar fracture treatment and the technique of percutaneous pedicle screw placement certainly have a synergistic relationship. Although percutaneous pedicle screw placement was initially applied to degenerative spinal conditions, this technique has more recently been increasingly utilized in spine trauma care. The construct is biomechanically analogous to those placed in open techniques, but the percutaneous approach relies on muscle splitting rather than muscle stripping, as is typical of the open approach. Minimally invasive stabilization can be performed either with paired parasagittal Wiltse-style approaches or through multiple small incisions large enough to accommodate the pedicle screws. The overall goals are to stabilize the spinal injury while minimizing blood loss, surgical time, and complications, such as surgical site infection, while decreasing the physiologic burden of surgery. While percutaneous instrumentation is most often placed without the addition of a fusion, in cases in which arthrodesis is felt to be necessary, a facet arthrodesis can be performed through the same percutaneous incisions that are utilized for pedicle screw placement.

The indications for percutaneous stabilization and the necessary construct length are similar to open instrumentation, with potential contraindications including incomplete neurologic injury that necessitates direct decompression of the spinal cord or nerve roots, fracture-dislocations in the neurologically intact patient who may have a risk for neurologic deterioration without an open direct reduction, and in cases of delayed fixation in which postural reduction is not expected to restore adequate spinal alignment. As with open fusionless techniques, percutaneous instrumentation is ideally suited to fractures through ankylosed spine segments (Fig. 77.11) and flexion-distraction injuries with a primarily bony component (see Fig. 77.8). Additional indications include unstable burst fractures in the neurologically intact patient (Figs. 77.12 to 77.14) and multiple-level fractures (Figs. 77.12 to 77.15) in which percutaneous instrumentation over multiple segments are possible with much less blood loss and surgical time compared to open procedures, while avoiding a long fusion and the potentially long-term deleterious consequences associated with fusion, including loss of spine flexibility and adjacent-segment degeneration. The polytrauma patient with stable thoracolumbar fractures can be difficult to manage with orthoses, especially when pelvic, abdominal, and/or chest trauma makes bracing impractical. Percutaneous stabilization may facilitate immediate patient mobilization and the avoidance of skin breakdown from the orthosis or prolonged bed rest. Percutaneous stabilization can also be considered for spine fracture-dislocation patients with complete neurologic injury, with the intention to restore stability and indirectly decompress the spinal canal. Furthermore, a focal direct decompression through a small midline incision can be performed in tandem with percutaneous instrumentation placement several levels above and below the level of injury in those cases in which decompression is necessary. This is particularly useful in cases of ankylosing spondylitis with neurologic compression related to fracture displacement and/or epidural hematoma. Percutaneous instrumentation can also be used to provide additional stability after an anterior or anterolateral corpectomy and arthrodesis, a technique that is

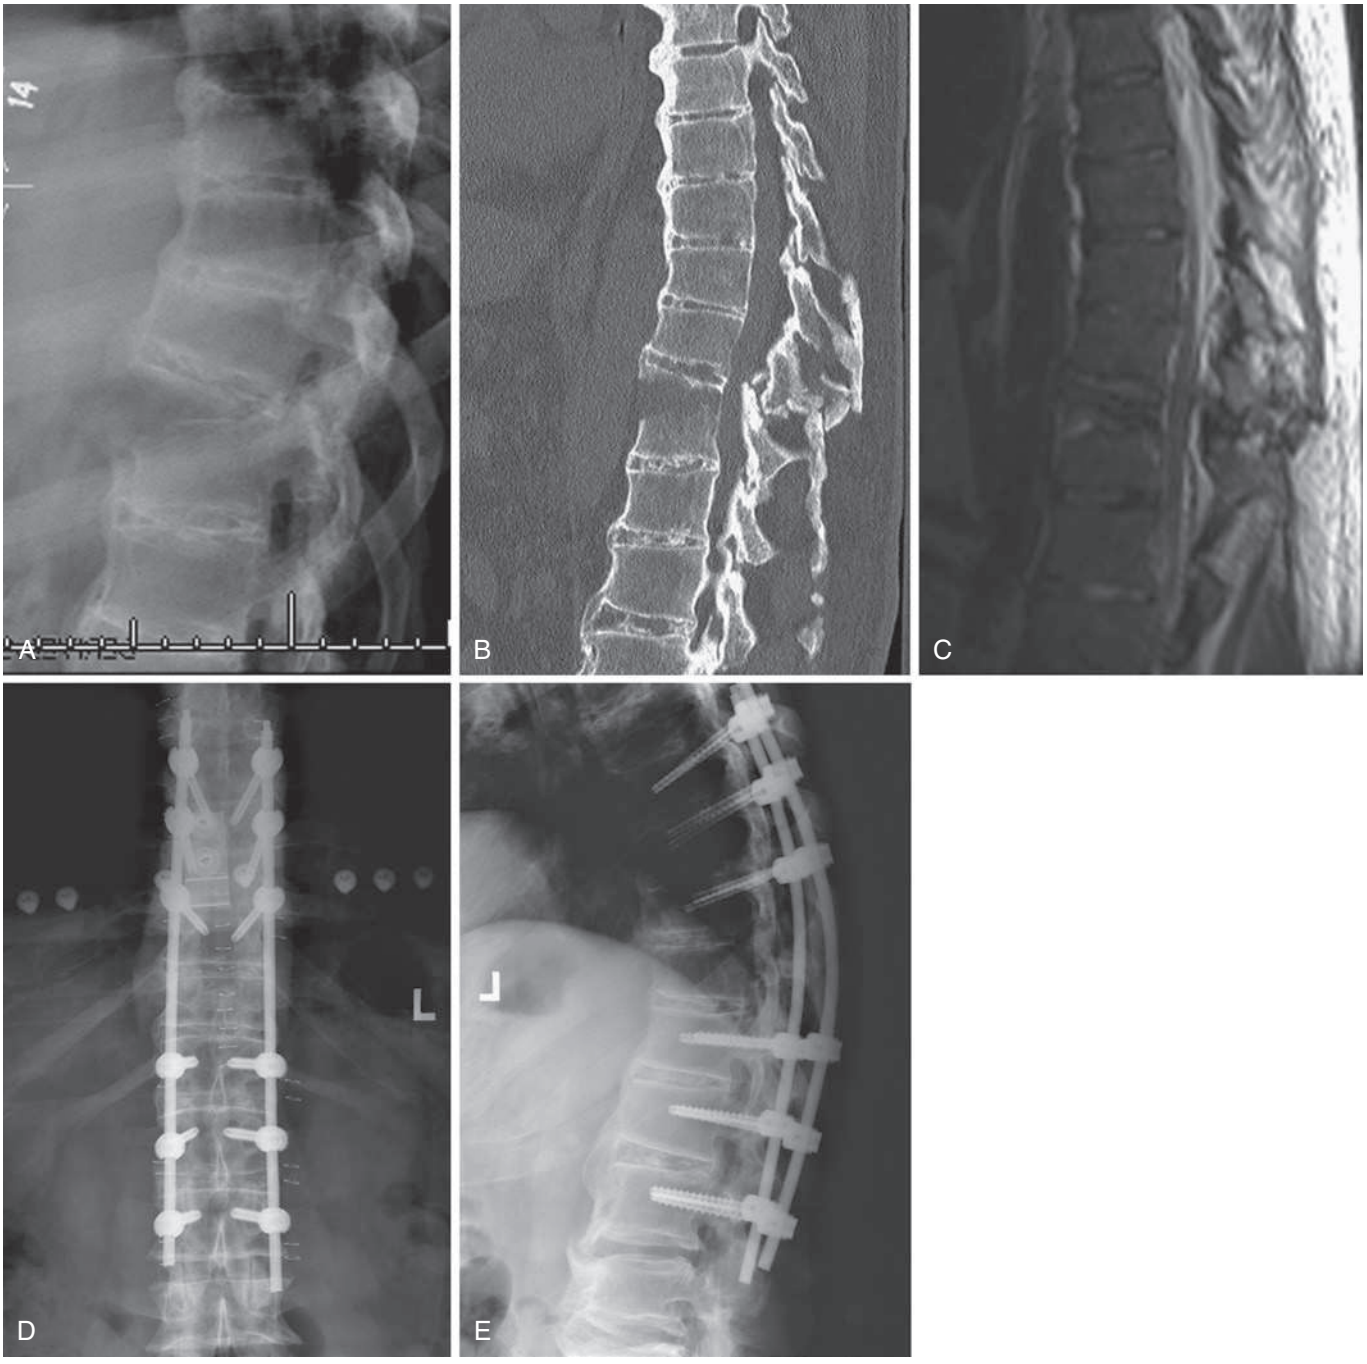

FIG. 77.11 Extension injury through an ankylosed spine stabilized with posterior percutaneous instrumentation placement. (A) Lateral radiograph shows an ankylosed spine with a fracture gap anteriorly, also seen on (B) sagittal computed tomography imaging and (C) magnetic resonance imaging. (D–E) The fracture was reduced with intraoperative positioning, a focal decompression was performed, and the fracture was stabilized with posterior percutaneous pedicle screw instrumentation.

most commonly performed in patients with a thoracolumbar burst fracture and neurologic injury.

Multiple authors have shown that percutaneous stabilization techniques can be performed safely and efficiently with a low rate of complications compared to open techniques.[127–132] Percutaneous stabilization may also have the added benefit of avoiding the need for or an alternative to brace immobilization in certain patients.[133] Grossbach et al. retrospectively compared open versus percutaneous techniques for treatment of flexion-distraction injuries and found similar clinical and radiographic outcomes but shorter operative times and less blood loss in the percutaneous group.[133] Furthermore, no difference in the rate of adverse events was found between the two groups. Other authors have reported comparable findings.[134–137] Ni et al. successfully treated 36 burst fracture patients using percutaneous instrumentation, with an average operative time of 78 minutes and an average blood loss of 75 mL.[138] Additionally, percutaneous pedicle screw placement

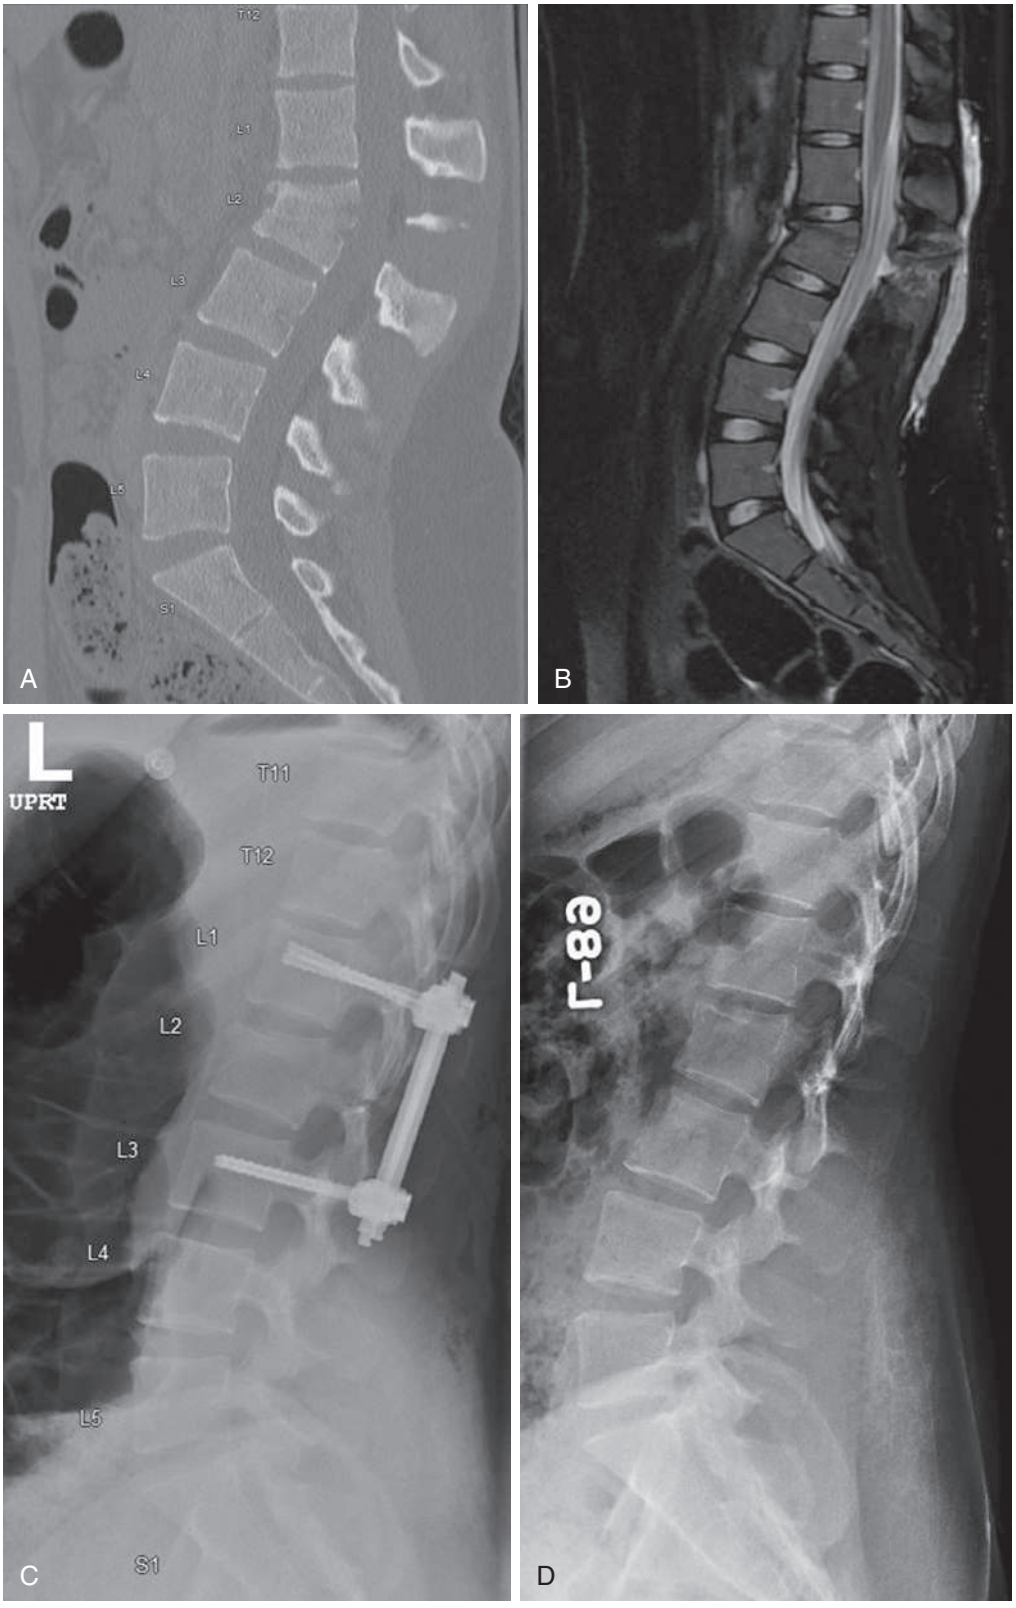

FIG. 77.12 Flexion-distraction injuries with a primarily bony component stabilized with posterior percutaneous instrumentation placement. (A) Sagittal computed tomography image and (B) T2-weighted magnetic resonance image show a flexion-distraction injury associated with vertebral body compression. (C–D) The fracture was successfully reduced intraoperatively and was stabilized with posterior percutaneous pedicle screw instrumentation.

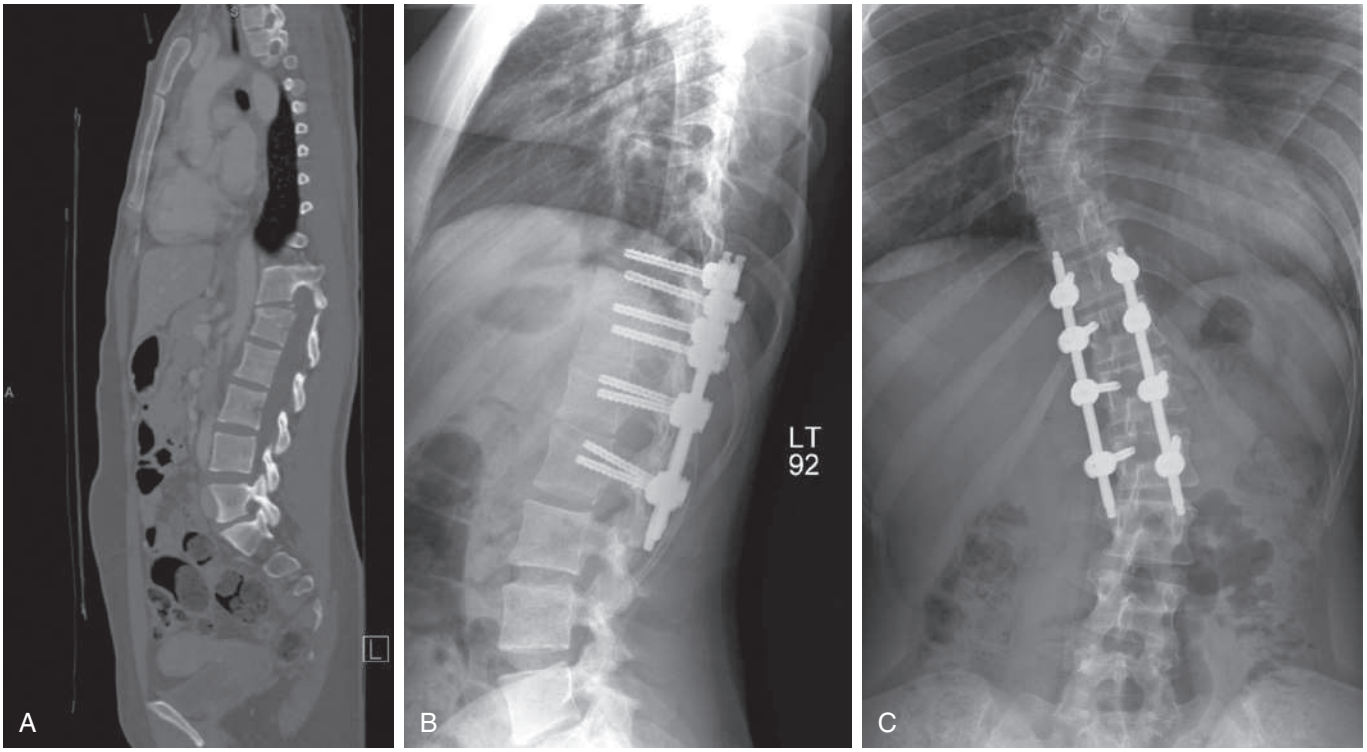

FIG. 77.13 Unstable burst fracture in a neurologically stable patient with idiopathic scoliosis. (A) Sagittal computed tomography image shows an L1 burst fracture with unilateral perched facet. Note that the spinal deformity complicates the imaging interpretation. Surgical stabilization with posterior percutaneous instrumentation placement is shown on (B) lateral and (C) anteroposterior radiographic images.

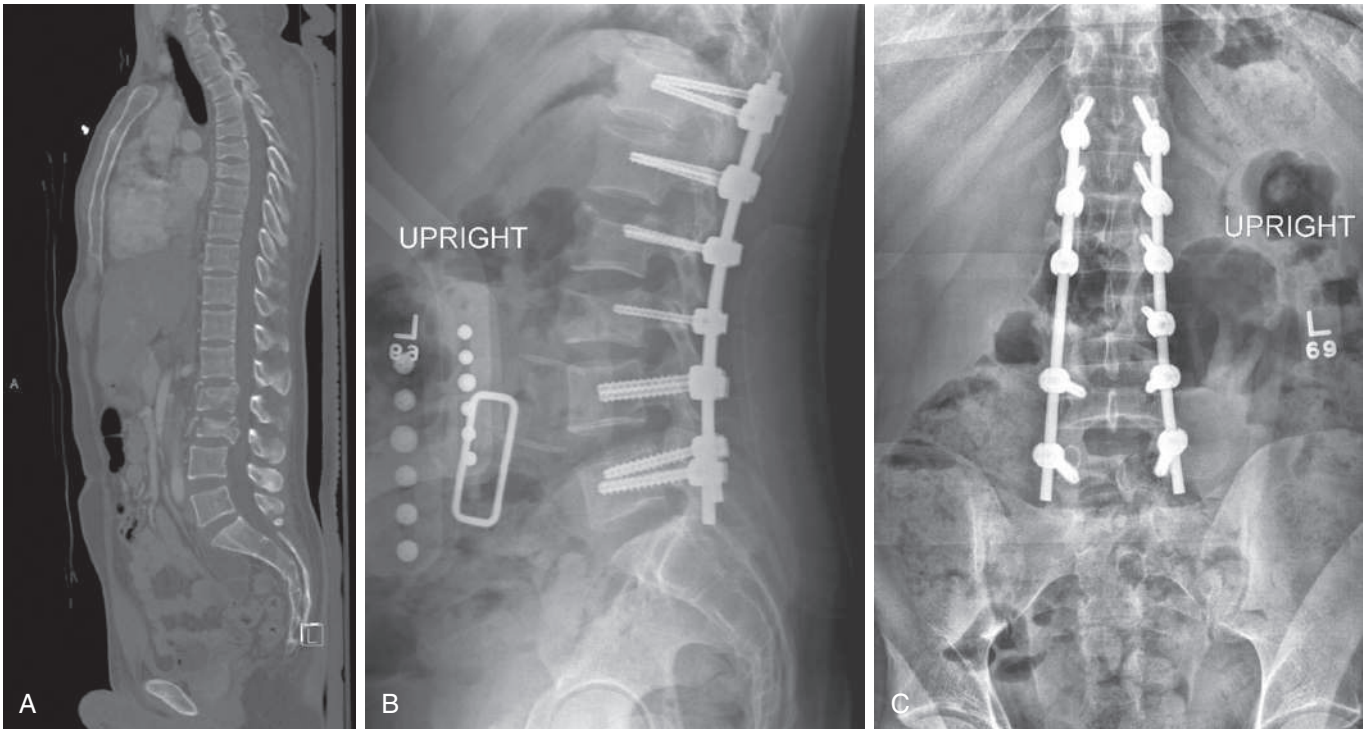

FIG. 77.14 Multiple-level burst fractures treated surgically with posterior percutaneous instrumentation placement. (A) Sagittal computed tomography shows consecutive burst fractures at L2 and L3, with the patient unable to tolerate mobilization using a thoracolumbar brace. Surgical stabilization with posterior percutaneous pedicle screw instrumentation is shown on (B) lateral and (C) anteroposterior radiographic images.

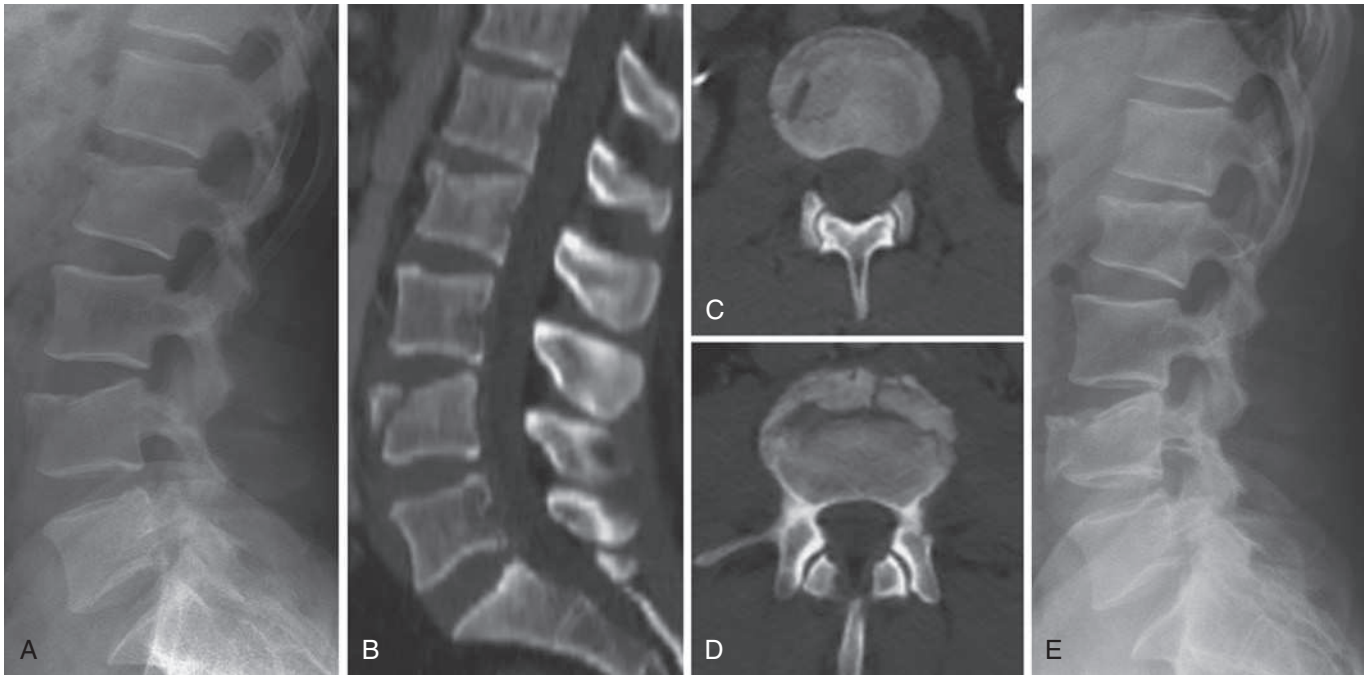

FIG. 77.15 Compression fractures treated in a brace. The compression fractures of L2 and L4 are shown in (A) the lateral radiograph, (B) sagittal computed tomography images, and axial computed tomographic images (C is L2 and D is L4). (E) Two years later, the fractures are healed.

using conventional fluoroscopic techniques has been shown to be highly accurate in the trauma setting.[139–141]

Balloon-Assisted Reduction and Cement Augmentation of Thoracolumbar Fractures

Several authors have reported percutaneous balloon-assisted reduction techniques with or without vertebral body augmentation.[142–151] This technique can be utilized in combination with open surgery or percutaneous pedicle screw instrumentation. The theoretical advantages include aiding in fracture reduction and providing anterior column support through a minimally invasive approach, avoiding the added surgical physiologic burden associated with an open reduction, which would typically require an anterior or combined AP approach. Using the balloon-assisted reduction and cement augmentation technique combined with percutaneous stabilization for thoracolumbar spine fractures, Zairi et al. have shown the technique to be a viable option associated with stable long-term clinical and radiographic results.[152] Singer et al. reported similar results when applied to the pediatric population.[153] Overall, the role of this technique is not yet clear.

Treatment of Specific Injuries

Sprains and Minor Fractures

Sprains and isolated minor fractures are not associated with neurologic deficits or spinal instability; they can usually be treated symptomatically, with or without bracing.[154,155] If a brace is chosen for comfort, it need not be rigid. The main concern with these injuries is misdiagnosis and undertreatment of a more serious spinal injury, such as with disruption of the PLC, or sacral fracture associated with an L5 transverse process fracture. Consideration must be given to the mechanism of injury and clinical examination; if there is doubt, advanced imaging techniques should be used to assess for more significant occult injury. It should also be kept in mind that patients with minor spine fractures may have more significant intraabdominal injuries.[156] Patients with isolated sprains and minor fractures should be able to mobilize readily, and full recovery is expected over a 6-week to 6-month period depending on the extent of the injury, with most patients returning to unrestricted activities within 6 to 12 weeks.

Traumatic Disc Herniations

Isolated disc herniations secondary to high-energy trauma are sufficiently rare that it is not possible to comment on the rate of neurologic injury, appropriate treatment, or long-term outcomes. Terhaag[157] found only four traumatic disc herniations in his series of 1771 patients with disc lesions. The literature is scarce on this subject.[158–160] Treatment protocols are similar to that of nontraumatic disc herniations, with an initial trial of nonoperative management and early mobilization. Bracing is not necessary. Preference may be given to early surgical intervention if there is severe radiculopathy or a dense nerve root motor deficit caused by the disc herniation. Emergency surgery would be indicated

if the patient presented with or developed a cauda equina syndrome.

Compression Fractures

Compression fractures are usually intrinsically stable and rarely cause neurologic deficits. They occur most frequently due to a low-energy mechanism in elderly osteopenic patients, but also occur due to higher-energy mechanisms in patients with normal bone. This discussion is directed toward fractures in patients with normal bone—osteoporotic compression fracture treatment is discussed in more detail in Chapter 89. Compression fractures were classically treated with postural reduction and plaster cast immobilization.[161,162] The use of plaster casts gave way to less cumbersome brace treatment; these fractures can be reliably treated with bracing the vast majority of the time, using either a three-point hyperextension type or a custom-molded orthosis (see Fig. 77.15).[163,164]

The prognosis is generally favorable, though some patients will complain of persistent back pain long after the fracture has healed. Several clinical reviews did not find a correlation between the initial injury severity and the degree of residual pain.[49,165,166] Other studies, however, have shown a correlation between the severity of injury and back pain.[167–172] It is from these studies that the degrees of vertebral body height loss and traumatic kyphosis became criteria for surgical treatment in a small proportion of these fractures.

Surgical stabilization may be considered when there is significant traumatic kyphosis and/or vertebral body height loss, especially in the setting of PLC compromise. It is difficult to say with certainty at what point the degree of deformity is deemed significant and the transition should be made from brace to surgical treatment, but commonly cited numbers are 30 degrees of traumatic kyphosis and 50% vertebral body height loss, with these fractures thus deemed unstable.[169] Individual patient factors and overall spinal alignment need to be considered as well. Posterior pedicle screw instrumentation with fusion is the usual mode of surgical treatment, either short-segment or long-segment depending on the circumstances. Provided that the fracture is treated surgically within the first 7 to 10 days of injury, significant reduction can usually be achieved posturally and additional correction may be achieved with distraction through the pedicle screws with the intact ALL preventing overdistraction. An anterior approach is not necessary for decompression because there is no retropulsion into the canal, but it may be considered when there is a residual bone void anteriorly after the fracture is reduced or in delayed fracture treatment when an anterior release is necessary to achieve a reduction. Fractures treated surgically generally have a good prognosis, similar to stable compression fractures treated in a brace. There are no meaningful randomized trials comparing surgery with brace treatment in these "unstable" high-energy compression fractures. Osteoporotic compression fractures are generally stable and may be treated in a brace, although persistent pain may be an indication for vertebroplasty or kyphoplasty. The efficacy of vertebroplasty is a source of controversy, which is discussed more thoroughly in Chapter 89.[173,174]

Burst Fractures

Burst fractures range in severity from those that are barely distinguishable from stable compression fractures to devastating unstable injuries causing paralysis. Although the three-column theory of spinal stability proposes that all burst fractures are by definition mechanically unstable because two of the three columns are disrupted, in reality, this is not always the case. Stability is a continuum; thus, the concept of "stable burst fractures" and "unstable burst fractures" has evolved. Stable burst fractures are treated with bracing, and unstable burst fractures are treated with surgery, but considerable controversy surrounds the transition from a "stable" fracture pattern to an "unstable" fracture pattern. The factors guiding treatment are the presence or absence of a neurologic deficit, extent of spinal canal compromise, degree of deformity (vertebral body height loss and angular kyphosis) at the site of injury, and integrity of the posterior osteoligamentous complex.

As with compression fractures, there is controversy regarding the role of imaging measurements in guiding operative versus brace treatment. The commonly cited radiographic measurements are the degree of kyphotic deformity, percent of vertebral body height loss, and percent of canal compromise. It is unclear as to the role that these variables play in actual fracture stability. The historical significance of these measurements dates to the pre-MRI era and is based on their association with posterior ligamentous injury. Investigators postulated three radiographic parameters that were associated with posterior osteoligamentous complex disruption and thus were unstable injuries: kyphosis greater than 30 degrees, vertebral body height loss of 50%, and canal compromise of 50%. As MRI was introduced and the PLC could be more reliably imaged, it became clear that this was not necessarily true. Canal compromise in particular has not been associated with adverse long-term outcomes in the absence of a neurologic deficit, especially because we know that significant resorption of retropulsed bone occurs over time. High degrees of canal compromise, well in excess of 50%, can be asymptomatic neurologically below the level of the conus. It is possible to have even 80% of the spinal canal filled with bone fragments yet have the patient remain intact neurologically. Similarly, vertebral body height loss of greater than 50% can be tolerated, provided that there is no neurologic injury and no significant traumatic kyphosis. Of these classic three parameters, the one that seems to be best associated with instability and may be the best indication for surgical treatment is the degree of traumatic kyphosis.

Brace treatment has been established as appropriate for neurologically intact patients with less than 30 degrees of traumatic kyphosis, less than 50% vertebral body height loss, and no or minimal injury to the posterior ligamentous complex.[175–181] A few authors have even advocated brace treatment for burst fractures with greater than 50% height loss and in some instances when kyphosis exceeds 30 degrees, provided that the injury is otherwise stable.[177] Another group of authors have suggested that a subset of stable burst fractures (AO type A3) without neurologic injury may even be treated without brace immobilization.[180] However, it is important to consider

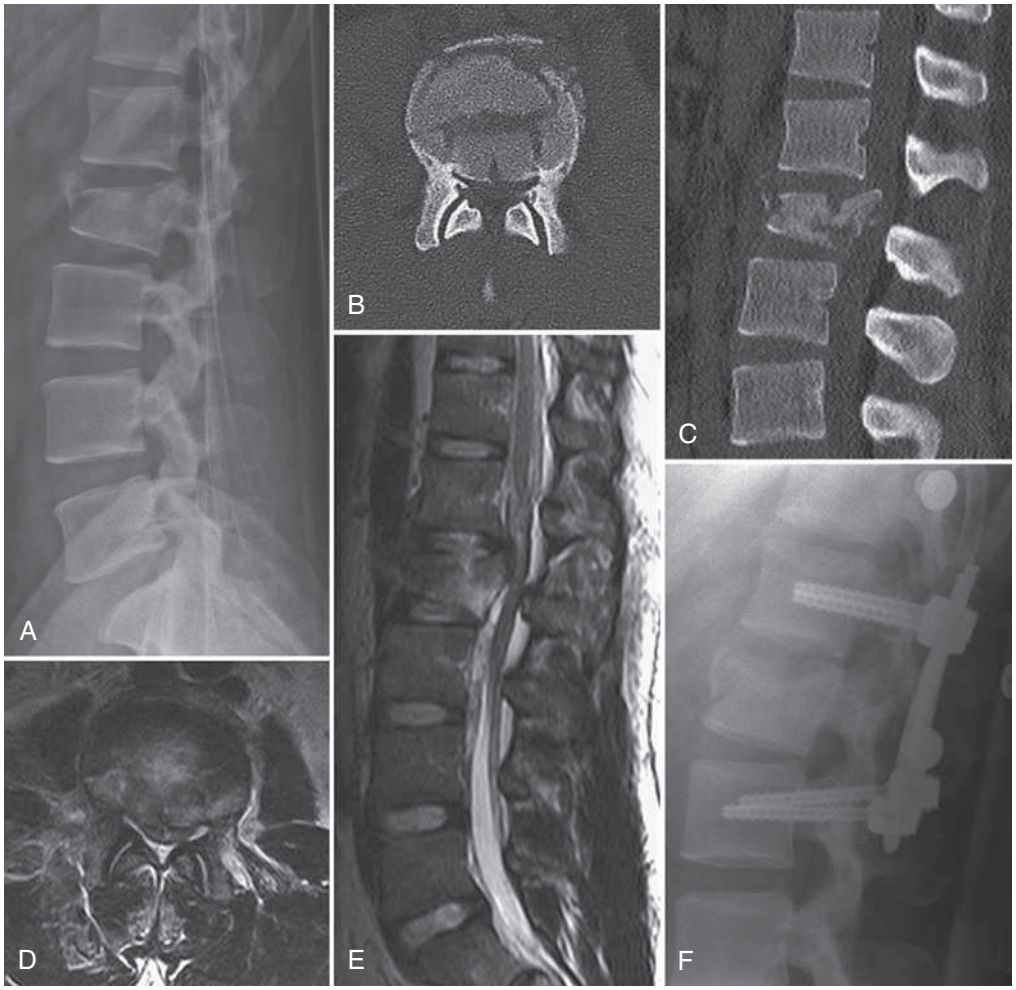

FIG. 77.16 Burst fracture treated surgically. (A) Lateral radiograph. (B) Axial computed tomography (CT) image showing canal compromise of approximately 75%. The patient was neurologically intact. (C) Sagittal CT image. (D) Axial and (E) sagittal T2-weighted magnetic resonance images showing compression of the neural elements. (F) Lateral postoperative radiograph showing short-segment pedicle screw instrumentation.

individual patient factors and overall sagittal alignment in deciding on operative versus nonoperative management with or without bracing, rather than relying on strict radiographic criteria to make the decision.

Burst fractures with a neurologic deficit are defined as unstable because of the neurologic injury, regardless of the extent of deformity or the integrity of the posterior elements, and are best treated surgically. This gives the best chance of neurologic recovery and prevents neurologic deterioration in incomplete injuries by stabilizing the fracture, as well as allowing early mobilization of the patient with paralysis. Exceptions can be made for mild isolated nerve root injuries in an otherwise mechanically stable fracture pattern, with a high rate of neurologic recovery under these circumstances.[181] The dorsally displaced fragments from the vertebral body usually cause the neural element injury, typically necessitating direct decompression. Laminectomy alone is contraindicated because it tends to be destabilizing and does not effectively decompress the neural elements.[22,164] Direct decompression is most reliably accomplished via an anterior approach, but it can also be performed via a posterior transpedicular approach.[94,182–185]

Burst fractures with PLC disruption are mechanically unstable, thus are best treated with surgery. Posterior pedicle screw instrumentation, either open with fusion or percutaneously without fusion, restores the posterior ligament tension-band effect and is the treatment of choice in neurologically intact patients (Fig. 77.16).[186,187]

In cases with a highly comminuted vertebral body and/or loss of greater than 50% of the vertebral body height, consideration may be given to performing anterior surgery to restore the integrity of the anterior column (Fig.77.17).

Exceptions to surgical management of burst fractures with posterior column injury should be made when the posterior injury consists of isolated sagittal lamina fractures, minimally displaced facet or spinous process fractures, and minimal facet opening. Under these circumstances, the PLC may retain its integrity; these injuries are therefore potentially stable. Consideration should be given to nonoperative treatment. True disruption of the PLC means that the tension-band stabilizing effect of the posterior elements is lost, as may occur with facet subluxation, dislocation, and fracture-dislocation. This leads to progressive instability; surgery is therefore indicated for

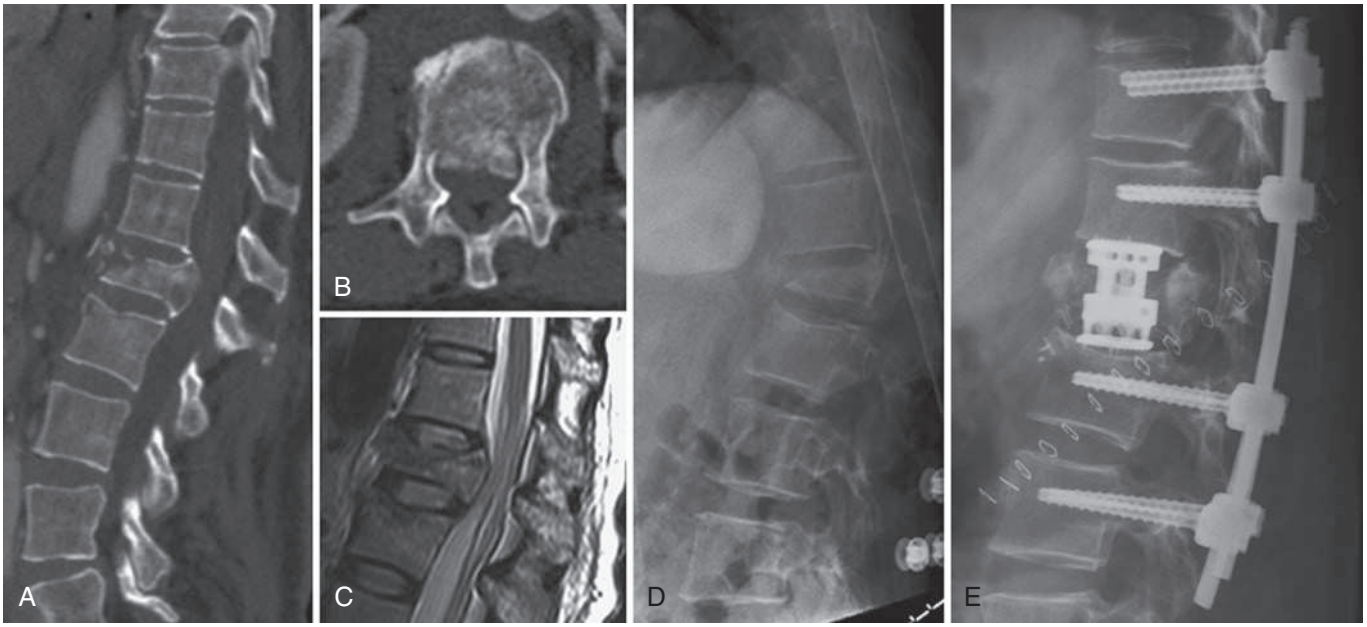

FIG. 77.17 Burst fracture treated surgically, with a staged anteroposterior procedure. It was believed that the degree of vertebral body height loss and angular kyphosis was best treated with restoration of the anterior column followed by posterior pedicle screw instrumentation. stabilization purposes. In those fractures with posterior element injury, the difficulty lies in discerning the extent and significance of this component of the injury and its implications on stability. When the significance of a posterior element injury is borderline, it is usually safe to carefully mobilize a neurologically intact patient in a brace and closely assess for progressive instability with serial upright radiographs.

Long-term outcomes are mainly related to the extent of neurologic injury. For patients who are neurologically intact, the prognosis is generally favorable.[188–192] Rates of residual pain and disability as well as the ability to return to vigorous work are similar in surgically and nonsurgically treated patients. There are few prospective randomized studies on these rates, however, which show conflicting results.[188,190] If a kyphotic deformity reduction is performed surgically or with bracing, some loss of correction can be expected on long-term follow-up.[191,192] Radiographic parameters—including residual kyphosis, vertebral body height loss, and canal compromise—have not been definitively shown to be associated with long-term outcomes (Fig. 77.18).[177,178,188,190,192]

Of these three measurements, kyphosis greater than 30 degrees is the least desirable and is probably most commonly believed to be a predictor of long-term back pain.[1]

Flexion-Distraction Injuries (Chance Fractures and Chance Variants)

The incidence of neurologic deficit in flexion-distraction injuries is relatively low, perhaps 10% to 15%.[193,194] The injury classically occurs with lap-belt car restraints and is associated with a high incidence of intraabdominal injury.[195] The deforming forces occur in the sagittal plane, with displacement manifesting as focal kyphosis due to gapping of the posterior elements. Injuries through bone may be acutely unstable, but tend to heal reliably via primary osteosynthesis. Injuries through the PLC do not heal as well and carry a more guarded prognosis. Brace treatment therefore is more likely to be successful in stable bony injuries. Minimally angulated bony injuries may be treated in a brace. Minimally angulated ligamentous injuries may also be considered for brace treatment, but need to be followed closely to make sure healing occurs. Ligamentous injuries are more likely to require surgery than a purely osseous injury. Caution should be used when declaring these injures minimally angulated because the kyphotic deformity may reduce with gravity when the patient is imaged in the typical supine position. Swelling and tenderness over the spinous processes is potentially indicative of such a situation. MRI will show the extent of posterior injury in questionable cases. Unstable injuries of both the bony and ligamentous types are best treated surgically. The main difficulty with this type of injury is determining stability. Although a minimally angulated fracture may be obviously stable, and a large focal kyphotic deformity may be obviously unstable, it is the cases that fall between these extremes that pose a dilemma. LeGay et al.'s series of 18 patients showed an association of initial kyphotic deformity greater than 17 degrees with a poor prognosis.[195] Glassman et al.'s series of 12 cases in children showed that brace treatment failed when the initial kyphotic deformity was greater than 20 degrees.[196] These numbers are consistent with biomechanical studies that show substantial structural injury, with potential instability occurring somewhere between 12 and 17 degrees of traumatic focal kyphosis, and definite instability beyond 19 to 22 degrees of focal kyphosis.[197–200] These numbers are helpful in guiding treatment in borderline

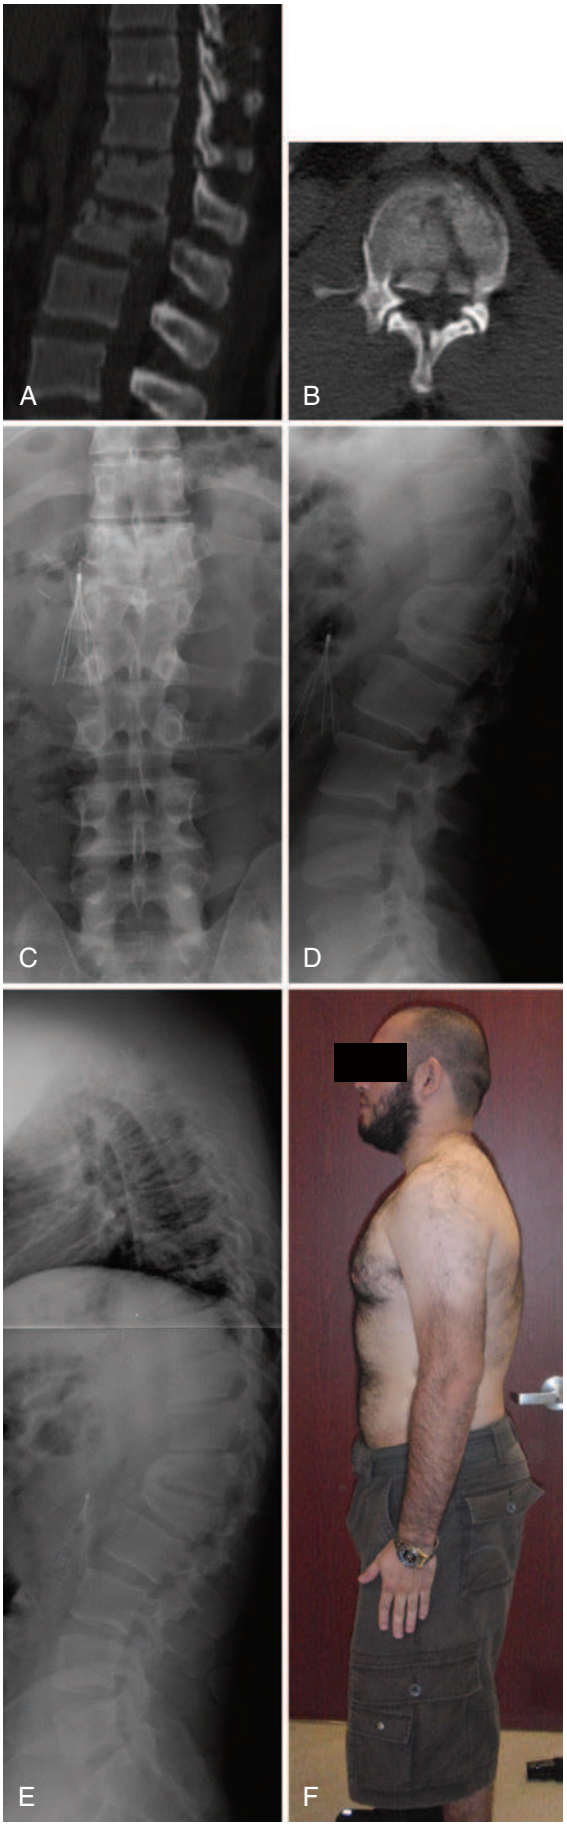

FIG. 77.18 This burst fracture was treated with bed rest and bracing because the patient was unable to undergo surgery. (A) Injury sagittal computed tomography image. (B) Axial computed tomography image. (C–E) Radiographs almost 2 years after the injury. The fractures have healed, and there is spontaneous fusion across T12–L1 anteriorly. (F) Though there is residual kyphosis of greater than 30 degrees on the lateral radiograph, the patient's clinical appearance is normal. He has no back pain and has returned to full activities.

cases. It is also reasonable under borderline circumstances to brace and cautiously mobilize the neurologically intact patient and obtain serial radiographs to see if instability becomes apparent.

Surgery typically consists of posterior pedicle screw instrumentation and fusion across the injured level (Fig. 77.19). This serves as a tension band and effectively counteracts the distractive forces across the posterior elements. Instrumentation may cross two or three levels depending on the anatomy of the injury. Consideration may be given to performing percutaneous pedicle screw instrumentation without fusion in a primarily bony injury, allowing the fractures to heal, then removing the instrumentation 6 to 9 months after injury. It should be noted, however, that this technique has not been proven. Whatever technique is chosen, the goal is to achieve anatomic reduction and stabilization, which under most circumstances is readily achieved because this injury occurs as a result of tensile forces, thus tends to be less destructive than those injuries that occur secondary to compressive forces. Careful intraoperative patient positioning on a standard spine frame with support under the hips and chest usually results in excellent reduction of the injury, and the native anatomy is restored. Long-term prognosis therefore tends to be favorable in neurologically intact patients.[195,196,201,202]

Fracture-Dislocations

Fracture-dislocations are highly unstable injuries and result in neurologic injury in 75% or more of patients.[1,54] There is no role for bracing. Surgical treatment should proceed as soon as possible. If surgery must be delayed, the patient should be carefully transferred to a rotating bed. Awake positioning is usually well tolerated with proper patient coaching before surgery and may be considered in patients with a normal neurologic examination or incomplete neurologic injury. This allows the patient to maintain muscle tone and self-protect against further spinal subluxation. It also allows for real-time monitoring of neurologic status. Posterior pedicle screw instrumentation and fusion can usually be limited to two levels above and below the injury, though longer constructs may be required (Fig. 77.20).

Anterior procedures are usually not necessary. Prognosis depends primarily on neurologic status.

Extension and Extension-Distraction Injuries

Extension injuries are rare, thus it is difficult to comment on the incidence of neurologic deficit, but it is high, perhaps

FIG. 77.19 Flexion-distraction injury (Chance fracture). (A–B) Computed tomography images showing the vertebral body compression fracture component of the injury. (A) A subtle minimally displaced fracture through the pedicle is seen. (B) A possible subtle nondisplaced pars fracture can be appreciated. (C) Sagittal T2-weighted magnetic resonance imaging shows disruption of the posterior ligamentous complex. Because the injury films showed normal spinal alignment, bracing was attempted. (D) Subsequent upright radiograph shows loss of vertebral body height, distraction posteriorly (*arrow*), and focal kyphosis. (E) Alignment was restored with posterior pedicle screw instrumentation, and the posterior element distraction is reduced, as shown by the arrow.

75%.[73,160] These injuries tend to be unstable, especially in the AS and DISH populations, but also when there is posterior element disruption in an otherwise normal spine. Brace treatment may be considered when the injury is minimally displaced in an otherwise normal spine, but this injury pattern is unusual. Otherwise, surgery is indicated. The spine should be assumed to be highly unstable and consideration given to awake positioning. In the ankylosed spine, multiple points of fixation are necessary because of poor bone quality, usually three levels above and below the injury. Percutaneous pedicle screw instrumentation is ideal because the spine is immobile and fusion is not necessary (see Fig. 77.11), but may be

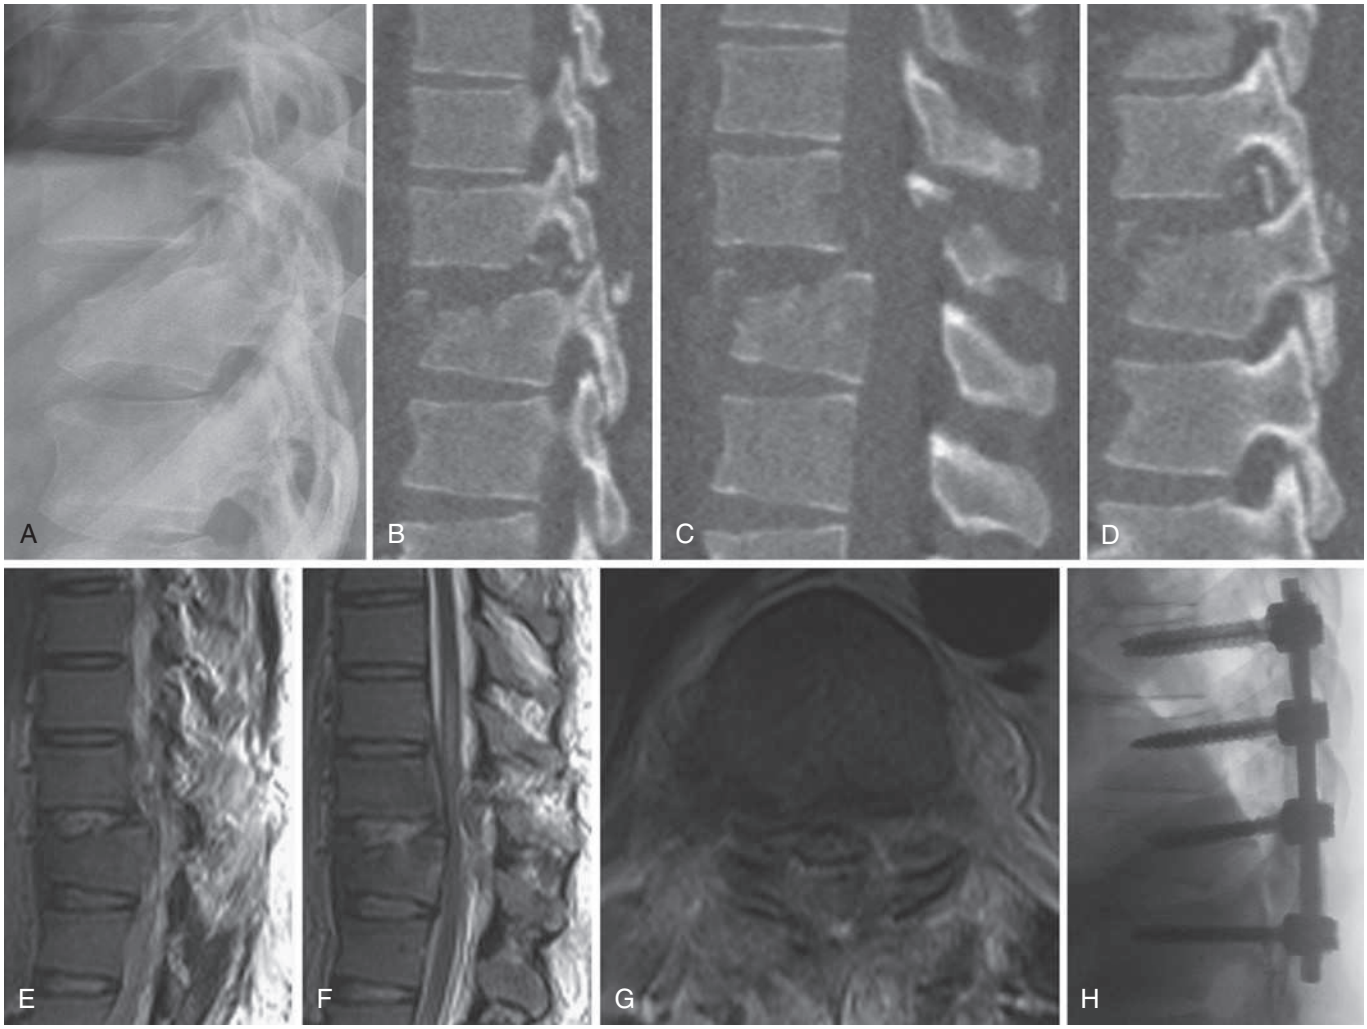

FIG. 77.20 Fracture-dislocation. (A) Lateral radiograph showing listhesis and facet dislocation, better demonstrated by the (B–D) sagittal computed tomography images. (E–F) Sagittal T2-weighted magnetic resonance images. (G) Axial T2-weighted magnetic resonance image. (H) The dislocation was reduced intraoperatively, and a posterior instrumented fusion was performed.

technically challenging for a variety of reasons, including the degree of kyphosis and difficulty visualizing the pedicles on fluoroscopy. Healing reliably occurs via primary osteosynthesis. Prognosis depends primarily on neurologic status.

Penetrating Injuries: Gunshot Wounds

Penetrating injuries are usually secondary to gunshot wounds and are rarely mechanically unstable, even in the setting of a neurologic deficit. Neurologic injury is common, with gunshot wounds being the third leading cause of spinal cord injury after motor vehicle accidents and falls.[203] Injuries involving a single spinal column do not require bracing, but those involving two or three columns should be braced for 6 to 12 weeks. Instability is seen in those rare cases with significant comminution of the vertebral body with extension of the injury through the posterior elements. This is the rare type of gunshot wound to the spine that may require surgical stabilization. Low-velocity (handgun) wounds are the most common type of injury in the civilian population; local wound care in this population can usually be performed in the emergency department. High-velocity (rifle) gunshot wounds are less common in the civilian population, for which debridement should be performed in the operating room.

Surgery may be indicated to remove a bullet from the spinal canal if it is causing compression of the neural elements and there is a neurologic deficit. Below the level of the conus, significant motor improvement may be seen, although this does not seem to be the case above T12.[204] With a stable neurologic deficit, surgery should be performed at 7 to 10 days after injury to allow the dura and surrounding soft tissues to heal, thus simplifying the operation.[205] Cerebrospinal fluid cutaneous fistulas occur 6% of the time after laminectomy to remove the bullet, but delaying surgery 7 to 10 days after injury may decrease the incidence.[205] With a progressive neurologic deficit, surgery should be performed as soon as it is safe to proceed. Instrumentation is usually not required unless instability is created during decompression to remove the bullet. Surgery may also be considered to remove a bullet from the disc space if mechanical symptoms occur and to

avoid potential lead poisoning. Lead toxicity may result from a bullet bathed in synovial fluid, which may also be true with a bullet in the disc space.[206]

Spine infections following gunshot wounds are well recognized, most commonly following injury to a hollow viscus, such as the colon. For gunshots not involving visceral injury, prophylactic parenteral antibiotics should be administered for 72 hours, with a low incidence of subsequent spine infection. For gunshots involving contaminated visceral injury, broad-spectrum parenteral antibiotics should be administered for 7 to 10 days, although a shorter course may be adequate.[207] Infection rates may range from 5% to 10% with these regimens.[205,207,208]

It is common for patients with spinal cord injuries secondary to a gunshot wound to experience local and referred pain radiating into the paralyzed extremities. Surgical decompression does not seem to help.[204,206] Pain usually slowly resolves with time; medications such as nonsteroidal antiinflammatory drugs, amitriptyline, carbamazepine, gabapentin, or pregabalin may be of benefit.

Summary

Treatment of thoracic and lumbar spine injuries should be guided by an understanding of spinal anatomy, the biomechanics of spinal stability, neurologic status, and overall medical condition of the patient, including other injuries. The goal is to achieve neural element decompression in the case of a neurologic deficit, maintain or restore spinal stability and alignment, and mobilize the patient expeditiously while minimizing the risk of complications. The majority of thoracic and lumbar injuries in the neurologically intact patient can be managed nonoperatively with bracing. The most common exception to this is the unstable Chance fracture, which has a low incidence of neurologic injury but is often mechanically unstable. Most injuries with an associated neurologic deficit are best treated surgically. Unstable spine fractures, with or without neurologic deficit, are usually best treated surgically. The management of certain injuries continues to be controversial, especially burst fractures of moderate severity in the neurologically intact patient. It is difficult to determine the degree of instability with these fractures; consequently, they may be treated operatively in one surgeon's hands and nonoperatively in another's. Across all thoracic and lumbar spine injury types, the greatest difficulty in decision making occurs in neurologically intact patients with radiographic parameters that fall in the transition zone between what are classically considered to be stable and unstable injuries. It is uncertain what is the best approach in these cases; multiple factors must be considered in determining the most appropriate course of action.

PEARLS

1. Thoracic and lumbar burst fractures without significant posterior column disruption can usually be treated nonoperatively with bracing and early mobilization in neurologically intact patients. Significant posterior column disruption may be directly diagnosed with bilateral facet joint widening and should be suspected when there is focal kyphosis of greater than 30 degrees, 50% loss of vertebral body height, or interspinous process widening.
2. Traditional radiographic indicators of spinal instability are not strongly supported by the literature. Consideration may be given to treatment with a brace on a case-by-case basis in the neurologically intact patient with radiographic measurements in excess of 50% canal compromise and/or 50% vertebral body height loss.
3. Surgical decompression and stabilization are usually indicated in thoracic and lumbar spine injuries associated with a neurologic deficit attributable to the injured level.
4. Percutaneous pedicle screw stabilization is promising (but unproven) in the treatment of thoracic and lumbar spine fractures, especially in cases of ankylosing spondylitis and Chance fractures because healing of these injuries occurs by direct osseous union.
5. Intravenous methylprednisolone is an option, but not a guideline, in cases of blunt spinal cord injury and may be dosed in accordance with the NASCIS protocol. There are risks associated with administration of high-dose steroids, which must be balanced with the potential benefits on a case-by-case basis.

PITFALLS

1. Spine injuries are noncontiguous in 5% or more of cases; radiographic investigations should therefore usually include the entire spine once a significant spine injury is diagnosed.
2. Spine injuries are often missed on initial examination, especially noncontiguous injuries in patients with multiple injuries.
3. Short-segment pedicle screw fixation is effective in some cases and has the benefit of sparing fusion levels. The literature is mixed, with relatively high rates of failure reported in some series. These constructs should be used with caution, especially when there is loss of anterior or middle column support.
4. Contemporary techniques, such as percutaneous pedicle screw stabilization, have an increasingly important role in the treatment of thoracolumbar fractures associated with spinal ankylosis for which arthrodesis is arguably not necessary. However, their role in stabilization of thoracolumbar fractures in a nonankylosed spine is still evolving.
5. Neurologic injury in burst fractures is typically caused by anterior neural element compression from the retropulsed vertebral body. In these cases, laminectomy alone as a decompressive procedure is not effective and may further destabilize the spine. The offending vertebral body fragment must be directly addressed, which may be done reliably from an anterior or lateral approach, or in some cases via a posterior approach.
6. In patients with neurologic injury, an accurate assessment of neurologic status can only be made after the patient has recovered from spinal shock. This almost always occurs within 48 hours of injury.

KEY POINTS

1. The most controversy in the management of thoracic and lumbar spine injuries involves surgical versus nonsurgical treatment of burst fractures.
2. Thoracic and lumbar spine burst fractures in neurologically intact patients can usually be treated nonoperatively with bracing.

3. Surgery is usually appropriate in patients with neurologic injury and/or significant spinal instability.
4. The goal of surgery is to achieve neural element decompression in the case of a neurologic deficit, restore spinal stability and alignment, and allow for patient mobilization while minimizing the risk of complications.
5. The entire spine should be imaged when a spine fracture is detected, especially when a neurologic deficit is present, because noncontiguous spine injuries occur up to 5% of the time.

   This sentinel work is commonly quoted to describe the basic biomechanics of thoracolumbar fracture stability. Denis broke from the traditional two-column theory of spine stability by introducing the concept of the middle column on the basis of a retrospective review of 412 thoracolumbar injuries.
4. Bracken MB, Shepard MJ, Collins WF, et al. A randomized, controlled trial of methylprednisolone or naloxone in the treatment of acute spinal-cord injury. Results of the Second National Acute Spinal Cord Injury Study. *N Engl J Med*. 1990;322(20):1405-1411.
   The NASCIS II trial was a multicenter, randomized, double-blind, placebo-controlled trial in patients with spinal cord injuries. Methylprednisolone was administered as a bolus of 30 mg/kg, followed by infusion at 5.4 mg/kg per hour for 23 hours. Patients treated with methylprednisolone within 8 hours of injury had a small but significant improvement compared with placebo in motor and sensory recovery. This study led to the adoption of the high-dose methylprednisolone protocol in many countries. However, many spine surgeons feel the potential risks of steroid administration outweigh the potential benefits, and the use of steroids in spinal cord injury remains controversial.

CHAPTER 78

Sacral Fractures

SECTION XI

Carlo Bellabarba
Richard A. Lindtner
Richard J. Bransford

The sacrum acts as a keystone at the junction of the pelvis and the spinal column. It protects lumbosacral neurologic function and maintains pelvic and spinal column alignment. Accordingly, sacral fractures can potentially compromise stability of the pelvic ring, the spinopelvic junction, or both. Injuries to the sacrum may result in deformity, chronic pain, and loss of lower extremity, bowel, bladder, and sexual function. Consequently, treatment of sacral fractures needs to optimize both structural and neurologic outcome and requires a thorough understanding of neural decompression and skeletal reconstruction techniques. The severity of sacral fractures varies widely from insufficiency fractures in osteopenic patients to complex fracture patterns seen in high-energy injury mechanisms, such as motor vehicle collisions or falls from significant heights. Care of these patients must take into consideration the associated injuries in the trauma patient and the underlying medical conditions in patients with metabolic bone disease. Coordination of diagnostic and treatment efforts between the spine surgeon and other surgical, medical, critical care, and rehabilitation specialists is necessary to obtain optimal results.

Anatomic and Biomechanical Considerations

The sacrum is the lowest functional portion of the spinal column and provides an anchor for the mobile lumbar spine. Lumbosacral motion occurs through the lumbosacral intervertebral disc and the paired zygapophyseal (facet) joints. In addition to the usual intervertebral stabilizing structures, the lumbosacral articulation is further stabilized by the iliolumbar ligaments connecting the L5 transverse processes to the crest of the ilium and the sacrolumbar ligaments that have an origin contiguous with the iliolumbar ligament and insert into the anterosuperior aspect of the sacrum and sacroiliac joint.[1] These structures make the L5–S1 motion segment inherently more stable than the more cephalad lumbar motion segments.

The sacrum has an inclination that is balanced by a cascade of lumbar lordosis, thoracic kyphosis, and cervical lordosis so that a plumb line from C7 typically passes through the posterior aspect of the L5–S1 intervertebral disc. The sacral inclination angle, defined as the angle between a tangent to the dorsal surface of the sacrum and a vertical reference line, varies between 10 and 90 degrees and is usually between 45 and 60 degrees.[2,3] Pelvic incidence measures the orientation of the lumbosacral junction relative to the pelvis and approximates 50 degrees in the general population.[4] It is normally referred to in the context of sagittal plane deformities and is valuable in determining sagittal alignment when treating sacral fractures. Sacral fractures that significantly alter spinal sagittal alignment, usually by shifting the C7 plumb line anteriorly, may result in difficulty in maintaining an erect posture, compensatory hyperlordosis, and associated functional deficits[5] (Fig. 78.1).

The sacrum forms the posterior segment of the pelvic ring through the sacroiliac joints. Forces transmitted through the lumbosacral articulation into the upper sacrum propagate laterally across the sacroiliac joints to the pelvis (Fig. 78.2). Because of these load-transferring properties, the sacrum has been described as the keystone of the pelvic ring.[6] More specifically, the sacrum functions as a "true keystone" in the pelvic outlet plane, in which the orientation of the sacrum relative to the ilium is such that axial forces lock the sacrum into the pelvic ring and further stabilize the sacroiliac articulation. In the pelvic inlet plane, the sacrum is shaped like a "reverse keystone" and its position in this plane is inherently unstable, permitting pelvic ring motion (Fig. 78.3). This pelvic ring instability necessitates substantial intrinsic and extrinsic ligamentous stabilization of the sacroiliac joints. Intrinsic stability is provided by the substantial interosseous ligaments and posterior sacroiliac ligaments as well as the relatively weaker anterior sacroiliac ligaments. Extrinsic stability is provided by the sacrospinous and sacrotuberous ligaments of the pelvic floor.[7]

The sacrum itself is composed of five kyphotically aligned vertebral segments. The upper two sacral segments are similar in size to the lumbar vertebrae, whereas the lower three sacral segments rapidly diminish in size.[8] Intersegmental fusion begins between the lowest two segments around the age of 15 years and proceeds in a cephalad direction until the sacrum is

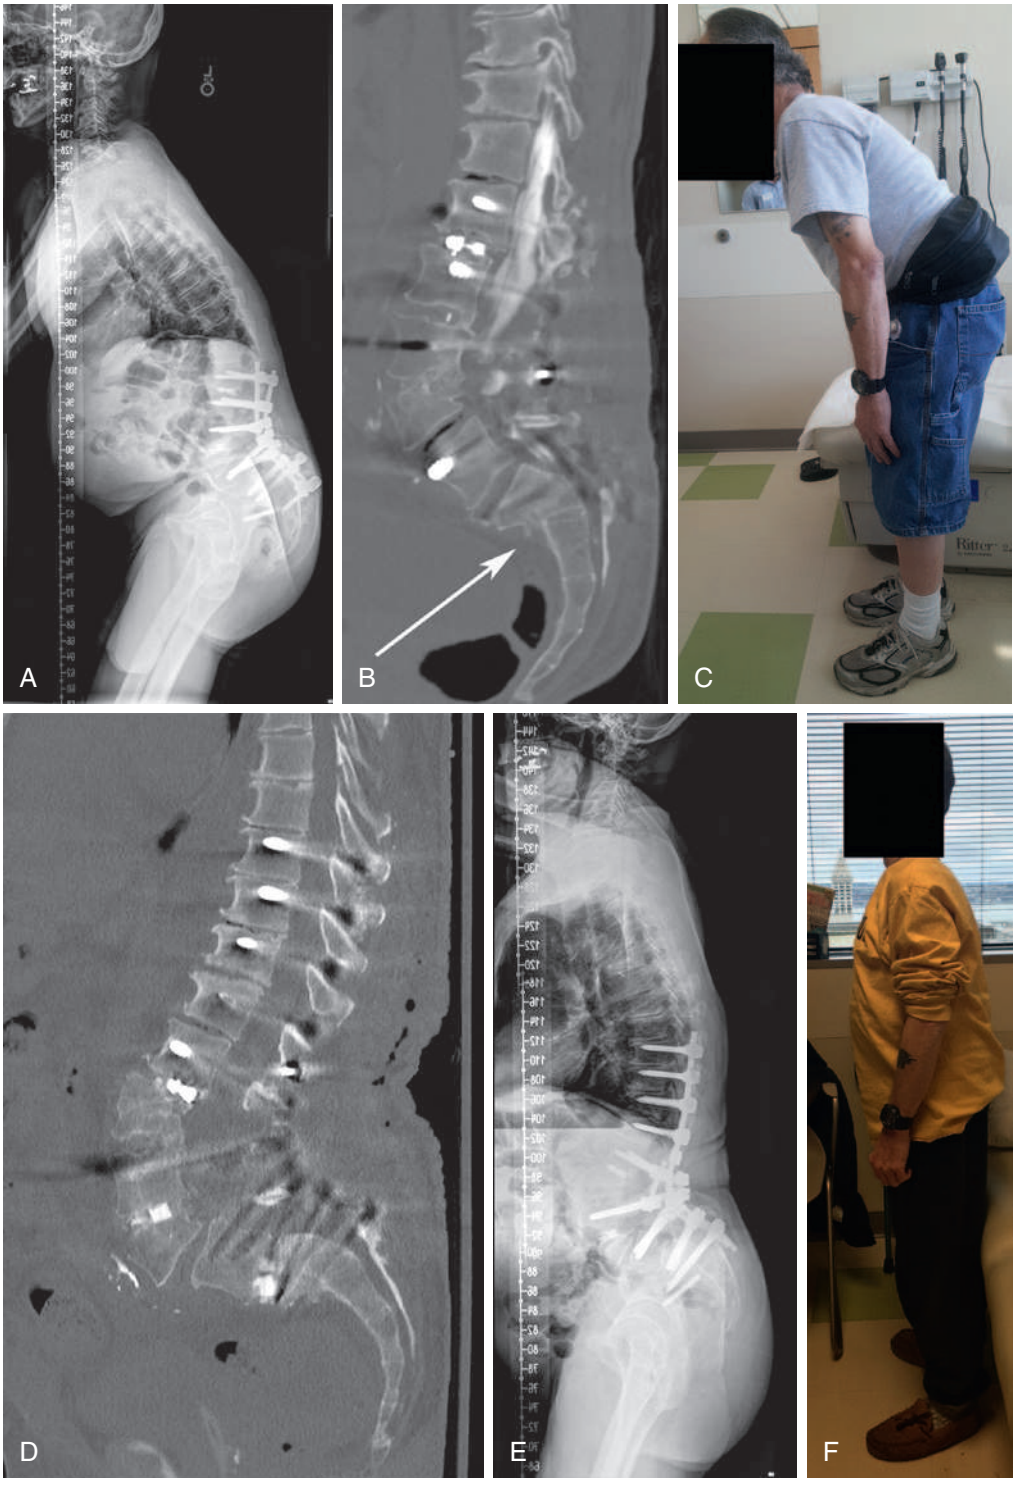

FIG. 78.1 Sagittal plane malalignment after malunited AO type C3 sacral fracture. Because of its caudal location, malunited fractures of the sacrum can have highly deleterious effects on spinal alignment. (A) Lateral spine radiograph and (B) sagittal computed tomographic (CT) image of the lumbosacral spine after L4 pedicle subtraction osteotomy had been done in an unsuccessful attempt at treating severe sagittal malalignment due to kyphotically malunited AO type C3 sacral U fracture (*arrow*). (C) Persistent, severely positive sagittal plane deformity. (D) Sagittal CT image and (E) lateral radiograph after L2 pedicle subtraction osteotomy largely restored physiologic sagittal plane alignment (F). Stabilizing sacral fractures in acceptable alignment helps prevent the need for more complex and risky reconstructive operations in the future.

completely fused by 25 to 30 years of age. Significant variability in upper sacral anatomy can exist in the form of transitional vertebrae and sacral dysplasia. Forms of transitional vertebrae include a sacralized lumbar segment, an incomplete congenital fusion of L5 to the sacrum that is usually unilateral, and a lumbarized sacrum identified by a persistent articulation between the S1 and S2 segments.[9] Complete or bilateral sacralization may result in dysplastic sacral morphology with the upper sacrum located cephalad relative to the iliac crests. Because upper sacral variability results in significant alteration in the relationships among the sacrum, pelvis, and spinal column, as well as their adjacent neurovascular structures, anatomic variations must be recognized during the evaluation and treatment of sacral fractures, particularly if surgical treatment is considered.[10]

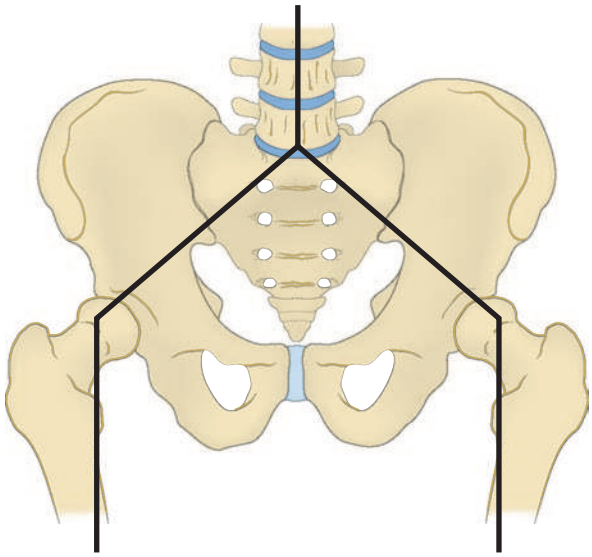

FIG. 78.2 Weight-bearing axis of the spinal column and pelvic ring.

The upper sacral body, which constitutes the base of the mobile spine, consistently has the highest density of cancellous bone, with the S1 segment adjacent to the superior endplate having the greatest density overall. The ventral aspect of the upper S1 body that projects anteriorly and superiorly into the pelvis is termed the *sacral promontory.* The sacral ala, the lateral portion of the sacrum that articulates with the ilium through the sacroiliac joints, is largely cancellous and is formed by the coalescence of the sacral transverse processes. There is wide variability in sacral alar morphology among individuals, and the ala can be substantial broad shoulders of bone or narrow, partially segmented structures. The cancellous alar bone is hypodense, particularly in older individuals, and an alar void is a consistent finding in middle-aged and older adults.[11,12] The relative difference in bone density between the upper and lower sacral body predisposes this transitional area to fracture. The hypodense ala are predisposed, particularly in the older and osteopenic person, to fracture line propagation. This effect is accentuated by the relative strength of the sacroiliac joint ligaments that stabilize and prevent their displacement or disruption. Similarly, younger individuals injured before complete ossification of the sacrum are predisposed to disruption at the S1–S2 level owing to relative weakness at that interval. The relatively sparse alar bone density must also be taken into consideration when planning reconstructive procedures.

The posterior surface of the sacrum is convex and is formed by the coalescence of posterior elements. Accordingly, the middle sacral crest corresponds to the spinous processes, the intermediate sacral crests correspond to the zygapophyseal joints, and the area in between corresponds to the laminae. The lowest one or two sacral segments have incompletely formed bony posterior elements, resulting in an aperture into the sacral spinal canal known as the sacral hiatus. Enlargement of the sacral hiatus may relatively weaken the sacrum and predispose it to fracture.[13]

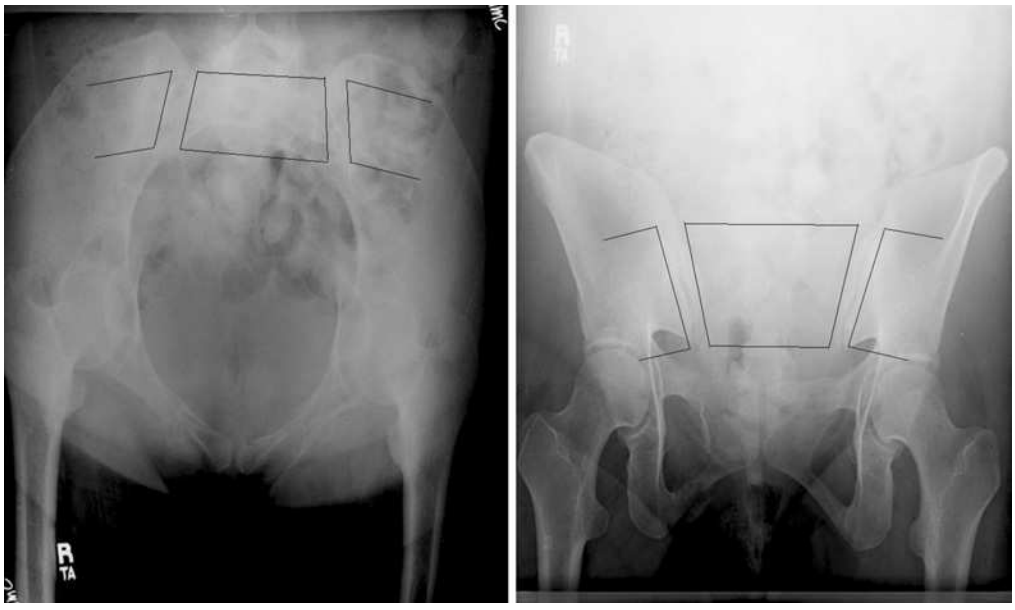

FIG. 78.3 Keystone and reverse keystone configuration of the sacrum in the pelvic ring.

Sacral pedicles and laminae form the lateral and posterior borders of the spinal canal as it tapers in size distally from a triangular cross-section at the S1 level to a flat and narrow cross-section at the most caudal segments. The dural sac typically ends at the S2 level and the filum terminale attaches its caudal end to the coccyx. At the junction of the body and the sacral ala are four paired ventral and dorsal neuroforamina through which the ventral and dorsal sacral nerve root rami pass, respectively. The relative space available to the sacral nerve roots in the ventral foramina is lowest at the S1 and S2 levels, where the nerve roots occupy one-third to one-fourth of the foraminal area compared with the S3 and S4 levels, where the nerve roots occupy one-sixth of the available foraminal space. It follows that the lower sacral roots are less likely to be impinged upon in injuries involving displacement and narrowing of the neuroforamina.[14]

Numerous structures positioned adjacent to the sacrum may be injured in sacral fracture-dislocations. The majority are neurovascular structures, with the rectum being the only visceral structure in close proximity. Below the rectosigmoid junction, located at the S3 level, the mesentery disappears and the rectum lies directly adjacent to the sacrum.[15]

The dorsal nerve roots exit through their respective posterior neuroforamina to supply motor branches to the paraspinous muscles and cutaneous sensory branches that form the cluneal nerves. Anteriorly, the L5 nerve root is intimately associated with the sacrum as it passes underneath the inferior edge of the sacrolumbar ligament and drapes over the anterosuperior aspect of the sacral ala. It anastomoses with the L4 ventral ramus and, in passing caudally, adjacent to the sacral ala, is joined by the exiting ventral sacral nerve roots to form the sacral plexus.[16] Branches of the sacral plexus include the sciatic nerve, pudendal nerve, superior gluteal nerve, and inferior gluteal nerve. In addition, the sympathetic chain lies directly on the ventral sacrum immediately medial to the neuroforamina. At each level, it distributes a gray ramus communicans to the ventral nerve root. Therefore, the sacral plexus mediates major lower extremity function, as well as bowel, bladder, and sexual function. The dual innervation of the perineal structures from both the left and right sacral plexus is protective of bowel, bladder, and sexual function. These functions are largely preserved in the event of transection of the sacral nerve roots unilaterally, whereas bilateral transection causes complete loss of function.[17]

The presacral area has an extensive vascular network that is highly variable. The middle sacral artery typically courses ventrally along the midline of the L5 vertebral body, across the L5–S1 disc space and the sacral promontory and down the sacrum after branching from the aorta at the common iliac bifurcation. The common iliac arteries subsequently give rise to the internal iliac arteries that lie anterior to the sacroiliac joints and give off both superior and inferior lateral sacral arteries. The superior lateral sacral artery traverses the upper sacroiliac joint and proceeds caudally just lateral to the sacral foramina, giving off spinal arteries that pass through the S1 and S2 ventral foramina to the spinal canal. The inferior lateral sacral artery traverses the inferior aspect of the sacroiliac joint before anastomosing with the middle sacral artery and giving off spinal arteries that pass through the S3 and S4 ventral foramina.[9] The internal iliac veins lie posteromedial to the internal iliac arteries and course caudally. They are located medial to the sacroiliac joint directly adjacent to the sacral ala.[15] The internal iliac veins are the repository of an extensive presacral venous plexus. This plexus is formed by extensive anastomoses between the lateral and middle sacral veins and receives transforaminal veins that communicate with epidural veins in the spinal canal.[1,8,18] This extensive vascular network renders anterior exposures to the sacrum impractical and perilous.

History and Classification

Sacral fracture classifications have prioritized several different features over time and have evolved over the past 70 years to emphasize variables that are currently believed to have the most impact on treatment and prognosis: the presence of neurologic deficits, posterior pelvic instability, and spinopelvic instability.

Bonnin reported the first classification of sacral fractures in 1945.[19] He divided sacral fractures by mechanism of injury into those occurring as a result of either direct or indirect forces. Direct force injuries occurred from a projectile or a fall. These were isolated injuries to the sacrum and had minimal or no impact on either spinal or pelvic instability. Conversely, with indirect injuries resulting from the transmission of forces through a disrupted pelvic ring, he described several anatomic patterns of injury, including the propensity of the sacrum to fracture through the S1 and S2 neuroforamina at the junction of the ala and the body, resulting in a "broken link in the solid connections between the ilium and the vertebral column." In addition to pelvic ring and/or spinal column instability, anatomic patterns of injury that included the neuroforamina or spinal canal were noted to be associated with possible neurologic deficit. Specifically, S1 or S2 nerve root injury was common in his cases. Bowel and bladder dysfunction as a result of lower sacral nerve root injury was sometimes also seen.[19]

Several other classification schemes based on the identification of additional injury patterns were subsequently proposed.[20,21] None was widely adopted until 1988, when Denis and colleagues,[14] based on a series of 236 sacral fractures, formulated a simplified anatomic classification that correlates fracture location with the incidence of neurologic injury. This classification divides the sacrum into three zones (Fig. 78.4). In zone 1, or the alar zone, fractures remain lateral to the neuroforamina throughout their course. In zone 2, or the foraminal zone, fractures are located in the transition area between the sacral ala and body and involve one or more neuroforamina while remaining lateral to the spinal canal. In zone 3, or the central zone, fractures involve the spinal canal. The key relationship is that the incidence and the severity of neurologic injury increases as fractures are more centrally located. Accordingly, in the series of Denis and colleagues, zone 1 fractures had a 5.9% incidence of neurologic injury, primarily to the L5 nerve root as it coursed over the ala. Zone

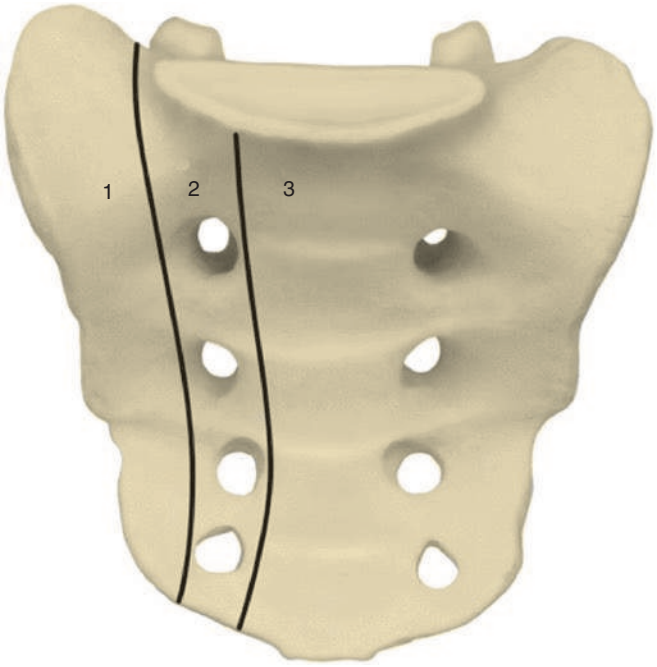

FIG. 78.4 Denis and coauthors[14] categorized sacral fractures according to the location of fractures relative to the sacral foramina (zones 1, 2, and 3). More medially located fractures have a higher risk of neurologic deficits and a worse prognosis.

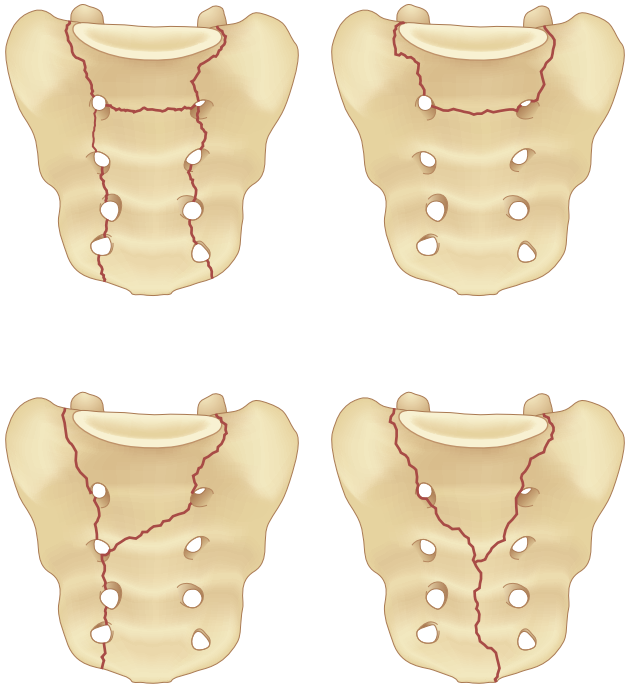

FIG. 78.5 Descriptive classification of sacral fractures: Sacral U variants with spinopelvic instability include (clockwise from top left) H, U, Y, and lambda fractures.

2 fractures had a 28.4% incidence of associated neurologic injury occurring as a result of either foraminal displacement and resulting impingement on the exiting nerve root or of the "traumatic far-out syndrome," in which the L5 nerve root is caught between the L5 transverse process and the displaced sacral ala. Zone 3 fractures had a 56.7% incidence of neurologic injury resulting from injury at the level of the spinal canal, with 76.1% of these individuals having bowel, bladder, and sexual dysfunction. Denis and colleagues[14] noted a spectrum of zone 3 sacral fracture-dislocations, including both transverse and longitudinal fracture line orientations, and described a subtype that they termed a *sacral burst fracture*, consisting of retropulsion of the sacral body with intact sacral laminae.

Gibbons and colleagues[22] subsequently considered 44 cases of sacral fracture according to the Denis classification system. They found a 34% incidence of neurologic injury overall. Six of 25 patients (24%) with zone 1 injuries had L5 and/or S1 nerve root injuries. Two of seven patients with zone 2 injuries similarly had L5 and S1 deficits. No patient with zone 1 or 2 injuries had bowel or bladder dysfunction. Three of five patients with zone 3 injuries had neurologic injury, two with bladder dysfunction. Gibbons and colleagues[22] used these findings as a basis for a classification of neurologic injury from sacral fractures. Neurologic injuries were classified as follows: 1, no injury; 2, lower extremity paresthesias only; 3, lower extremity motor deficit with intact bowel and bladder function; or 4, impaired bowel and/or bladder control. They also noted that significant neurologic deficit is rare in transverse sacral fractures below the S4 level. This classification system, while simple, does not address incomplete injuries or sexual function.

Huittinen,[23] in a postmortem study of 42 individuals with posterior pelvic ring disruptions, studied the incidence and anatomic basis of nerve injuries. A total of 40 lumbosacral nerve injuries were identified in 20 of the autopsies. A total of 53% were traction injuries and 38% were ruptures. Compression injuries, the most amenable to surgical intervention, were present in only 20% of the nerve injuries.

Because of the high potential for neurologic injury, as well as spinal column instability, sacral body (Denis zone 3) fractures have been specifically considered by several investigators. Early case reports often characterized the injury pattern as solely a transverse fracture, possibly owing to imaging limitations.[24–26] Computed tomography (CT) demonstrates that most transverse fractures of the upper sacrum have complex fracture patterns. The majority of these injuries are now understood to consist of a transverse fracture of the sacrum with associated longitudinal or "vertical" injury components, usually in the form of bilateral transforaminal fractures that extend as far rostrally as the lumbosacral junction, the so-called sacral "U" fracture. Variations in fracture line propagation include the "H," "Y," and "lambda" fracture patterns (Fig. 78.5). There is also a high incidence of L5 transverse process fractures, indicating disruption of the iliolumbar ligament.[27]

Roy-Camille and colleagues[28] reviewed their experience of 13 patients with transverse sacral fractures, 11 as a result of attempted suicide by jumping. They classified the fractures as type 1, flexion deformity of upper sacrum (angulation alone); type 2, flexion deformity with posterior displacement of the upper sacrum on the lower sacrum (angulation and posterior translation); and type 3, anterior displacement of the upper sacrum without angulation (anterior translation alone). On

the basis of cadaveric studies, they hypothesized that types 1 and 2 were caused by impact with the lumbar spine in flexion, whereas type 3 fractures were caused by impact with the lumbar spine and hips in extension.[28] Strange-Vognsen and Lebech[29] subsequently reported a case of comminution of the upper sacrum without significant angulation or translation that they termed a *type 4 injury relative to the Roy-Camille classification.* They hypothesized that in type 4 injuries the lumbar spine was in the neutral position at the point of impact (Fig. 78.6). A type 5 injury, which consists of segmental comminution of the sacrum, has been proposed by Schildhauer and coauthors.[30] All of these injuries are caused by indirect forces to the lumbosacral junction. Unfortunately, the location of the transverse component of the sacral body fracture is not specified by this classification system. Defining the transverse sacral fracture as high (involving S2 or above) or low (involving S3 or below) can be helpful from both a biomechanical and neurologic standpoint.[24]

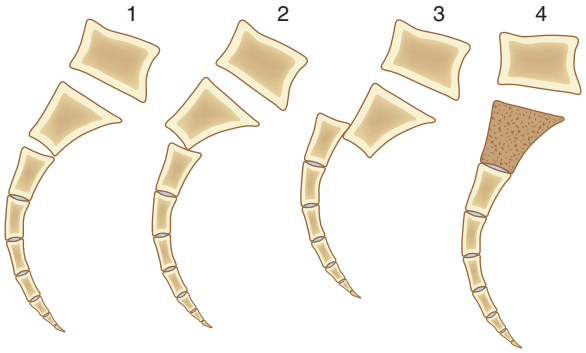

FIG. 78.6 Roy-Camille classification of sacral fractures. The Roy-Camille classification,[28] as modified by Strange-Vognsen and Lebech,[29] categorizes AO type C3[45] fractures according to sagittal plane angulation and displacement.

Other patterns of sacral fractures have been identified as resulting from specific mechanisms or having predictable patterns of associated injuries. In particular, in contrast to transverse Denis zone 3 sacral fractures, midline longitudinal Denis zone 3 sacral fractures have a low incidence of neurologic injury and constitute a very different injury from the standpoint of treatment and prognosis (Fig. 78.7).[31-33] This injury, in which the sacrum is disrupted through a sagittal plane fracture, was originally reported by Wiesel and colleagues in 1979, who suggested that these fractures may have a lower incidence of neurologic injury than transverse fractures because the nerve roots are displaced laterally instead of being subjected to the compression or possibly even transection that can result from shear forces associated with displaced transverse fractures.[33] Bellabarba and colleagues[31] subsequently described this injury as a variant of the anteroposterior compression pelvic ring injury. In their series of 10 patients, none had neurologic deficits in contradistinction to the high incidence of neurologic injury reported in patients with predominantly transverse sacral fractures through the spinal canal.[31]

Even in the absence of a transverse fracture line, sacral fractures can be associated with spinal column instability. Isler

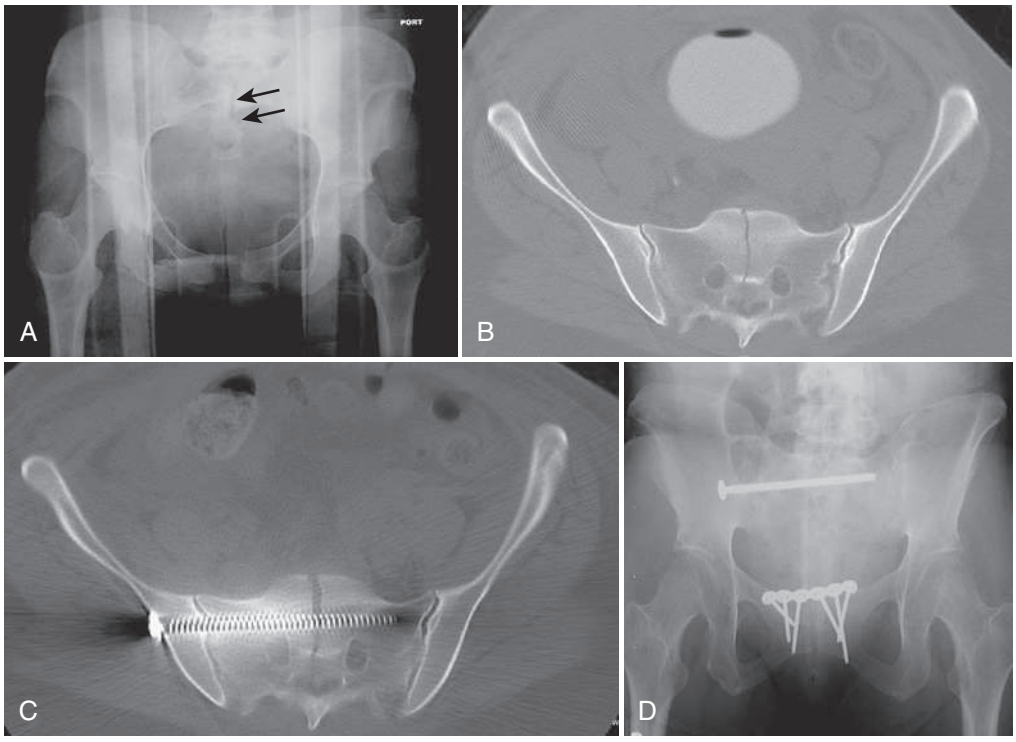

FIG. 78.7 (A–B) An unusual Denis zone 3 variant that is usually not accompanied by neurologic deficits consists of a longitudinal fracture of the sacral vertebral bodies that does not extend into the neuroforamina (arrows). Because this is typically the most benign of the longitudinal sacral fracture patterns, it has been designated as AO type B1. (C–D) After treatment with iliosacral screw fixation and symphyseal plating.

described variations of longitudinal sacral fractures through the S1 and S2 neuroforamina that result in L5–S1 motion segment instability owing to facet joint disruption (Fig. 78.8).[34] Injuries with the fracture line lateral to the S1 articular process are not associated with instability of the lumbosacral articulation because the L5–S1 articulation remains continuous with the stable fracture component of the sacrum. Fracture that extends into or medial to the S1 articular process, however, may disrupt the associated facet joint and potentially destabilize the lumbosacral junction (Fig. 78.9). Complete displacement of the facet joint can cause a locked facet joint, making sacral fracture reduction difficult with closed methods alone. Facet disruption may also cause posttraumatic arthrosis and late lumbosacral pain.

In contrast to sacral fractures that occur as a result of high-energy mechanisms of injury, the precipitating event in sacral insufficiency fractures is often not identifiable or may be related to a fall onto the buttocks from a standing or sitting position. Insufficiency fractures occur in weakened bone, and these injuries typically occur in postmenopausal women due to osteoporosis. Conditions contributing to the suboptimal bone quality, such as chronic corticosteroid use or a history of radiation therapy to the pelvis, are often present (Fig. 78.10).[35] The presenting symptoms are often vague and frequently consist of poorly localized low back pain that may be exacerbated by sitting and standing, possibly with lumbosacral radiculopathy. These fractures are typically oriented vertically and occur through the ala adjacent to the sacroiliac joint. There may also be a transverse component resulting in more complex sacral "U"-fracture variants. Because of the predisposition of these patients to osteoporotic fractures, there is high association with insufficiency fractures at other sites, most commonly the pubis and thoracolumbar vertebrae. Neurologic deficits are uncommon in most series.[36,37] Cauda

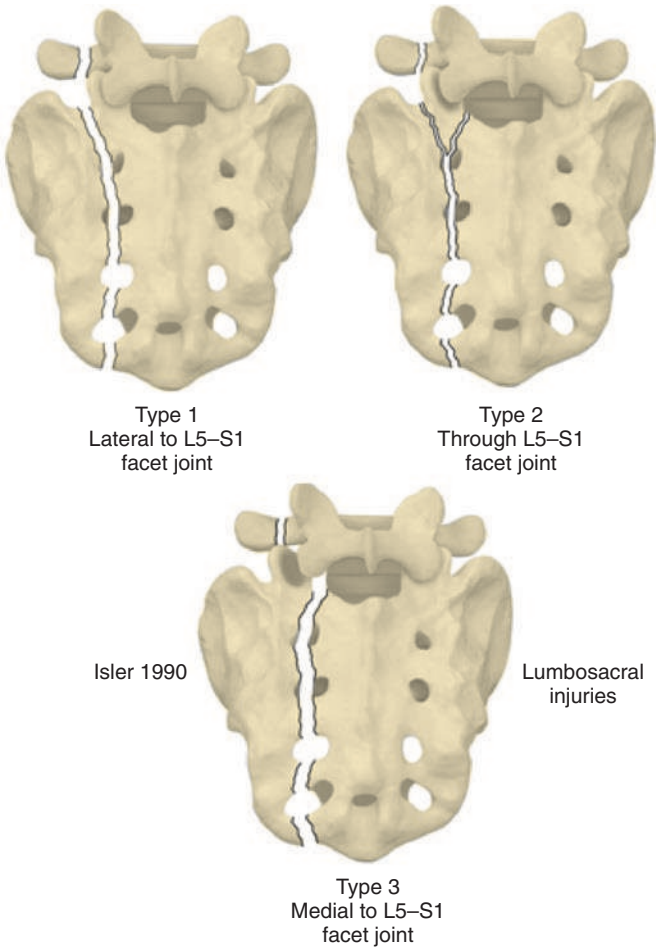

FIG. 78.8 Isler classification of sacral fractures.[34] Isler classified vertical sacral fractures according to the location of the fracture relative to the L5–S1 facet joint. Fracture patterns that extend medial to the L5–S1 facet joint (types 2 and 3) result in spinopelvic instability.

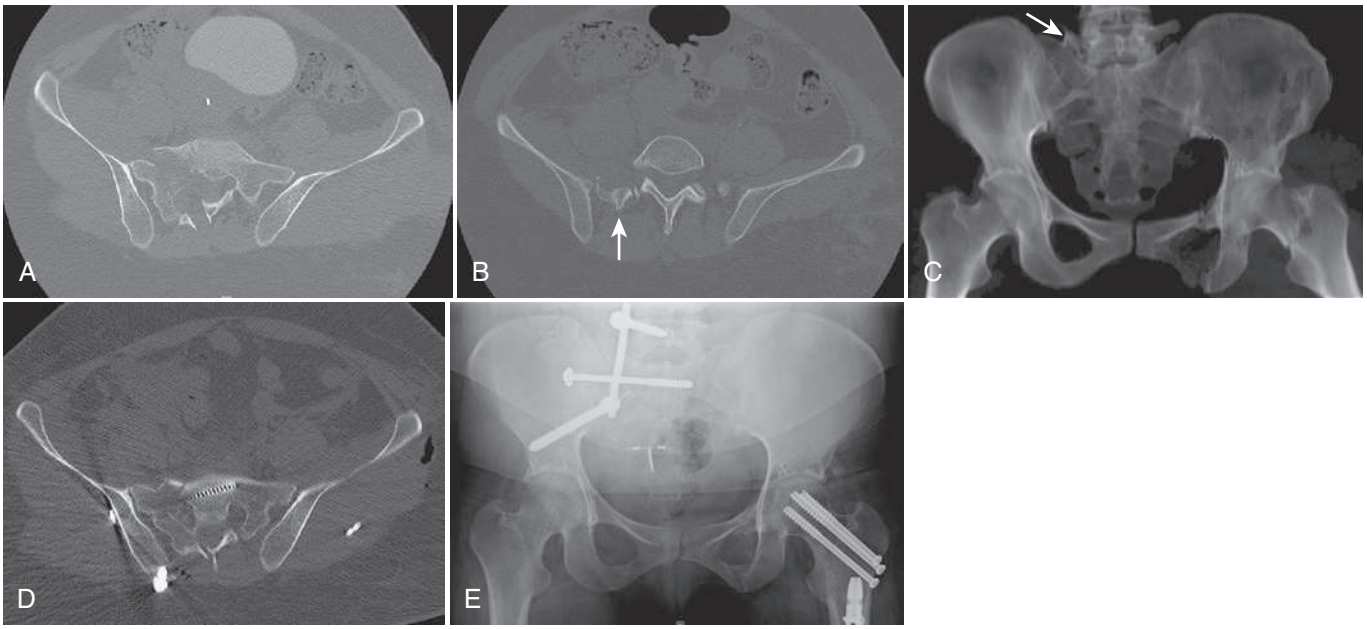

FIG. 78.9 (A) Displaced Denis zone 2 sacral fracture associated with (B–C) dislocation of the L5–S1 facet joint, Isler type 3. (D–E) After open reduction and triangular osteosynthesis.

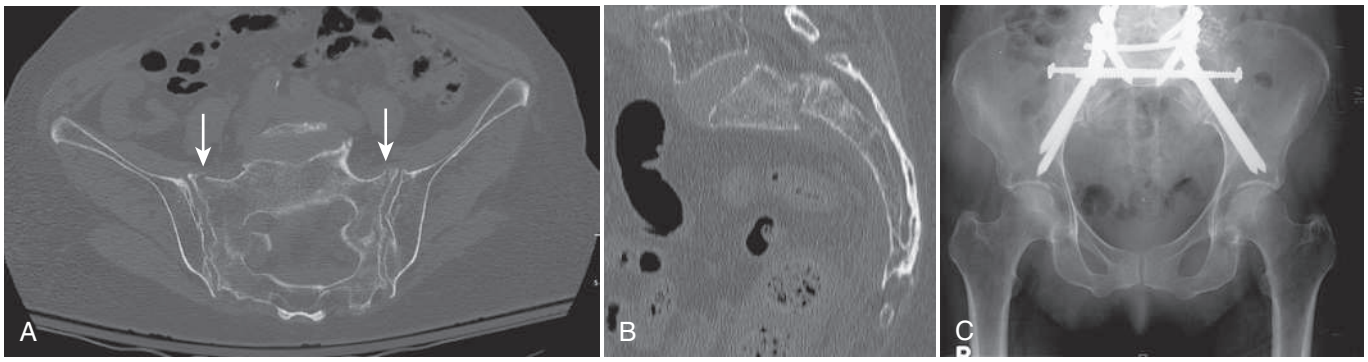

FIG. 78.10 (A–B) Sacral U insufficiency fracture in a patient with a history of radiation therapy to the pelvis for cervical cancer who had recently developed severe low back pain and progressive loss of bowel and bladder function. (C) After treatment with decompression and lumbopelvic fixation, her bowel and bladder function returned and she was able to resume pain-free normal activity.

equina dysfunction has been reported, however, and neurologic status must be carefully considered.[38]

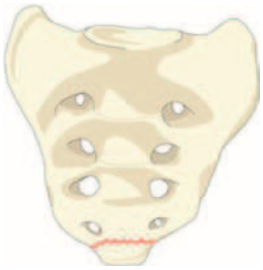
Mechanical factors related to the transfer of forces from the lumbosacral spine to the pelvis may also cause sacral insufficiency fractures in the patient predisposed to osteoporosis.[29] Specifically, unilateral sacral insufficiency fractures have been identified contralateral to the convex side of lumbar scoliosis.[36] Pelvic stress concentration as the result of lumbosacral spine fusion has also been described[39]; sacral insufficiency fractures caudal to previous lumbar fusions are also increasingly being reported. These fractures probably represent failure of the sacrum to withstand forces concentrated there as a result of the large cephalad lever arm.[40–44]

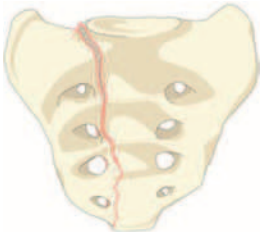
Stress fractures of the sacrum, as opposed to insufficiency fractures, occur in bone that is not weakened by a pathologic process. They are seen in individuals whose activity level causes repetitive stress that exceeds the bone's reparative ability. High-demand individuals, such as endurance athletes and military recruits, are particularly susceptible. As with individuals with insufficiency fractures, these patients may present with vague and nonspecific low back pain. Other areas of stress fracture may cause additional symptomatic areas; femoral neck fractures, in particular, must be considered in the instance of groin pain. In some instances, the etiology of low-energy sacral fractures may be related to both repetitive stress and insufficiency. In particular, sacral fractures in female athletes with amenorrhea may result from both overuse and osteopenia.

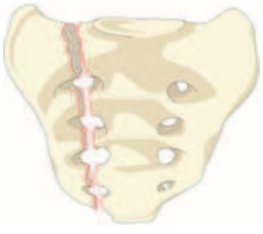
A recent AO Spine–led effort has categorized sacral fractures based primarily on the following: (1) the extent and type of instability; (2) the severity of neurologic injury; and (3) associated injuries or conditions that may influence treatment or prognosis.[45] This was done with the goal of combining the various existing classifications and other published observations described earlier into a comprehensive classification system that helps guide treatment and correlates with prognosis (Fig. 78.11). This system is designed to complement the separate AO Trauma pelvic fracture classification. Type A fractures range from inconsequential injuries to severely displaced transverse fractures that occur below the sacroiliac joint, and therefore result in neither posterior pelvic nor spinopelvic instability. Type B fractures are longitudinal or "vertical" fracture patterns that result in posterior pelvic instability without compromise of the spinopelvic junction. Type C injuries result in spinopelvic instability with or without posterior pelvic instability. Type A and type B fractures are each divided into three subtypes, and type C injuries are divided into four subtypes, categorized according to injury severity based on greater risk of neurologic deficit or of instability. Neurologic injury is classified according to the same system used by the AO Spine classification throughout the entire spine: NX, patient not examinable; N0, no neurologic deficit; N1, transient neurologic deficit; N2, nerve root injury; N3, incomplete spinal cord injury or cauda equina syndrome (either complete or incomplete); N4, complete spinal cord injury. Because sacral fractures do not occur at the spinal cord level, they cannot cause neurologic injuries more severe than N3. Modifiers that may affect treatment or prognosis include the following: M1, soft tissue injury (either an open or a closed degloving injury); M2, metabolic bone disease; M3, anterior pelvic or acetabular fracture; M4, sacroiliac joint injury.

Evaluation

Sacral fractures occur in two distinctly different patient groups. Most commonly, sacral fractures are the result of high-energy trauma. As noted previously, they are also increasingly being seen in patients with metabolic bone disorders that predispose to pathologic fractures. In both groups of patients, but more frequently in patients with insufficiency fractures, diagnosis is frequently delayed, which may result in further displacement or neurologic deterioration. In their retrospective analysis of 236 patients with sacral fractures, Denis and colleagues[14] found that in neurologically intact patients, the diagnosis of sacral fractures was made during the initial hospitalization only 51% of the time. The presence of a neurologic deficit increased the diagnostic accuracy to only 70%. As in most cases of diagnostic delay, the etiology of missed sacral fractures is multifactorial and ranges from the relative difficulty in identifying these fractures on screening anteroposterior pelvis radiographs combined with the presence of associated injuries







TYPE	General Description		Specific (Injury Types)	Images
A.	Lower Sacral (Coccygeal) Injuries (Below SI Joint)	No Impact on Pelvic Ring or Spinopelvic Instability	A1. Coccygeal or Lower Sacral Compression or Ligamentation Avulsion Injury

in the trauma patient to low clinical suspicion in patients with insufficiency fractures.[14,46] With the increased use of full-body CT scans to evaluate polytrauma patients, delayed diagnosis of sacral fractures has become much less common in patients with high-energy injuries.

In trauma patients, the transfer of energy resulting in a fracture of the sacrum often causes other injuries, including life-threatening head and thoracoabdominal trauma. In these patients, emergent resuscitation is the top priority. Accordingly, Advanced Trauma Life Support protocol begins with a primary survey during which conditions that are immediately life threatening are addressed. Resuscitation is focused on maintaining cardiopulmonary and hemodynamic stability. Only after this primary goal has been achieved should the secondary survey be completed, composed of examination of the patient to identify additional injuries.[47]

The secondary survey includes screening evaluation of both the spinal column and pelvic ring. Precautions to maintain spinal column integrity are necessary; patients should be initially maintained on a flat surface and log-rolled side to side to prevent spinal column displacement. Evaluation includes inspection and palpation of the patient's back from the occiput to the coccyx. Sacral fractures commonly have overlying skin discoloration or lacerations, palpable step-offs or crepitus, localized tenderness, and hematomas, any of which can indicate the presence of a sacral fracture. Significant soft tissue contusion or internal degloving, analogous to Morel-Lavallee lesions seen with acetabular fractures, can have implications on subsequent treatment.[48] Manual compression over the iliac crests, both anteroposteriorly and laterally, may also help identify a sacral fracture. Perforations of the rectum or vagina can represent open sacral fractures, which can be detected with rectal and vaginal digital examination as well as the use of a speculum and proctoscope.

Because pelvic ring disruption may be associated with significant intrapelvic hemorrhage, temporary methods of pelvic ring stabilization may be necessary to reduce pelvic volume and provide provisional stability. These methods include the

application of a circumferential pelvic antishock sheet,[10] pelvic clamp, anterior external fixator, or skeletal traction, depending on the pelvic ring fracture pattern. Associated vascular injury, particularly to the hypogastric arterial system, may require embolization to adequately control arterial hemorrhage.[49]

Determining the patient's neurologic status is of paramount importance in patients with sacral fractures.[50–52] A rectal examination is performed early in the workup of all multiply injured patients, even in the absence of obvious sensorimotor deficits in the extremities, to evaluate perianal sensation, anal sphincter tone, and voluntary perianal contraction and to assess for presence of anal wink and the bulbocavernosus reflex. The bulbocavernosus is a polysynaptic reflex that is generally useful in testing for spinal shock and gaining information about the state of spinal cord injuries, but is particularly useful in evaluating sacral root function. The test involves monitoring anal sphincter contraction in response to squeezing the glans penis or clitoris, or tugging on an indwelling Foley catheter. The reflex is spinal mediated and will be absent with injury to the S2–S4 spinal nerves. The absence of the reflex without sacral root or conus medullaris trauma indicates spinal shock. A straight-leg raise test may be useful in the cognitively unimpaired patient to assess for entrapment of the lumbosacral plexus. Overall severity of neurologic injury is graded according to the American Spinal Injury Association modification of the Frankel grading system. Extremity motor function is further graded on a scale of 0 to 5 to establish the American Spinal Injury Association motor score, and a sensory level is obtained. Neurologic examination can only distinguish injuries to the L5 and S1 levels, however, and injuries to the lower sacral roots cannot be more specifically identified beyond obtaining a perianal sensory level.

Fracture displacement can cause neurologic injury from a variety of mechanisms, including angulation, translation, and direct compression by displaced bone fragments. Potentially reversible injuries include contusion, compression, and traction. Recovery of transected or avulsed nerve roots cannot be expected. Delayed neurologic deficit can occur from epidural hematoma, late fracture displacement, or callus formation[19] and should be promptly reinvestigated to determine its cause.

There are multiple adjunctive methods for the evaluation of the neurologic status in a patient with a sacral fracture. Electrodiagnostic studies may be of value in the evaluation of cognitively impaired patients and in differentiating upper motor neuron injuries or spinal cord injury from cauda equina injury in patients with head or more rostral spinal column injury, in the evaluation of patients with urinary tract injury, and for intraoperative monitoring.[53] Conventional electromyography (EMG) and somatosensory-evoked potentials may be useful for the evaluation of L5 and S1 function, while pudendal somatosensory-evoked potentials and anal sphincter EMG can be used to evaluate the sacral roots below the S1 level. These electrodiagnostic techniques are typically not used in the setting of acute injuries, however.[54–57] EMG is particularly limited in the acute setting because abnormalities may take weeks to develop. Possible abnormalities on sphincter EMG include detrusor areflexia, uninhibited sphincter relaxation, or denervation. For patients with neurogenic bladder, serial postvoid residuals or cystometrography are useful diagnostic aids.

Careful scrutiny of the anteroposterior pelvic radiograph, if available, allows for a majority of sacral fractures to be identified. Nevertheless, with the use of plain radiographs alone, sacral fractures can be easily missed, owing to a variety of circumstances. Because of its sagittal inclination and the juxtaposition of the iliac wings, sacral fractures can be difficult to visualize on the anteroposterior radiograph. This is particularly true of injuries with less obvious deformity of the pelvic ring that present mainly with displacement of the transverse sacral component and spinopelvic instability. Osteopenic bone and sacral dysmorphism can also obscure landmarks, making the identification of fractures more challenging.

The increasingly routine use of more sophisticated imaging techniques in the initial assessment of the trauma patient's visceral injuries, such as CT of the abdomen and pelvis, has facilitated the detection of previously under-recognized sacral fractures. The identification of a sacral fracture on these studies mandates complete radiographic evaluation, including a dedicated CT scan of the sacrum with 2-mm or less axial cuts and sagittal and coronal reformations to allow the detail required for determining the fracture configuration, resulting instability pattern, and extent of sacral canal and neuroforaminal compromise (Fig. 78.12).[58] Three-dimensionally reformatted CT scans may add insight into fracture morphology for less experienced clinicians or in the case of highly complex fracture configurations.

Several additional plain radiographic projections can yield important information. The pelvic inlet and outlet views, obtained with 45-degree caudal and 60-degree cephalad tilt, respectively, are standard techniques for evaluating pelvic ring injuries. The Ferguson view, a coned-down true anteroposterior view of the sacrum, is obtained with a 30-degree cranially inclined projection. A lateral radiograph is useful in evaluating sacral inclination and the presence of a transverse fracture. Useful radiographic indicators of sacral injuries include abnormalities in the contour of the sacral foramina and sacral arcuate lines and the presence of a "paradoxical inlet" view of the sacrum on the anteroposterior pelvic view. Their presence strongly suggests a sacral fracture, and further investigation should be done. These radiographic projections can also be obtained from three-dimensional reconstruction of the initial posttraumatic CT image, limiting the need for additional imaging studies.

Magnetic resonance imaging is not usually helpful except in cases of unclear neurologic deficits or discrepancies between skeletal and neurologic levels of injury, although it may provide early evidence of lumbosacral nerve root avulsion.[59] Recent advances in magnetic resonance imaging neurography allowing for visualization of lumbosacral plexus injuries may be of some help in their evaluation, although at this point it is neither a reliably effective nor a practical diagnostic tool.

General Principles

Decision making in sacral fracture treatment is primarily based on the fracture pattern and location and neurologic

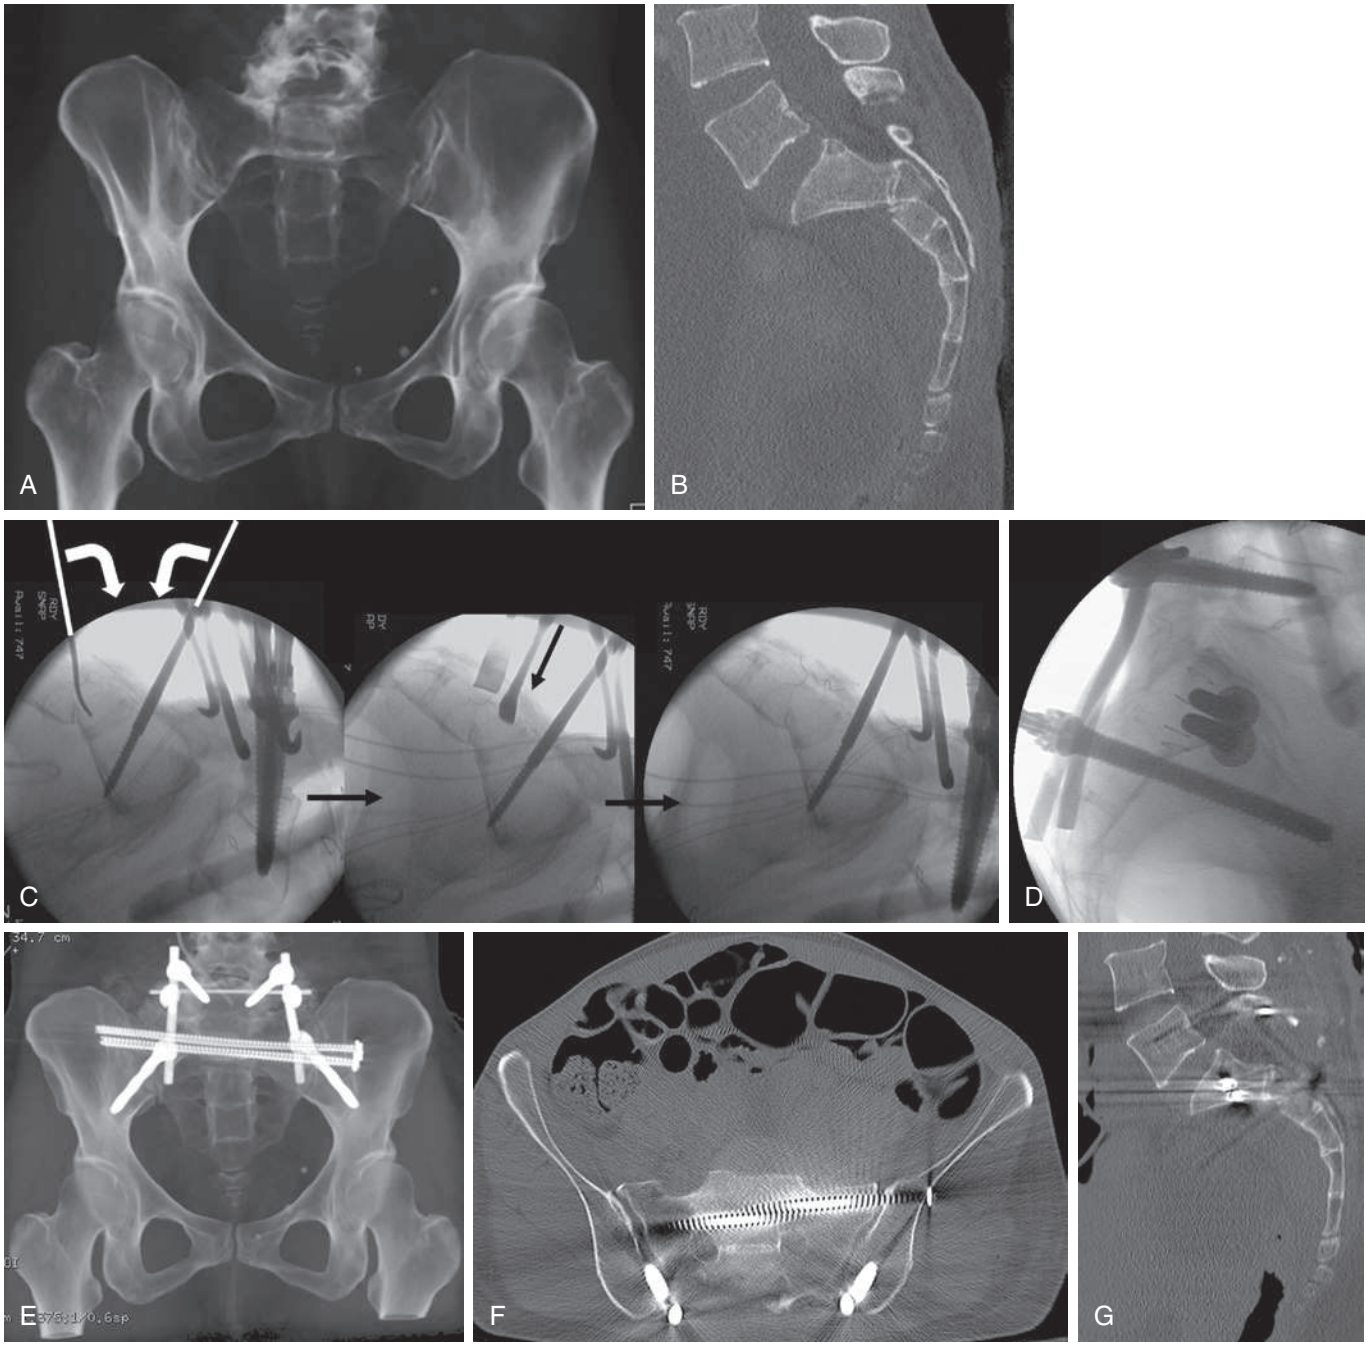

FIG. 78.12 Reduction and stabilization of AO type C3, Roy-Camille type 2 sacral fracture. (A) Despite severe sacral fracture displacement with cauda equina syndrome after a 10-foot fall, this anteroposterior view of the pelvis appears deceptively benign in the absence of pelvic ring deformity. (B) This sagittal computed tomographic (CT) image illustrates kyphosis, retrolisthesis, and spinal canal compromise consistent with Roy-Camille type 2 variant of AO type C3 fracture. Note the distended urinary bladder due to loss of sacral root function. (C) Intraoperative radiographs demonstrate reduction techniques, which include mobilization of impacted fracture fragments with an elevator and direct manipulation of the fracture fragments with Schanz pin joystick placed in the upper sacral fracture fragment. (D) After acceptable fracture reduction, provisional stabilization is achieved with transiliac-transsacral screw fixation, which is then supported by spinopelvic fixation. (E) Postoperative anteroposterior reconstruction of the pelvis. (F) Axial CT image, and (G) sagittal CT reformation of the sacrum demonstrate restoration of acceptable alignment and decompression of the sacral spinal canal and foramina. This patient regained sacral root function.

status. Surgical indications include the presence of instability, malalignment, and neurologic deficit. Other key factors are the patient's general medical condition and additional injuries, particularly in the trauma patient. Hemodynamic instability or compromised pulmonary function may preclude early surgical stabilization in critically injured patients. Conversely, the benefits of early mobilization in trauma patients with pulmonary injuries may make early surgical stabilization advisable.[60,61] Surgical timing in patients with closed-head injuries in particular is controversial, and skilled perioperative management is essential to prevent secondary brain injury.[62,63] Isolated sacral fractures in the patient who is otherwise healthy may be amenable to a period of recumbency followed by protected weight bearing. Chronic medical conditions also need to be considered and may require an initial period of nonoperative stabilization before surgical intervention while medical conditions are optimized.

Careful examination of the fracture pattern is essential in determining if the sacral fracture is associated with instability of the weight-bearing axis and whether this involves posterior pelvic instability, spinopelvic instability, or a combination of the two. Unilateral longitudinal fractures through the ala (AO type B2) or foraminal (AO type B3) zone maintain continuity of the contralateral weight-bearing axis, allowing weight bearing on that side (Fig. 78.13; also see Fig. 78.9). Bilateral displaced longitudinal fractures (AO type C2), as well as transverse fractures with associated bilateral longitudinal fractures through the upper sacrum (AO type C3), dissociate the spinal column from the pelvic ring and represent complete disruption of the weight-bearing axis.[28,64–66] Weight bearing on either lower extremity may cause displacement in these instances. Conversely, transverse fractures below the sacroiliac joint (AO type A) have no implication on the weight-bearing axis and therefore on either posterior pelvic or spinopelvic instability, as long as they are not associated with secondary fracture lines extending rostrally.[67]

Neurologic deficit needs to be correlated with fracture anatomy. Residual compression of nerve roots at the level of the spinal canal or neuroforamina due to impingement by bony fragments or malalignment of the spinal canal at the fracture site with the cauda equina draping over a kyphotic ridge should be identified. Possible neurologic deterioration from persistent fracture instability should also be considered. Although the presence of a neurologic deficit is an indication for operative intervention, the effectiveness of surgery in improving neurologic outcomes after fracture of the sacrum remains unproven since the literature on this topic consists primarily of small, heterogeneous case series without consistent grading and definitions of neurologic dysfunction.[14,20–22,24,26,27] Therefore, each case needs to be individually considered; our opinion is that surgical decompression, which usually can also be achieved with fracture reduction and stabilization, should be considered in the presence of a potentially reversible neurologic injury.

Functional outcome studies have demonstrated that a minority of sacral fracture patients returned to their preinjury vocational status over a year after injury. Although the vast majority of patients sustained long-term physical and mental

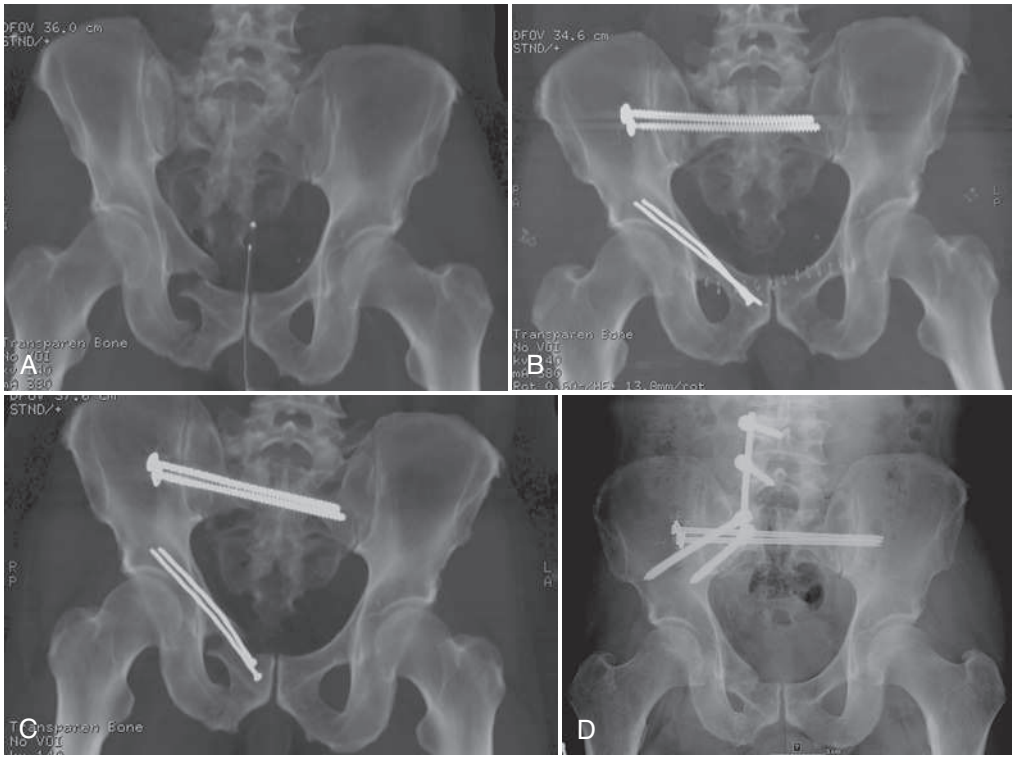

FIG. 78.13 (A) Right AO type B3 (Denis zone 2) sacral fracture treated with (B) closed reduction and percutaneous iliosacral screw and superior pubic ramus fixation. (C) Early fracture displacement required (D) revision with the triangular osteosynthesis variant of lumbopelvic fixation.

impairment, the severity of these impairments did not correlate directly with fracture characteristics but was more a function of associated injuries and sacral root function.[68,69]

Nonoperative Treatment

The traditional treatment of sacral fractures was by nonoperative means. Nonoperative treatment consists of a period of recumbency followed by protected weight bearing and possibly bracing to minimize load transfer to the sacrum. The period of recumbency varies considerably, depending on the extent of fracture instability. Recumbency is usually required in insufficiency fractures for pain control; in unstable fractures, it is required to allow for callus formation and to decrease the possibility of displacement. Displaced fractures are treated with skeletal traction to improve alignment and bifemoral traction has been used to improve alignment in complex sacral fractures with bilateral involvement.

Nonoperative treatment in displaced, high-energy sacral fractures can be problematic, however, and contradicts modern trauma principles of early mobilization of patients with multiple injuries. Although surgical complications can be avoided by using closed treatment methods, potential disadvantages include life-threatening pulmonary and thromboembolic events that are associated with prolonged recumbency in patients with multiple injuries, the development of decubitus ulcers, the inability to reliably relieve sacral canal and neuroforaminal compression, and the potential for late instability causing neurologic deficits and fixed deformities that are difficult to correct (see Fig. 78.1).[70]

Nonoperative treatment is most attractive in patients with minimally displaced, unilateral sacral fractures without associated neurologic deficits. Mobilization is usually with a walker or crutches enabling toe-touch weight bearing on the injured side. These patients must be followed carefully for fracture displacement, which may warrant surgical stabilization. Insufficiency or stress fractures are also usually amenable to nonoperative treatment in spite of frequent bilateral involvement. Along with activity modification and correction of underlying metabolic conditions, nonoperative treatment has a high likelihood of success in the majority of insufficiency and stress fractures and is usually the treatment of choice in these fractures. However, if patient mobility or pain control is sufficiently compromised, operative intervention, preferably with percutaneous techniques, may be the better option (Fig. 78.14).[38]

Operative Treatment

The goals of surgical treatment are twofold: (1) neurologic decompression in cases of neurologic deficit and (2) realignment and stabilization of the bony architecture in cases of significant displacement or instability. The timing of surgical intervention is dictated by many factors. The presence of an open fracture, either externally or into the alimentary or genital tracts, requires expeditious operative intervention with irrigation and debridement followed by surgical stabilization in cases with the potential for recurrent or persistent fracture displacement through the open wound. Neurologic deficit also suggests the need for immediate surgical decompression, though associated injuries and the patient's physiologic state may dictate the feasibility of doing so, given that decompression within 2 weeks of injury appears to be an acceptable time frame. Severe angulation of a transverse sacral fracture may also tent the overlying soft tissues and cause skin breakdown, particularly in patients whose body habitus or general physical condition predisposes them to pressure sores. In many cases, the multiply injured patient's physiologic status is the main determinant in the timing of operative intervention.

Neurologic Decompression

Decompression of the neural elements can be achieved by either direct or indirect means. Indirect decompression can sometimes be achieved simply with fracture reduction. An attempt at indirect decompression is best accomplished before consolidation of the fracture hematoma.[71] If neural impingement persists and is associated with a neurologic deficit, direct decompression should be considered.

In patients with sacral root deficits, direct decompression alone by laminectomy and removal of compressive bone fragments without stabilization has been advocated as a method for providing sacral root decompression, therefore theoretically enhancing the possibility of neurologic recovery while minimizing the potential for complications associated with more extensive dissection and surgical stabilization.[24] Whereas unilateral injuries can be approached with a parasagittal exposure, the surgical exposure for bilateral injuries is preferably through a posterior midline approach. The parasagittal approach is not recommended for anything more than percutaneous spinopelvic fixation of bilateral injuries because it limits exposure to the spine and may result in the need for bilateral parasagittal exposures, which are even less desirable owing to the potential for soft tissue necrosis. Intraoperative fluoroscopy is useful for orientation and to assess alignment and decompression of the spinal canal. Decompression can be performed focally for selective ventral foraminal impingement or to achieve a more comprehensive decompression of the S1–S4 neural elements. In the instance of L5 root entrapment between the L5 transverse process and an alar bone fragment, decompression is performed by following the root laterally onto the shoulder of the ala and removing the offending fragment.

The possibility of significant epidural bleeding during direct decompression requires experience with techniques of epidural hemostasis. Similarly, experience with neural element repair is essential and dural tears that are encountered should be repaired if possible. The dura at the sacral level is often relatively thin and friable, and direct repair is often best performed with fine (e.g., 6-0) monofilament suture. Augmentation with fibrin glue may be used to increase the strength of the repair. Often, a direct repair is not possible owing to the severity of the disruption, in which case a patch may be required. In many cases, the disruption is through individual nerve roots caudal to the termination of the dural sac at the S2 level and is irreparable.

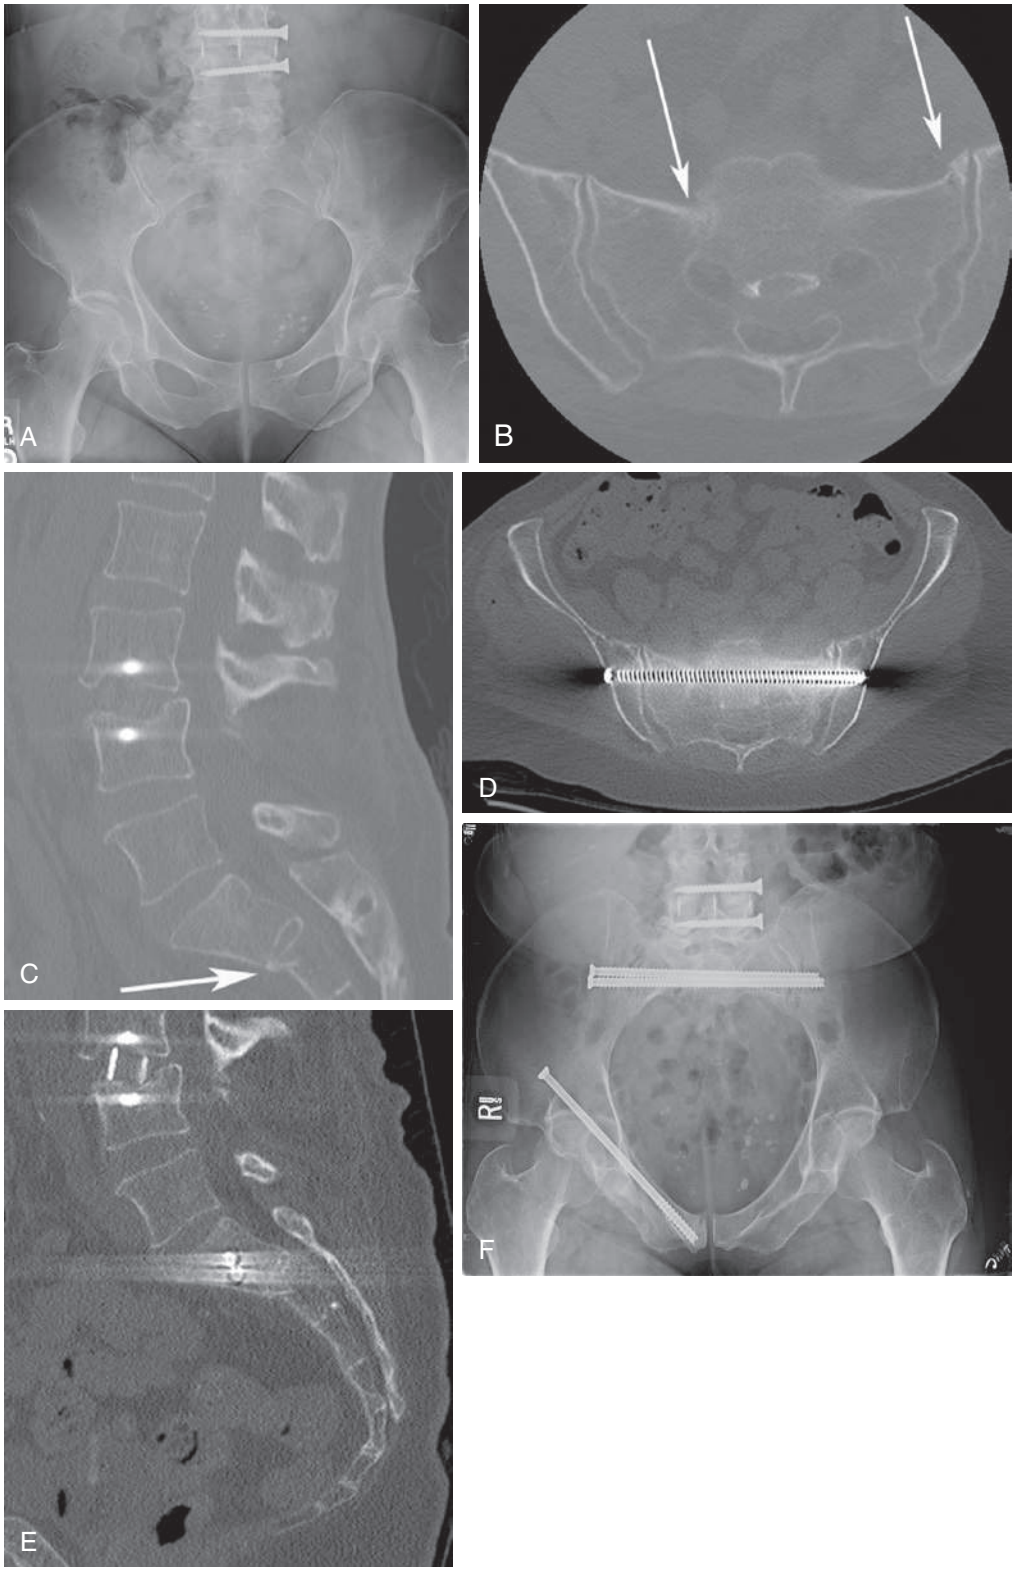

FIG. 78.14 AO type C0 sacral insufficiency fracture with right pubic ramus fracture treated by supine closed percutaneous transiliac-transsacral screw fixation. (A) Preoperative anteroposterior radiograph of the pelvis plus (B) axial and (C) sagittal lumbosacral spine computed tomographic (CT) images demonstrate minimally displaced sacral U insufficiency fracture (*arrows*) and right pubic ramus fracture in a patient with severe acute low back pain and sciatica whose symptoms were initially attributed to nonunion of a previous L3–L4 arthrodesis. (D) Postoperative axial and (E) sagittal CT images and (F) pelvic inlet radiograph after percutaneous fixation with two percutaneous transiliac-transsacral screws and a right percutaneous pubic ramus screw.

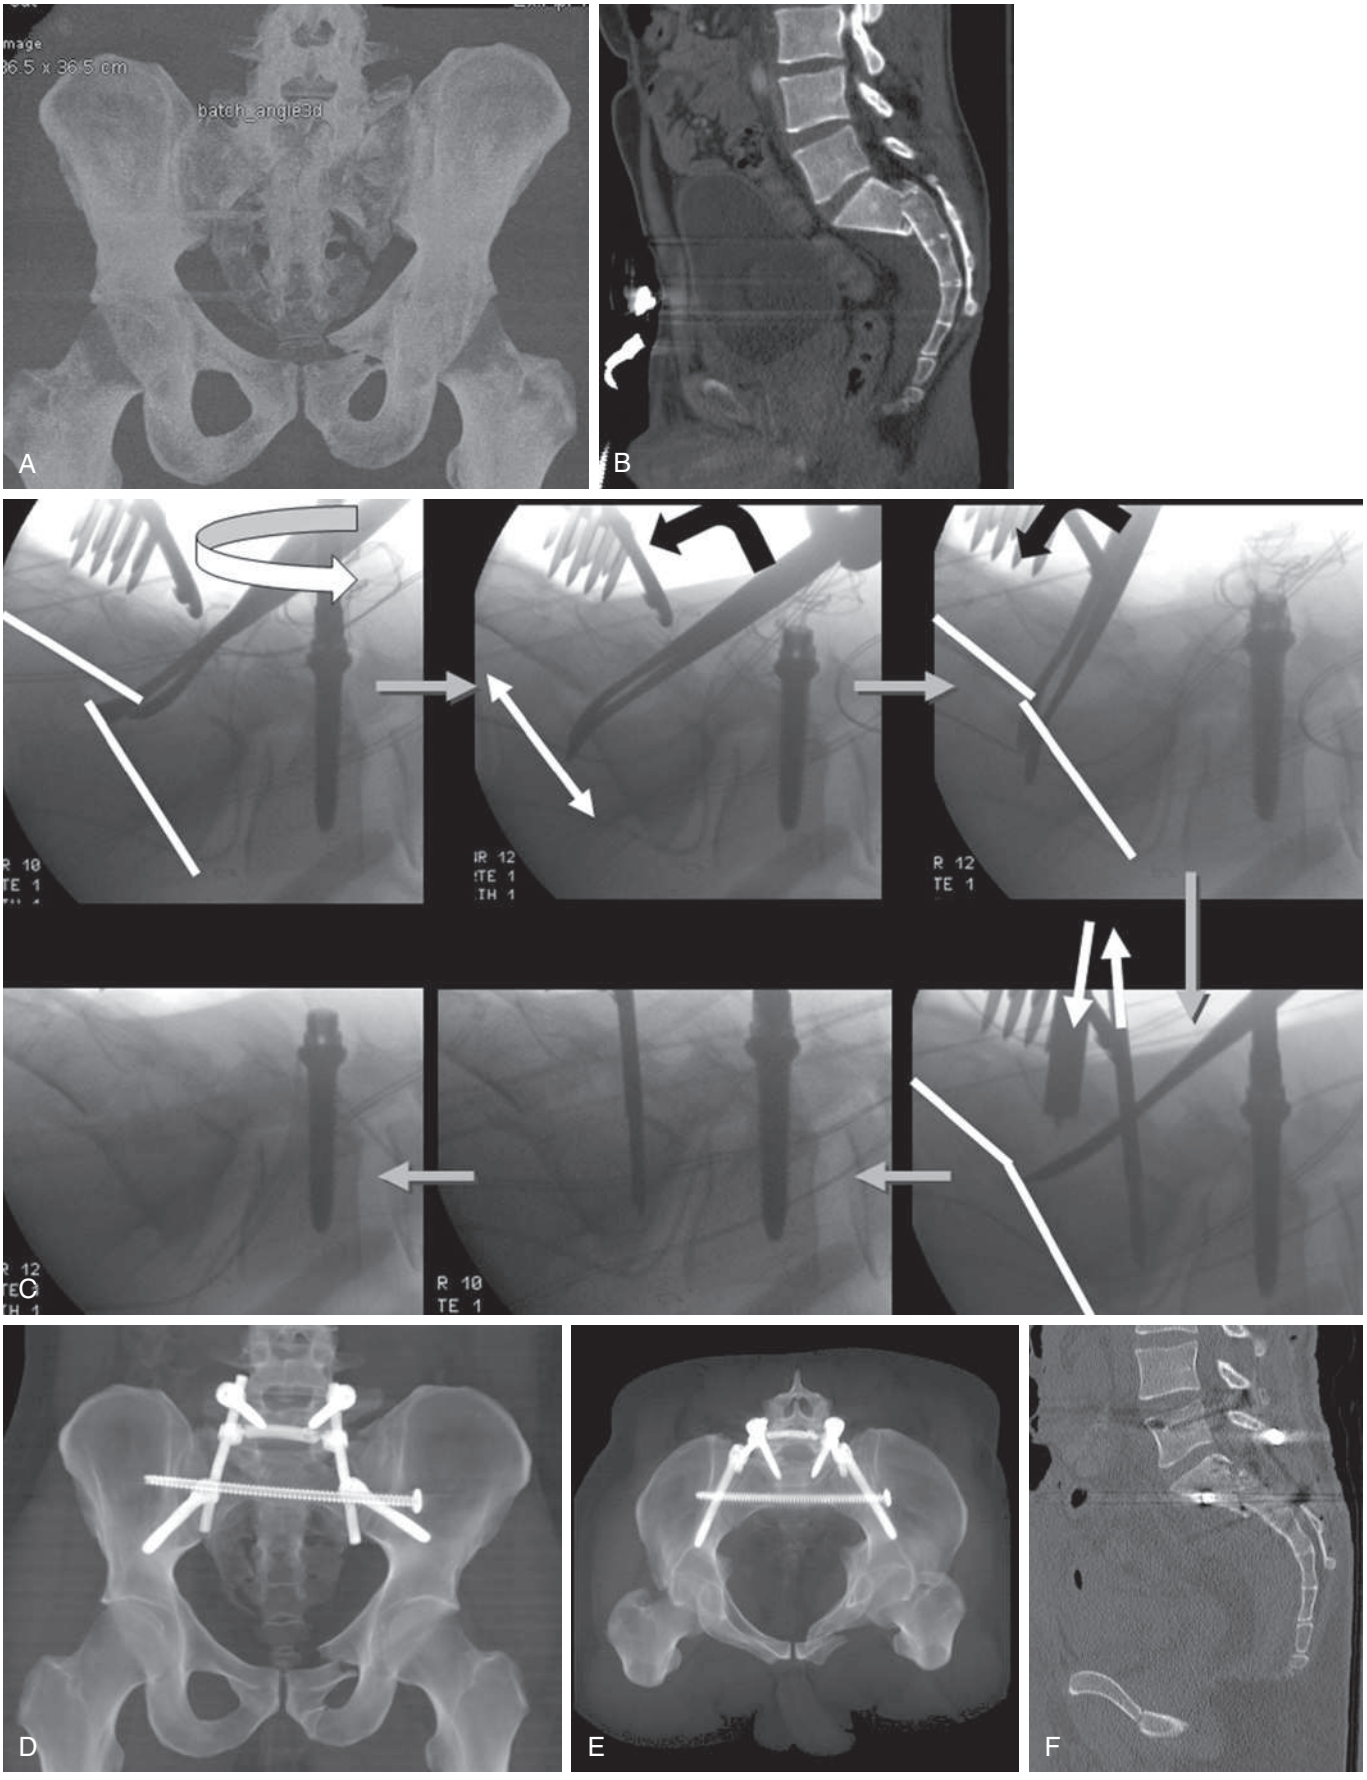
The utility of posterior decompression without fracture reduction and stabilization is limited, however, in cases of neural impingement caused by fracture displacement and is generally not recommended. In situations in which fracture displacement contributes significantly to nerve root compression, decompression is difficult to achieve solely with laminectomy and foraminotomy, and it is usually necessary to realign and stabilize the fracture.

Fracture Reduction Techniques



Unilateral Injuries

Unilateral, vertical AO type B sacral fractures are most commonly treated with closed reduction using distal femoral traction and percutaneous iliosacral or transiliac-transsacral screw fixation in the supine position. In more highly displaced fractures in which an acceptable closed reduction cannot be achieved, or if foraminal compression requires an open decompression and open reduction can be performed, typically prone through a posterior paramedian approach is appropriate. Exposure is typically performed as far medially as the spinous process of the sacrum, on which a reduction clamp can be hooked to provide medial-lateral fracture compression. A small soft tissue window can also be made along the lateral aspect of the ilium in order to place the other end of the clamp. Once the fracture is exposed, the fracture edges are debrided of soft tissue and foraminal debris can often be removed through the fracture surface. Reduction is then achieved by identifying fracture lines that correspond to each other. This can be particularly challenging in more comminuted fractures, but usually appropriate length can be assessed at the sciatic notch by either palpation or direct visualization. Once appropriate length has been established, the fracture is realigned and reduction is achieved with clamps placed between the sacral spinous processes and the ilium. Fixation is then undertaken percutaneously, usually with iliosacral or transiliac-transsacral screws. Decompression is performed if still deemed necessary.

Bilateral Injuries

When considering displaced sacral "U" fracture variants (AO type C3 injuries), spinal canal and foraminal compromise due to translation and angulation are often the main cause of nerve root compromise. In these cases, decompression, realignment, and stabilization are required. Realignment and stabilization of these fractures can be difficult, typically involving the following: (1) restoration of fracture length, (2) mobilization of impacted fracture fragments, (3) fracture reduction by direct manipulation, (4) provisional fracture stabilization with iliosacral or transiliac-transsacral screws, and (5) definitive fracture stabilization with spinopelvic fixation (Figs. 78.12 and 78.15). Fracture length can be obtained through distal bifemoral traction or direct manipulation with various instruments, including the universal distractor secured to the L5 pedicle and ipsilateral ilium (Fig. 78.16). The use of specialized fracture reduction tables designed for the treatment of pelvic fractures may also assist with reduction. Once length is obtained and access to the anterior column of the transverse fracture has been achieved by laminectomy and sacral root retraction, elevators or a lamina spreader can be used to pry the impacted fracture fragments apart (see Figs. 78.12 and 78.15). A combination of instruments can then be used to reduce the fracture, such as a threaded Schanz pin placed into the upper sacral body, which can be used as a joystick to help realign the fracture (see Figs. 78.12 and 78.15). The kyphotic segment may further be reduced by retracting the upper sacral nerve roots and using a bone impactor to directly reduce the apex of angulation. Reduction of the bilateral vertical sacral fracture components can be performed in a manner similar to that described earlier for unilateral sacral fractures. Once reduction is achieved, provisional stabilization can be obtained with either iliosacral or transiliac-transsacral screw fixation (see Figs. 78.12 and 78.15). In some situations, particularly when the patient's anatomy allows for placement of multiple screws, this may provide enough stability. However, as will be described later, spinopelvic fixation provides additional stability and is typically used for definitive fixation of AO types C1 through C3 injuries. The typical reduction techniques are illustrated for Roy-Camille type 2 (see Fig. 78.12) and type 3 (see Fig. 78.15) sacral fractures. In situations in which anatomic reduction of the sacral kyphosis cannot be achieved or maintained, as is common with Roy-Camille type 2 variants of AO type C3 fractures in particular, sacral root decompression within the sacral canal can be enhanced by resection of the apex of the kyphosis along the anterior spinal canal, over which the sacral roots would otherwise be draped (see Fig. 78.12B).

FIG. 78.15 AO type C3 (Roy-Camille type 3). Reduction and stabilization of AO type C3, Roy-Camille type 3 sacral fracture. (A) Anteroposterior computed tomographic (CT) reconstruction of the pelvis and (B) sagittal CT image of the sacrum demonstrate Roy-Camille type 3 variant of AO type C3 sacral fracture with anterior pelvic ring injury and severe urinary bladder distention caused by sacral root dysfunction. (C) The sequence of fracture reduction is illustrated, involving prying open the transverse fracture with elevators, followed by fracture manipulation with a Schanz pin inserted as a joystick into the upper sacral body, and direct pressure applied to the posterior lower sacrum by a spike-pusher. Once the fracture had been reduced, a transiliac-transsacral screw was placed for provisional stability, followed by spinopelvic fixation, as illustrated on postoperative (D) anteroposterior and (E) inlet reconstructions. (F) Postoperative sagittal CT image of the sacrum demonstrates restoration of sagittal plane alignment and decompression of the spinal canal. Anatomic reduction is typically easier to achieve with Roy Camille type 2 fractures.

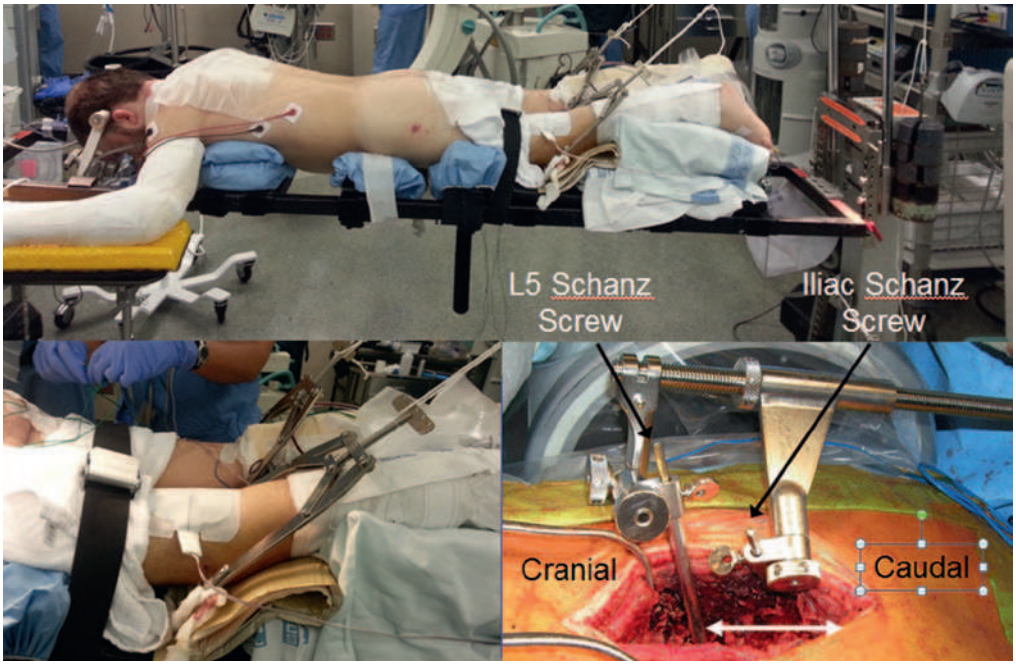

FIG. 78.16 Restoration of fracture length can be the most challenging step in reducing complex sacral fractures. Several techniques can be used to restore fracture length at the spinopelvic junction, including distal femoral traction and the use of a femoral distractor anchored to the lumbar pedicles and the ipsilateral iliac wing.

Surgical Stabilization Techniques

The goal of surgical fixation is to avoid prolonged recumbency and to correct and prevent fracture displacement and malalignment, which may lead to postural difficulties, chronic pain, and nerve compression. Hart et al. reported that restoration of appropriate sagittal alignment of sacral fractures decreases pain by preventing compensatory lumbar hyperlordosis, allowing for a more physiologic alignment of the lumbar spine (see Fig. 78.1).[5] Therefore, pelvic incidence can be used as an intraoperative guide to lumbopelvic alignment and adequacy of reduction.

There are three broad categories of fixation types for sacral fractures: (1) direct osteosynthesis of the sacrum, (2) posterior pelvic ring stabilization, and (3) spinopelvic fixation. The appropriate fixation type is based on the fracture pattern and location. Optimal stabilization may require use of multiple sacral fixation techniques. The three situations most commonly encountered in this decision-making process involve the following: (1) low transverse sacral fracture below the sacroiliac joint, in which there are no implications of either posterior pelvic or spinopelvic instability; (2) vertical sacral fracture with unilateral pelvic instability (and intact spinopelvic junction); and (3) complex sacral fracture with spinopelvic and usually also posterior pelvic instability (e.g., sacral "U" fracture variant or bilateral vertical sacral fracture). These three categories correspond, respectively, to the A, B, and C fracture types proposed in the new AO spinopelvic injury classification (see Fig. 78.11).

AO Sacral Fracture Classification Type A Injuries

These injuries include sacral fractures without posterior pelvic or spinopelvic instability. A few fixation options have been described to treat isolated transverse or oblique sacral fractures without pelvic involvement. Roy-Camille[28] described a technique for direct osteosynthesis of sacral fractures with sacral alar plates. The plates are placed lateral to the dorsal foramina and oriented vertically. The orientation of these plates is theoretically optimal to allow for compression loading across a transverse fracture. Although not recommended for stabilization of spinopelvic dissociation injuries, direct plating alone may be useful in maintaining alignment of transverse sacral fractures below the sacroiliac joints because these fractures are not subject to the high loads seen with fractures involving the weight-bearing axis, and the goal of their treatment is primarily to avoid pain due to prominence or nonunion.[67] It can be combined with spinopelvic fixation techniques if there is a need to maintain alignment of the lower sacrum while having to stabilize a contiguous spinopelvic dissociation injury. Sacral alar plating alone therefore has few clinical applications. Its utility is usually in combination with other methods of surgical stabilization in the treatment of sacral fractures involving the weight-bearing axis.[72]

AO Sacral Fracture Classification Type B Injuries

These injuries include sacral fractures with posterior pelvic but not spinopelvic instability. Displaced unilateral vertical sacral fractures are generally treated with posterior stabilization.

Sacral bars, tension band plating, iliosacral screws and, most recently, transiliac-transsacral screws have all been described as a means of stabilizing the posterior pelvic ring.[53,73,74] Simonian and Routt,[75] in a biomechanical study of cadaveric specimens, found no difference in the resulting pelvic ring stability between the various constructs. Sacral bars and tension band plating are both predisposed to soft tissue problems owing to their location superficial to the nearly subcutaneous dorsal sacrum.[73] The potential for dorsal soft tissue compromise is minimized by the use of iliosacral or transiliac-transsacral screw fixation; these methods have become the most widely used for posterior pelvic ring fixation. In all methods of posterior pelvic ring stabilization, however, fixation is perpendicular to the weight-bearing axis and does not provide adequate stabilization for immediate weight bearing.[74,76,77]

Iliosacral and transiliac-transsacral screw fixation are usually performed in a percutaneous manner, with minimal blood loss. The success of percutaneous fixation depends on the surgeon's ability to achieve an anatomic reduction under fluoroscopic visualization; otherwise, in addition to the problem of malreduction, a safe trajectory for iliosacral/transiliac-transsacral screw placement cannot be reliably established.[61,78] These techniques can be performed with the patient in either a supine or prone position depending in part on surgeon preference and on the potential need for either concurrent anterior pelvic ring stabilization or open posterior reduction or decompression of foraminal debris. In spite of its advantages, iliosacral and transiliac-transsacral screw fixation have several potential pitfalls. In the instance of comminuted longitudinal fractures through the neuroforamina (AO type B3), overcompression of the foramina can occur if the screws are placed using interfragmentary compression, which can potentially lead to nerve root injury.[79] However, in experienced centers, the reported rate of neurologic injury is low even without the use of electrodiagnostic monitoring.[80] Like other methods of closed reduction and posterior pelvic ring stabilization alone, percutaneous iliosacral and transiliac-transsacral screw fixation carry the disadvantage of not allowing for reduction of sacral angulation. Combining these techniques with open reduction can provide the necessary kyphocorrection, but may not provide the adequate stability for preventing failure of fixation and recurrent deformity. In the case of sacral comminution or osteoporosis, transiliac-transsacral screws should be used in lieu of iliosacral screws since fixation into the contralateral ilium is likely to provide far better stability than fixation of an iliosacral screw into the compromised bone of the sacrum. As mentioned previously, the orientation of the screw perpendicular to the fracture's deforming forces may also contribute to a higher likelihood of fixation failure (see Fig. 78.13). Nevertheless, iliosacral and transiliac-transsacral screw fixation have been shown to be effective in the stabilization of unstable longitudinal sacral fractures.[81] A 3-month period of protected weight bearing is recommended with iliosacral and transiliac-transsacral screw fixation.

AO Sacral Fracture Classification Type C Injuries

These injuries include sacral fractures with spinopelvic instability. Contrary to sacral bars and posterior tension band plating, which are largely ineffective in stabilizing multiplanar sacral fractures with a transverse component, iliosacral and transiliac-transsacral screws can also be used successfully in patients with minimally displaced sacral "U" fracture variants, whether AO type C0 or C3, as well as in bilateral vertical sacral fractures (AO type C2). In a series of 13 patients who had fractures with minimal sacral angulation and displacement allowing for in situ screw placement, Nork and colleagues[82] found bilateral percutaneous iliosacral screw fixation to be safe and effective in treating minimally displaced sacral U-type fracture patterns. In our experience, this technique has been particularly well suited for treatment of AO type C0 sacral U variant insufficiency fractures (see Fig. 78.14). However, this minimally invasive method does not allow for reduction of fracture angulation. Moreover, if a near-anatomic reduction cannot be achieved, the safe zone for iliosacral and transiliac-transsacral screw trajectory may be small or absent, thus also precluding its use in more complex and highly displaced injuries.[78] Iliosacral or transiliac-transsacral screw fixation alone is therefore not generally recommended for patients with displaced AO type C3 (sacral U) fractures and their variants if they are irreducible by closed manipulation or if neural decompression is required.

Lumbopelvic fixation provides the biomechanically strongest fixation of sacral fractures.[83] This technique was derived from the Galveston method of anchoring the caudal end of long thoracolumbar rod constructs into the ilium. Sacral fracture fixation is obtained rostrally by pedicle screw fixation in the lumbosacral spine and caudally by long screw fixation in the ilium.[84–94] The construct spans the sacrum and restores the integrity of load transfer from the lumbar spine to the pelvis.[44,83] Lumbopelvic fixation can be applied unilaterally (triangular osteosynthesis) to add more stability to iliosacral/transiliac-transsacral screw fixation for highly displaced or comminuted unilateral AO type B or AO type C1 longitudinal sacral fractures, or bilaterally for AO type C2 and C3 spinopelvic dissociation injuries and occasionally AO type C0 injuries. The strength of the construct permits immediate weight bearing without the use of external bracing (see Figs. 78.12 and 78.15).

Bilateral lumbopelvic fixation is most commonly indicated for AO types C2, C3, and some C0 injuries and is performed through a midline longitudinal dorsal approach with the patient in the prone position. Screw placement may be performed under fluoroscopic guidance or some other form of navigation to ensure correct screw orientation. A thorough understanding of pelvic anatomy is necessary for verification of correct iliac screw placement. Screw malposition can be catastrophic, potentially injuring neurovascular structures in the sciatic notch or the pelvic viscera or penetrating the acetabulum. Choice of a more anterior iliac screw starting point, such as along the medial (rather than posterior) surface of the posterior ilium or on the dorsolateral surface of the sacrum, can help prevent excessive prominence of the iliac screw heads. Infection and wound-related problems are common, however, and have been found to approach 20%.[85,90] In situations in which formal open reduction is not required but iliosacral/transiliac-transsacral screw fixation is considered to

be insufficient, percutaneous lumbopelvic fixation can be used to provide enhanced stability while mitigating the risk of wound-related complications. Formal lumbosacral arthrodesis is not typically performed in the absence of preexisting pathology (e.g., spondylolisthesis) or injury to the lumbosacral facet joints. Hardware removal is generally performed 6 months postoperatively after imaging studies have confirmed healing of the sacral fracture. Hardware removal is not performed in patients who have had lumbosacral arthrodesis. In these cases, because formal sacroiliac joint arthrodesis is not usually performed, in many instances the rod will break from fatigue failure, an expected consequence of continued sacroiliac joint motion. Late rod fracture is asymptomatic in the majority of cases, and the need for routine hardware removal in all circumstances is questionable.[85,90]

The optimal stabilization of complex sacral fractures may require the use of a combination of the three categories of fixation described earlier. For instance, sacral U or H fractures can be stabilized with the use of iliosacral or transiliac/transsacral screw fixation combined with lumbopelvic fixation to obtain optimal fixation in the "horizontal" direction to stabilize the posterior pelvic ring and in the "vertical" direction along the weight-bearing axis to neutralize spinopelvic instability.[83,89] Lumbopelvic fixation of sacral fractures requiring neural decompression may also benefit from adjunctive sacral plating, which, in this case, is used solely to fine-tune fracture realignment and to prevent recurrent displacement and resulting nerve root compression, allowing the lumbopelvic fixation to neutralize the bulk of the loads being transferred across the sacrum.

Summary

Sacral fractures have emerged from relatively underappreciated entities to injuries whose optimal treatment is recognized to have profound consequences on the patient's functional outcome. Advances in diagnostic imaging continue to provide additional insights into the structural and neurologic aspects of the injured sacrum, allowing comprehensive injury assessment even in the cognitively impaired and polytraumatized patient. In cases of neurologic deficit, excessive malalignment or instability, surgical intervention involves neurologic decompression, fracture realignment, and surgical fixation in order to optimize long-term outcomes. The timing of surgical intervention is determined by several factors, including the patient's associated injuries, overall physiologic condition, and the presence of neurologic deficits, open fractures, or soft tissue compromise that places skin at risk of necrosis. Surgical options continue to expand as new stabilization methods and implants are developed. Surgeons now have a wide spectrum of procedures at their disposal, ranging from minimally invasive to comprehensive stabilization techniques. Many issues concerning evaluation and treatment remain controversial and, in the absence of comparative treatment trials, conclusions are currently based largely on anecdotal reports and observations. The benefits of any proposed treatment need to be weighed carefully against the potential risks and must be individualized to the patient and specific injury. Treatment decisions continue to be based on a substantial degree of intuition and foresight gained from experience. The challenge to the spine surgeon remains to implement the available resources effectively as our understanding of the pathophysiology of these injuries grows.

PEARLS

1. The evaluation of sacral root function is paramount in patients with sacral fractures and should include assessment of anal sphincter tone, voluntary anal contraction, sharp/dull perineal sensation, and reflexes, such as the anal wink and bulbocavernosus reflex.
2. Intraoperative bilateral distal femoral traction and the universal distractor applied across the spinopelvic junction can help achieve the fracture length required for reduction in complex AO type C3 sacral U fractures.
3. In patients with associated anterior pelvic ring or acetabular fractures, fixing the anterior pelvic injury first facilitates reduction of complex sacral fractures and, in some acetabular fractures, decreases the risk of articular malreduction.
4. Accurate placement of iliac screws can be facilitated and confirmed with a true lateral C-arm trajectory that allows superimposition of the sciatic notches and the obturator outlet (teardrop) view.
5. When placing spinopelvic fixation, a starting point along the medial aspect of the posterior ilium or within the sacrum allows for iliac screw heads to be buried as deep as possible relative to the posterior ilium, which minimizes the risk of screw prominence that might require reoperation.

PITFALLS

1. Spontaneous partial fracture reduction can lead to the deceptively innocuous radiographic appearance of an inherently unstable injury.
2. A fracture–dislocation in this region can lead to critical blood loss.
3. The subcutaneous nature of the sacrum exposes any open surgical approach in this region to higher risk of infection.
4. Sacral root decompression is typically not successfully achieved when there is significant residual fracture malreduction.
5. Diagnostic delay may increase the risk of prolonged neurologic deficit and fixed spinal deformity that is difficult and risky to correct.

KEY POINTS

1. The sacrum is a keystone structure that is important to the structural integrity of the base of the spinal column and posterior pelvic ring. Therefore, depending on the fracture pattern, fracture of the sacrum may have implications on posterior pelvic or spinopelvic stability.
2. Sacral fracture classifications are based on fracture location, pattern of instability, and risk of neurologic deficits.
3. Sacral fractures generally occur as the result of either high-energy injuries, in which associated injuries will likely have an impact on treatment decisions, or low-energy injuries due to sacral insufficiency, in which associated medical comorbidities are likely to influence treatment decisions.
4. Multidimensional (CT) imaging of the sacrum is essential for evaluating fracture patterns and determining the extent of instability.

5. Various options exist for the treatment of sacral fractures. Minimally displaced fractures can often be treated nonoperatively. Displaced, unilateral longitudinal (AO type B1–3) fracture patterns result in posterior pelvic instability and are generally treated with reduction and iliosacral or transiliac-transsacral screw fixation. Unilateral lumbopelvic fixation provides additional stability for widely displaced injuries, those requiring a decompression procedure, or those involving the L5–S1 facet joint (AO type C1). Bilateral lumbopelvic fixation is the most stable construct for complex sacral fractures with bilateral involvement and spinopelvic dissociation (AO types C2 and C3). In situations with neural compromise, decompression usually requires excision of bony fragments causing nerve root compression, as well as fracture realignment and stabilization. Multiplanar, minimally displaced sacral insufficiency fractures (AO type C0) may require surgical treatment, in which case iliosacral or transiliac-transsacral screw fixation is most commonly used.

   The subject of sacral neurologic injury is frequently overlooked. This publication provides a meaningful sacral root injury severity classification and provides class 3 data supporting the concept of decompression surgery.
3. Huittinen VM. Lumbosacral nerve injury in fracture of the pelvis. *Acta Chir Scand Suppl*. 1972;429:7-43.
   This seminal publication provided the foundation for an improved understanding of sacral root function and prevalence of transection and the possibility for recovery. It also underscored the potential for patients with unilateral preservation of S2 and S3 roots to have meaningful bowel and bladder control.
4. Peretz AM, Hipp JA, Heggeness MH. The internal bony architecture of the sacrum. *Spine*. 1998;23:971-974.
   These authors provide an important review of the structural idiosyncrasies of the sacrum. On the basis of these findings, the relevance of the S1 segment in transferring the lumbar loads to the iliac wings is underscored. Furthermore, the foundations for ideal fixation points for sacral promontory, alar, and iliac screw placement are provided.
5. Routt MLC, Nork SE, Mills WJ. Percutaneous fixation of pelvic ring disruptions. *Clin Orthop*. 2000;375:15-29.
   The authors provide a retrospective review of minimally invasive stabilization strategies for posterior pelvic ring disruption. This technique has strongly influenced the treatment of patients with pelvic ring injuries.
6. Schildhauer TA, Ledoux WR, Chapman JR, et al. Triangular osteosynthesis and iliosacral screw fixation for unstable sacral fractures: a cadaveric and biomechanical evaluation under cyclic loads. *J Orthop Trauma*. 2003;17:22-31.
   These authors provide biomechanical data for the stiffness of lumbopelvic stabilization techniques using simple current segmental spine fixation components over posterior sacroiliac screw fixation for vertically unstable sacral fractures.
7. Bellabarba C, Schildhauer TA, Vaccaro AR, Chapman JR. Complications associated with surgical stabilization of high-grade sacral fracture dislocations with spino-pelvic instability. *Spine*. 2006;31(suppl 11):S80-S88.
   These authors provide an analysis of morbidity associated with high-grade sacral fracture-dislocations and their treatment. They identified traumatic dural tears or root avulsions in 74% of patients. Wound-healing problems including postoperative infection or draining seroma or hematoma were present in 26% of patients, with no cases of chronic osteomyelitis. Hardware prominence was problematic, particularly early in the series. There was a notable absence of nonunion, malunion, and failure of fixation.
8. Schildhauer TA, Bellabarba C, Nork SE, et al. Decompression and lumbopelvic fixation for sacral fracture-dislocations with spino-pelvic dissociation. *J Orthop Trauma*. 2006;20:447-457.
   These authors provide a retrospective review of a series of patients with high-grade sacral fracture-dislocations and cauda equina injuries who were treated with lumbopelvic fixation. They noted that this method of fixation reliably achieved the goal of correction of sacral kyphosis and provided adequate stabilization, thereby preventing fracture malunion or nonunion. Neurologic improvement occurred in 83% of patients and depended primarily on completeness of the injury and continuity of sacral roots. The majority of complications were wound related or associated with hardware prominence.
9. Gardner MJ, Routt ML Jr. Transiliac-transsacral screws for posterior pelvic stabilization. *J Orthop Trauma*. 2011;25:378-384.
   These authors provide a comprehensive assessment of the use of transiliac-transsacral screw fixation, which provides a more stable alternative to iliosacral screw fixation, particularly in the presence of extensive comminution or osteopenia of the upper sacral bodies.

79 CHAPTER Acute Treatment of Patients With Spinal Cord Injury

Rajiv Saigal
Matthew F. Gary
Allan D. Levi

Introduction

In spite of many decades of active research, traumatic spinal cord injury (SCI) is a devastating disease that still lacks good treatment options. It can dramatically impact a patient's quality of life, lessens life expectancy, and is most common in adolescents and young adults with many years left to live.[1] The emotional and financial burdens placed on these patients and their families are immense. Likewise, the societal costs from long-term care and lost productivity of this mostly young population are vast. Much knowledge of SCI pathophysiology has been gained, yet translating preclinical successes in the laboratory to human patients remains challenging. Current treatments for the acute SCI patient are far from a cure. However, progress has been made in ensuring the best possible long-term recovery. A multidisciplinary approach to treating these patients in high-volume centers using evidence-based guidelines is the ultimate goal.

Epidemiology

There are approximately 17,000 new cases of SCI in the United States each year and 282,000 people living with an SCI.[1] The prevalence of SCI patients has been increasing due to improved survival in both the acute and chronic phases of the disease process. Due to their higher incidence of trauma, males are approximately 4 times more likely to have SCIs than females.[1] The average age at injury (42 years)[1] has climbed substantially over the last 5 decades from the age of 29 years in the 1970s. Pediatric SCIs, aged 15 years or younger, are exceedingly rare (3.5%); in contrast, injuries in the elderly are on the rise, particularly due to falls.

Patients may present with any degree of neurologic impairment. Nationwide, 45% present as incomplete tetraplegic, 21% present as incomplete paraplegic, 20% as complete paraplegic, and 13% as complete tetraplegic.[1] Given comorbidities, the mortality in the first year after injury is significantly higher in older (>60 years) patients who sustain a spinal cord injury.[2] The racial distribution of individuals with an SCI are 66.5% white, 26.8% black, 8.3% Hispanic, and 2.0% Asian.

The financial burden of SCI treatment is high. The first-year cost per patient ranges from approximately $350,000 in American Spinal Injury Association (ASIA) D classified patients (see Initial Evaluation section) to over $1 million for C1 to C4–injured tetraplegic patients.[1] Estimated lifetime costs for a 25-year-old SCI patient ranges from $1.6 to $4.7 million. Direct medical costs for these patients in the United States are estimated to be over $14.5 billion per year. In addition, another $5.5 billion is relinquished in lost productivity.[3] This cost is directly related to the affected level, severity of deficits, and age at the time of injury.

Motor vehicle accidents (38%) and falls (30.5%) account for the vast majority of SCIs.[1] A total of 13.5% are the result of violence, including gunshot wounds and stabbings; 9% are caused by sports-related trauma. Medical or surgical causes, including iatrogenic injury, account for another 5%. The remaining 4% have other etiologies.

Initial Evaluation

The initial evaluation of the suspected SCI patient follows that of acute trauma. Securing the airway, ensuring voluntary or mechanical ventilation, and maintaining circulation take highest precedence, as with all trauma patients. Patients should be immobilized on a backboard with straps and with a cervical collar from initial encounter until at least when definitive imaging is obtained; less rigid immobilization is not recommended.[4] In patients with penetrating trauma, resuscitation should be prioritized over immobilization due to worse mortality rates when the former is delayed.[4] For patients requiring intubation, the neck should be maintained in a neutral posture. Patients should be moved with log roll precautions until thoracic and lumbar injuries have been ruled out. Patients must be assessed for any concomitant injuries. Polytrauma and associated traumatic brain injury are common in SCI patients.

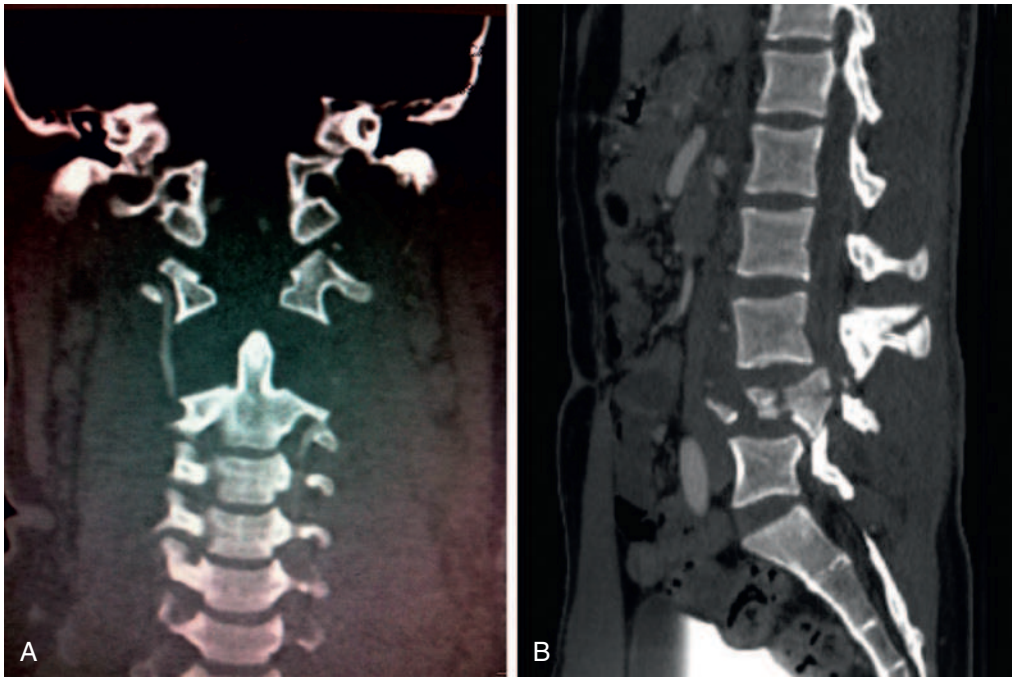

FIG. 79.1 (A) Coronal thin-cut computed tomography scan reconstruction, demonstrating a severe nonsurvivable C1–C2 distraction injury along with an occipital cervical dislocation. (B) Severe L4 burst fracture with retro portion into the spinal canal. The scan demonstrates the bony features of the injury with exquisite quality.

Once the patient is stabilized, a detailed neurologic assessment should follow, including testing all major upper and lower extremity motor groups and dermatomal sensation. Examination of rectal tone and sensation are part of the routine spine trauma assessment of distal sacral nerve root function. Otherwise neurologically complete SCI patients who maintain rectal tone and/or sensation have improved prognosis compared to those who do not. Based on the motor and sensory exam, the ASIA impairment scale (AIS) grade should be determined. The AIS includes five scoring grades ranging from A (neurologically complete injury) to E (neurologically intact). These divisions are important for prognosis.

In major trauma centers, computed tomography (CT) images with sagittal and coronal reconstructions are completed for all suspected SCI patients (Fig. 79.1). Cervical spine fractures through the transverse foramina may be associated with injury to the vertebral arteries; CT angiography or traditional catheter-based angiography may be completed to rule out such vascular injuries, including dissection, pseudoaneurysm, or occlusion (Fig. 79.2). Clearing the unconscious patient with high-resolution CT scans of the spine has greater than a 99.9% sensitivity and specificity; thus, modern CT alone is sufficient in detecting unstable cervical spine injuries in trauma patients.[5] Magnetic resonance imaging (MRI) is not always necessary but may be a useful adjunct in assessing the degree of spinal cord or nerve root compression and any ligamentous injury (Fig. 79.3). The degree of canal compromise in relation to the spinal cord and nerve roots is best assessed with this imaging modality. MRI can also assess the severity of SCI, including the extent of signal change and associated intraparenchymal blood, which carries a worse prognosis for neurologic recovery.[6] Fortunately, significant hematomas, which compress the spinal cord after trauma, are uncommon except in the setting of ankylosing spondylitis, where it should be diligently sought.[7]

A high-quality CT scan will identify nearly all unstable fractures. In a level 1 trauma center retrospective study of 690 patients, all acute traumatic cervical spine injuries seen on MRI were already identified on CT.[8] Thus, even the comatose or obtunded patient may be cleared of cervical spine injury by CT-based imaging.[8] In the absence of imaging, cervical immobilization is not necessary in neurologically intact, awake, alert, nonintoxicated patients without neck pain.[4] Upon completion of initial workup, admission to an intensive care unit (ICU) is recommended.

Blood Pressure Management

Optimizing spinal cord perfusion is a critical consideration in the acute management of traumatic SCI. The acute traumatic patient frequently presents in a hypovolemic state; the SCI patient is at added risk of neurogenic shock. The latter may occur from injury onset up until approximately 6 weeks due to unopposed parasympathetic output in the setting of interrupted sympathetic pathways.[9] As mentioned earlier, the priorities of trauma resuscitation take early precedence in management. The circulation focus also has indirect benefit to the spinal cord in maintaining an adequate perfusion pressure. In order to maintain adequate blood pressure, SCI patients should be given intravenous (IV) volume resuscitation and pressors, as needed. Hypotonic solutions should be avoided

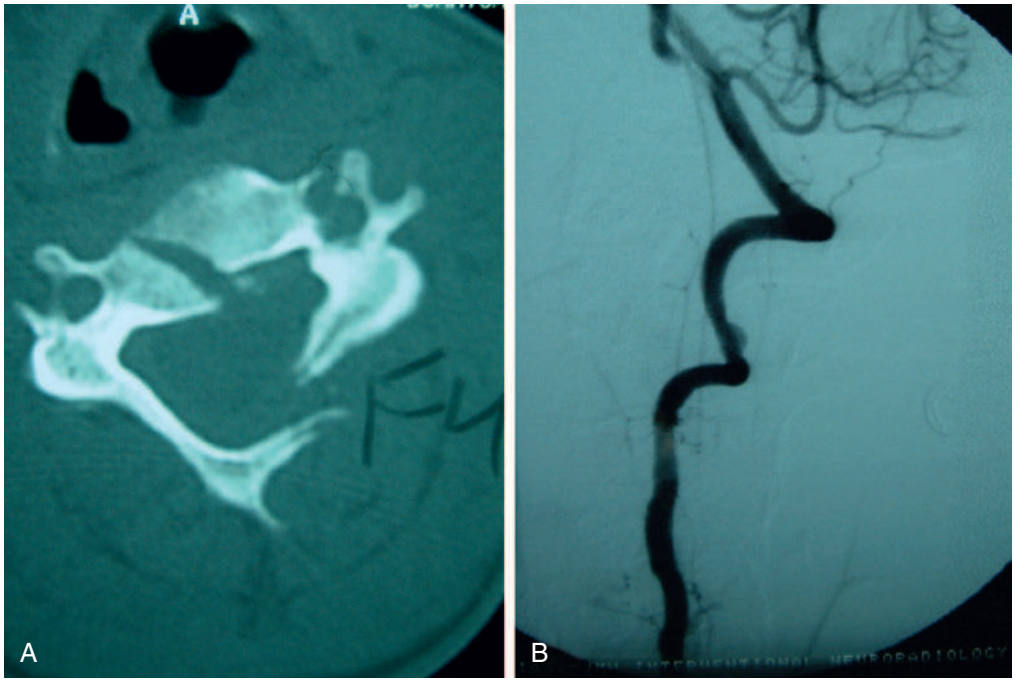

FIG. 79.2 (A) Complex cervical fracture through the body and lamina with an associated fracture of the vertebral artery foramen. (B) Associated injury to the vertebral artery with dissection and pseudoaneurysm seen on catheter-based angiogram.

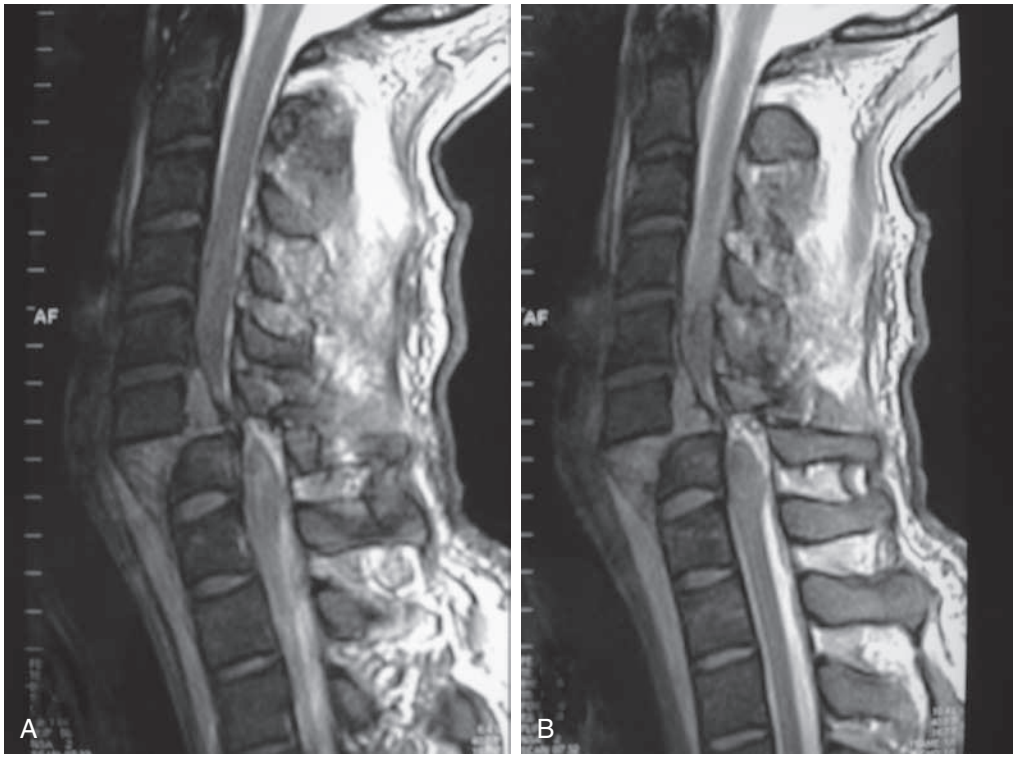

FIG. 79.3 Sequential sagittal magnetic resonance images C6–C7 vertebral body dislocation with associated tearing of the disc and severe compression of the spinal cord at that level. The posterior ligament complex is also disrupted.

in order to minimize risk of cerebral edema. Immediate resuscitation generally is achieved with crystalloid solutions with a transition toward colloids and/or blood transfusions in anemic patients.[9] Intravascular volume should be restored prior to pressor use in order to avoid adverse medication effects when possible and to maximize their efficacy when necessary.[9]

Recent guidelines make level 3 recommendations to avoid episodes of hypotension (defined as systolic blood pressure <90 mm Hg) and maintain mean arterial pressure (MAP)

greater than 85 to 90 mm Hg for 7 days after injury.[10] In order to achieve these goals, admission to an ICU and placement of appropriate monitoring devices, such as an arterial line, are recommended.[10]

There are no randomized clinical studies to support these blood pressure goals, and such trials may never materialize due to a lack of perceived equipoise. Nonetheless, preclinical and clinical studies provide a limited basis for empirical support of this practice.[11]

Animal models show evidence of decreased spinal cord blood flow after SCI. In a feline contusion model of SCI, white matter blood flow decreased by 50% in placebo-treated animals.[12] In a nonhuman primate clip compression model of SCI, there was a 5.6-fold decrease in blood flow to gray matter and 4.8-fold decrease to white matter, emphasizing the importance of restoring more normal perfusion; blood transfusion nearly doubled spinal cord blood flow.[13] A study of 77 cervical and thoracic SCI patients managed with aggressive resuscitation and MAP maintenance above 85 mm Hg for 7 days in addition to surgical decompression/stabilization and IV methylprednisolone (MP) showed that 60% of cervical and 33% of thoracic ASIA A patients improved by one ASIA grade; 30% of cervical and 10% of thoracic patients regained the ability to walk.[14] The 7-day target was chosen in order to exceed the 3- to 5-day window during which maximal spinal cord edema occurs in animal studies.[15] A study of 50 cervical SCI patients treated with a MAP goal of 90 mm Hg showed no AIS improvement in motor-complete patients with a "severe hemodynamic deficit" compared to 45% improvement in those with adequate hemodynamics.[16] Hemodynamic deficit was defined based on pulmonary vascular resistance and systemic vascular resistance.[16] In a recent analysis of high-resolution ICU vital sign data on SCI patients, a higher proportion of recorded MAPs below the target of 85 mm Hg was associated with poorer outcomes.[17] A systematic review found no difference in outcome between 85 and 90 mm Hg as the therapeutic MAP target.[9]

The choice of pressor for maintaining MAPs above 85 or 90 mm Hg may have an impact on adverse events. Although dopamine is a common first-line agent in SCI management, it may be associated with higher risk. A study in shock patients showed greater arrhythmia risk and greater risk of death after treatment of cardiogenic shock with dopamine versus phenylephrine.[18] A retrospective study found a 69.2% medical complication rate with dopamine compared with 46.5% with phenylephrine administration after SCI.[19] Complications included troponin leak, atrial fibrillation, ventricular tachycardia, severe tachycardia (heart rate >130 beats/min) or bradycardia (heart rate <50 beats/min).[19] Thus, there is reason to question use of dopamine as a first-line pressor after SCI and need for renewed study on optimal vasopressor choice. With isolated peripheral vasoconstrictor effects via α-adrenergic agonism, phenylephrine may be a good pressor choice in low thoracic or lumbar injuries, but some have suggested using phenylephrine with caution in cervical and high thoracic injuries.[9,20] When sympathetic output is disrupted in such lesions, resulting in neurogenic shock, there is generally a need for both α- and β-adrenergic stimulation. Dopamine and norepinephrine can accomplish this.[9,21] Dobutamine is used infrequently due to vasodilatory effects and risk of bradycardia.[22] Vasopressin, isoproterenol, and milrinone are generally avoided in SCI, the former due to diuretic effects and risk for hyponatremia and the latter two due to lack of efficacy.[9,23]

Of note, while there is a greater availability of data to support use of MAP goals for nonpenetrating injury, this is less true for penetrating injuries, such as stab or gunshot wounds through the spinal cord. A small retrospective series suggested that induced hypertension via a MAP goal of 85 mm Hg may have no impact on functional outcome after penetrating SCI.[24]

Surgical Timing

There is a growing body of literature to support early surgical intervention in SCI. The definition of early surgery for traumatic SCI in the past has varied from 8 to 72 hours; this should be kept in mind in an evaluation of the literature.[25] In general, there appears to be a trend to decreased hospital length of stay and shortened ICU stays when surgical decompression is offered within 72 hours.[26–32]

In 2012, Fehlings et al.[33] published a well-designed, prospective cohort study of 313 patients with cervical traumatic spinal cord injury (tSCI) comparing early and late decompressive surgery using a 24-hour cutoff. The study was nonrandomized and patient selection for the early versus the late group was up to the surgeon based on clinical factors. This stresses the importance of assessing whether the two groups are truly comparable. It is important to note that the mean time to surgery in the early and late groups was 14.2 and 48.3 hours, respectively. Patients demonstrated a 19.8% and 8.8% improvement of greater than or equal to 2 AIS grades in the early and late groups, respectively, corresponding to 2.8 times higher odds in the early group. Follow-up was conducted at 6 months after injury. This trial represents the largest prospective trial specifically addressing the question of early versus late decompression in acute tSCI. Despite its importance, this study has major limitations that must be considered. First, were the two groups, early versus late surgery, comparable? In the early surgery group, there were 57.7% of patients with AIS A and B injury versus 38.2% in the late surgery group ($P < .01$). This is a problem in that patients with AIS C and D type injuries have a ceiling on the degree of improvement that they can achieve, and it is impossible for AIS D–injured patients to improve 2 AIS grades. There were 35.9% of patients in the late surgery group with AIS D classification versus only 24.7% in the early surgery group. Another potential confounding variable is whether spinal shock played a role, masking the neurologic exam in the early surgery group. Patients in the early surgery group were significantly younger (45.0 vs. 50.7 years old; $P < .01$) and a greater proportion received steroids ($P = .04$). Although this was a prospective study, the decision to offer early surgery was left to the discretion of the attending surgeon.[33] Some have suggested that an even earlier time point for decompression may be more beneficial. A recent retrospective study showed improved spinal cord independence measures, ASIA impairment scale, and motor function for cervical decompressions performed within 8 hours of injury.[34] Preclinical animal data suggested

that early decompression is effective in improving neurologic outcomes with or without concomitant administration of MP.[35]

Neuroprotective Strategies

There are a number of neuroprotective strategies that are in various phases of investigation. Steroids, gangliosides, and spinal cord cooling will be discussed later. More recent pharmacologic strategies for tSCI include riluzole, a sodium channel blocker that is approved by the US Food and Drug Administration (FDA) for treatment of amyotrophic lateral sclerosis, and minocycline, an antibiotic that is a tetracycline analog, that are in phase II/III studies.

Steroids

There remains no clearly beneficial pharmacotherapy for acute traumatic SCI, although many have been studied. Administration of IV MP is the most highly studied, perhaps the most controversial therapeutic option, and the subject of three National Acute Spinal Cord Injury Studies (NASCIS). MP was chosen due to effects on reduction of membrane lipid peroxidation with possible beneficial effects on blood flow and neuronal excitability.[36] The first NASCIS trial assessed two doses of MP.[37] The high-dose MP consisted of a 1000-mg IV bolus, followed by 250 mg IV every 6 hours given over 10 days. The standard dose was 100 mg IV bolus, followed by 25 mg IV every 6 hours for 10 days. The primary outcome was motor and sensory examinations at 6 weeks and 6 months. No difference in motor function, pinprick, or light touch was found between the low dose and high dose of MP. There were higher early fatalities with high-dose MP (relative risk [RR], 3.1 deaths ≤14 days; RR, 1.9 deaths 15–28 days) and higher wound infections with high-dose MP (RR, 3.6).[37] Important limitations were the lack of a nontreatment control group and only 54% patient availability at final follow-up.

After NASCIS I, preclinical data suggested that a higher (30 mg/kg) MP loading dose might be optimal after SCI.[36,38–40] Following these studies, NASCIS II was planned to compare a higher-dose MP to naloxone and placebo.[41] The three study arms were (1) MP: 30 mg/kg IV bolus + 5.4 mg/kg/h × 23 hours; (2) naloxone: 5.4 mg/kg IV bolus + 4 mg/kg/h × 23 hours; and (3) placebo. The primary outcome was again motor and sensory examination at 6 weeks and 6 months. Naloxone, an opioid antagonist, was included in the study due to functional utility seen in preclinical animal studies, possibly due to effects on blood pressure and/or cord perfusion.[12,42] In NASCIS II, naloxone and MP given more than 8 hours after injury did not lead to neurologic improvement. When given within 8 hours of injury, MP led to increased change in motor (16 vs. 11.2 placebo; $P = .03$), pinprick (11.4 vs. 6.6; $P = .02$), and touch (8.9 vs. 4.3; $P = .03$) scores. Important limitations to interpreting these data were the post-hoc application of the 8-hour limit and reporting of only unilateral results.

NASCIS III consisted of three study arms: (1) 24-hour MP: 30 mg/kg IV bolus + 5.4 mg/kg/h × 24 hours; (2) 48-hour MP: 30 mg/kg bolus + 5.4 mg/kg/h × 48 hours, and (3) tirilizad: 2.5 mg/kg every 6 hours × 48 hours.[43] Tirilizad was chosen due to its expected effects on decreasing peroxidation of the neuronal membrane. There was no nontreatment control. The primary outcome was motor function and change in Functional Independence Measure (FIM) at 6 weeks and 6 months. Compared to 24-hour MP, 48-hour MP led to a nonsignificant trend toward neurologic improvement. In the subset of patients with 48-hour MP initiated 3 to 8 hours after treatment, the neurologic improvement was significant relative to 24-hour MP. However, the 48-hour MP group had significantly higher rates of severe sepsis and pneumonia.

Given modest and questionable benefits from MP in the NASCIS trials combined with higher rates of adverse events in these and other studies, the most recent American Association of Neurological Surgeons/Congress of Neurological Surgeons (AANS/CNS) guidelines changed MP from a treatment option to a level 1 recommendation against utilization.[44] The guidelines change was highly controversial, with leading experts arguing that there were no new data since the prior guidelines to support the downgraded MP recommendation.[45] Experts agree that MP should not be administered in patients who lack a neurologic deficit.[21]

In the setting of mixed recommendations, one important consideration is the patient's desire for treatment. A recent study showed that 69.6% of chronic SCI patients favored selective use of MP and 29% felt that all acute SCI patients should receive it; only 1.4% were against administration in all circumstances.[46] A total of 59.4% thought that even small motor or sensory improvement would be "extremely important" to them. However, only 4% of patients who arrived within the MP window and were able to communicate were asked about their preference. Given the controversial nature of MP, treating physicians might consider discussing risks and benefits with patients and involving them in the treatment decision. Additionally, when considering MP treatment, the balance of risks and benefits may be improved by judicious patient selection toward those with lesser risk of adverse events, such as the younger, previously healthy patient.

GM-1 Ganglioside

GM-1 ganglioside forms a component of the central nervous system (CNS) membrane. It had been shown in preclinical studies to facilitate regeneration and regrowth and to promote neuroprotection. In a small randomized, controlled single-center trial in SCI, a 100-mg IV daily dose of GM-1 for 18 to 32 days after 72 hours of MP (250 mg IV bolus followed by 125 mg every 6 hours) led to significant improvement in Frankel grade, with a 50% rate of at least one grade improvement versus 28% in MP-only treated patients.[47] There was also significantly better 1-year improvement in ASIA motor score of 39.6 in MP plus GM-1 patients versus 21.6 in MP-only patients.[47] However, a larger multicenter randomized control trial was not able to validate the results.[48] There were three therapeutic arms: (1) GM-1 low dose (LD): 300 mg IV bolus + 100 mg daily × 56 days; (2) GM-1 high dose (HD): 600 mg bolus + 200 mg daily × 56 days; and (3) MP only. All patients also received IV MP according to the NASCIS II protocol. The

primary outcome was the percentage of patients with greater than or equal to 2-grade AIS improvement at 26 weeks. Overall, 70.2% of MP plus GM-1–treated patients (69.8% LD vs. 71.7% HD) achieved this goal, but 71.2% MP-only treated patients did as well. There was a 5.8% death rate in GM-1 patients compared to 5.5% for MP only.[48] Neither GM-1 trial included a placebo group with no pharmacologic treatment. Given the lack of clear therapeutic benefit, AANS/CNS guidelines also recommend against treatment with GM-1 ganglioside.[44]

Hypothermia

Induced local or systemic hypothermia is a treatment option for tSCI and a current topic of active research. Initially, multiple preclinical studies showed neuroprotective effects of induced hypothermia in traumatic brain and animal studies.[49,50] Hypothermia has been utilized successfully in other domains, such as reducing hypoxic-ischemic encephalopathy after cardiac arrest and reducing incidence of SCI after aortic aneurysm surgery.[51] In traumatic brain injury clinical trials, induced hypothermia was associated with decreases in intracranial pressure but mixed functional outcome.[52–55]

Attempts at local cooling in human SCI patients began in the 1970s.[56–60] Using an epidural cooling system during the time of surgical decompression for cervical or thoracic ASIA A patients, 65% improved at least one ASIA grade.[61] Of 14 patients in the cervical cohort, five patients converted to ASIA B, three to ASIA C, and one to ASIA D.[61] Of six patients in the thoracic cohort, one converted to ASIA B, two to ASIA C, and one to ASIA D.[61]

Systemic modest hypothermia, defined as cooling to 32°C to 34°C via a central venous catheter, has recently been the focus of several clinical studies in SCI (Fig. 79.4).[51,62,63] Of 35 neurologically complete cervical ASIA A adult patients who received 48 hours of cooling starting at a mean of 5.8 hours after injury, 43% improved at least one AIS grade by last follow-up.[64] A total of 23% regained some motor function and 11% improved to AIS D or better. The most common associated adverse events were atelectasis (83%), pleural effusion (54%), anemia, pulmonary edema (43%), electrolyte disturbance, and urinary tract infection (37%). There was an associated 14% rate of thromboembolic events. There were several exclusionary criteria, including cardiac history, Raynaud disease, bleeding, pregnancy, thrombocytopenia, pancreatitis, blood dyscrasia, hyperthermia on admission, penetrating injury, and patients showing neurologic improvement within 12 hours.[64] Given the high conversion rate for initially complete SCI patients, hypothermia is an area of interest for future study but requires prospective, randomized validation.

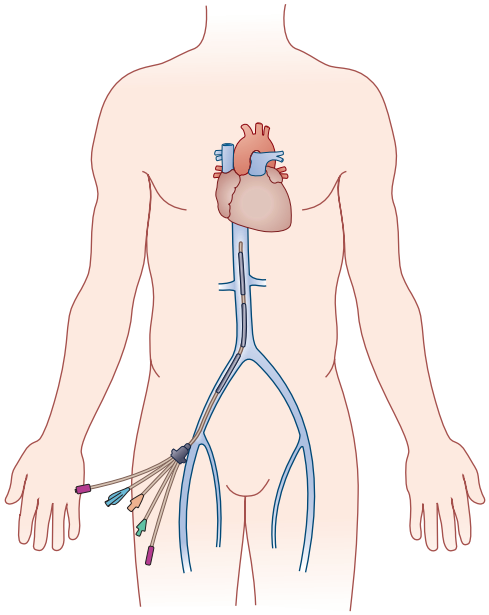

FIG. 79.4 Hypothermia catheter with several ports. The balloon catheter resides within the inferior vena cava. A closed-loop system exists in which cold saline circulates at a rate to achieve the desired systemic temperature by cooling the blood rushing by the catheter.

Managing Body Systems Complications Related to Spinal Cord Injury

Pulmonary

SCI patients are at high risk for pulmonary complications. A total of 11% of early mortality is due to atelectasis, pulmonary embolism, edema, pneumonia, or aspiration.[11] Vital capacity is often restricted, especially in high cervical injuries. Of SCI patients, 70% have some degree of respiratory insufficiency.[65] Thoracic spine injuries are frequently associated with rib fractures and/or hemothorax as a contributing factor. Aside from continuous pulse oximetry, the SCI patient should be monitored with arterial blood gas measurements to assess for early signs of respiratory failure.

Integument

Wound and skin complications, including decubitus ulcers, are of high concern in SCI patients. Acute management should include steps to decrease the likelihood of their development. Between 30% and 50% of SCI patients will develop a pressure ulcer to some degree in the first month postinjury.[21] Patients should be transferred from a rigid backboard as soon as it is deemed safe. When available, specialized, pressure-controlled hospital beds should be used in patients with limited mobility.[21] Nursing care should include patient repositioning every 2 hours to limit the shear stress on dependent skin.[21] Once spine injuries are stabilized with surgery and/or bracing, as indicated, patients should be mobilized early. Thus, early surgical stabilization also has indirect benefits on skin protection.

Thromboembolic

Venous thromboembolic complications, including deep vein thrombosis (DVT) and pulmonary embolism, occur frequently in SCI patients. Scientific literature shows wide-ranging incidence rates, from 7% to 100% in SCI patients with inadequate prophylaxis.[66–79] Level 1 evidence exists to support chemical and mechanical prophylaxis.[66] Chemical prophylaxis

may consist of subcutaneous low-molecular-weight heparin or LD heparin combined with sequential compression devices on the lower extremities. Appropriate prophylaxis reduces the incidence of venous thromboembolism below 5% in the first weeks after SCI.[74] Level 2 recommendations support commencing chemical prophylaxis upon admission or within 72 hours and continuing for a 3-month duration.[66] Such therapy is generally held for 24 hours before and after surgery. Inferior vena cava filters should be used judiciously when other prophylactic mechanisms are not possible.

Urinary

Many acute SCI patients require placement of a Foley catheter. Patients may initially present with urinary retention from an atonic bladder in the acute setting of spinal shock. Documentation of initial bladder volume on presentation or of postvoid residual volume in patients who are able to urinate is helpful in assessing the degree of neurologic dysfunction. The placement of an indwelling catheter puts patients at risk for the development of urinary tract infection. Thus, if voluntary bladder function does not resume after the acute phase, patients should be transitioned to a system of intermittent catheterization every 4 to 6 hours. Bladder distention is a leading cause of autonomic dysreflexia in the SCI population. Thus, vigilant bladder care is necessary to avoid potentially life-threatening complications.

Nutrition

Similar to trauma, and particularly CNS injury, the acute SCI patient may present in a hypercatabolic state.[80] Such patients require a nutritional source to meet high metabolic demands. Indirect calorimetry may help assess the patient's nutritional needs.[80] There are level 3 recommendations to support early enteral nutrition. However, there is no clear evidence that early nutrition leads to improved neurologic outcome or decreased length of stay.[80]

Rehabilitation

Ultimately, intense inpatient rehabilitation is critical to maximize functional returns (Fig. 79.5).

FIG. 79.5 A patient in rehabilitation after a cervical spinal cord injury shown increasing upper extremity strength and performance.

Summary

Acute management of the SCI patient is a complex undertaking, requiring dedicated multidisciplinary care. Admission to an ICU or dedicated SCI unit is recommended. Hypotension should be avoided and MAP maintained above 85 mm Hg for 7 days. In patients with ongoing spinal cord compression from their trauma, early surgical decompression and stabilization should occur, at least within 24 hours. There is no clear clinical benefit from pharmacotherapy. MP is the most widely prescribed, based on the NASCIS II protocol, although its use is waning due to controversial guidelines changes and potential risks. Induced hypothermia is under active study as a treatment option. The treating provider should anticipate associated medical risks of SCI, including respiratory compromise, infection, DVT, and development of decubitus ulcers, with steps taken to mitigate their development. Clinical attention to each of these areas helps maximize neurologic function and minimize the chance of death from associated complications.

PEARLS

1. Current guidelines provide level 3 recommendations to avoid episodes of hypotension (defined as systolic blood pressure <90 mm Hg) and maintain MAP greater than 85 to 90 mm Hg for 7 days after injury.
2. There is a growing body of literature to support early (<24 hours) surgical intervention in SCI.
3. New neuroprotective strategies under investigation for SCI include hypothermia, riluzole, and minocycline.

PITFALLS

1. The average age at time of SCI has increased substantially over the last 5 decades, from the age of 29 years in the 1970s to 42 years currently.
2. The most recent AANS/CNS guidelines changed MP from a treatment option to a level 1 recommendation against utilization. Use of MP remains controversial and most experts would agree that there is no role for its use in complete (AIS A) thoracic SCI.
3. SCI has systemic effects that affect every organ system, especially pulmonary, cardiovascular, integument, and urinary.

KEY POINTS

1. CT images with sagittal and coronal reconstructions are completed for nearly all suspected SCI patients.

2. Early surgery, particularly for cervical SCI, is routinely accepted as safe, with the most recent studies suggesting improved long-term neurologic outcomes.
3. While steroid use for SCI remains controversial, there are a number of neuroprotective strategies that are being investigated for safety and efficacy, including hypothermia, riluzole, and minocycline.
4. Health care providers of SCI patients should anticipate associated complications of SCI, including respiratory compromise, infection, DVT, and development of decubitus ulcers, with steps taken to mitigate their development.

80 CHAPTER Vertebral Artery Injuries Associated With Cervical Spine Trauma

Adam L. Shimer
Alexander R. Vaccaro

Vertebral artery injury (VAI) due to blunt cervical trauma is often initially asymptomatic; however, potentially devastating sequelae—including embolism, arterial dissection, and stroke—make this condition a diagnostic challenge and treatment dilemma. Recent improvements in diagnostic imaging have led to a higher rate of VAI detection, but the optimal treatment of VAI in the setting of cervical spinal trauma remains controversial. Although treatment of symptomatic VAI is prudent in nearly all settings, the treating physician must balance the treatment of asymptomatic patients with the complications of anticoagulation therapy and possibly the delay of surgical intervention when a diagnosis of vertebral arterial disruption is encountered.

Anatomy

The right vertebral artery (VA) arises from the right subclavian artery distal to the origin of the common carotid artery. On the left side, the VA usually arises directly from the subclavian artery. In 3% to 6% of cases, however, it may arise from the arch of the aorta as a separate vessel. From the vessel's origin at the subclavian to its intracranial termination, the VA can be divided into four anatomic segments. The first portion (V1) extends from the subclavian take-off to the foramen transversarium of C6 as it travels between the longus colli and anterior scalene muscles. The second portion (V2) of the artery then courses cephalad through successive transverse foramina until the level of C2, where the arteries diverge and then course superiorly to enter the more laterally situated foramen transversarium of the C1 vertebral body. The third segment (V3) begins on exiting the C1 foramen transversarium, where it lies in a groove along the superior margin of the posterior arch of the atlas. It then turns anteromedially and passes through the foramen magnum, lying anterior to the medulla oblongata. The fourth and final segment (V4) is intracranial after it pierces the dura mater. The VA then joins with the contralateral artery to form the basilar artery, which feeds the circle of Willis and contributes to the posterior circulation of the brain. This confluence is the anatomic basis of unilateral VA occlusion often being asymptomatic.

Epidemiology

As improved, higher-resolution imaging protocols have been developed and instituted, the incidence of detectable VAIs has increased. Although VAI has been reported as a result of low-energy movements—such as chiropractic manipulation,[1,2] yoga, and sudden head turning[3-5]—discussion of incidence is most appropriate for consideration in high-energy cervical spine trauma, such as motor vehicle collisions and falls.

Investigation into incidence of VAI began as reports on small cohort groups and then later matured into larger prospective studies. Louw and colleagues[6] were the first to investigate VAI in bilateral facet dislocation in a prospective fashion using digital subtraction angiography (DSA) and detected arterial occlusion in 9 of 12 (75%) patients. Willis and colleagues[7] defined "high-risk" groups as those with criteria of either cervical spine fracture involving the transverse foramen or bilateral facet dislocations and, using DSA, detected VAI in 12 of 26 (46%) patients. Miller and colleagues[8] described a broader definition of "high-risk" criteria, including (1) cervical spine fracture–dislocation, (2) neurologic findings not explained by brain imaging, (3) Horner syndrome, (4) Le Fort II or III fracture, (5) skull base fracture, or (6) expanding neck soft tissue injury. Of 216 patients who met the criteria, they found 49 (22.7%) VAIs. Biffl and colleagues'[9] selection criteria were even more inclusive and found 92 VAIs among 605 patients (15.2%). Using magnetic resonance angiography (MRA), Vaccaro and colleagues[10] noted a 37% rate of VAI with unilateral and bilateral cervical facet dislocations. In a follow-up study, Vaccaro found a 20% (12/61) incidence of VA occlusion in patients with subaxial cervical spine fractures.[11]

Later epidemiologic studies have used large level I trauma registries to more accurately define overall incidence of VAI in blunt trauma admissions. The incidence of VAI among total blunt trauma admissions ranged from 0.075% to 0.77%.[8,12,13] The studies had inherent variations due to location and referral pattern of the center and different imaging modalities used, including DSA, computed tomography (CT) angiogram, and magnetic resonance arteriography. Despite the relatively low overall incidence of blunt VAI in the overall trauma population, this small population of patients has a substantial risk of

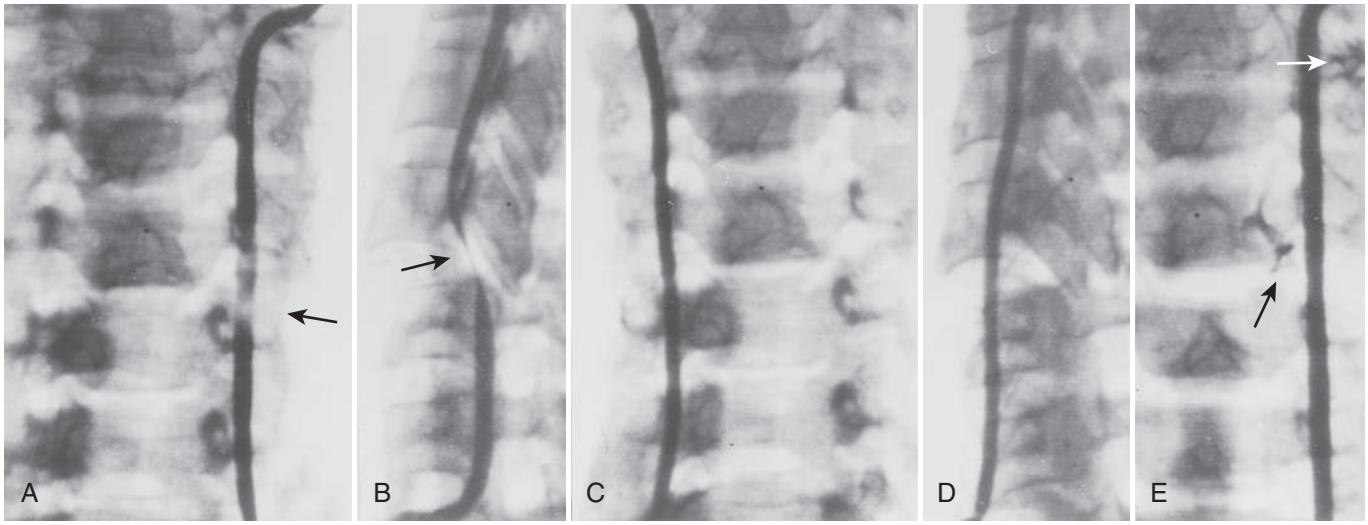

FIG. 80.1 Flexion-distraction stage II injury (lordotic position). A unilateral facet dislocation has been created at C4–C5. The (A) anteroposterior and (B) lateral projections show an hourglass-like stenosis of the left vertebral artery (*arrows*). The contralateral vessel (*right*) has a normal course in the (C) anteroposterior and (D) lateral projections. (E) Contrast extravasation by rupture of a local radicular artery (*black arrow*) and loosening of a muscular arterial ligature (*white arrow*) is demonstrated at dye injection into the left vertebral artery. (From Sim E, Vaccaro AR, Berzianovich A, Simon P. The effects of staged static cervical flexion–distraction deformities on the patency of the vertebral arterial vasculature. *Spine*. 2002;25:2180–2186.)

stroke and mortality,[14] thereby demanding screening criteria and structured protocols for detection of clinically silent lesions.

Mechanism and Types of Arterial Injury

Although VAI has been described at all levels, the V2 segment is the most commonly cited level of injury due to its confinement and tethering within the foramen transversarium, making it susceptible to shear forces during forceful cervical rotation or direct injury from fracture fragments.[15,16] Although less common, the tortuous V3 segment is vulnerable to injury due to its tethering between the foramen transversarium of the atlas and the atlanto-occipital membrane.[17]

Cervical flexion-distraction fracture patterns most commonly result in VAIs, followed by flexion-compression injuries (Figs. 80.1 and 80.2).[11] A review of the literature suggests that a rotational component to the cervical spine may also be a risk factor for VA occlusion.

In an attempt to better refine patient screening criteria for VAI, Cothren and colleagues[13] reviewed 17,007 blunt trauma patients, 125 of whom had cerebral vascular injuries associated with cervical spine injuries. The injuries were characterized as subluxations in 56 (48%) patients, C1 to C3 cervical spine fractures in 42 (36%), and extension of the fracture through the foramen transversarium in 19 (16%). Cervical spine fractures were the sole indication for screening in 90% of the study population. Screening yield of all patients admitted with one of these three fracture patterns was 37%. Therefore, they recommended focused screening for patients with cervical subluxations, fractures through the transverse foramen, or fractures of C1 through C3.

Injury to the VA in the setting of nonpenetrating cervical trauma is most likely due to a stretching mechanism.[18] Sim and colleagues[19] demonstrated in a cadaveric cervical spine model that the static deformity of a flexion-distraction stage II to stage IV subaxial cervical injury resulted in significant compression/stretch of the vertebral arterial vasculature (Figs. 80.3 to 80.5). Initially, the vessel, or a portion of its intimal lining, is injured through excessive distraction in a flexion-distraction injury owing to the soft tissue attachments of the vessel in the foramina transversaria. Secondary events, such as thrombus formation, may then lead to occlusion of the vessel lumen. Recanalization over time after blunt injury to the VA was not a feature observed in a long-term follow-up study reported by Vaccaro and colleagues[10] of image-confirmed vertebral vessel disruption. The lack of recanalization suggests that significant vessel intimal disruption occurs and that thrombus formation is not the only factor involved in vessel occlusion.

The intima of the VA is highly sensitive to shear forces experienced during high-energy blunt trauma. Because the vessel adventitia is more resilient, isolated intimal disruption can lead to a spectrum of clinical entities, including an intimal flap with resultant thrombus formation or a dissection as the intima and adventitia separate cranially. Thrombus and dissection can lead to occlusion. If the energy transmitted is high enough, the adventitia can fail, leading to a pseudoaneurysm formation[20] or transection if complete.

DSA provides the most anatomic detail of arterial injuries. A dissection of the VA has been shown to be the most common pattern of VAI, followed by occlusion. Multiple studies have demonstrated that dissections tend to resolve, whereas occlusions, as a rule, do not recanalize regardless of therapeutic attempts.[10,21,22]

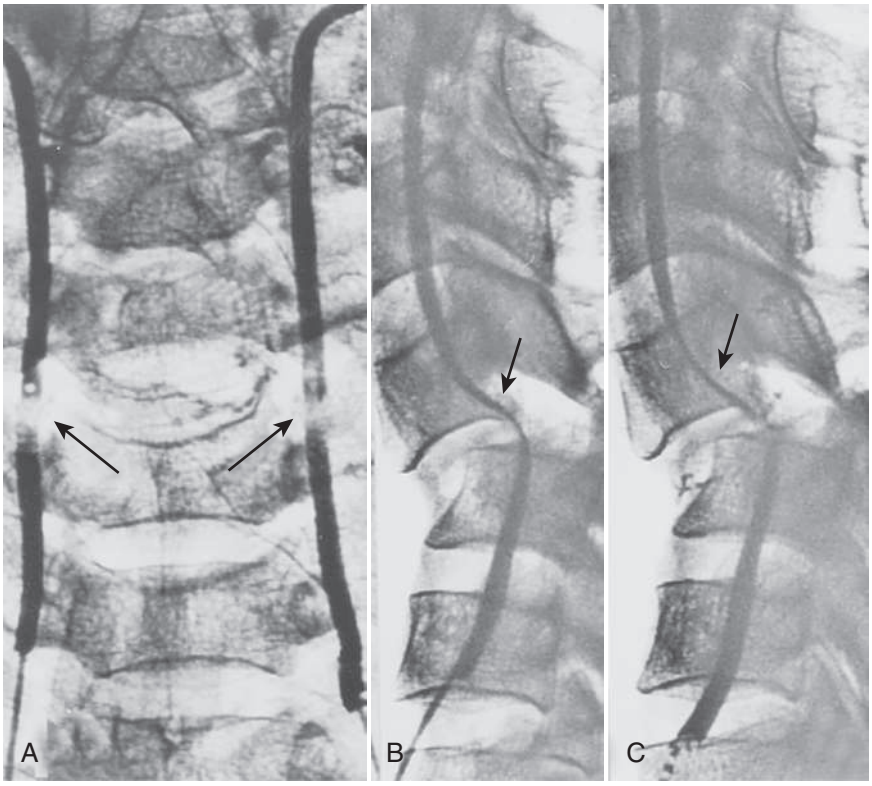

FIG. 80.2 Flexion-distraction stage III injury. A bilateral facet dislocation has been created at C4–C5. The (A) anteroposterior and lateral projections (B, *right*, and C, *left vertebral artery*) reveal excessive thinning of dye flow without complete obstruction (*arrows*) in both the vertebral vessels. (From Sim E, Vaccaro AR, Berzianovich A, Simon P. The effects of staged static cervical flexion–distraction deformities on the patency of the vertebral arterial vasculature. *Spine*. 2002;25:2180–2186.)

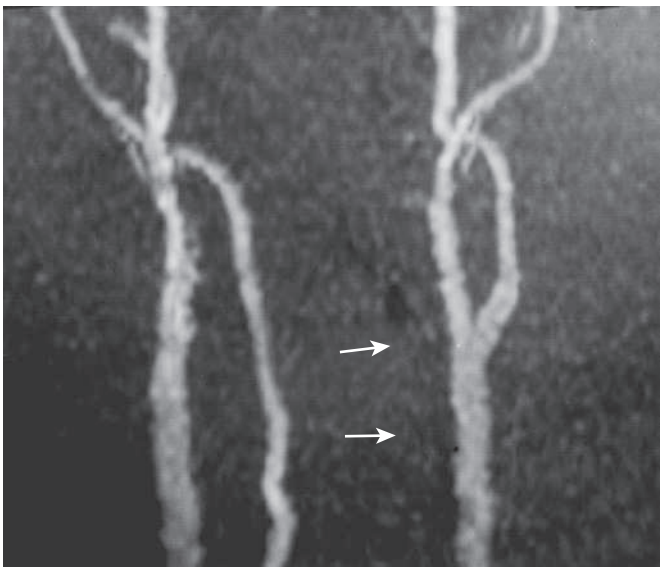

FIG. 80.3 A 73-year-old woman incurred a flexion-distraction injury at C5–C6 after a fall. A magnetic resonance angiography coronal projection image from a two-dimensional time-of-flight dataset shows evidence of normal antegrade flow in the common carotid arteries bilaterally and the right vertebral artery. There is absence of flow in the expected course of the left vertebral artery (*arrows*). (From Vaccaro AR, Gregg KR, Flanders AE, et al. Long-term evaluation of vertebral artery injuries following cervical spine trauma using magnetic resonance angiography. *Spine*. 1998;23:789–794.)

Clinical Diagnoses

Abundant collateral circulation feeding the vertebrobasilar system and posterior circulation of the brain often allows unilateral disruption of the VA to remain asymptomatic. When this collateral circulation is diminished in situations of atherosclerosis or anatomic variations, patients may initially present with symptoms of vertebrobasilar insufficiency (VBI). Symptoms of VA insufficiency may manifest as dizziness, dysarthria, dysphagia, diplopia, blurred vision, and tinnitus.[17]

Initially, asymptomatic patients can have progression of symptoms either acutely or delayed due to embolism, thrombus extension, or dissection. Heros and colleagues[23] described a patient who sustained a VAI with a resultant cerebellar infarction despite having a normal contralateral artery. To explain the infarction, the authors postulated that the thrombosis had extended distally to the intracranial portion of the VA. Interestingly, Six and colleagues[24] reported a case of an asymptomatic posttraumatic bilateral VA occlusion. Angiography demonstrated occlusion of both VAs but with the presence of blood flow through the intramuscular collateral vessels of the thyrocervical trunk and by collaterals from the superficial occipital artery. In fact, Blam and colleagues[25] conducted a retrospective review of 1283 patients

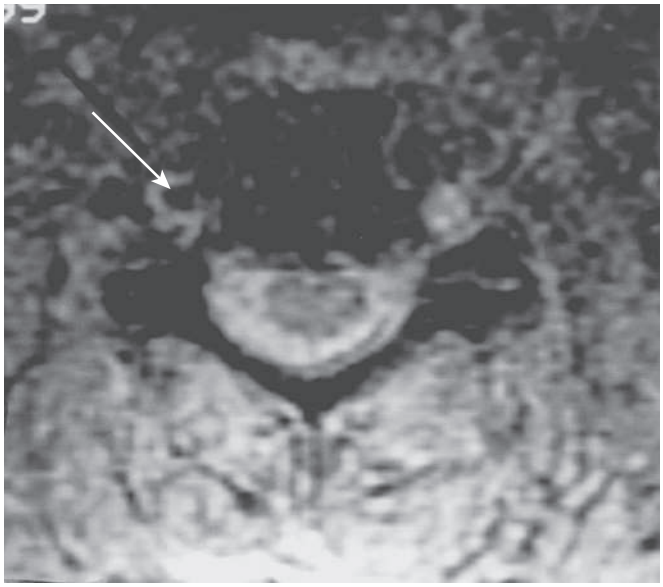

FIG. 80.4 A 51-year-old woman sustained a C4–C5 flexion-distraction injury after a motor vehicle accident. This patient underwent a posterior cervical fusion. Magnetic resonance imaging revealed a C4–C5 central herniated disc, resulting in spinal cord compression. Cord edema was seen from C3 to C5. An axial magnetic resonance angiography gradient-echo image obtained at the mid-C4 level shows a hypointense focus (compared with the normal [hyperintense] left foramen transversarium) contained within the right foramen transversarium (*arrow*) that is consistent with acute thrombosis of the right vertebral artery. (From Vaccaro AR, Gregg KR, Flanders AE, et al. Long-term evaluation of vertebral artery injuries following cervical spine trauma using magnetic resonance angiography. *Spine*. 1998;23:789–794.)

with cervical spine trauma and determined that a normal neurologic examination is not predictive of VA patency after significant cervical spine trauma. These authors also noted that VAI was observed in similar frequency in both neurologically intact and motor incomplete patients (American Spinal Injury Association [ASIA] classifications C and D).[25]

The interval between spinal injury and the development of vertebrobasilar symptoms varies greatly from immediately after trauma to up to 3 months later.[17,26] The late onset of symptoms suggests a process of vertebral vessel thrombus formation at the injury site with clot propagation or embolism and subsequent infarction. Therefore, clinicians should be aware that late symptoms and signs of VBI after cervical spine trauma may be a manifestation of VAI that occurred at the time of trauma.[11] Vaccaro and colleagues[10] demonstrated that 83% of patients with a known traumatic vertebral vessel injury demonstrated no flow reconstitution after an average follow-up of 25.8 months. The one patient who did show reconstitution of flow was thought to have a resolution of vertebral arterial spasm that initially compromised flow.

Imaging Modalities

DSA is a type of fluoroscopy technique used in interventional radiology to clearly visualize blood vessels in a bony or dense soft tissue environment. Images are produced using contrast medium by subtracting a "precontrast image," or the mask from

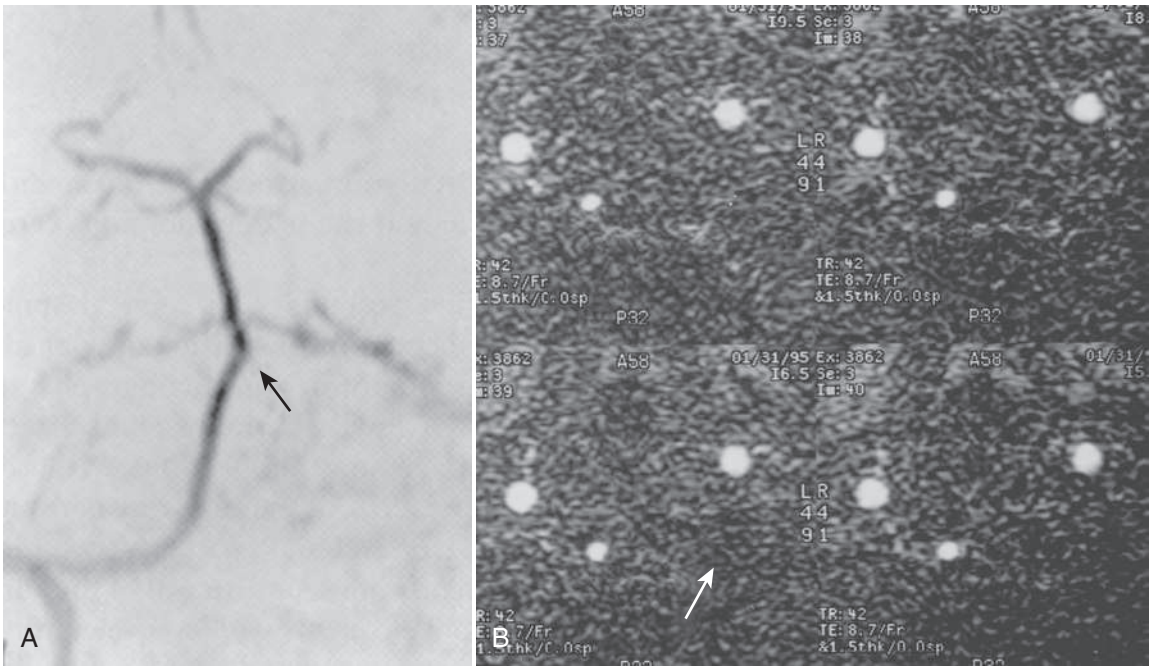

FIG. 80.5 A 28-year-old man sustained a flexion-distraction injury at the C5–C6 level following a motor vehicle accident. (A) Coronal projection image from a two-dimensional time-of-flight magnetic resonance angiography dataset shows the junction of the right vertebral artery with the basilar artery at the expected location of the vertebrobasilar junction. The distal left vertebral artery is absent (*arrow*). (B) Four transaxial contiguous images from a two-dimensional time-of-flight dataset show absence of flow-related enhancement in the left foramen transversarium, which is consistent with occlusion of the left vertebral artery. (From Vaccaro AR, Gregg KR, Flanders AE, et al: Long-term evaluation of vertebral artery injuries following cervical spine trauma using magnetic resonance angiography. *Spine*. 1998;23:789–794.)

later images, once the contrast medium has been introduced into a structure. DSA has routinely been described as the gold standard for detection of VA abnormalities. It is the only imaging technique that can reproducibly detect subtle intimal abnormalities. DSA is also the only technique that allows an interventional neuroradiologist to perform interventions if deemed necessary and appropriate. DSA, however, is time demanding, technique dependent, and invasive, with inherent risks including iatrogenic arterial perforation, puncture-site hematoma/false aneurysm, and dye toxicity. Because of this, DSA may not be a suitable screening tool, leading to development of alternate tests including computed tomography angiography (CTA) and MRA. However, neither of these techniques has proven to match the sensitivity or specificity of DSA.

CTA is a technique that combines precisely timed high-speed, multidetector CT imaging shortly after a bolus of contrast dye through a peripheral intravenous line. Using bolus tracking, a specific anatomic site—in this example, the vertebral arteries—can be imaged without the need for cannulating a catheter directly to the site, thereby eliminating many possible complications associated with DSA. In addition, the amount of dye used in CTA is substantially less than that used in DSA. The majority of high-energy trauma patients require head and cervical spine scans; therefore, this imaging modality can be done in the same clinical setting as other required trauma-specific imaging studies. The previous-generation four-detector CT scanner was widely found to be inadequate for VAI injury. Newer high-speed 16-detector CT scanner imaging is far superior in resolution and in its ability to bolus track. Therefore, this technique has experienced near-universal acceptance within the radiology community as a replacement for DSA. Eastman and colleagues[27] found that CTA was nearly identical to DSA for detection of VAI in 162 patients determined to be at risk of injury. As imaging technology continues to improve, subsequent studies utilizing 32- and 64-channel multidetector CT have found that DSA can confidently and effectively be replaced with CTA.[28]

Although these less-invasive imaging techniques are attractive for the reasons stated earlier and despite wide acceptance in the radiology literature, some trauma surgeons remain skeptical of CTA accuracy. Biffl and colleagues[21] have questioned their ability to detect all vascular lesions when compared with the gold standard DSA. The investigators developed a grading scale to evaluate the performance of MRA and CTA: grade I, dissection with less than 25% luminal narrowing; grade II, dissection with more than 25% luminal narrowing; grade III, pseudoaneurysm; grade IV, occlusion; and grade V, transection. Forty-six consecutive patients underwent CTA or MRA in conjunction with DSA. Although adequate for dramatic lesions, the more subtle grades I, II, and III lesions were routinely missed by CTA or MRA.

Malhotra and colleagues[29] also noted that, increasingly, CTA has been replacing DSA in suspected VAI injuries and selected 119 patients who met screening criteria (facial/cervical–spinal fractures; unexplained neurologic deficit; anisocoria; lateral neck soft tissue injury; clinical suspicion) out of 7000 level I blunt trauma admissions and performed DSA and CTA. In agreement with Biffl's study, they found an alarming rate of missed VAIs using CTA that were visualized using DSA. The authors went as far as to say that using CTA was dangerous due to the risk of missed injuries. Miller and colleagues' study also found CTA and MRA to be inadequate screening tools.[8] Although many investigators have shown failures of CTA to detect subtle lesions, Berne and colleagues[30] have asserted that CTA is sufficient for detection of clinically relevant injuries (i.e., high-grade injuries). Although screening criteria may be employed to direct a dedicated CTA of the cerebrovascular system, another consideration is to integrate a CTA of the VA into the standard CT trauma series protocol. Langner and colleagues[31] developed such a protocol and found that an optimized craniocervical CTA can be easily integrated into a whole-body CT protocol for polytrauma patients. They assert that no additional screening technique is necessary to identify clinically relevant vascular injuries. This type of protocol could lead to a more liberalized screening of all trauma patients, as recommended by some investigators.[32]

MRA uses magnetic resonance imaging (MRI) with specifically designed sequences or gadolinium dye to image arterial blood flow. Similar to CTA, MRA offers a minimally invasive alternative to DSA. In addition, MRA is nonionizing. MRA can be performed in the same clinical setting as a spine or brain MRI. Although many studies have compared CTA to the gold standard DSA, there are relatively fewer studies comparing the sensitivity and specificity of MRA in detecting VAI.

The most common noncontrast, flow-based method is inflow angiography, or "time-of-flight" (TOF), which is simply ordinary MRI using settings that make flowing blood much brighter than stationary tissue.

MRA based on an injected contrast medium (usually containing gadolinium) is currently the most common form of MRA. The contrast medium is injected into a vein, and images are acquired during the first pass of the agent through the arteries. Provided that the timing is correct, this may result in images of high quality. An alternative is to use a contrast agent that does not, as most agents do, leave the vascular system within a few minutes but remains in the circulation up to an hour (a "blood-pool agent"). Because longer time is available for image acquisition, higher-resolution imaging is possible. A problem, however, is the fact that both arteries and veins are enhanced at the same time.

Veras and colleagues[33] performed a retrospective review of patients with VAI to determine the ideal MRA imaging sequence. They noted that two-dimensional TOF sequencing was a more effective imaging sequence than the three-dimensional time-of-flow because of a reduced false-positive signal dropout. Axial T1-weighted MRI was useful because of its ability to delineate the absence of flow from an intimal occlusion, including an intraluminal clot. In a dog model, Ren and colleagues[34] found that MRA was comparable with DSA for evaluation of VAI.

Screening

As discussed in the previous section, many studies have demonstrated the convenience, low risk, and reliability of

modern multidetector CTA to detect blunt cerebrovascular injury (BCVI), including vertebral artery injury. Determining which patients are at a high risk of BCVI and who should have a CTA is an important aspect of the detection and treatment algorithm. The most often used criteria are that set forth by the Denver group. The "Denver" criteria include (1) an injury mechanism compatible with severe cervical hyperextension with rotation or hyperflexion; (2) Lefort II or III midface fractures; (3) basilar skull fractures involving the carotid canal; (4) closed head injury consistent with diffuse axonal injury with Glasgow Coma Scale score less than 6; (5) cervical vertebral body or transverse foramen fracture, subluxation, or ligamentous injury at any level, or fracture at the level of C1–C3; (6) near-hanging resulting in cerebral anoxia; or (7) seat belt or other clothesline-type injury with significant cervical pain or swelling.[35] The "Denver" criteria have been widely adopted, but more recent studies have asserted that the screening be more focused[36] or more relaxed.[37]

Treatment

Treatment considerations should be divided into (1) symptomatic with evidence of stroke, (2) symptomatic without evidence of stroke, and (3) asymptomatic VAI.

Several different methods of therapy have been used to treat symptomatically occluded VAs. The American Association of Neurological Surgeons/Congress of Neurological Surgeons Guidelines consensus concluded that patients with posterior circulation stroke and VAI have a better outcome when treated with intravenous heparin than patients who do not receive this treatment.[38] Fibrinolysis with streptokinase has also been described to successfully restore flow with varied results.[39]

Although the exact mechanism is ill defined, be it ischemia or embolic, the outcome of patients who develop symptoms of posterior circulation ischemia without stroke and are treated with intravenous heparin[1,40–42] is similar to that of patients receiving no treatment.[6,43] In the symptomatic patient, Schellinger and colleagues[41] advocated the initial use of heparin with a target-activated partial thromboplastin time of at least twice the baseline value followed by oral anticoagulation (warfarin) for at least 3 to 6 months as a secondary prophylaxis.

Complications associated with anticoagulation in the trauma population range from 25% to 54%.[44] Bleeding complications include intracranial hemorrhage, gastrointestinal bleeding, retroperitoneal hemorrhage, and excessive surgical site bleeding. In fact, in a study by Eachempati and colleagues,[45] only 14% of trauma patients were deemed candidates for full anticoagulation. These facts have led physicians to focus more on antiplatelet therapy as opposed to heparinization.

In appropriately selected candidates with a symptomatic dissecting VA, surgical intervention may include vertebral vessel resection followed by grafting. Another method of arresting vessel flow is through the use of catheter embolization with Guglielmi detachable coils.[46-48] Today, the gold standard surgical procedure for a symptomatic vertebral dissection remains ligation of the injured VA proximal and distal to the site of the lesion rather than primary repair.[47] As mentioned previously, ligation is well tolerated if there is adequate collateral flow.

The treatment of asymptomatic VAIs has been controversial in the past. In the previous edition of this text, in the majority of level I trauma centers, formal treatment was not recommended for a patient with an asymptomatic VAI after trauma.[24,48] Multiple groups have since endorsed the use of aspirin (acetylsalicylic acid [ASA]) for treatment of all VAI. The use of ASA has been shown to prevent stroke and potentially increase the chance of arterial injury healing and flow abnormality resolution.

Because of the risk of rupture and embolic source, a pseudoaneurysm of the VA is usually aggressively treated most commonly with coil embolization or stenting.

Transection of the VA is a life-threatening emergency due to hemorrhagic shock and/or airway compromise. Treatment is airway management, resuscitation, and emergent interventional neuroradiology embolization.[49] An additional reason to routinely evaluate for the presence of a vertebral vessel disruption in an asymptomatic patient is to ensure safety of the intact vessel if surgical intervention with implants that may put the vertebral vasculature at risk are to be used.

Summary

Despite its controversial treatment, the diagnosis of VAIs after blunt cervical trauma is beneficial in that it may alter or modify the proposed surgical procedure and may explain late onset of symptoms consistent with VBI. The potential risk for injury to the uninjured VA should be known to the surgeon when operating on the cervical spine, especially when performing procedures that may place the uninjured artery at risk (i.e., lateral mass plating or cervical pedicle screw placement). The physician must realize that the injured VA is a potential source for thrombus propagation and embolization with resultant neurologic injury. Imaging should be considered in all patients who present with signs and symptoms of VBI, especially in the presence of a cervical dislocation, high cervical spine (C1–C3) fracture, or fracture involving the foramen transversarium. Multiple societies have published practice management guidelines for the screening and treatment of BCVI. The Eastern Association for the Surgery of Trauma[50] and Western Trauma Association[51] reported guidelines very similar to those described in this chapter in 2010 and 2009, respectively. The consensus statement from the American Association of Neurological Surgeons/Congress of Neurological Surgeons recommends anticoagulation for VAI with evidence of posterior circulation stroke and recommends consideration for anticoagulation in symptomatic VAI without evidence of stroke. Vertebral artery injury without symptoms should be treated with aspirin when deemed safe from a bleeding risk perspective. These recommendations in general have continued to be supported by the majority of contemporary studies. Fortunately, because of adequate collateral circulation, most VAIs remain asymptomatic.

PEARLS

1. Most VAIs are asymptomatic because of sufficient collateral blood flow through the contralateral vertebral artery.
2. VAIs should be suspected after blunt cervical trauma when patients present with neurologic deficits, such as dysarthria, dizziness, diplopia, and dysphagia.
3. Flexion-distraction injuries are most commonly associated with VAIs, followed by flexion-compression injuries.
4. Imaging should be considered in the setting of specific cervical spine injuries, such as cervical dislocations, fracture involving the foramen transversarium, and injuries to the upper cervical spine (C1–C3) to rule out VAI.
5. Anticoagulation with intravenous heparin is recommended for patients with VAI who have evidence of posterior circulation stroke. Aspirin should be utilized for all other VAIs if no contraindication exists.

PITFALLS

1. DSA provides the most detailed, highest-resolution imaging of the vertebral artery pathoanatomy but is an invasive procedure with potential risks.
2. CT and magnetic resonance arteriograms may be acceptable screening tools for clinically relevant VAIs but may fail to detect more subtle lesions. CTA sensitivity and specificity continues to improve with higher-number detector channels.
3. Anticoagulation treatment is associated with potentially significant complications, such as hemorrhage, stroke propagation, and neural ischemia.
4. Surgeons should be cognizant of prior cervical spine trauma and possible VAI when performing procedures that may place the uninjured vertebral artery at risk (i.e., lateral mass plating).
5. Most VA occlusions do not reconstitute their blood flow, and late neurologic deterioration may occur from extension of the arterial thrombus, emboli formation, and resultant infarction.

KEY POINTS

1. VAIs are most commonly seen in cervical spine fractures involving the foramen transversarium, upper cervical spine (C1–C3), and cervical subluxations/dislocations. Intimal disruption and secondary thrombus formation is the most common pattern of vascular injury seen in cervical spine fractures. Most VAIs are asymptomatic due to sufficient collateral blood flow through the contralateral VA.
2. In the previously shown fracture patterns, it is suggested that advanced imaging (MRA or CT arteriography) of the VAs is performed to evaluate for injury. DSA provides the most detailed, highest-resolution imaging of the VA pathoanatomy but is an invasive procedure with potential risks. CT and magnetic resonance arteriograms may be acceptable screening tools for clinically relevant VAIs but may fail to detect more subtle lesions.
3. Key neurologic signs and symptoms of vertebrobasilar (posterior/cerebellar) insufficiency can be subtle and include dysarthria, dizziness, diplopia, and dysphagia.
4. Anticoagulation with intravenous heparin is recommended for patients with VAI who have evidence of posterior circulation stroke. Aspirin should be utilized for all other VAIs if no contraindication exists.

   A prospective study determined at 25.8-month follow-up that the majority of patients (83%) who sustained a vertebral artery injury secondary to cervical spinal trauma did not reconstitute the occluded vertebral artery.
3. Cothren CC, Moore EE, Biffl WL, et al. Cervical spine fracture patterns predictive of blunt vertebral artery injury. *J Trauma*. 2003;55:811-813.
   Blunt cerebrovascular injury is associated with complex cervical spine fractures that include subluxation, extension into the foramen transversarium, or upper C1 to C3 fractures. One of these three injury patterns was observed in 90% (subluxations in 48%, C1 to C3 cervical spine fractures in 36%, or extension of the fracture through the foramen transversarium in 16%) of blunt cerebrovascular injuries associated with cervical spine trauma at one institution. Patients sustaining such cervical fractures should undergo prompt screening.
4. Biffl WL, Ray CE Jr, Moore EE, et al. Noninvasive diagnosis of blunt cerebrovascular injuries: a preliminary report. *J Trauma*. 2002;53:850-856.
   This is the first description of a VAI grading system from I to V in order of severity (partial occlusion to transection). CT and MR angiography can identify VAI, but they regularly miss more subtle grade I, II, and III injuries. Future technical modifications may improve their accuracy, but in the interim, arteriography remains the gold standard for diagnosis. If arteriography is not available, CT or MR angiography should be used to screen for VAI in patients at risk.

81 CHAPTER Spinal Orthoses for Traumatic and Degenerative Disease

Michael J. Vives

Braces have played an integral role in the management of spinal pathologic processes for thousands of years. Smith, in his 1908 article "The Most Ancient Splints," described brace use in ancient Egypt more than 2500 years ago.[1] Much of the early literature focused on treatment of spinal deformities, including Galen's chest-strapping method and Paré's leather-lined metal jacket, popular in the late 16th century.[2] Nicholas Andry developed the "iron cross" in the early 18th century for cervical immobilization, consisting of a straight metal upright with a cross and metal ring attached to the top for support of the head.[3] Today, spinal bracing continues to be a mainstay of treating deformity (covered elsewhere in this text) and the management of traumatic and degenerative spinal disorders. In medical terms, spinal braces are referred to as orthoses, which are defined as externally applied devices that restrict motion, correct deformity, or improve function in a particular body segment.[4]

Spinal orthoses can be broadly categorized based on the body segment that they are employed to immobilize: cervical (CO), cervicothoracic (CTO), thoracolumbosacral (TLSO), lumbosacral (LSO), and sacroiliac (SIO). This chapter focuses on the biomechanics, laboratory studies, and the classic and recent clinical results of commonly used commercially available spinal orthoses. The US Food and Drug Administration (FDA) has classified spinal orthoses as class I devices. As a result, they have not been subject to the strict regulations and scrutiny applied to implantable devices. The currently available knowledge on these devices is the product of observations of varying degrees of scientific merit. Additionally, many commercially available products do not have peer-reviewed data to support their purported effectiveness. The prosthetics and orthotics community has produced numerous publications in print and online trade journals regarding their products and design developments, but comparatively little is published in medical journals familiar to practicing spine specialists. A PubMed search using the key words "spinal orthoses" will result in a fraction of the results that an Internet search will yield. The paucity of readily available peer-reviewed literature has presumably contributed to the variability of prescribing patterns among spine specialists. Bible and colleagues illustrated this point using a questionnaire study of the postoperative bracing preferences among spine surgeons.[5] Most of the respondents braced their patients postoperatively, but there was no consensus on the type, duration, or indications for bracing. In this chapter, therefore, we have attempted to discuss the available data and review design features of various orthoses rather than make specific recommendations on the superiority of one commercial product versus another. Hopefully, the information provided can help clinicians choose the appropriate orthoses to meet their patients' needs.

Biomechanics and Biomaterials

An improved understanding of spinal biomechanics has led to advances in spinal bracing. Conceptually, the spine can be thought of as a series of semirigid bodies interconnected by viscoelastic linkages. Spinal kinematics involves motion in six degrees of freedom, with rotation about three axes and translation along the three coordinates.[6] For clinical considerations, testing (particularly involving human subjects) has generally been confined to three planes of motion: flexion-extension, axial rotation, and lateral bending.

The efficacy of a particular orthosis to limit spinal motion has been tested using various methods, including radiography and goniometry. Standard radiography, typically utilizing flexion-extension views, has been commonly employed. Cineradiography evaluates motion through the use of fluoroscopy. Goniometry utilizes external devices attached to the subject to measure spinal motion. It has been demonstrated to correlate fairly well with radiographic techniques[7] and avoids exposing subjects to radiation. However, there is some decreased accuracy and lack of information on motion at any particular segment. Motion analysis systems that permit spinal motion to be measured in three dimensions have been utilized more recently to study the efficacy of orthoses.[8,9]

Because bracing attempts to control the position of the spine through the application of external forces, orthotic design must account for regional variations of the surrounding anatomy and accommodate vulnerable structures. This includes the vital soft tissue about the anterior neck, the rigid thoracic rib cage, the compressible abdomen, and the bony pelvis at the base of the lumbar spine. The surrounding soft tissue envelope has a substantial effect on the ability of an externally applied force to control spinal movement. Pressure measurements on the soft tissues may be an objective way to

assess the fit of a spinal orthosis. The role of soft tissue pressure measurement as an index of applied corrective or stabilizing force, however, remains unclear.[10,11] The intervening soft tissue envelope is also an area of potential complications: problems include breakdown, local pain, decreased vital capacity, and increased lower extremity venous pressure.[12]

Along with our improved understanding of the biomechanics of spinal bracing, improvements in the materials available for brace manufacture have led to dramatic advances in their design. During the 18th century, braces were generally constructed of leather, iron, and wood. German developments in the 19th and early 20th centuries led to many new brace designs, with paper cellulose and glue being added to wooden or iron frames.[4] Newer composite materials, polymer resins, and thermoplastics have led to a proliferation of commercially available orthoses that are lightweight and comfortable without sacrificing the stability afforded by the heavier, more cumbersome designs of the past. New low-density polyethylene shells have considerable flexibility off the body, facilitating donning and doffing, but once strapped have comparable vertical stiffness to other rigid designs. Commonly used materials in the fabrication of orthoses are listed in Box 81.1.

Beyond the advances in our understanding of biomechanics and biomaterials, advances in computer engineering have led to innovative methods for customized production of orthoses with decreased time requirements. At our institutions, efforts to limit the length of inpatient admissions have necessitated a close working relationship between the treating physicians and the orthotists. A computerized database of key measurements that have been recorded over the years has allowed our orthotists to develop digitized models of various sizes and body types utilizing computer-aided design/computer-aided manufacturing technology (CAD/CAM). Using this approach, simple measurement at the sternal notch, xiphoid, and waist along with linear measurements can be performed and integrated with CAD/CAM technology to rapidly design a precision-fit orthosis in a fraction of the time needed for standard mold-based orthoses. Researchers have evaluated this approach for bracing patients with idiopathic scoliosis. Braces comparable to those made using traditional mold techniques (in comfort and curve correction) could be produced in roughly one-third of the time previously required.[13] Continuing advances in this area include the development of handheld three-dimensional laser imagers that utilize reflectors placed on the patient to capture shape information. This technology is already frequently used in limb applications and is becoming more commonly employed for spinal applications.

FIG. 81.1 Philadelphia collar. The design includes anterior and posterior shells that are fastened with Velcro straps. The anterior hole is for a tracheostomy tube.

Cervical Orthoses

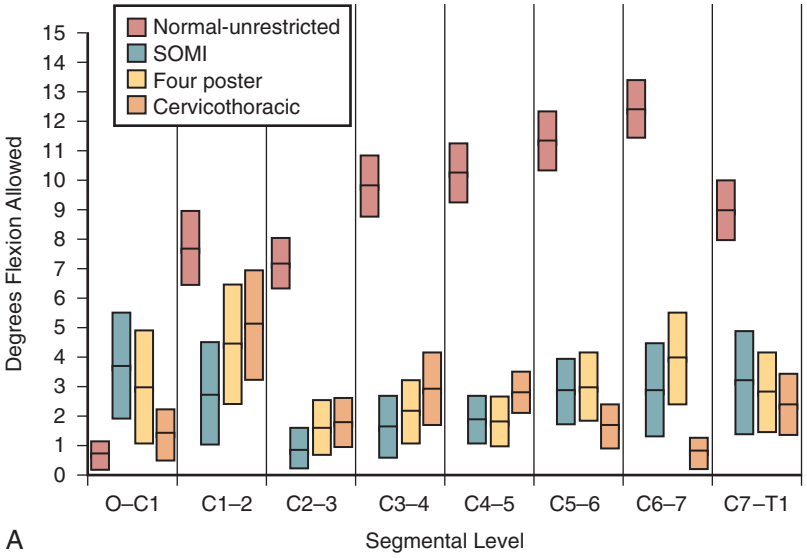
The cervical region provides a challenge for externally applied spine immobilization due to the soft tissue structures about the neck and high level of mobility of the spine segments. COs can be divided into two broad categories: soft and rigid. Soft collars provide comfort and proprioception but little immobilization, decreasing flexion and extension by 5% to 15%, lateral bending by 5% to 10%, and axial rotation by 10% and 17%.[14] They are often used in the treatment of whiplash-type injuries or muscular strains about the neck, where proprioceptive feedback helps "remind" a patient to voluntarily restrict motion. Such proprioception appears to be reasonably effective in the course of everyday living. Miller and colleagues evaluated the amount of motion recorded by 10 subjects during various functional tasks of everyday living. They found that the amount of motion was not significantly different whether soft or rigid COs were used.[15]

Rigid COs are available in several forms, but all forms must be able to accommodate the vital soft tissue structures in the neck while simultaneously providing rigid immobilization of the mobile cervical spine. This is generally accomplished by firm seatings about the base of the skull and upper thorax connected by a rigid column. Most include an anterior opening to accommodate a tracheostomy tube. Rigid COs are generally used to provide stabilization to the midcervical spine. Examples of COs include the Philadelphia collar (Fig. 81.1), the Miami J collar (Ossur; Fig. 81.2), the Aspen CO (Aspen; Fig. 81.3), and the Malibu collar (Fig. 81.4).

FIG. 81.2 Miami J cervical orthosis. (A) Anterior view. (B) Posterior view. The design includes anterior and posterior shells with a soft lining that can be changed for hygiene purposes.

FIG. 81.3 Aspen cervical collar. (A) Anterior view. (B) Posterior view. The design includes patented tabs that allow the collar to better conform to the patient when tightened.

FIG. 81.4 Malibu collar. (A) Anterior view. (B) Lateral view. The design features include tight-fitting chin and occipital rests and more anterior and posterior extension onto the thorax than the Philadelphia collar.



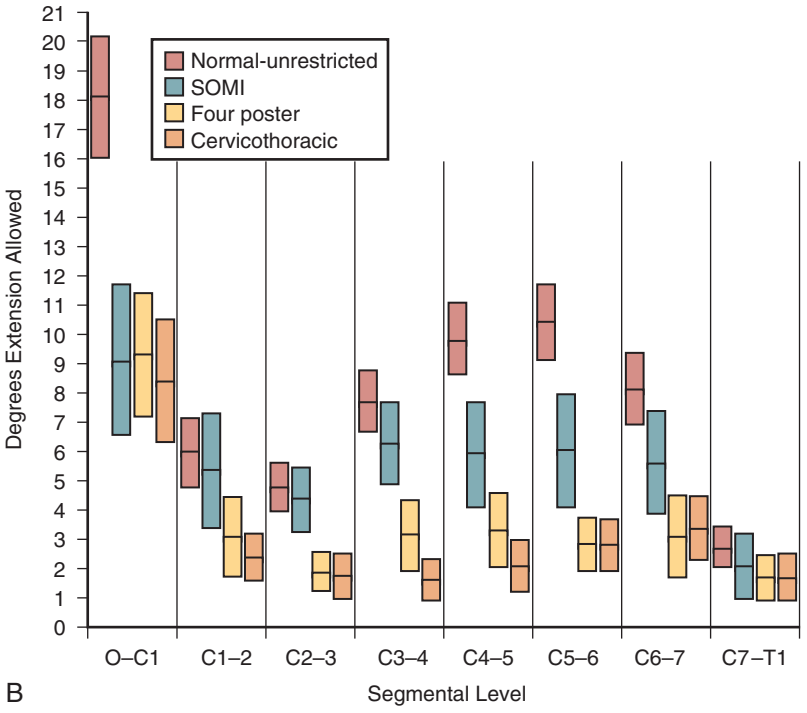
The landmark study evaluating the effectiveness of various orthoses in immobilizing the cervical spine was performed by Johnson and colleagues.[16] The methods of this study have often been emulated and its results frequently quoted since its publication in 1977. The authors evaluated the soft collar, Philadelphia collar, four-poster orthosis, sterno-occipito-mandibular immobilizer (SOMI), and a cervicothoracic orthosis. They utilized radiographs and overhead photographs taken at the extremes of motion in flexion-extension, rotation, and lateral bending. They quantified sagittal plane motion for each brace at every level of the cervical spine (Fig. 81.5). As others had demonstrated, they found that a soft collar offered no restriction of motion in any plane. They found that increasing the length of the orthosis (extending it onto the thorax) and increasing the rigidity of the connection improved flexion control, but lateral bending and total flexion and extension were less controlled. They also demonstrated increased motion between the occiput and C1 in all braces compared with the unbraced state. This "snaking," or paradoxical motion, has subsequently been described throughout the cervical and thoracolumbar spine.[17–19]

Another study by Askins et al. compared five commonly used COs in terms of their efficacy in restricting cervical motion.[20] Radiographic and goniometric measurements found the NecLoc (Ossur) orthosis to be superior to the Miami J, Philadelphia, Aspen, and Stifneck (Laerdal) orthoses in terms of flexion-extension, rotation, and lateral bending. The Miami J collar was also found to be significantly superior to the Philadelphia and Aspen orthoses in extension and combined flexion-extension. Motion analysis systems have been used in recent studies, which typically measure gross rather than segmental movement of the cervical spine.[8,9] Interestingly, these have reported findings different from the aforementioned studies in comparing efficacy among commonly used orthoses. However, as other methods have also found, these studies reported that flexion-extension and rotational movements were more effectively restricted than lateral bending among all of the collars. Separate studies in children have also demonstrated differing performance among commercially available pediatric collars, with the Miami J and NecLoc demonstrating better motion limitation than the Philadelphia collar.[21]

Many hospitals have an in-house inventory of COs so that they are readily available without the need for an orthotist. Predicting the appropriately sized collar can be somewhat imprecise, however. A study by Bell et al. investigated the adverse effects of an ill-fitting Miami J CO using electromagnetic sensors.[22] The authors compared motion in healthy subjects using a Miami J of correct size to one that was too small and one that was too big, among other orthoses. They found that the ill-fitting COs allowed a significant increase in motion in multiple planes when compared to the correctly sized Miami J. The authors reiterated the importance of correct fitting of a CO to avoid the potentially detrimental effects of excessive motion. In an effort to provide customized fitting with decreased inventory, some manufacturers offer adjustable COs. Gao compared the motion restriction of adjustable COs to standard COs in healthy participants across a range of loading levels.[23] They found that the adjustable COs were as effective as standard COs. In our institution, we have found that nursing and nonspine clinicians can have difficulty in

adjusting such collars despite educational efforts. Hands-on involvement of the spine specialist or orthotist may be necessary to ensure appropriate fit of the adjustable COs.

Known complications of COs include skin breakdown over bony prominences, such as the occiput, mandible, and sternum. Skin breakdown is especially prevalent in multitrauma patients with prolonged recumbency and in patients with altered sensorium. One study reported orthosis-related decubiti in 38% of patients with associated severe closed-head injuries.[24] Molano Alvarez et al. reported a 23.9% incidence of pressure sores in their series of patients with acute cervical spine injury placed in a cervical collar.[25] The pressure sores were found at day 7, on average, and were most frequently noted over the chin, occipital, and suprascapular areas. The authors found that pressure sores were associated with a higher injury severity score, longer time on mechanical ventilation, longer stays, and a greater percentage of catheter carriers of intracranial pressure. In addition, days spent in a cervical collar and presence of edema are thought to be significant predictors of skin breakdown.[26] Plaisier and colleagues compared the skin pressure associated with the use of the Stifneck, Philadelphia, Miami J, and Aspen/Newport collars in supine patients.[27] They found that the Miami J and the Aspen collars produced the lowest chin and occiput pressures, both being below the mean capillary closing pressure. Tescher et al.[28] assessed the effects of four commercially available cervical collars on mandibular and occipital tissue-interface pressure using custom-sized pads from a proprietary capacitive pressure-sensing transducer system. These authors found that the Miami J collar, with and without Occian back, had



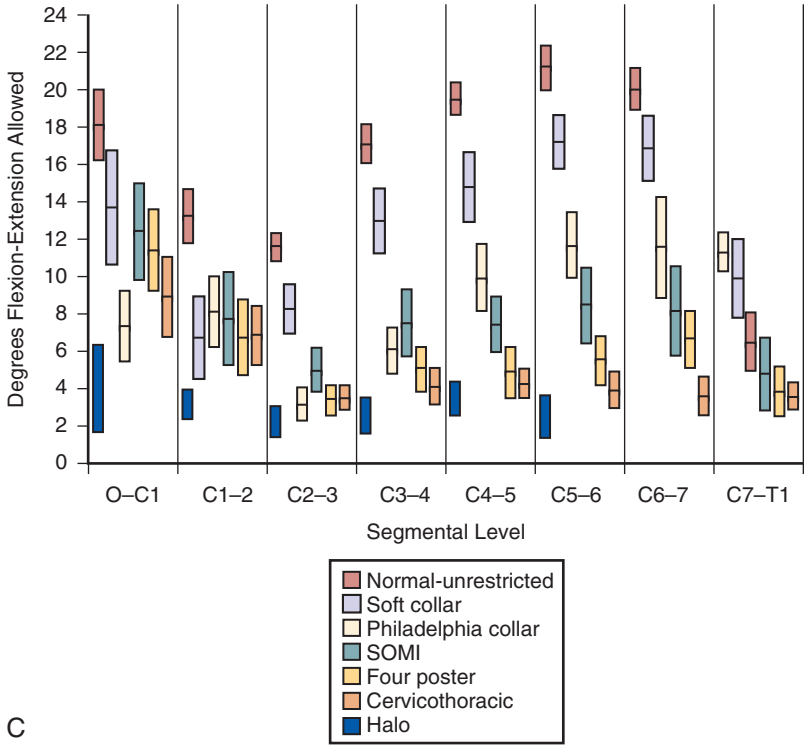


FIG. 81.5 Graphs demonstrating motion allowed in the normal cervical spine compared with cervical orthoses. FIG. 81.5, cont'd (C) Degrees of flexion-extension allowed at each cervical segment in a variety of orthoses compared with the normal unrestricted cervical spine. (From Johnson RM, Hart DL, Simmons EF, et al. Cervical orthoses: a study comparing their effectiveness in restricting cervical motion in normal subjects. *J Bone Joint Surg Am*. 1977;59:332–339.)

the lowest levels of mandibular and occipital pressure when compared to the Aspen and Philadelphia collars. Increased intracranial pressure as a consequence of rigid cervical orthotic immobilization has been described. As a surrogate for intracranial pressure, Karason et al. measured jugular venous pressure by catheter in healthy subjects with and without COs.[29] They found that most commercially available COs resulted in a significant increase in jugular venous pressure. Hunt and colleagues directly studied the effects of rigid collar placement on intracranial pressure in head-injured patients.[30] They found that rigid collars cause a small but significant increase in intracranial pressure, which may have deleterious effects in patients with severe head injuries and preexisting intracranial hypertension. They recommend early removal of rigid collars from head-injured patients once cervical spine injury has been excluded. Aspiration and dysphagia are at times anecdotally attributed to cervical collar use, but studies have been inconclusive. When using healthy volunteers performing swallowing studies, some mechanical changes in swallowing physiology were noted, but no aspirations occurred.[31] A causal link between cervical collar use and aspiration in injured or elderly patients has been suggested but not proven.

Methods for immobilizing the cervical spine of patients in the field have also been extensively studied. These include use of a cervical collar, a short board or sandbag technique, or a combination of a collar and short board. Cline and coworkers compared the Hare extrication collar, the Philadelphia collar, and their immobilization protocol, which consists of a short board with forehead and chin straps.[32] They concluded that the short board with straps provided the best immobilization and that the addition of a Philadelphia collar did not provide additional benefit. Podolsky and colleagues[33] utilized goniometry to evaluate the immobilization provided by soft collar, hard collar, Philadelphia collar, Hare extrication device, and their sandbag technique (which utilizes a board plus forehead tape). They found that the sandbag technique provided the most effective immobilization but that the addition of a Philadelphia collar provided additional benefit. In the presence of a dissociative injury at the occipitoatlantal or atlantoaxial level, extrication collars can result in abnormal separation between the vertebrae.[34] While this was demonstrated in a cadaver study, further research is necessary to determine if field management protocols should be modified to manage this risk.

The role of cervical collars following surgery for degenerative disease is an area of ongoing investigation and controversy. Bible at al., in their questionnaire of orthosis usage among spine surgeons, found that orthoses were more often used after anterior cervical spine procedures as the complexity of the procedure increased.[5] Campbell et al. evaluated the effect of a cervical collar after single-level anterior cervical fusion with plating on fusion rates and clinical outcomes in an FDA-regulated, multicenter controlled trial.[35] They found similar clinical outcome parameters and a trend toward higher rates of fusion in the nonbraced group compared to those treated with a cervical collar. In addition, there was no difference between proportion of patients returning to work.

Cervicothoracic Orthoses

CTOs generally consist of occiput and chin supports attached to anterior and/or posterior thoracic plates. Examples include the SOMI (Fig. 81.6), the Minerva brace (Fig. 81.7), and the

FIG. 81.6 Sterno-occipito-mandibular immobilizer (SOMI). The three upright rods that extend from the mandibular and occipital rests all connect on the anterior thoracic plate.

Yale brace (Fig. 81.8). Compared with COs, these devices improve control in all planes of motion and are particularly suited for immobilization of the middle to lower cervical spine and upper thoracic spine. This improved rigidity, however, comes at the expense of patient comfort. Some of the earlier authors distinguished between the two/four-poster designs and those with more extensive connections between the head and thoracic components.[16] The more recent standardized classification system, however, categorizes the poster braces as CTOs along with the other designs. The traditional four-poster brace was shown to limit 79% of overall cervical flexion-extension and limit midcervical flexion to a comparable degree as the more rigid CTOs.[4,36] Because of their heavy design and high resting pressures on the chin and occiput,[7] this brace is less commonly used today.

The SOMI (see Fig. 81.6) utilizes metal uprights to connect occipital and mandibular rests to a sternal plate that is secured to the thorax by padded metal "over-the-shoulder" straps and additional circumferential straps that cross in the back. Because there is no posterior thoracic plate, the occipital rests are supported by uprights from the sternal piece. This results in adequate control of flexion but deficient control of extension throughout the cervical spine.[16,36] These braces are fairly comfortable to patients but also are associated with high resting pressures at the chin and occiput.[7]

The original Minerva brace consisted of a heavy custom plaster jacket that created difficulties in maintaining patient

FIG. 81.7 Minerva cervicothoracic orthosis. (A) Anterior view. (B) Posterior view. This design has an expansive occipital flare to help limit rotation.

FIG. 81.8 Yale brace. (A) Anterior view. (B) Posterior view. Note the similarities of the head rest to a Philadelphia collar, from which the early version was originally adapted.

hygiene and obtaining radiographs.[37] As a result of the difficulties encountered in managing patients with this device, the halo came into popular use. Later, the thermoplastic Minerva body jacket (TMBJ) was developed that preserved the noninvasive nature of the original concept. Its lightweight, bivalved, polyform shell allowed improved patient comfort and hygiene and interfered less with follow-up radiographs.[38] Donning this brace is somewhat complex, often requiring an orthotist for proper application. More recently, a prefabricated version of the Minerva body jacket has been developed, the Minerva CTO (see Fig. 81.7). Its design features a forehead band attached to a large occipital flare. Sharpe and colleagues reported that this orthosis limits overall sagittal plane motion by 79%, axial rotation by 88%, and lateral bending by 51%.[39]

The Yale brace (see Fig. 81.8) was originally designed as a modified Philadelphia collar with custom-molded anterior and posterior polypropylene thoracic extensions.[40] The modern version is prefabricated and usually made of Kydex. Although lighter and less cumbersome than most of the other CTOs, the Yale brace has similar efficacy in controlling motion. In Johnson's study, the Yale brace restricted 87% of overall flexion-extension, 75% of axial rotation, and 61% of lateral bending.[41] Whereas the CTOs have been shown to be fairly effective at limiting motion of the cervical spine, they should not be expected to rigidly immobilize below the C7–T1 level despite their thoracic components. The use of any of the CTOs in bedbound patients can be problematic, as the tendency for cephalad migration of the brace in the semirecumbent position increases the likelihood of pressure phenomena on the chin or occiput.

Ivancic recently devised a novel skull-neck-thorax model to study the effectiveness of both COs and CTOs, given the limitations inherent in using live human subjects.[42] This model utilizes a cadaveric cervical specimen, plastic skull, and mannequin thorax and load input flexibility testing to determine three-dimensional load-displacement properties. Braced and unbraced states in uninjured models were initially compared. He demonstrated that cervical orthoses effectively immobilized the entire cervical spine in flexion-extension and the lower cervical spine in lateral bending. They appeared least effective at restricting lateral bending of the upper cervical region and axial rotation of all spinal levels, except C1–C2. As other researchers had demonstrated, CTOs improved immobilization of the lower cervical spine compared to standard collars. He subsequently performed further study using the same approach in experimentally created injuries, including atlas fractures, type 3 dens fractures, midregion subaxial extension-compression injuries, and lower cervical flexion-compression injuries.[43] Successive improvement in immobilization was noted comparing collar to CTO in extension at the injured midregion spine and flexion at the injured lower cervical spine.

Halo Vest

It is generally agreed that the halo vest provides the most rigid immobilization of the cervical spine of all the currently used orthoses and is particularly effective in the upper cervical spine. Originally inspired by a device used by Bloom to treat

facial fractures in pilots with overlying burns during World War II, modified versions were used by Nickel and Perry to immobilize patients with polio who had undergone posterior cervical fusion.[44,45] The early halo devices consisted of a circumferential stainless steel ring with four pins for skull fixation. The ring was attached to a plaster jacket by upright posts.[46] Numerous improvements have been made to the various components of the halo vest, but the overall design principles remain the same. A ring is fixed to the skull with multiple pins. The ring is then attached to a vest by four connecting rods. Newer rings are made of composite materials, which have the beneficial properties of light weight, radiolucency, and compatibility with magnetic resonance imaging. There does not appear to be a difference in fixation strength between newer radiolucent graphite rings and the earlier titanium ones.[47] Rings that are open posteriorly or have crown-type designs allow for ease in placement since the head of the patient does not need to be passed through the ring. Additionally, because the patient is not lying on the back of the ring, there is less risk of cervical spine fracture displacement through ring manipulation.

The initial halo vest was fashioned from heavy plaster of Paris. With the development of plastic technology, lightweight, easily applied vests of various sizes based on chest circumference have been fabricated (Fig. 81.9). Adjustable straps and supports help customize the fit. The connecting rods have been anodized to prevent seizing of the metal during tightening. The connecting rods in many designs are made of carbon fiber for their radiographic lucency as well as for compatibility with magnetic resonance imaging. Torque wrenches are included in the application sets to prevent overtightening of the bolts that connect the rods to the vest and ring. Mirza and colleagues[48] found that most commercially available vests provide comparable immobilization. Factors associated with decreased motion include increasing vest snugness, decreasing the deformability of the vest, and appropriate fit and application.

Technological advances have also been made in the field of halo pin materials and pin design. The popular pin composition at this time is stainless steel. Different pin-tip designs have been studied to determine which may provide the greatest resistance to shear frequently encountered at the pin-bone interface. Interest has arisen regarding a bullet-type tip that may be able to withstand higher shear forces.[49,50] Some systems have torque wrenches that break off at a set torque.[51] These wrenches are made to be low profile, allowing for ease of use in cramped areas, such as the posterior aspect of the skull.

FIG. 81.9 Halo vest (Bremer). This crown-type design allows easier placement in the supine position.

Application Principles

Because many of the complications of halo fixation are related to inappropriate site selection or technique, a thorough understanding of pin insertion principles is essential. Many years of clinical data have fine-tuned the optimal location of halo pin placement. To minimize pin complications but maximize the rigidity of the halo-vest frame, two anterior and two posterior pins are usually placed. The standard position of the two anterior pins is 1 cm superior to the orbital rim, over the lateral two-thirds of the orbit, below the level of the greatest circumference of the skull (Fig. 81.10). This is considered the safe zone. In a cadaveric study, it was found that the skull thickness in this region averaged approximately 2 mm for the outer cortical table and 3 mm for the intercalvarial space or inner diploë. A more recent study demonstrated that skull thickness in these areas gradually increases with age.[52] Pins placed too medial may damage the supraorbital or supratrochlear nerves. Also, the frontal sinus has a varied position in the midline. The outer table of the frontal sinus is often very thin,

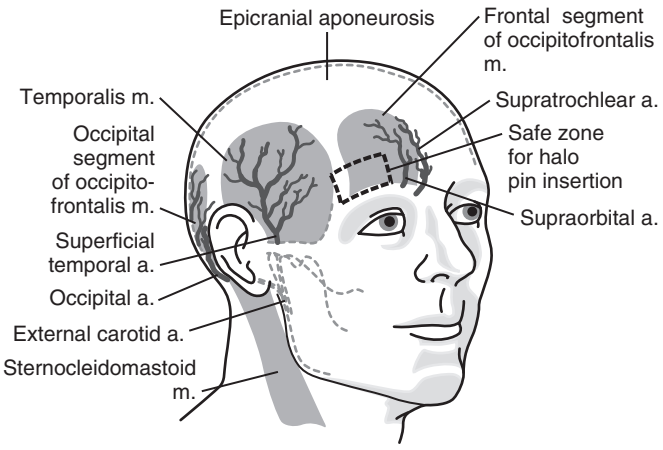

FIG. 81.10 Diagram of the safe zone for placement of anterior halo fixator pins. (From Ballock RT, Botte MJ, Garfin SR. Complications of halo immobilization. In: Garfin SR, ed. *Complications of Spine Surgery*. Baltimore: Williams & Wilkins; 1989:376.)

which can lead to perforation with medial pin placement. Laterally placed anterior pins over the temporalis fossa have been suggested to avoid unsightly scarring over the anterior forehead. At this location, however, the zygomaticotemporal nerve may be injured, which provides sensation to the area over the temple. Also, by entering through the temporalis muscle, the pin often causes irritation during mandibular motion (e.g., eating). Additionally, in cadaveric studies, in this region the skull was found to have a thin outer and inner table with minimal cancellous diploë.[53] An alternative frontolateral pin site has been described as just in front of the temporalis muscle, several centimeters below the equator in or near a triangular forward projection of the temporal hairline.[54] Skull thickness in this region was similar to the standard supraorbital position when measured by computed tomography (CT). The investigators suggested this as a safe alternative with better cosmesis.

Placement of posterior pins is less critical than for anterior pin location. There are no neuromuscular structures at risk and the skull has a near-uniform thickness, with the thickest section being straight posterior. Direct posterior pin placement is avoided, however, because the patient would lie on this pin when supine. The pins are usually placed diagonally opposite to the anterior pins, approximately 1 cm superior to the upper helix of the ear. Care must be taken to avoid any contact between the ring/pin and ear while remaining inferior enough to the equator of the skull to prevent superior pin migration.

Because skull shapes differ, placing pins perpendicular to the tangent of the skull may be difficult. Because the halo is not a static unidirectional device, shear forces act at each of the pin sites. Triggs and associates,[55] in a biomechanical study, evaluated the transverse shear forces to failure of pins placed in decremental angles from 90 degrees, 75 degrees, and 60 degrees. The load to deformity and failure was substantially higher for pins inserted perpendicular to the outer cortex of the skull as compared with 60 degrees. To minimize the incidence of pin loosening, it is important to try to place pins as perpendicular to the skull as possible to provide the most strength at the pin-bone interface.

The original pin-insertion torque recommendations of 6 in-lb were based on empiric observations. Cadaver studies, however, have shown that pins inserted at up to 10 in-lb of pressure barely penetrate the outer table.[51] Biomechanical testing has demonstrated that 8 in-lb of insertional torque offers a more rigid pin-bone interface when compared with 6 in-lb.[50] Clinical trials in adults have borne this out, with reduced pin site loosening as well as less infection at the pin sites.[51]

Application of the halo apparatus proceeds in a stepwise fashion (Box 81.2). After ring application, with the cervical spine protected by manual traction, the patient's trunk can be elevated 30 degrees for vest placement. The posterior portion of the vest is applied and connected to the halo, followed by the anterior portion. Alternative methods include log rolling the patient, although it may be difficult to maintain cervical alignment. In rare instances of a stable fracture pattern, or after surgical internal fixation, the patient can be instructed to sit upright and the vest can be applied. All the vest locking bolts are then tightened to 28 in-lb of torque preset on the screwdriver. Once all the bolts are tightened, cervical spine alignment should be confirmed radiographically. The pins should be retightened 24 to 48 hours after placement. Baum and colleagues have documented an immediate drop of 2 to 4 in-lb in pin fixation purchase after vest placement.[56] A commonly used pin-care regimen consists of daily cleansing with dilute hydrogen peroxide (50/50 with water) on a cotton swab. Patients should follow up at predetermined intervals to confirm lack of halo-vest complications. A recent study compared a new pin-care regimen using chlorhexidine and regular torque checking as a standard protocol.[57] They demonstrated a pronounced reduction of pin-site infection compared to a saline regimen for pin care.

BOX 81.2 Application of the Halo Skeletal Fixator

1. Determine ring or crown size (hold ring or crown over head to visualize size).
2. Determine vest size (from chest circumference measurement).
3. Identify pin site locations.
4. Shave hair at posterior pin sites.
5. Prepare pin sites with povidone-iodine solution.
6. Apply local anesthesia.
7. Advance sterile pins to level of skin.
8. Have patient close eyes.
9. Tighten pins at 2-in/lb increments in diagonal fashion.
10. Tighten pins to 8-in/lb torque.
11. Apply lock nuts to pins.
12. Maintain cervical traction and raise patient trunk to 30 degrees.
13. Apply posterior portion of vest.
14. Apply anterior portion of vest.
15. Connect anterior and posterior portions of vest.
16. Apply upright posts and attach ring to vest.
17. Recheck fittings, screws, and nuts.
18. Tape vest-removing tools to vest.
19. Obtain cervical spine radiographs.

From Botte MJ, Garfin SR, Byrne TP, et al. The halo skeletal fixator: principles of application and maintenance. *Clin Orthop Relat Res.* 1989;239:12–18.

Biomechanical Analysis

The skull pins of most commonly used halo systems can withstand shearing forces of approximately 100 N in normal physiologic motion.[58,59] Although compressive pin forces may decrease by more than 80% over 3 months, shearing resistance may be better preserved.[53] Experiments on cadavers and physical models following the American Society for the Testing of Materials (ASTM) indicate that a shear force on the order of 1100 N is needed to abruptly dislodge skull pins inserted through an open carbon fiber ring.[60]

Whereas the halo is the most rigid external orthosis for immobilization of the cervical spine, some motion and force transmission to the cervical elements do occur. In early studies, the halo device was found to permit only 4% of flexion-extension, 4% of lateral bending, and 1% of rotational motion of the normal native cervical spine.[16] However, follow-up studies have shown that such significant immobilization is not routinely accomplished. One study has demonstrated up to 51

degrees of motion with halo immobilization.[19] Segmentally, the greatest motion was observed at the occiput-C1 level (11.5 degrees). The least motion was observed at C2–C3 (6.7 degrees). Interestingly, when flexion was observed at one segment of the spine, extension was observed at another level, the phenomenon known as "snaking." Motion of the cervical spine was observed with patient position changes from supine to prone or from supine to sitting. However, there was no increased motion at the level of injury. In contrast, Anderson and collaborators reported in a clinical series greater than 3 degrees of angulation and 1 mm of translation at the fracture site in 77% of the patients evaluated.[61] A more recent study evaluated the effect of cyclic physiologic loading on halo performance in a mannequin model.[62] The investigators found that after a few cycles of loading, analogous to a few steps taken by a patient, the support provided by a halo orthosis becomes nonlinear. When analyzed through straightforward structural modeling, they found that the nonlinearity permitted mild head motion while severely restricting larger motion. They speculated that halo design could be optimized to permit mild spinal loading to foster bony healing while neutralizing pathologic loads.

Studies have also examined the directional force generated by the halo device. Maximal forces appear to be exerted in the mediolateral plane. However, in daily activities, anteroposterior and vertical forces are much larger. This was confirmed by Lind and colleagues, who observed no horizontal motion in the halo device.[19] They reported significant differences in distractive forces between the supine and upright positions that can be attributed to the added weight of the head. Distractive forces were most increased with deep breathing, shoulder shrugging, and arm elevation, although no patient experienced any discomfort. These high distractive forces were most elevated in patients with tight-fitting vests. It was noted that the halo vest can be elevated by the sternum and the scapulae. They recommended that there be at least 30 mm of space between the sternum and the vest to prevent gross motion of the vest with daily activities. Conversely, a recent study evaluated motion of the injured cervical spine while moving from upright to supine and prone positions.[63] The investigators used composite models (surrogate head, cadaveric cervical specimen, and mannequin torso) comparing properly applied and loose-fitting vests. Snaking motion was again observed, but was significantly more in loose-fitting vests. Another study using the same model found that a loose suprastructure displayed increased lateral bending motion at C6–C7.[64] As such, there appears to be a window of proper vest fit, outside of which immobilization is compromised. Patients should be cautioned regarding exercises that involve twisting and bending, because these tend to transmit undesirable forces to the cervical spine through the halo.

Complications

Although clinical studies have clearly demonstrated the efficacy of the halo device, complications with its use are not infrequent. Absolute contraindications to halo usage include cranial fracture, infection, and severe soft tissue injury at the proposed pin sites.[65] Awareness of the most commonly seen complications can help minimize their severity and avoid catastrophic sequelae. Pin loosening has been identified as one of the most common problems with the halo device.[66] In two large studies, pin loosening was observed in 36% and 60% of patients.[67,68] The hypothesized decrease in compressive pin forces with time was confirmed in a biomechanical study utilizing instrumented halos in three patients. Pin force values at the time of halo-vest application and at subsequent clinical visits were compared by Fleming and associates.[69] They measured an 83% drop in torque pressure by the time of halo removal. They believed that the mechanism of pin loosening was through bone resorption at the pin tip. To help decrease loss of the halo because of loosening, if there is no sign of infection, the pins may be retightened to 8 in-lb of torque as long as resistance is met on the first few turns of the pin. If no resistance is met, then a new pin should be placed in another position. The old pin should be kept in place until the new pin has been rigidly placed to keep the correct orientation of the ring on the skull.

Halo-pin infection rates have been documented to occur in approximately 20% of cases.[67,68] If drainage and erythema continue at a pin site even with aggressive pin care, bacterial cultures should be obtained and appropriate oral antibiotics started. If cellulitis persists or an abscess forms, the pin should be removed and placed in another position. The patient may require incision and drainage of the abscess with parenteral antibiotics.[67]

Skull and dural penetration by a halo pin are rare complications. It is often related to patient falls. Clinically, the patient may present with a headache, malaise, or visual disturbances if symptomatic pin penetration has occurred. Radiographs taken tangential to the skull may demonstrate whether pin perforation of the inner table has occurred. Clear cerebrospinal fluid leakage from the pin site is a definitive sign that dural puncture has occurred. In these circumstances, a new pin should be placed in another region and the old pin removed.[68] Elevation of the head decreases intracerebral pressure and facilitates closure of the dural tear. These tears usually heal in 4 to 5 days. If the tear does not heal or an infection is suspected (subdural abscess), formal surgical intervention may be necessary.[70]

Patients may report difficulty swallowing during halo immobilization. Deglutition dysfunction leading to aspiration has been reported.[71] In a study performed at a level 1 trauma center, Bradley et al. reported a 66% prevalence of dysphagia that resulted in longer intensive care unit and hospital stays.[72] The authors recommended formal swallowing evaluation for all such patients to reduce the risks of aspiration. Many instances of swallowing difficulty are a result of the cervical spine being immobilized in the extended position. Efforts to flex the cervical spine while maintaining cervical reduction may assist in resolution of dysphagia.[70]

Pressure sores have been reported in 4% to 11% of patients during halo immobilization.[67] These sores frequently develop underneath the vest or cast vest secondary to pressure against prominent bony surfaces, or due to insufficient padding or incorrect sizing of the vest. Principles of pressure sore

prevention include frequent turning, adequate vest padding, and routine skin inspections. Pressure sores are more prevalent in patient populations using a cast vest rather than the padded prefabricated plastic vest. This is especially important in patients with neurologic deficits who may not have normal sensation over their trunk. Alternative strategies to halo immobilization, such as rigid internal fixation, should be considered in this patient population (spinal cord injury). Pressure sore treatment may require split-thickness skin grafting and/or employing rotational muscle flaps for coverage.[68]

A prospective study by van Middendorp et al. investigated the incidence and risk factors associated with complications during halo-vest immobilization over a 5-year period in 239 patients.[73] There was a 6% incidence of death, although only one was directly related to the immobilization. There was a 5% incidence of pneumonia; however, elderly patients did not have an increased risk of pneumonia. There was also a 12% incidence of pin-site infection, which was significantly related to pin penetration through the outer table of the skull. The authors reiterated that, although there were relatively low rates of major complications, awareness of the substantial rates of minor complications is necessary to prevent further morbidity.

Halo-vest immobilization in the elderly is an area of increasing concern due to reports of significant morbidity and mortality. Tashjian et al. investigated the morbidity and mortality of halo usage in patients over the age of 65 years in treating odontoid fractures compared to a rigid cervical orthosis or operative fixation.[74] Of the patients treated with a halo vest, 42% died compared to 20% in the nonhalo group. This difference was statistically significant. There was also a significantly increased rate of major complications in the halo-vest group. The authors concluded that treatment of odontoid fractures in the elderly with a halo are associated with significant morbidity and mortality. Other authors have evaluated the treatment of elderly patients with type 2 odontoid fracture with cervical collars and found that fracture stability by either osseous or fibrous union could be achieved with acceptable clinical results.[75]

Pediatric Considerations

Halo immobilization has been successful in the treatment of children and infants after both unstable cervical injuries and congenital abnormalities.[76,77] The recommended pin torque pressure in children is 2 to 5 in-lb owing to the skull being thinner and more pliable than the adult skull.[76] In patients younger than 3 years, a multiple low-torque pin-insertion technique is recommended to achieve maximal stability.[78]

In young children, up to 12 pins can be inserted at 2 in-lb of torque pressure under general anesthesia. Halo pins should be placed under the largest diameter of the skull, with care to avoid the frontal sinus and temporal regions. Some authors recommend a computed tomogram of the head to identify the location of suture lines and bone fragments (in congenital cases) before placement of the halo.[65] Furthermore, in the presence of open suture lines and fontanelles, vigilant care must be taken to make sure that equal pressure is placed symmetrically on the skull through the halo pins to prevent skull deformity.

Owing to sizing issues in this age group, a custom-made ring and vest are often required. Once the halo is placed, the vest is applied in normal fashion and connected to the halo. Children require the same pin care as adults. Baum and colleagues observed that children have a higher rate of pin loosening than adults.[56] Children with halo fixators should have close parental and medical supervision.

Noninvasive Halo

A noninvasive halo (NIH) has been investigated as an alternative that avoids invasive pin placement while potentially providing more immobilization than a CTO. This orthosis consists of a halo mask that encircles the patient's head over the forehead and the chin and attaches to a rigid anterior vest. DiPaola et al. performed a biomechanical evaluation of conventional and noninvasive halos in cadaveric C1–C2 and C5–C6 instability models using various maneuevers.[79] The authors found less cervical spine motion during application of the NIH compared to the conventional halo. The conventional halo, however, did provide superior immobilization during the log roll maneuver, although the halos were similar during the sit-up maneuver. Skaggs et al. treated 30 children with stable spines in an NIH postoperatively and found only one complication.[80] Sawers et al. retrospectively reviewed the use of an NIH to treat 19 patients for cervical trauma.[81] All fractures healed in acceptable alignment without neurologic deterioration; there was one case of occipital ulceration and two cases of noncompliance. Although NIH is a tempting option to avoid the potential complications associated with traditional halo usage, there is insufficient data to recommend its usage as an equivalent alternative.

Thoracolumbar and Sacral Orthoses

SIOs, LSOs, and TLSOs are available in flexible and rigid variations. The flexible versions have a similar design to their rigid counterparts but provide only mild immobilization. SIOs generally encircle the pelvis, spanning the tops of the iliac crests to the trochanters. These may provide relief in traumatic postpartum separation of the sacroiliac joints. LSOs extend from the pelvis to the xiphoid anteriorly and the inferior angle of the scapula posteriorly. TLSOs extend higher, generally to the midscapular level.

Flexible Thoracolumbosacral and Lumbosacral Orthoses

Flexible LSOs and TLSOs are prescribed by some for the treatment of low back pain. These corset-style devices are adjustable by means of laces, hooks, or Velcro straps. Some authors have reported that these types of orthoses decrease the myoelectric activity of the paraspinal muscles and increase

intraabdominal pressure, possibly resulting in decreased loads on the intervertebral discs.[82,83] Others have reported increased myoelectric activity, as measured through surface electrodes on the paraspinal muscles, when certain tasks are performed in braced subjects.[84] Less controversy surrounds the effect on the abdominal muscles, with several authors reporting decreased measured myoelectric activity with brace wear.[83,85] Design modifications to improve brace effectiveness have included the use of pneumatic lifters designed to transfer some of the patient's upper body weight from the lumbar spine to the iliac crests (Fig. 81.11). In a survey of 44 patients who completed an 8-week regimen using the Orthotrac Pneumatic Vest (Orthofix, Inc.), 59% reported moderate to significant improvement of mechanical back pain symptoms.[86] The role of lumbar supports for prevention and treatment of low back pain continues to be an area of controversy because clinical studies on their efficacy are conflicting. Jellema and colleagues performed a systematic review of the literature to assess this issue.[87] They searched the Medline, Cinahl, and Current Contents databases, the Cochrane Controlled Trials Register, and the Embase database. Two reviewers independently assessed methodologic quality and performed data review. In performing a quantitative analysis, they classified the strength of evidence as strong, moderate, limiting or conflicting, or no evidence. Only four of the 13 studies identified were believed to be high quality. They determined that, based on the literature available, there is no strong evidence to support the use of lumbar supports for prevention or treatment of low back pain.

Rigid Thoracolumbosacral and Lumbosacral Orthoses

Most conventional TLSOs are more effective in limiting motion in the sagittal plane than in controlling rotation or lateral bending. The Jewett hyperextension brace is an example of a non–custom-molded TLSO brace (Fig. 81.12).

FIG. 81.12 Jewett brace. (A) Anterior view. (B) Posterior view. The anterior pads cross the sternum and pubic symphysis. The posterior pad crosses the upper lumbar spine. The design attempts to provide extension with three-point fixation.

FIG. 81.13 Knight-Taylor orthosis. (A) Anterior view. (B) Posterior view. Control of thoracic sagittal plane motion is achieved through axillary straps attached to posterior thoracic uprights.

It applies three-point fixation to the torso through anterior pads on the symphysis pubis and sternum and a posterior pad midway between the anterior pads. This arrangement of forces places the spine in slight extension. Similar to cervical collars, this brace is best in controlling motion in the flexion-extension plane and less effective in controlling lateral bending and rotation. The Knight-Taylor brace (Fig. 81.13) is another commonly prescribed TLSO and can be prefabricated or custom molded. It has a corset-style front for abdominal compression and lateral and posterior uprights attached to over-the-shoulder straps for thoracic control. Prefabricated TLSOs often consist of clamshell-style braces that can be ordered to measurements and usually are fabricated of ⅛- to 3⁄16-inch low-density polyethylene with a full ¼-inch foam liner. The anterior and posterior shells are fastened in place with three Velcro closures per side. Some manufacturers include pneumatic bladders in the abdominal and/or lumbar areas to help customize the fit and accommodate volume changes. Prefabricated "customizable" TLSOs are also commercially available with apron-style fronts that can be adjusted with Velcro straps and telescoping sternal pads (Fig. 81.14). These braces provide good control in all three planes, but once again the major restriction is in the flexion-extension plane. For optimal control in all three planes between T5 and L4, a fully custom-molded TLSO (Fig. 81.15) should be used. These are often formed from high-temperature thermoplastic that is custom fitted from a plaster cast formed from the patient. When immobilization proximal to T5 is required, a cervical

FIG. 81.14 Prefabricated "customizable" thoracolumbosacral orthosis. This particular design (Orthomerica) has an apron-style front with an adjustable sternal pad to help customize the fit.

FIG. 81.15 Custom-molded thoracolumbosacral orthosis. (A) Anterior view. (B) Posterior view. This bivalve design can be made from a plaster cast of the patient or created with an algorithm based on key measurements.

extension should be included.[88] If immobilization distal to L4 is needed, a thigh cuff should be added to the orthosis to control pelvic motion.[89,90]

Compared with COs, few studies have been performed to scientifically evaluate the ability of external orthoses to immobilize the thoracolumbosacral spine. In one study, a molded TLSO provided 94% restriction in lateral bending and 69% restriction of flexion-extension in the lumbar spine.[91] The amount of restriction in lumbar rotation was inconsequential because of the limited rotation of the lumbar spine under unbraced normal conditions. In the thoracic spine, the device restricted flexion-extension by 49%, lateral bending by 38%, and total rotation by 60%. Brown and Norton conducted one of the most referenced studies on motion restriction with lumbar external supports.[89] They evaluated three rigid LSOs, one flexible LSO, and a TLSO. Kirschner wires were inserted into the spinous processes of volunteers. The angles between the wires were measured to determine the amount of motion. Radiographic evaluation was also performed. Of note, they reported increased motion across the lumbosacral junction in all of the braces. Increased motion at L4–L5 was also noted while the subjects were sitting. Compared with the unbraced state, all of the braces resulted in some flexion at L4–L5 and L5–S1 while standing. Lumsden and Morris[92] reported similar findings when they studied lumbosacral rotational motion in subjects wearing either a chairback brace or an LSO corset. Volunteers had Steinmann pins placed in their posterior superior iliac spines. Motion was determined by radiographs and measurement of pin rotation. In each case, they found that the braces increased motion at the lumbosacral level. Fidler and Plasmans[90] used radiographs to compare the effect on lumbosacral motion of a corset, a brace, and a plaster jacket with and without a thigh cuff. They found that the custom-molded plaster jacket provided the best immobilization at the L1–L3 level. The mean percentage of motion allowed at L4–L5 and L5–S1 was 32% and 70%, respectively, in a lumbar brace without a thigh extension. The addition of a unilateral thigh extension decreased allowable motion at these levels to 12% and 8%, respectively. To improve immobilization at the L4–S1 levels, they recommended adding a thigh cuff to the orthosis. Other authors have reported similar findings, noting an additional 15% to 30% reduction in motion at L4–L5 and L5–S1 with the addition of a unilateral thigh extension.[93,94] To study the ability of orthoses to restrict motion in the injured spine, Rubery and colleagues created experimental burst fractures in cadaver spines and utilized an electromagnetic motion tracking and analysis system to track angular and linear displacement during routine "patient maneuvers."[95] Both prefabricated and custom-molded TLSOs were found to diminish, but not eliminate, angular motion at the fracture site. Their effect on linear translation was minimal, however.

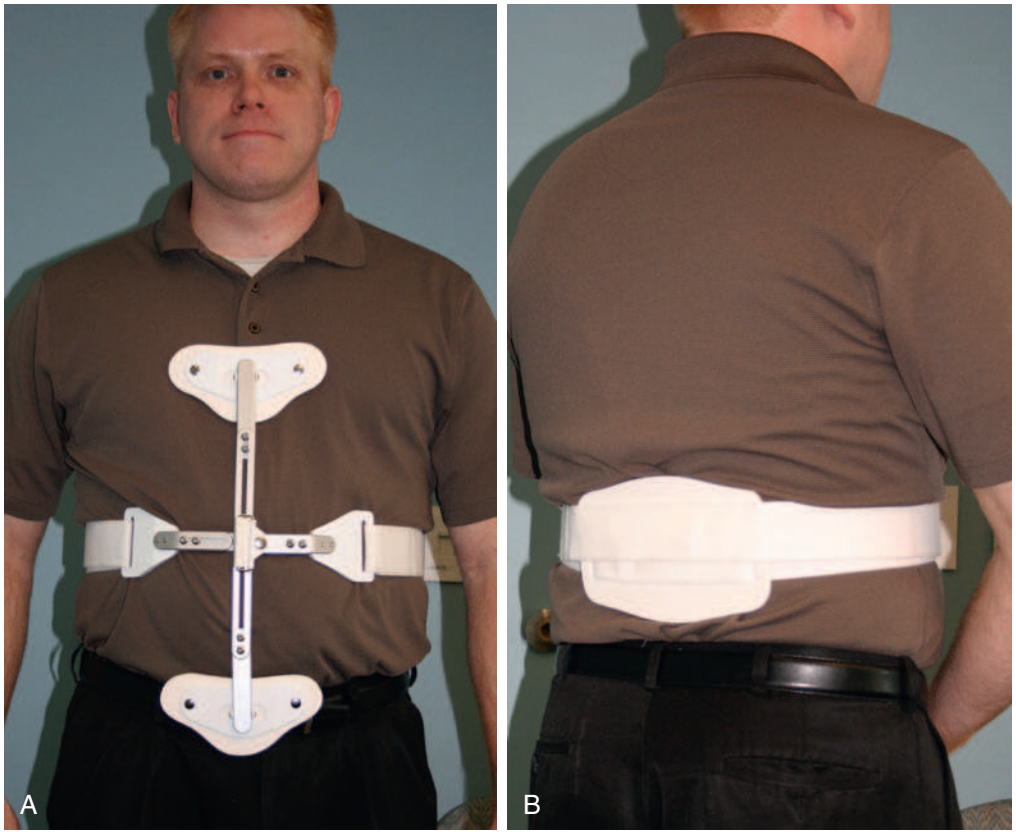

FIG. 81.16 CASH brace. (A) Anterior view. (B) Posterior view. The lightweight design is better tolerated by elderly patients compared with bulkier braces.

Indications for TLSOs are less well defined than for COs. Bracing for compression fractures of the thoracolumbar spine is not tolerated well by the elderly. Treatment in these patients usually consists of early mobilization and close follow-up. A soft binder or corset may provide support and symptomatic relief. The CASH brace (Patterson Medical; Fig. 81.16) is another lightweight alternative that may be reasonably tolerated. A recent study by Kim et al. compared treatment outcomes of patients with osteoporotic compression fractures treated using a rigid brace, soft brace, and no brace in a randomized controlled trial.[96] The Oswestry Disability Index scores for the patients treated without a brace were not inferior to those with soft or rigid braces. Furthermore, the improvement in back pain and progression of anterior body compression were similar among the three groups.

In younger patients, however, anterior column fractures are often the result of greater energy than their osteoporotic counterparts; therefore, a more cautious approach is often favored. These patients are commonly treated with a rigid Jewett or Knight-Taylor brace. However, the need for rigid bracing of these fractures is still a matter of debate. Ohana and associates[97] retrospectively reviewed the outcome of 129 young patients with mild compression fractures who were treated with or without a Jewett hyperextension brace. They found that one-column fractures of the thoracolumbar spine with as much as 30% compression can be safely treated without bracing, instead prescribing early ambulation, hyperextension exercises, and close follow-up. In addition, there is no consensus on the use of TLSOs after lumbar spine surgery for degenerative disease. In one questionnaire study, 49% of spine surgeons stated that they utilize braces after lumbar spine surgery, with no statistically different frequency of use between instrumented and noninstrumented fusions.[5]

Burst fractures comprise another entity in the spectrum of thoracolumbar injuries. Historically, neurologically intact patients with burst fractures were treated with bed rest for 4 to 12 weeks, followed by progressive mobilization. Today, controversy exists as to which injuries require surgical stabilization and which can be treated with bracing and early mobilization. Any neurologic deficit is often an indication for operative management. Other commonly mentioned criteria for surgery, rather than bracing, include canal compromise of 50% or more, kyphotic deformity of greater than 30 degrees, and posterior column involvement. The final determination, however, often remains a case-by-case judgment on the part of the treating specialist. Chow and colleagues[98] retrospectively studied functional outcomes in 24 patients treated with hyperextension body casts and/or Jewett hyperextension braces for thoracolumbar burst fractures. None of these patients had posterior column fractures, significant kyphosis, or neurologic deficit. Patients were initially treated with bed rest and log roll precautions until the predictable ileus and abdominal distention resolved 2 to 3 days later. At that point, patients were placed in a cast or brace and progressively mobilized. Patients were followed for a minimum of 1 year. They concluded that hyperextension casting or bracing with early mobilization

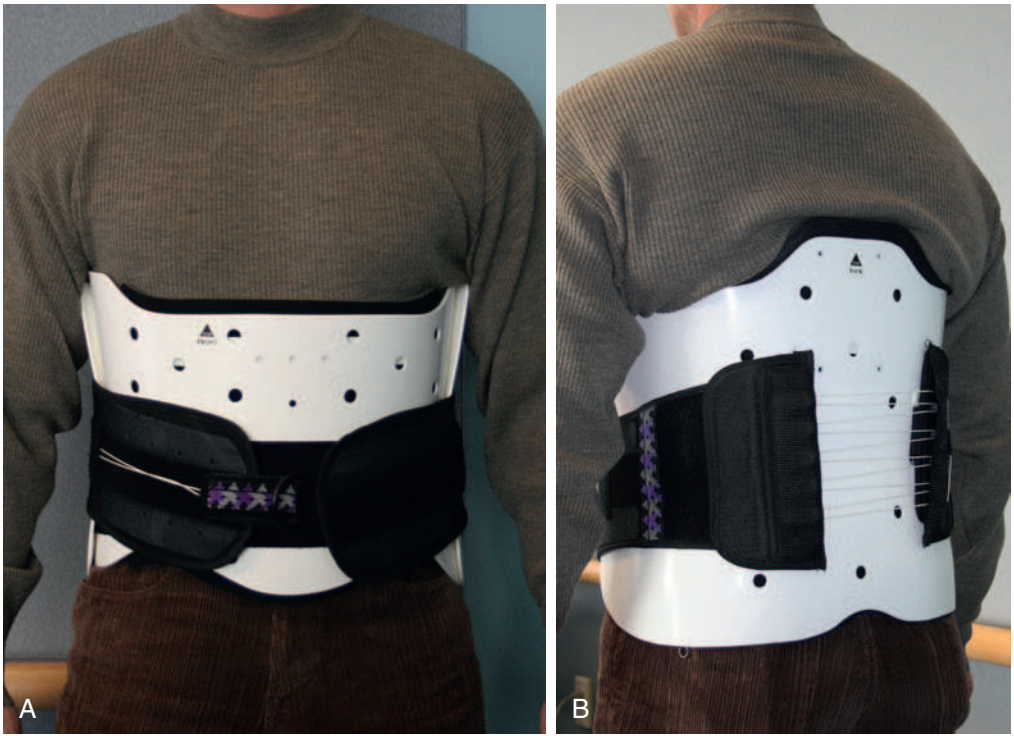

FIG. 81.17 Prefabricated lumbosacral orthosis. (A) Anterior view. (B) Posterior view. This design (California Compression Jacket, Orthomerica) has a patented "rip cord" used to help adjust the snugness of the fit.

reduced hospital time, avoided costs and risks of surgery, and allowed patients a relatively early return to work. Additionally, the authors mentioned that patients treated nonoperatively tended to experience moderate back pain up to a year after the injury and that this pain eventually diminished over time. Other more recent studies have also suggested that, in the absence of a neurologic deficit, operative and nonoperative treatment have comparable results. In a restricted cohort study, Stadhouder and colleagues found similar pain scores, disability indices, and general health outcomes at midterm follow-up.[99] A recent meta-analysis pooling patients from four trials made similar observations, again suggesting that nonoperative treatment in a brace has similar results to operative treatment but with lower costs and complications.[100]

LSOs (Figs. 81.17 and 81.18) are often prescribed for treatment after arthrodesis for degenerative conditions. As discussed earlier, several studies demonstrate little or no immobilizing effect from wearing LSOs and possibly an increase in L4–L5 and L5–S1 motion after application of these orthoses. The point continues to be debated. Post–lumbar fusion bracing is believed by some to help relieve pain and decrease the risk of pseudarthrosis and fixation failure; therefore, it is prescribed by some surgeons for up to 12 weeks postoperatively. Others believe that lumbosacral orthoses do little to immobilize the lumbar spine beyond the stabilization provided by rigid operative fixation.[101] Yee et al. recently performed a randomized controlled trial to assess the benefit of wearing a lumbar corset for 8 weeks after lumbar fusion for degenerative conditions.[102] Complication rates and rate of revision surgery were not different between the groups. Rohlmann and colleagues[103] evaluated the effect of a brace on loads on internal spinal fixation devices. The implant loads were measured using telemeterized fixators in six patients for several positions and activities, including sitting, standing, walking, bending forward, and lifting an extended leg in a supine position. They found that none of the braces tested was able to markedly reduce the loads on the fixators. They observed that higher fixator loads were often observed while wearing a brace. The same research group more recently studied the effect of an orthosis on the loads acting on a vertebral body replacement.[104] Telemeterized vertebral body replacements were implanted in five patients undergoing lumbar corpectomy. They found that the average resultant force on the vertebral body for 26 common daily activities was reduced by 19% with a hyperextension orthosis, particularly activities performed in a sitting position.

While many studies have examined the ability of spinal orthoses to immobilize the spine during daily activities, others have examined the impact of wearing them on such essential functions. Frownfelter et al. examined the effect of TLSOs on pulmonary function in healthy adults.[105] They found that wearing the brace had a significant effect on forced vital capacity and forced expiratory volume in 1 second both at rest and with exertion. Furthermore, they demonstrated that an abdominal cutout in the brace improved pulmonary function, especially with activity. They postulated that this was due to reduced restraint on abdominal expansion and suggested that this modification be considered in patients with compromised pulmonary function. Hofmann and colleagues studied the effect of LSOs on driving. Braking parameters in 30 healthy volunteers were measured with and without bracing using a custom-made automobile simulator.[106] They found that the spinal orthoses led to a significant increase in brake reaction time, which could lead to lengthening the total

FIG. 81.18 Prefabricated lumbosacral orthosis. (A) Anterior view. (B) Posterior view. This design (Aspen) has a posterior cutout window that avoids direct pressure over a midline incision.

stopping distance. Patients should therefore be counseled on this potential effect when they seek to resume driving.

Summary

Spinal orthoses continue to be commonly prescribed for the management of both traumatic and degenerative conditions. There are many different types commercially available. The scientific evidence to document their effectiveness is variable. Despite the potential for complications, the halo remains the most rigid of external cervical immobilizers. A thorough appreciation of the biomechanics of spinal orthoses and their potential complications can help maximize their utility and minimize associated morbidity. Ongoing collaboration between the medical and prosthetics/orthotics communities is necessary as new technology continues to emerge.

Acknowledgment

Unless noted otherwise, the orthoses in the figures were supplied by Precision Orthotics and Prosthetics, Linden, NJ. The models are Paul Goodman, CO, Ryan, CPO, and David Sussman, CPO, all of Precision Orthotics and Prosthetics. We greatly appreciate their contribution to this chapter.

PEARLS

1. Halo pins should be retightened 24 to 48 hours after placement since fixation purchase decreases after vest placement.
2. In infants younger than 3 years, a multiple low-torque pin insertion technique is recommended to achieve maximal stability given decreased skull thickness and increased pliability.
3. When external immobilization is desired cephalad to T5, a cervical extension should be added to the TLSO.
4. When external immobilization is desired caudal to L3, a thigh cuff may improve the stability offered by a TLSO.

PITFALLS

1. A properly sized and fitted orthosis is essential to provide desired support and avoid soft tissue complications.
2. While commercially available collars come in a range of sizes, predicting appropriate fit can be difficult. Spine specialists may need to give direction to ancillary staff in determining and confirming the appropriate size.
3. Rigid cervical collars may exacerbate intracranial hypertension in patients with severe head injuries; therefore, early efforts to exclude coexistent cervical injuries should be pursued.
4. Excessive extension may precipitate swallowing difficulty in patients immobilized in halo vests.
5. Halo-vest immobilization in the elderly has been associated with substantial morbidity and mortality; thus, operative treatment of selected injuries in this age group may actually offer more favorable risk-benefit profiles.

KEY POINTS

1. Spinal orthoses are externally applied devices that serve to restrict motion in that particular body segment. They can be broadly categorized based on the region they are employed to immobilize: cervical (CO), cervicothoracic (CTO), thoracolumbosacral (TLSO), lumbosacral (LSO), and sacroiliac (SIO).

2. The indications and usage of spinal orthoses is a subject of ongoing investigation, and there is a lack of consensus among spine surgeons on their use in postoperative patients.
3. Improved flexion control of the cervical spine may be obtained by increasing the length of the orthosis (extending it onto the thorax) and increasing the rigidity of the connections between the proximal (submandibular and occipital) and distal (thoracic) rests.
4. The halo vest provides the most rigid immobilization of the cervical spine of all the currently used orthoses. However, complications are not uncommon and halo usage in the elderly can be associated with significant morbidity and mortality.
5. Most conventional TLSOs are more effective in limiting motion in the sagittal plane than in controlling rotation or lateral bending.
6. Several studies demonstrate little or no immobilizing effect from wearing LSOs and possibly an increase in L4–L5 and L5–S1 motion after application of these orthoses. Their utility for the treatment of back pain or as postfusion adjuncts is therefore debatable.

82 CHAPTER Spinal Cord Injury Rehabilitation

Andrew L. Sherman
Kevin L. Dalal

Spinal cord injury (SCI) is a catastrophic event that results in impairments that impact various aspects of the patient's bodily function. SCI is not only devastating to the individual, it also imposes a burdensome cost to society. These injuries typically affect young and previously healthy individuals who now require urgent and comprehensive emergency care, frequently involving medical and surgical stabilization. The SCI patient then arrives on the rehabilitation unit and must learn to manage basic bodily functions despite seeing slow or no neurologic recovery. Finally, the SCI patient is expected to learn to perform once simple and now complex tasks of daily living independently with the goal of returning home. The amount of time available for recovery in the inpatient setting prior to discharge is continually shrinking in the current medical climate.

SCI is defined as an injury to the spinal cord that partially or completely interrupts its main functions: motor, sensory, and reflex activities. Egyptian physicians long ago labeled SCI as an ailment not to be treated at all[1] because they feared that the pharaoh would kill them if they let a patient die under their care. Prior to World War I, SCI typically resulted in early death. Significant advances in treatment began during World War II and have continued to progress, allowing many individuals with SCI to live far longer than previously expected. Today, many patients with SCI can expect to live a normal or almost normal lifespan. As a result, the numbers of persons alive today in the United States with SCI has increased to over 200,000.[2]

Epidemiology

In 1970, the first federally funded Spinal Cord Injury Model Systems (SCIMSs) were developed. Currently, 14 such centers have received this designation by the National Institute on Disability, Independent Living, and Rehabilitation Research (NIDILRR). Each center is a comprehensive interdisciplinary service that integrates all aspects of care for the SCI patient, from the initial injury to lifelong follow-up. The model center's guiding principles were set forth by Sir Ludwig Guttman, a British physician who pioneered these advances in the care of SCI patients during World War II:[1]

1. Transfer of the SCI patient to a specialized unit as soon after injury as possible.
2. Unit management by a physician who is knowledgeable and dedicated to spinal care.
3. A team of allied health professionals who are trained in the intricacies of spinal cord problems.
4. A commitment to vocational pursuits.
5. An emphasis on psychosocial and recreational needs.
6. Provision for follow-up care for the lifetime of the individual.

The 14 current Model Spinal Cord Injury Care System (MSCICS) centers (and eight previously designated centers) have been contributing clinical information to the National Spinal Cord Injury Statistical Center (NSCISC) database following a jointly agreed upon protocol. They have been able to report results based on an estimated 13% of all SCI injuries in the United States occurring since 1973. The database contains information on approximately 25,000 spinal cord injured persons.[3] The end result is a wealth of information regarding injury trends from 1973 to 1998 and some updates that include information through the year 2004. The data not only allows physicians to know the current status of SCI patients but also has given physicians insight into trends in the demographic data. These changes in the demographics of SCI have allowed rehabilitation programs and centers to adapt to reduce costs and ultimately improve the quality of medical rehabilitative care for their patients with SCI.[4]

Incidence, Race, Age, and Gender

According to the NSCISC database, there are approximately 11,000 new cases (40 per million in the US population) each year. However, this number is based on older data from the 1970s. The prevalence is estimated to be 225,000 to 296,000 persons and growing.[3] The recently updated national SCI Statistical Center statistics estimates the prevalence at 255,702.

Between 1973 and 2004, 66% of patients were white, 21% were African-American, and 9.7% were Hispanic.[3]

Cervical injuries resulting in tetraplegia occur in 54% of SCI patients. Lumbar and thoracic injuries causing paraplegia comprise the rest (45%). A few (1%) were discharged as "normal" or indeterminate. Since 1990, the number of patients with complete SCI has exceeded the incomplete injuries (56% vs. 44%).[3] Since 2000, however, the most common injury has been incomplete tetraplegia (34.7%), followed by incomplete paraplegia (23.0%), complete tetraplegia (18.5%), and complete paraplegia (18.5%).

SCI most commonly affects young adults. Population-based data shows that the highest incidence of injuries (51.6%) occurs in the 16- to 30-year-old group.[3] However, the most recent trends suggest that SCI is occurring with increasing frequency in older persons. The result is that the fastest growing population of new SCI patients is over 60 years old at onset. Since 1990, the incidence of SCI in persons older than 60 years has increased from 4.5% in the 1970s to 12%.[3] As of 2007, the average age at the time of injury has increased from 28.7 years to 38.9 years. Additionally, while SCI is an injury that occurs primarily in males (81.6% since 1973), some centers are reporting increasing numbers of females sustaining SCI.

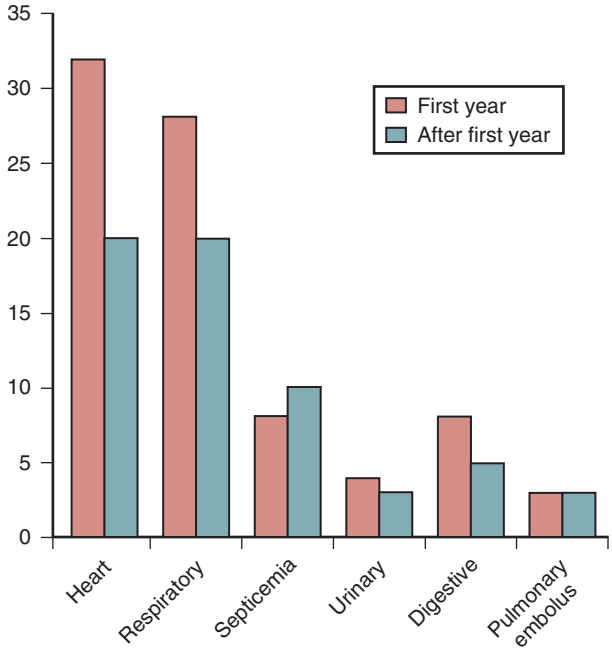

FIG. 82.1 Causes of death after spinal cord injury.

Life Expectancy

Life expectancies for persons with SCI have continued to steadily increase over time. Mortality rates, however, while improving, continue to be highest during the first year after injury. Complete injuries still have lower ultimate survival rates than incomplete injuries. The degree of neurologic impairment as measured by the Frankel Grade or the American Spinal Injury Association (ASIA) Impairment Scale and the level of injury were significantly correlated with mortality risk. For example, the average life expectancy of a 20-year-old who sustains complete paraplegia is 66 years. This compares to 61 years for a C5–C8 injury, 57 years for a C1–C4 injury, and 43 years for a ventilator-dependent patient. This compares to the normal life expectancy in the general population of 77 years and in a patient with an incomplete SCI of 72 years.[5] The factors that can increase life expectancy are favorable circumstances for good health, community integration, and higher income.[6]

Mortality

Many years ago, the leading cause of death among persons with SCI was renal failure. Pulmonary embolism (PE), usually in the first few weeks after injury and usually associated with a deep vein thrombosis (DVT), was another frequent cause of death. Advances in urologic management, DVT and PE prevention, and early mobilization have reduced the number of early deaths in SCI patients. Today, renal failure rarely occurs in the acute SCI setting. Because more SCI patients live not only through first year after injury but also survive to old age, cardiovascular disease has become a more frequent cause of death (Fig. 82.1). Nash and colleagues[7] demonstrated that SCI is an independent risk factor for developing multiple risks for cardiovascular disease, such as elevated cholesterol levels. Respiratory illness, particularly pneumonia, is now the leading cause of death among older SCI patients with cervical injuries.[8] The cause of death in persons with paraplegia is more varied. In addition to heart disease, cancer, suicide, and septicemia are the leading causes.

Etiology

The causes of SCI are typically divided into traumatic and nontraumatic. The top five causes of traumatic SCI in males are auto accidents, falls, gunshot wounds, diving, and motorcycle accidents.[3] The top three causes remain the same in women but the final two are medical complications and diving (Fig. 82.2).[3]

The major trend is that violent injuries have decreased from 20% in the 1990s to 9.8% in 2004.[3] Geographic variations occur depending on the state or city. In the older SCI patients, in addition to falls, nontraumatic causes of SCI—such as cancer, vascular injuries, and infection—make up a larger proportion of injuries. Etiology is also reported in terms of major groups. Fig. 82.3 illustrates the frequency of various causes of SCI.

Classification of SCI

There are three basic physiologic functions of the spinal cord. The ascending tracts in the cord receive sensory information from the somatic and visceral receptors through dorsal root ganglia and transmit this information to higher centers. The descending tracts receive signals from higher centers and ultimately transmit these signals to target sites via the ventral roots. The other basic function of the spinal cord is to modulate these signals via a variety of local mechanisms.

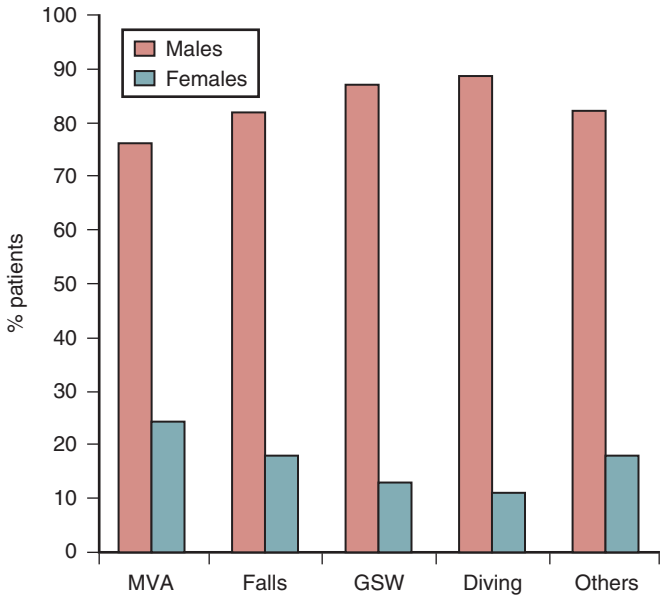

FIG. 82.2 Causes of spinal cord injury by gender of patients. GSW, gunshot wound; MVA, motor vehicle accident. (Modified from Jackson AB, Dijkers M, DeVivo MJ, Poczatek RB. A demographic profile of new traumatic spinal cord injuries: change and stability over 30 years. *Arch Phys Med Rehab.* 2004;85:1740–1748.)

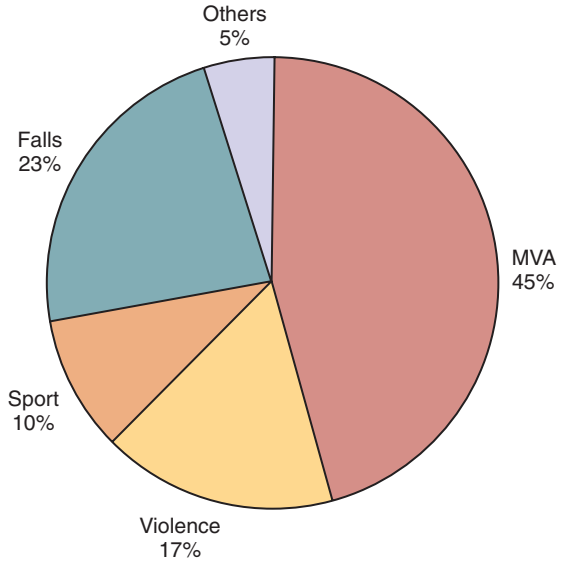

FIG. 82.3 Etiology of causes of spinal cord injury overall for both genders. MVA, motor vehicle accident. (Modified from Jackson AB, Dijkers M, DeVivo MJ, Poczatek RB. a demographic profile of new traumatic spinal cord injuries: change and stability over 30 years. *Arch Phys Med Rehab.* 2004;85:1740–1748.)

Assessment, treatment, and classification of SCI flow directly from the anatomy, physiology, and topography of the spinal cord. Classification or grouping of patients allows the rehabilitation physician to predict the outcome and ultimate function in a majority of patients based on others with similar injuries. This allows the rehabilitation team to design a rehabilitation program appropriate for each SCI patient to provide the best opportunity to maximize the patient's potential functional outcome.

TABLE 82.1 American Spinal Injury Association (ASIA) Impairment Scale

Scale Grade	Description
A	Complete—No motor or sensory function is preserved in the sacral segments S4–S5.
B	Incomplete—Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4–S5.
C	Incomplete—Motor function is preserved below the neurologic level and more than half of key muscles below the neurologic level have a muscle grade <3.
D	Incomplete—Motor function is preserved below the neurologic level and at least half of key muscles below the neurologic level have a muscle grade of ≥3.
E	Normal—Motor and sensory function is normal.

There are two assessment tools used in the evaluation of patients after SCI.[9] One is the neurologic classification of SCI using the ASIA impairment scale. The other is the functional score or Functional Independence Measure (FIM) score. The most accurate way to assess a patient who has suffered an SCI is to perform a standardized physical examination as outlined by the ASIA. The neurologic examination includes two key components—the motor and sensory exam with required and optional elements. The result allows the clinician to compile a score and determine the completeness of injury. The neurologic level is also determined by rules set forth in the ASIA examination. From these data, a functional classification is assigned to each patient. This information can then be used to design each patient's rehabilitation program and predict the patient's functional outcome based on previous patients with similar injury classifications.

The ASIA impairment scale measures the degree of completeness of injury using categories from A to E (Table 82.1). Complete paralysis is defined as the absence of sensory and motor function below the level of injury, including the lowest sacral segments, and incomplete paralysis as preservation of sensation below the level of the injury, including the lowest sacral segments. Sacral sparing is defined as voluntary anal contraction or the presence of dull touch and pinprick sensation in the rectal and perianal area.

The motor component of the ASIA impairment scale measures the strength of each muscle on a 6-point scale (0–5) and sensation for pinprick and dull touch on a three-point scale (0–2). The motor level of SCI is defined as the lowest normal motor segment that has a grade 3 or more, provided that the muscles above that level are graded as a 5. The motor level best reflects the severity of impairment and disability during rehabilitation.

The FIM score is a widely accepted functional assessment tool and is currently used as an indicator of function in patients with SCI. The FIM is an 18-item scale. There are two categories of items, motor and cognitive. Individual items in each category score from 1 to 7, ranging from "total assistance" to "complete independence." There are 13 items of motor scoring important in determination of self-care, sphincter control, and mobility (Box 82.1). Scores falling below 6

BOX 82.1 Functional Independence Measure (FIM) Scale

Motor Items

Self-care
Seating
Grooming
Bathing
Dressing upper body
Dressing lower body
Toileting

Sphincter Control

Bladder management
Bowel management

Mobility

Bed, chair transfer
Toilet transfer
Tub, shower transfer
Walking/wheelchair
Locomotion
Stairs

FIM Scale Level of Function Scoring

Independent
7—Complete independence
6—Modified independence

Modified Dependence

5—Supervision
4—Minimal assist
3—Moderate assist

Complete Dependence

2—Maximal assist
1—Total assist

indicate that the patient requires another person for assistance. Many rehabilitation units now use FIM scores to measure patient outcomes. Quality assurance units use this data from groups of patients to draw inferences on the effectiveness of the rehabilitation unit.

Clinical Syndromes

Many patients, especially those with complete SCIs, can be precisely described strictly based on their neurologic level, However, there are certain clinical syndromes describing variations in incomplete SCIs. Principal among these named syndromes include central cord, anterior cord, posterior cord, Brown-Séquard, conus medullaris, and cauda equina syndromes.[10,11]

Central Cord Syndrome

The most common type of incomplete SCI in the elderly is the central cord syndrome. It also carries with it a relatively favorable prognosis for recovery. The mechanism of injury is usually hyperextension of an already stenotic cervical canal, producing central hematomyelia.[12] Because the lumbar and sacral motor tracts are located in the periphery of the white matter, the syndrome is characterized by motor weakness of the upper extremities greater than the lower extremities and sacral sparing. Recovery occurs more favorably in younger patients. Between 87% and 97% of patients younger than 50 years will eventually ambulate versus 31% to 41% of those older than 50 years. Hand intrinsic function is last to recover and usually incompletely in all ages.

Anterior Cord Syndrome

This is an injury to the anterior two-thirds of the spinal cord, including both gray and white matter. The posterior columns are preserved. The mechanism of injury is either due to cervical or thoracic fractures with retropulsion of disc or bone fragments or lesions of the anterior spinal artery. The resulting SCI is most commonly complete paralysis with spasticity. In the lower extremities, deep pressure and proprioception are preserved. However, the prognosis for motor recovery is relatively poor.

Posterior Cord Syndrome

Posterior cord syndrome is the least common incomplete SCI and is characterized by absence of position sense. There is usually preservation of pain, temperature, and touch. Motor function is impaired to variable extents.

Brown-Séquard Syndrome

This injury occurs with a functional hemisection of the spinal cord. The most common cause is a gunshot or knife wound. The classic presentation is ipsilateral loss of motor function, ipsilateral loss of dorsal column sensation, and contralateral loss of pain and temperature below the level of the lesion. Overall, these patients have the greatest potential for functional outcome and ambulation (75–90%).[13] Bowel and bladder continence is regained in 82% and 89%, respectively.

Conus Medullaris, Epiconus, and Cauda Equina Syndromes

Patients with these lesions present with similar motor and sensory deficits but can also be differentiated. Patients typically present with patchy lower extremity weakness, saddle anesthesia, and incontinence of stool. Urinary retention is more common than incontinence. Lesions of the cauda equina exhibit lower motor neuron signs, including decreased lower extremity motor tone, absent lower extremity and bulbocavernosus reflexes, flaccid bladder, and asymmetric weakness. High conus (epiconus) lesions may have upper motor neuron findings mixed with the lower motor neuron findings.

Cauda equina lesions carry a much more favorable prognosis for functional motor and sensory recovery, especially when surgical/medical treatment occurs promptly. Bowel, bladder, and sexual function return less frequently, however, often leading to adjustment and psychological difficulties. The long-term outcomes in patients with cauda equina injuries are compounded by a very high incidence of severe neuropathic lower extremity pain not usually seen in conus injuries. Thus,

patients recovering from cauda equina injuries may have long-term physical and emotional disabilities despite their seemingly "normal" outward appearance even after successful physical rehabilitation.

Therapy Approaches

The rehabilitation of the SCI patient should begin from the moment of injury. An immediate response—transfer to a level I trauma center—and prompt medical and surgical treatment helps mitigate medical complications and facilitates preservation of neurologic function. In the acute hospital setting, consultation with an SCI specialist should be done immediately for recommendations regarding treatment of neurogenic bowel and bladder, prophylaxis of DVT and PE, prophylaxis of gastric ulcer, preventing atelectasis and pneumonia via proper pulmonary management, and preventing skin ulcers with proper positioning in bed and turning every 2 hours. Physical and occupational therapies are initiated in the acute hospital unit once the spine is stabilized. Range of motion (ROM) is performed on the shoulders, hips, elbows, and heel cords. ROM should be performed twice daily to prevent joint contractures and can be taught to family members. Splints are made for the upper extremities for the same reason. The patient begins to build tolerance to out-of-bed sitting and is taught weight shifting to prevent pressure ulcers.

Once the acute treatment is completed and the patient deemed medically stable, the patient can be transferred to an acute inpatient rehabilitation unit.[14] As economic pressures accelerate the transfer process from postoperative care to acute inpatient rehabilitation, patients with high tetraplegia may achieve medical stability while the patient is still on a ventilator. The weaning process can be improved by ramping up exercise demand and tolerance in the ventilator-dependent patient.

An accelerated path through their hospital stay to rehabilitation may have negative consequences as well. Patients may not have a chance to fully psychologically adjust to their injury. Additionally, the length of stay (LOS) on the rehab service has become progressively shorter as well. Such shorter LOSs may necessitate that the patient may not fully plateau in their physical, psychological, and functional recovery until they are transitioned to the outpatient setting. Therefore, it is imperative that the rehabilitation be focused and aggressive to accomplish as much as possible in a shorter amount of time. The challenge is to provide SCI patients with the highest quality rehabilitative care despite these imposed constraints so that they leave the hospital with the best possible outcome.

On the rehabilitation unit, the SCI patient begins a new journey. The basic skills of mobility, self-care, and bladder/bowel management must be learned to the maximum degree of independence that the injury and recovery allows. Often, this can be a slow, frustrating process. Though total independence is the ultimate goal, often, modified or various degrees of assistance is the more realistic objective. The level of neurologic injury best predicts the level of independence and mobility that each patient can achieve,[15] even though individual variability occurs. In addition to their therapy, patients on an SCI unit can utilize other resources, such as computer programs and handbooks, to supplement their understanding of their disease process. Many patients also receive counseling for emotional and psychological adjustment, discover initial vocational options for their future, and participate in recreational and leisure activities that ease their reintegration into society. SCI patients who suffer concurrent head trauma receive cognitive testing and retraining. SCI patients who remain on ventilators receive more advanced respiratory and speech therapy. Finally, each patient is discharged to the most independent living situation possible. During the rehabilitation stay, the therapy team can perform a home evaluation to determine any necessary home modifications to maximize independent living with the appropriate adaptive equipment.

The rehabilitation process involves multiple different organ systems, care teams, and longitudinal planning. The complex acute and chronic interplay between these services requires a dedicated interdisciplinary team to properly manage comprehensive rehabilitation and maximize outcome.[16] Historically, the leader of the team has been the rehabilitation physician, or physiatrist, who would delineate the rehabilitation goals, lead weekly team meetings, and decide when the program is complete. More recently, most rehabilitation programs have shifted to a more patient-centered approach, with the interdisciplinary team working toward goals set together with the patient.[17] With this approach, the patient, often the family, is intimately involved in deciding the direction of the rehabilitation and the date of discharge. The individual disciplines are listed in Table 82.2.[18]

TABLE 82.2 Interdisciplinary Team for Spinal Cord Injury Patients

Discipline	Role
Psychiatrist	Medical care, coordination of rehabilitation, team leader
Rehabilitation nurse	Daily care, medication, education, reinforce skills, transfers
Physical therapist	Gross motor skills, transfers, mobility (wheelchair, standing, ambulation)
Occupational therapist	Fine motor skills, activities of daily living (e.g., feeding, dressing, bathing)
Recreational therapist	Leisure activities, community reintegration, assistive technology use
Social worker	Obtain community resources; assist with disposition planning; communicate with insurance companies
Speech therapist	Assess cognitive status; provide communication, swallowing, and cognitive training
Respiratory therapist	Manage patients on respirator; provide respiratory treatments
Prosthetist/orthotist	Design and fabricate upper/lower extremity braces and prosthesis; fit spine braces
Vocational counselor	Test skills and interest; recommend training and assist with placement
Vendor	Wheelchair procurement and fitting, adaptive equipment

Recent advances in rehabilitation techniques have led to both increased functional outcomes and decreased LOSS. The Spinal Cord Injury Rehabilitation project, led by the Rocky Mountain Regional Spinal Injury System, used practice-based evidence research to identify the rehabilitation interventions most strongly associated with positive outcomes.[19] This would not necessarily correlate to shorter LOSs but could offer clinicians more evidence-based outcomes by which to base their treatments. Ultimately, what they found was that patient characteristics drove the outcomes more than the type of rehabilitation obtained. Thus, a patient with more severe injuries received more rehabilitation interventions and thus it was difficult to compare and contrast the types of therapy offered.[20]

Over the years, another one of the most influential advances to quickening the pace of rehabilitation has been in surgical stabilization. Historically, large, bulky cervical braces that included halos dominated rehabilitation units. Now, more advanced internal fixation has allowed patients to come onto the rehabilitation units almost immediately after surgery, usually with only a hard collar.[21] The less intrusive bracing allows patients to progress more quickly in their mobility training. A recent study touted the benefits of early surgical decompression on patient outcomes, including neurologic improvement of two levels more often.[22]

Medications have also allowed SCI patients to recover more quickly. Patients who were having difficulty with postural hypotension now can get upright sooner and for longer time periods. Other medications have decreased the incidence of DVT, PE, and spasticity. Those SCI patients slowed by neuropathic pain benefit from improved pain medications, specifically antiepileptics and serotonin-norepinephrine reuptake inhibitors (SNRIs). Aggressive percussive lung treatments have also decreased the incidence of pneumonia and "down time" on the unit. The functional rehabilitation program begins with an initial comprehensive assessment of the medical impairments, functional deficits, and environmental setup. Then, based on the findings, appropriate goals can be set and a treatment approach to reach those goals can be initiated and completed. Persons with complete SCI will typically plateau sooner, and their impairments can remain chronic and lifelong.

Therapists may choose from a number of treatment approaches to achieve the goal of functional independence and achieving maximum function. More than one different type of approach may also be used if felt appropriate by the therapist. Additionally, although therapy sessions and tasks are divided by discipline (e.g., transfer training by physical therapy, activities of daily living (ADLs) by occupational therapy), all therapists must utilize expertise from other specialists on the team to maximize functional restoration and treatment. Within that framework, treatment can be either restorative or compensatory. The goal of restorative treatment is simply to reverse the disability despite the impairment present even though the impairment cannot be reversed. In this case, the individual is encouraged to perform the ADL task the same way as before the injury, despite the impairment. Compensatory treatments aim to reverse the disability and the handicap by finding other means of traversing the divide created by the impairment without directly restoring the function. One example is utilizing equipment with special adaptations to eat or bathe. Either way, the function can be accomplished with modified independence or at least with the least setup or assistance possible at the time of discharge.

The choice of which method to use depends on the underlying condition of the patient. Most persons with complete SCI may regain one or two levels of neurologic function but are unlikely to regain any more neurologic return in the acute phase of recovery. Therefore, therapists most often utilize compensatory strategies to create independent function. However, persons with incomplete SCI may see tremendous neurologic recovery over time and are more appropriate for restorative therapy immediately. Therefore, therapists must carefully observe their patient and try to project the amount and speed of the recovery. If the patient's recovery is more rapid, restorative treatment strategies are more appropriate. One example would be employing standing balance strategies at the kitchen even when the patient cannot yet ambulate but should be able to in the near future. Areas of focus on the inpatient rehabilitation stay include the following:

- Bed mobility
- Transfer training
- Wheelchair training
- Functional mobility
- Self-dressing
- Self-feeding
- Bathing and grooming
- Neurogenic bladder management
- Neurogenic bowel management
- Assistive devices
- Home and environment modifications

Many advances in therapy techniques have improved treatment offered to SCI patients in rehabilitation. Functional electrical stimulation has been applied to patients both in the acute rehabilitation setting and later in the outpatient setting to upper and lower extremities.[23] Assisted or weighted standing and walking, even with patients with complete injuries, is now being tried in a few centers with promising early results.[24] One rehabilitation modality that does seem promising for SCI patients, especially those with paraplegia, and later in rehabilitation is exoskeleton ambulation assist devices.[25]

Technology and equipment innovation has greatly influenced the quality of care that SCI patients receive. Power wheelchairs can be equipped with standing options, wheels for outside use, the ability to navigate stairs, and automatic pressure relief. Manual chairs are now fitted with more advanced cushions, sport options, and "power assist" wheels. Power assist wheels allow the patient to contribute a variable amount of push force and were found to reduce energy costs of propulsion and decrease shoulder pain.[26] Most cars and vans can be outfitted with hand controls. Finally, computerized environmental control units and voice-activated systems have improved independence and freedom for patients with high-level tetraplegia.

Because shorter LOSs have moved patients home sooner, the majority of rehabilitation gains often occur in the outpatient

setting. Patients with chronic SCI some years after their injury may benefit from renewed or prolonged rehabilitation. Jacobs et al.[27] showed improvements in cardiovascular status after circuit strength training in SCI patients. Competitive sports for patients with disabilities offer not only physical but also psychological benefits. Technology has also fueled growth in the rehabilitative treatment of SCI patients long after injury. Tendon transfers had been coupled with a "freehand" implant to improve hand function in many tetraplegic patients.[28] Bladder implants or injections of botulinum toxin may reduce incontinence,[29] intrathecal baclofen pumps reduce malignant spasticity,[30] and functional electrical stimulation implants have allowed for limited amounts of standing and ambulation.[31] All of these devices can increase functional independence in the appropriate SCI candidate, but also require post-placement rehabilitation training.[32]

Medical Management

Rehabilitation should begin as soon as possible after SCI. The most important medical aspects in the acute period of rehabilitation include neurogenic bowel and bladder care, pulmonary management, thromboembolic and gastric ulcer prevention, and proper positioning in bed. If early medical complications can be prevented, the rehabilitation course is facilitated and the cost of care is significantly reduced.

Neurogenic Bowel Dysfunction

Neurogenic bowel dysfunction is common after SCI and has the potential to influence the social, emotional, and physical well-being of patients. Establishment of an effective bowel program during rehabilitation can minimize the development of disability related to neurogenic bowel. The goal is to control severe constipation, promote regularity, and prevent involuntary bowel movements. There are two types of neurogenic bowel dysfunction after SCI: reflexic and areflexic.[33]

Reflexic or upper motor neuron (UMN) bowel dysfunction is seen in patients with SCI above the conus medullaris. Voluntary control of bowel is lost in these patients but conus-mediated reflex activity and intestinal peristalsis are intact. The external anal sphincter becomes spastic due to spasticity of the pelvic floor, preventing stool evacuation. Stool accumulates in the colon unless reflex defecation is triggered. Bowel care in these patients may include[34]: (1) nutritional changes with increased fiber and fluid intake, (2) oral medication (lubricants and cathartics), (3) rectal chemical stimulation (suppositories or enema), and (4) mechanical digital stimulation.

Areflexic or lower motor neuron (LMN) bowel dysfunction is a result of lesions at or below the conus medullaris. Voluntary control of bowel is lost as well as sacral reflex activity. The external anal sphincter becomes atonic and flaccid, which increases the risk of fecal incontinence. Management of LMN bowel dysfunction includes[34]: (1) diet with fiber and some fluid restriction, (2) oral medication (bulk-forming agent), and (3) mechanical digital removal of stool.

Neurogenic Bladder Dysfunction

Urosepsis was the leading cause of death prior to introduction of intermittent catheterization (IC).[35] Urologic problems are the most common complications of SCI. The rate of urinary tract infections is 50% to 80% in the first year postinjury. The goal of bladder management during rehabilitation is to establish an effective and safe method of emptying the bladder and avoiding incontinence. There are two types of neurogenic bladder dysfunction: reflexic and areflexic.

Reflexic or UMN bladder is secondary to lesions above conus medullaris. It is characterized by (1) incontinence secondary to conus-mediated reflex contractions of bladder detrusor muscle, (2) spastic external urethral sphincter, and (3) detrusor/sphincter dyssynergia.

Areflexic or LMN bladder occurs in lesions below the conus medullaris. This condition is characterized by (1) denervated external urethral sphincter and (2) flaccid detrusor muscle, leading to overflow or stress incontinence.

Management of neurogenic bladder after SCI is similar for both types. The routine recommendations are based on clinical practice guidelines prepared by the Consortium for Spinal Cord Medicine[36]:

- Management of fluid intake to maintain daily urine output between 1.5 and 2 L
- Intermittent catheterization using clean or sterile technique
- Indwelling catheter for patients with poor hand control and lack of attendant care
- Suprapubic catheter for, most commonly, patients with urethral lesions
- External (condom) catheter for male patients with UMN bladder with reflex voiding
- Surgery

The two circumstances when surgery is indicated in the management of neurogenic bladder after SCI is to correct the failure to store or the failure to empty urine. The most commonly performed corrective procedures are augmentation of small capacity bladder with intestine, and sphincterotomy. The most frequent method of bladder management at discharge from SCI rehabilitation centers is intermittent catheterization (59%). However, a relatively high number of patients were discharged with indwelling catheters (13%).[4] A newer treatment for upper motor neuron neurogenic bladder when detrusor/sphincter dyssynergia is the problem is detrusor injections of botulinum toxin. This will relax the bladder and/or sphincter to allow catheterization to occur.[37]

Spasticity

Spasticity is seen frequently in patients after SCI. In 37% of patients, the spasticity is significant and requires chronic therapy. Spasticity may interfere with function, daily activities, and sleep. The severity of spasticity during rehabilitation in SCI patients varies. It has been reported that patients with cervical and upper thoracic injuries have a higher incidence of spasticity than patients with lower spine injuries.[38] The underlying processes involved in pathogenesis of hyperactive reflexes are multifactorial and involve both inhibitory and

excitatory neurotransmitters. The role of neurotransmitters in spasticity is not fully understood; therefore, the therapy is generally symptomatic. Immediately after SCI, there is a short period (2–3 weeks) of areflexia that is followed by a gradual occurrence of increased muscle tone below the level of injury. In mild to moderately severe cases, ROM and static stretching can be used to treat spasticity during rehabilitation.

Medication is usually indicated for severe and chronic spasticity. The different drugs that can be used for spasticity are, in order: (1) baclofen, (2) benzodiazepines, (3) tizanidine, and (4) dantrolene. Baclofen is a γ-aminobutyric acid (GABA) agonist, a major inhibitory neurotransmitter in the central nervous system (CNS). The starting dose is 10 mg 2 to 3 times daily with a total daily dose of 80 mg. Benzodiazepines facilitate the effect of endogenous GABA, and they are second-choice medication in treatment of spasticity since their sedative CNS side effects exceed that of baclofen. Tizanidine is an α-adrenergic receptor agonist with effects similar to noradrenaline. Noradrenaline belongs to the group of inhibitory neurotransmitters that prevent release of excitatory amino acids from nerve terminals. Tizanidine blocks hyperactive spinal reflexes and, similar to other antispastic medication, has a sedative effect on the CNS. Dantrolene has no effects on the CNS; it acts directly on skeletal muscle cells, where it inhibits contraction of myofibrils. The inhibitory effect of dantrolene is due to blockade of endoplasmatic release of calcium. Neurolytic nerve blocks and surgery (dorsal rhizotomy) are additional therapeutic modalities in the treatment of spasticity. These therapies are not frequently used, but may be indicated for severe spasticity unresponsive to medication. More often for refractory cases, SCI patients can benefit from baclofen being delivered directly to the spinal cord via an implant. When baclofen can be given by intrathecal pump, it can reduce the therapeutic dose 100 times, thus markedly decreasing the sedative side effects of the drug on the CNS. One recent study found reduced spasm frequency and severity with greater dose stability with intrathecal compared with oral baclofen. However, they found no difference in fatigue, quality of life, or function.[39]

Cardiovascular Complications

The primary mechanisms underlying cardiovascular abnormalities are related to the disruption of sympathetic control located in the cervical cord. The most frequent symptoms are orthostatic hypotension (68%) and bradycardia (71%).[40] Autonomic dysreflexia develops in patients with SCI above the T6 spinal segment.

Orthostatic hypotension after SCI is caused by passive vasodilatation below the level of injury, while bradycardia is due to uninhibited parasympathetic tone. Frequent associated clinical findings are weakness, dizziness, blurred vision, and fainting during positional changes. The majority of patients gradually develop adaptation to hypotension and may tolerate orthostasis for an extended period of time. During the period of rehabilitation, different measures can be effective, such as elastic stockings, abdominal binders, and slow mobilization from the bed. Also, in early periods after SCI, medication may be indicated. There are two oral agents with different mechanisms of action that can be used, midodrine and fludrocortisone. Midodrine is an α-1 adrenergic agonist (ProAmatine); it is the first-choice drug. Fludrocortisone (Florinef), a mineralocorticosteroid, enhances renal resorption of sodium and may be used as an alternative.

Autonomic dysreflexia (AD) is a serious complication after SCI.[41] It is characterized by a sudden onset of pounding headache, increase of blood pressure, and bradycardia. AD occurs in patients with SCI above the T6 spine segment. These patients have interrupted central inhibitory control of the thoracic sympathetic system. Therefore, various peripheral noxious stimuli below the injury (e.g., bladder distension, pressure ulcers, ingrown toenails, urinary tract infection, constipation) may lead to overstimulation of the sympathetic system. AD may have different causes; however, it is most commonly related to bladder or bowel distension.[41] Treatment of AD includes immediate repositioning of the patient in a sitting position and loosening of clothing or constrictive devices to allow a pooling of blood into the lower extremities. The placement of an indwelling catheter should be performed early because the most common cause of AD is bladder distension. If after the catheterization systolic blood pressure remains elevated over 150 mm Hg, an antihypertensive agent with rapid onset and short duration (nitrates or nifedipine) is recommended.[41] If bowel distension or impaction is suspected, antihypertensive medication needs to be administered prior to rectal examination for stool.

The incidence of thromboembolism is high in the acute stage of SCI. The routine screening for DVT showed positive results in 47% to 100% of patients.[42] Studies based on clinical parameters estimated lower incidence of DVT in acute SCI. The incidence of clinically diagnosed DVT was 11.4% in 1996, which was significantly reduced to 5.2% in 1998. The decline in the incidence of DVT is most likely the result of the introduction of low-molecular-weight heparin (LMWH).[43] Prevention of thromboembolism starts after injury and continues throughout rehabilitation. Current methods for prevention of thromboembolism used in SCI patients are mechanical (compression hose, boots, pneumatic devices), pharmacologic (unfractionated heparin, LMWH, warfarin), and inferior vena cava filter. A consortium organized by Paralyzed Veterans of America in 1997[42] recommended mechanical prevention for the first 2 weeks following injury. In patients with motor complete SCI, pharmacologic prevention with unfractionated heparin or LMWH is recommended for a minimum of 8 weeks or until discharge from the rehabilitation center. Patients with motor complete injuries and risk factors such as obesity, heart failure, cancer, lower extremity fractures, previous DVT, or age greater than 70 years may need their prevention extended after discharge. Recommendations for the prevention of thromboembolism in the rehabilitation phase of patients with SCI is based on the 6th American College of Clinical Pharmacy consensus in 2001.[44] LMWH or full-dose oral anticoagulation with warfarin was the initial recommended method, with inferior vena cava filter recommended in patients who failed or have contraindications to anticoagulation. A meta-analysis of 13 studies showed strong evidence

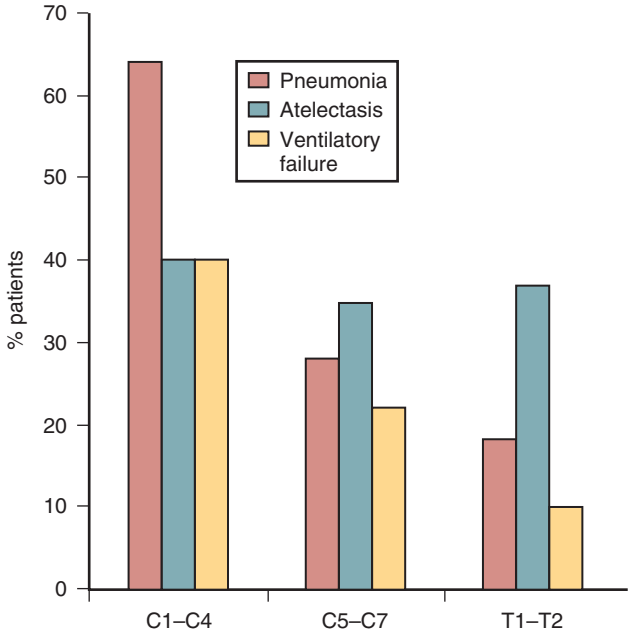

FIG. 82.4 Respiratory complications after spinal cord injury. (Modified from Jackson AB, Grooms TE. Incidence of respiratory complications following spinal cord injury. *Arch Phys Med Rehab.* 1994;75:270–275.)

to support the use of LMWH in reducing venous thrombosis events.[45] A higher adjusted dose of unfractionated heparin was also found to be more effective than 5000 units administered every 12 hours, although bleeding complication was more common. Treatment of thromboembolism in patients with SCI does not differ from treatment currently used in non-SCI patients.

Respiratory Complications

Respiratory complications are the most common early and late cause of death after SCI. Fig. 82.4 shows the most common respiratory complications in patients with different levels of SCI.[46] Pneumonia is the most common complication in high-level injuries, while atelectasis is seen in all groups of patients in similar frequency regardless of level of injury. Smith and coworkers found in over 18,000 veterans with SCI a steady rate of visits for acute respiratory infection, without a declining trend in frequency.[47]

There are several factors important in the pathophysiology of ventilatory abnormalities after SCI,[48] such as (1) restrictive ventilatory dysfunction as a result of muscle paralysis; (2) inability to cough, which is due primarily to paralysis of abdominal and intercostal muscles; and (3) hypersecretion of mucus. Overproduction of mucus (about 1 L/day) is due to absent sympathetic outflow and unopposed parasympathetic tone, which also leads to bronchoconstriction.

The neurologic level of injury mainly determines the management of respiratory complications after SCI. Patients with cervical injuries from C1 to C3 frequently need mechanical ventilation. These patients may benefit from diaphragmatic pacing in order to give them some freedom from the ventilator for periods of time and is becoming more common with the improvement of minimally invasive surgical techniques.[49] Patients with C4 to C7 and upper thoracic injuries often require the following treatments during rehabilitation: bronchodilators (β-adrenergic agonists and /or anticholinergics), mucolytic agents, and chest physiotherapy.

Later in the phase of rehabilitation and with the return of peripheral sympathetic tone, there is a decrease of mucus production. At this stage, respiratory treatments are focused on assisted cough and prevention of respiratory complications. All patients with cervical and high thoracic injuries need yearly vaccination for influenza and vaccination every five years for pneumonia.

Pressure Ulcers

Spinal cord injury causes profound changes in the structure and physiology of the skin, which leaves patients susceptible to the development of pressure ulcers. The incidence of pressure sores after SCI is high, with approximately 50% of chronic patients with SCI developing a pressure ulcer in their lifetime. Pressure ulcers are seen on the sacrum in 26%, on the ischium in 23%, on the heel in 12%, and on the trochanter in 10% of chronic SCI patients.[50] Several factors are responsible for the development of pressure ulcers after SCI but most important is prolonged pressure over a bone prominence. The cornerstones in the prevention of pressure ulcers are regular daily inspection of the skin and the performance of pressure relief techniques.

The management of pressure ulcers requires a multidisciplinary team approach. It is also important to provide sufficient nutritional support, treatment of comorbid conditions, and special support surfaces (cushions and mattresses). Two types of mattresses, static (foam, gel, air, or water) and dynamic (air pump with alternating pressure) are used to reduce pressure on the ulcer. Basic medical treatment used to include enzymatic debridement and moist wound dressing changes. More recently, ulcers have been treated with various growth factors and products such as transparent membranes, hydrogels, foams, alginates, and hyularonase.[51] Surgical repair is recommended when the ulcers are too large and only if nutritional and medical conditions of the patient are satisfactory.

Heterotopic Ossification

Heterotopic ossification (HO) is another early complication after SCI. Often occurring in the first month of rehabilitation, HO is often a cause of "fever of unknown origin." The incidence of HO after SCI is about 50%.[52,53] The etiology of HO is unknown. The pathology of HO is characterized by bone growth in extraarticular tissue of paralyzed extremities. Clinically, in the acute stage of HO, the most common findings are swelling, fever, and reduction in ROM of affected joint(s). The level of creatine phosphokinase in serum in the early stage may indicate the severity of muscle involvement. In the chronic stage, HO may limit the functional status of the patient. Diagnosis of HO in the early stages is based on a positive three-phase bone scintigraphy with technetium-99m diphosphonate. Prevention of HO with indomethacin in patients with SCI is effective if started early (3 to 4 weeks) after

injury.[54] Etidronate is first-line treatment for management of HO in the acute stage along with aggressive joint motion by physical therapy. Only when the heterotopic bone is mature up to 1 year after the onset can surgical resection be considered.

Osteoporosis and Fractures

In patients with SCI, there is significant bone loss in paralyzed limbs in the early period after injury. The most severely involved skeletal regions are the distal femur and proximal tibia. Bone densitometric studies showed that patients with complete paralysis might have bone loss of 30% in the first 3 months.[55] In later periods, bone loss will continue at a slower rate, reaching a new steady state after 2 years. At the final stages, bone mineral loss can be about 30% in the femoral shaft and 50% in the proximal tibia.[56] Patients who actually suffer fractures were found to have even higher bone loss: approximately 40% in femoral shaft and 70% in proximal tibia. Presently, there is no cure for osteoporosis after SCI. Many different preventive programs for bone loss have been evaluated. So far, all preventive measures have shown some positive effect on bone mass, but the effects are transient and the bone loss resumes as soon as the intervention stops. The incidence of lower extremity fractures after SCI is about 1% to 2% per year. Lower limb fractures are most often treated using a nonsurgical approach with the goal of maintaining functional independence. Use of splints and early mobilization are generally allowed initially in a supervised setting.

Pain

Pain prevalence is stable over time, ranging from 81% at 1 year after injury to 83% at 25 years.[57] Approximately 90% of patients with SCI have a delayed onset of pain and many are not finding adequate pain relief from commonly used medication.[58] Nepomuceno and coworkers[59] described the negative impact of pain on the life of patients with SCI. A total of 37% of patients with cervical injuries and 23% of patients with a lower level of SCI reported that if they had the chance, they would trade pain for loss of bladder, bowel, or sexual function. The majority of patients describe pain as stable or controlled, while others report that pain increased their disability. Of the different classifications of pain after SCI, the most commonly described are central neuropathic and musculoskeletal pain.[60,61] Clinical differentiation between central neuropathic and musculoskeletal pain is shown in Table 82.3.

Several mechanisms have been proposed in the pathophysiology of central pain, but the causes still remain uncertain. In contrast, musculoskeletal pain is most commonly due to spine injury or overuse of joint, tendon, or ligament structures. Treatment measures depend on which type of pain is being treated. There is no known cure for central pain. The most effective strategy in the management of central pain involves an interdisciplinary approach. However, only partial pain relief can be expected. The treatment strategies are:

1. Nonpharmacologic (transcutaneous electrical nerve stimulation, aerobic and anaerobic exercise, recreational activity, massage, acupuncture, heat or cold)
2. Pharmacologic
3. Psychosocial/biofeedback
4. Surgical (nerve blocks, dorsal root entry zone lesioning [the DREZ procedure], dorsal column spinal cord stimulator)

The guidelines from the World Health Organization proposal for the treatment of malignant pain can be applied in these patients: (1) nonopioid analgesics (nonsteroidal antiinflammatory drugs, e.g., acetaminophen) ± adjuvant (tricyclic antidepressants, SSRI, anticonvulsants); (2) opioid for moderate pain (oxycodone, codeine, hydrocodone) ± nonopioid ± adjuvant; and (3) opioid for severe pain (hydromorphone, morphine, fentanyl) ± nonopioid ± adjuvant. Caution should be employed in the use of opioids for chronic nonmalignant pain, especially neuropathic pain, as any efficacy could prove short-lived due to tolerance and dependence.[62] Another recent meta-analysis showed anticonvulsants to be of the most value in treating neuropathic pain of SCI.[63]

Musculoskeletal pain can be treated with mild analgesic, nonsteroidal antiinflammatory drugs, passive ROM, and trigger point injections.

TABLE 82.3 Characteristics of Pain After Spinal Cord Injury

	Pain	Activity	Location
Central	Burning, tingling, sharp, shooting	Not related	Anesthetic area
Musculoskeletal	Dull, aching	Aggravated	Above level of injury

Outcomes of Rehabilitation

Length of Stay

In general, patients with tetraplegia need a longer period for rehabilitation than patients with paraplegia. Similarly, patients with complete paralysis require a longer stay at rehabilitation centers than with incomplete paralysis. Statistical analysis showed that time needed for acute care has not changed during the past 20 years; however, significant changes were found in the LOS at the rehabilitation centers. Fig. 82.5 illustrates results from a database derived from the NSCISC database.[5] A dramatic reduction of LOS was documented at rehabilitation centers across the country from 1977 to 2000. The average LOS was 106 days in 1977, 90 days in 1987, 51 days in 1997, and 39 in 2004. The changes in the LOS of patients after SCI can mainly be attributed to measures that managed care instituted in the early 1990s.[64]

Discharge Disposition

The changes in the LOS of patients at rehabilitation centers had some effect on the discharge disposition of these patients. The results from the NSCISC database[4] obtained in 1997 showed that the majority of patients were still discharged home (91.2%); however, the percent of patients discharged to skilled nursing homes also increased (5.3%) as compared to 2.8% in 1990.

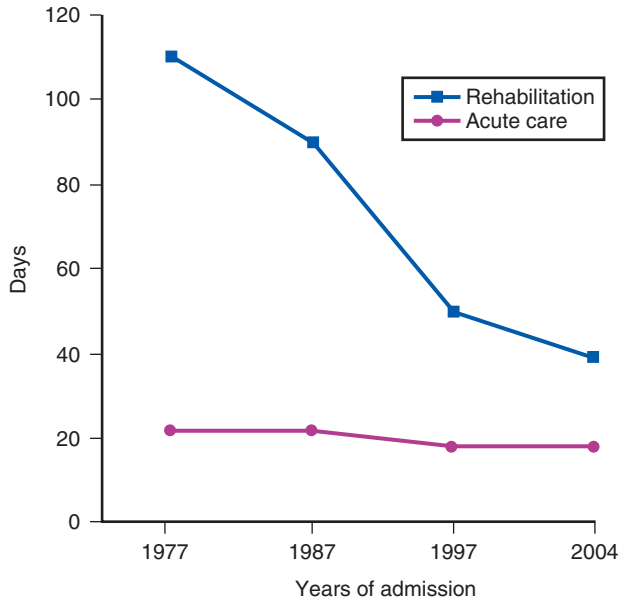

FIG. 82.5 Length of stay in rehabilitation centers after spinal cord injury. (Modified from Fiedler IG, Laud PW, Maiman DJ, Apple DF. Economics of managed care in spinal cord injury. *Arch Phys Med Rehab.* 1999;80:1441–1449.)

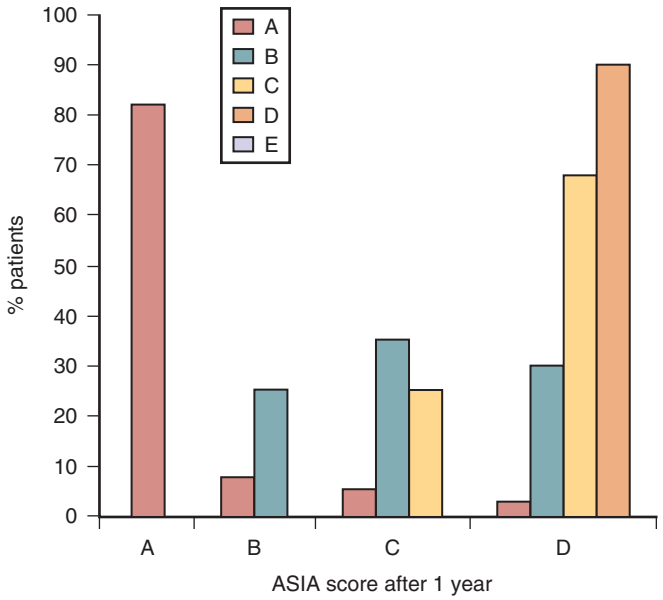

FIG. 82.6 Changes in motor function after spinal cord injury. The American Spinal Injury Association (ASIA) scale is used to grade motor function (see text for explanation of scale). (Modified from Marino RJ, Ditunno J, Donovan WH, Maynard F. Neurological recovery after spinal cord injury. *Arch Phys Med Rehab.* 1999;80:1031–1396.)

Gain of Motor Function

The outcomes of motor function are determined by the ASIA standardized evaluation previously discussed by using the ASIA examination and the data obtained from the NSCISC database.[65] The outcomes of motor function were related to rehabilitation and neurologic recovery and shown in Fig. 82.6. As illustrated in Fig. 82.6, about 10% to 15% of patients diagnosed as complete, or ASIA Impairment Scale classification AIS-A, will convert in 1 year to incomplete AIS-B, -C, or -D. Typically, neurologic return of motor function starts in the first month after injury but may continue for up to 24 months. Despite recent advances in pharmacologic treatment of SCI, prognosis for recovery of patients with an initial classification of AIS-A remains poor. The prognosis for motor function recovery of patients with AIS-B designation is intermediate. One-third of these patients remain unchanged, one-third converts to AIS-C, and one-third to AIS-D or -E. In the group of patients with the AIS-C designation, 70% will convert to AIS-D. Patients with an initial AIS-D designation showed functional improvement to AIS-E in 4%, while 96% of these patients remained in D category. Even after 5 years from traumatic SCI, results are not very different. Kirshblum et al. found that only 4.5% of patients with motor complete paralysis regained some motor or sensory recovery.[66]

Functional Independence (Charting ADL Improvement Objectively)

Currently, the most widely used, validated ADL evaluation scale is the Functional Independence Measure (FIM).[67] The FIM instrument evaluates nine areas of self-care, and can be applied multiple times throughout the course of treatment not only to provide a baseline of function but also to chart improvement in these key areas. The areas that the FIM reports on are self-feeding, grooming, bathing, dressing upper and lower body, toileting, and transfer to the toilet, tub, or shower. The FIM has demonstrated a high degree of interrelater reliability.[68] After the SCI patient leaves the hospital, the FIM can be continued in a self-reporting form (FIM-SR). Masedo et al. found the FIM-SR motor scales and total FIM-SR score are reliable and valid measures of perceived functional independence in individuals with SCI.[67]

Fig. 82.7 shows the results from the NSCISC database on FIM scores.[69] The data were obtained on admission and discharge from rehabilitation and at the followup after 1 year. There is a marked difference in FIM motor scores from admission to discharge from rehabilitation in all neurologic groups of patients. The greatest improvements are seen in patients with lower cervical and thoracolumbar injuries. There was very little change in FIM scores in all categories of patients beyond discharge from rehabilitation. Fig. 82.7 illustrates mean FIM motor scores for each neurologic group of patients and indicates that a score of 78 (13 motor items with scores of 6), correlating with functional independence, is reached only in patients with thoracolumbar injuries.

Despite the advantages that using a validated comprehensive ADL measure creates, there are significant limitations. Specifically, the FIM is not specific to SCI but is a general measure of any rehabilitation diagnosis. Thus, some aspects critical to SCI function, such as mastery of the environment and respiratory function, are not charted.

Therefore, the Spinal Cord Independence Measure (SCIM III), created a new, more comprehensive measure applicable to persons with paraplegia and tetraplegia, complete and incomplete.[70] Itzkovich et al. found that total agreement between raters was above 80% in most SCIM III tasks.[9,71] They also found

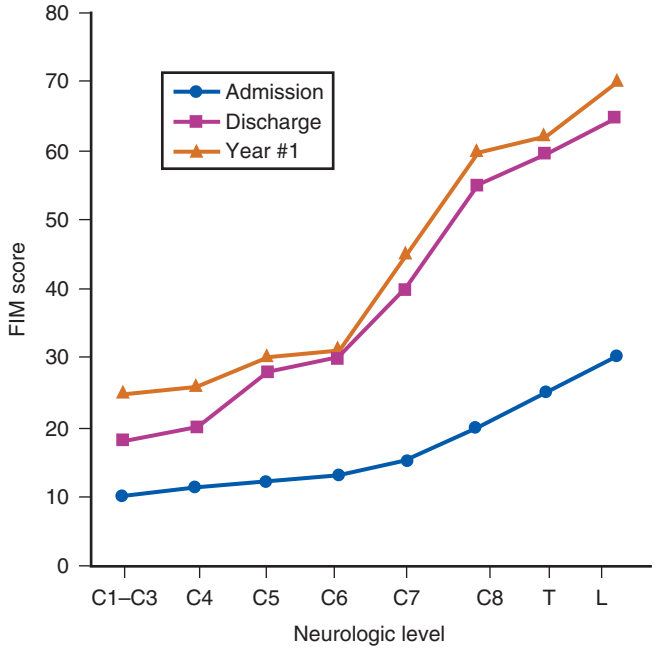

FIG. 82.7 Functional Independence Measure (FIM) of spinal cord injury patients at admission and discharge from rehabilitation center and 1 year thereafter (see text for explanation of score). (Modified from Hall KM, Cohen ME, Wright J, et al. Characteristics of the functional independence measure in traumatic spinal cord injury. *Arch Phys Med Rehab.* 1999;80:1471–1476.)

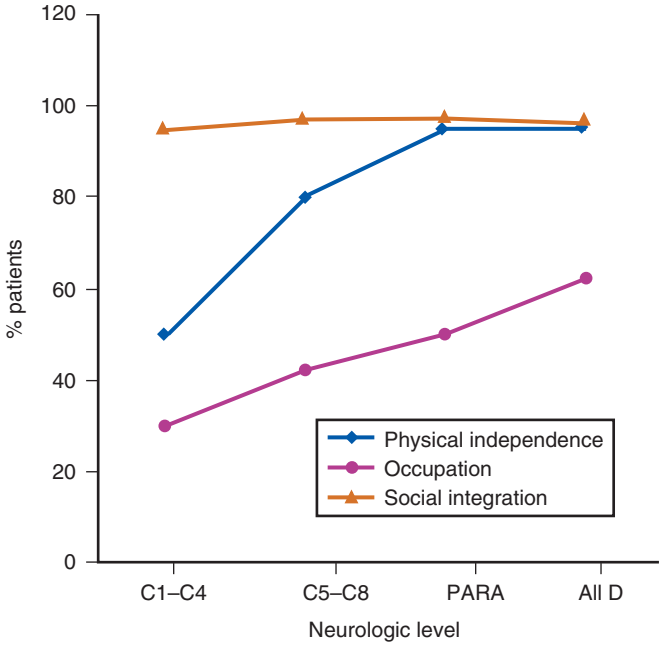

FIG. 82.8 Community integration after spinal cord injury. Each neurologic group included patients with American Spinal Injury Association scale A, B, and C (see text for explanation of scale). PARA, paraplegia. (Modified from Whiteneck G, Tate D, Charlifue S: Predicting community integration after spinal cord injury from demographic and injury characteristics. *Arch Phys Med Rehab.* 1999;80:1485–1491.)

that the SCIM III was more responsive to changes than FIM in the subscales of respiration and sphincter management and mobility indoors and outdoors. The measure is now undergoing final studies to see if it is more sensitive or specific for SCI patients than other measures while maintaining the practicality of the FIM. A new measure, called the SCI Functional Index, is currently in development and being validated as a potentially more specific measure than the FIM.[72] Functional ability level development and validation provides clinical meaning for the Spinal Cord Injury Functional Index scores.

Employment

More than half (57.4%) of those persons with SCI admitted to a Model System reported being employed at the time of their injury. The postinjury employment picture is better among persons with paraplegia than among their tetraplegic counterparts. By postinjury year 10, 32.4% of persons with paraplegia are employed, while 24.2% of those with tetraplegia are employed during the same year. National data from Model System Spinal Cord Centers revealed that the rate of employment of SCI patients is approximately 27% after rehabilitation.[73] Similar results were found for both genders: 24.1% in female patients and 27.7% in male patients. Important factors in obtaining employment after SCI were age, severity of injury, and educational level prior to injury.

Community Integration

Community integration of patients with SCI starts during inpatient rehabilitation and continues after discharge from the rehabilitation center. The involvement of human services plays a major role in assisting patients in the community. Fig. 82.8 depicts the three aspects of community integration after SCI: functional independence, social integration, and occupation. Data are obtained from the NSCISC database[74] indicate very high levels of social integration in all neurologic groups of patients after SCI. The lowest median score of community integration was found in occupation, as just mentioned. Community and athletic groups increase the levels of community integration. Activities that injured persons used to participate in can be modified for the wheelchair athlete or participant, increasing the quality of life for those injured. Sports for SCI patients include sailing programs, diving programs, wheelchair basketball teams, skiing, rugby, marathon racing, and Paralympic competitions.

In general, analysis of demographic data indicates that survivors of SCI with less severe neurologic injury, of younger age, of White race, and more education will achieve greater community integration.

Reintegration Into the Environment

As a part of most inpatient rehabilitation treatment programs, the home evaluation and the home visit are highly anticipated. The home visit can serve as a motivator for the SCI patient to reach his or her goals and participate fully. However, evaluating the home environment as early as possible in the rehabilitation process is also important so that appropriate goals can be set and needed modifications can begin earlier.[75]

The environmental evaluation begins with a family history (who is in the home), vocational history, and leisure history.

These are the components of the patient's lifestyle that allow the therapist to create a roadmap of where the injured patient was and where the patient needs to get back to, and even beyond, to maximize function. In certain cases, the therapist may find that the SCI patient was not functioning at optimal levels even before the injury due to psychiatric illness or other disorders.

The second component of the evaluation concerns the home structure itself. The therapist must create a picture of the home and environment that will allow for an understanding of what impediments might exist that will pose a barrier to maximizing function. Through knowing the individual limitations of their patient, the therapist can set therapy goals that may also involve making modifications to the home and environment to maximize function.[76] Ultimately, by marrying the functional abilities of injured patients to the environment that they are going to live within, the interdisciplinary rehabilitation team can help to maximize the quality of life of their SCI patients while minimizing cost to the patients and health care system.[75]

In summary, the key points to be gleaned from this section include the following. The rehabilitation of SCI patients begins from the moment of initiation into the health care system rather than when they are admitted to rehabilitation. Acute care treatment, including surgical choices, affects the rehabilitation methods chosen and speed of progress. Once in rehabilitation, close monitoring by the physiatrist is necessary to prevent medical complications of immobility. Finally, the entire rehabilitation interdisciplinary team must be involved in the treatment and goal setting to maximize outcome and minimize cost.

Acknowledgments

We thank Kresimir Banovac, MD, retired rehabilitation and endocrine medicine physician who coauthored the original manuscript, for his years of dedication to the field. We also thank Marine Dididze MD, SCI research physician, who assisted in the formatting of the chapter.

PEARLS

1. Rehabilitation of the SCI patient begins from the moment of injury and continues throughout the life of the patient.
2. The life expectancy of SCI patients continues to increase with improved medical and rehabilitative care.
3. Surgical advances have resulted in SCI patients being transferred more quickly to rehabilitation with improved functional abilities.
4. Shorter LOS in the rehabilitation unit has reduced inpatient cost but led to an increased need for prolonged outpatient rehabilitation.
5. Technological advances have impacted SCI patients by improving their mobility, function, and fitness.

PITFALLS

1. As patients with SCI live longer, the probability of developing cardiovascular and other medical problems associated with aging is increasing.
2. On average, patients with SCI have higher cholesterol levels and reduced levels of fitness compared to able-bodied persons of similar age. This can be improved with exercise training.
3. The increase in elderly patients with multiple comorbidities suffering SCI has led to an increase in medical complexity seen on rehabilitation units.
4. Many patients who suffer SCI do not have adequate insurance coverage to meet their complex medical, rehabilitation, and equipment needs.
5. Much of the new technology designed for treatment of SCI is expensive and not available currently for the majority of patients who could benefit.

KEY POINTS

1. *Timing of rehabilitation.* Rehabilitation and rehabilitation planning should start immediately when the patient arrives into the acute care system. Accurate assessment of neurologic level and an ASIA motor and sensory score facilitates initiation of treatment that can minimize deficits and allow for maximum functional recovery.
2. *Minimize medical complications.* As early as possible, rehabilitation should be started to prevent complications of immobility and provide the patient with the tools to succeed later in rehabilitation when the medical condition fully stabilizes.
3. *Optimize teamwork.* Rehabilitation of the SCI patient requires all members of the interdisciplinary team to work together in a coordinated fashion. This includes members of physical therapy, occupational therapy, specialized nursing, recreation therapy, the orthotics team, respiratory therapists, psychologists, social workers, and the vocational team. Creating achievable short-term and long-term goals will allow patients to work to achieve their optimum function.
4. *Demographics.* As more patients suffer SCIs who are elderly, many from nontraumatic causes, specialized rehabilitation programs will need to be created to address their unique medical and functional needs.
5. *Pain.* Chronic pain—neuropathic related to SCI or musculoskeletal related to acute or repetitive trauma—is often the chief identified problem that SCI patients identify. Optimal treatment of pain improves rehabilitation participation and optimizes function and quality of life.
6. *Future of rehabilitation.* Two trends are being seen that will continue into the future. The first is shorter length of inpatient stays, leading to increased importance and focus on outpatient rehabilitation. The second is the introduction of neurotechnology to supplement general strength rehabilitation, improve function, and even allow assisted ambulation.

CHAPTER 83

Arthritic Disorders

SECTION XII

David G. Borenstein

Rheumatologic disorders of the axial skeleton are an important cause of spinal pain. These inflammatory disorders affect the bones, joints, ligaments, tendons, and muscles that are anatomic components of the spine. The most important rheumatic disorders that cause inflammation of the joints of the axial skeleton are the seronegative spondyloarthropathies and rheumatoid arthritis (RA). The spondyloarthropathies are characterized by damage of the sacroiliac joints, axial skeleton, and peripheral large joints and the absence of rheumatoid factor. The seronegative spondyloarthropathies include ankylosing spondylitis (AS), reactive arthritis, psoriatic arthritis, and enteropathic arthritis. Genetic factors predispose patients to these illnesses. Environmental factors play a role as triggers of the inflammatory response in genetically predisposed individuals, but these factors have been only partially identified.

RA, a disease that causes chronic inflammation of the synovial lining of the joints, affects the cervical spine at the atlantoaxial junction and the subaxial apophyseal joints. These changes occur most commonly in patients with diffuse disease of long duration. Cervical spine involvement in RA is associated with a wide range of symptoms and signs, from mild neck pain and headaches to severe neurologic dysfunction consisting of radiculopathy, paresthesias, incontinence, quadriplegia, and sudden death.

In the seronegative spondyloarthropathies and RA, joint pain is most severe in the morning and improves with activity. Physical examination reveals localized tenderness with palpation and limitation of motion in all planes of motion of the axial skeleton. Laboratory abnormalities are consistent with systemic inflammatory disease but are nonspecific except for the presence of rheumatoid factor in 80% of patients with RA. Radiographic evaluation identifies characteristic joint space narrowing, sclerosis, and fusion in the sacroiliac joints; vertebral body squaring; and ligamentous calcification that may help in the differential diagnosis of a patient with spinal arthritis. Magnetic resonance imaging (MRI) is a valuable tool identifying individuals with sacroiliac or axial joint inflammation prior to radiographic alterations. This joint modification related to early inflammation identifies individuals with nonradiographic axial spondyloarthritis.

Although there are no cures for these illnesses, medical therapy consisting of nonsteroidal antiinflammatory drugs (NSAIDs), and disease-modifying antirheumatic drugs (DMARDs) can be effective in controlling symptoms and improving function, particularly with RA. Newer biologic therapies in the form of tumor necrosis factor (TNF)-α, interleukin (IL)-1, IL-6, and B-cell inhibitors, among others, offer the potential to prevent joint inflammation and destruction to a greater degree than with prior therapies.

The prognosis and course of these rheumatic conditions are rarely related to the extent of spine disease alone. Occasionally, atlantoaxial subluxation secondary to RA or the spondyloarthropathies may result in catastrophic neurologic dysfunction. In most circumstances, the status of disease in other areas of the musculoskeletal system and the severity of constitutional symptoms have a greater effect on the patient's daily existence.

Ankylosing Spondylitis

AS is a chronic inflammatory disease characterized by a variable symptomatic course and progressive involvement of the sacroiliac and axial skeletal joints. It is the prototype of the seronegative spondyloarthropathies. This disease complex is characterized by axial skeletal arthritis; the absence of rheumatoid factor in serum (seronegative); the lack of rheumatoid nodules; and the presence of a tissue factor on host cells, human leukocyte antigen (HLA)-B27.

Epidemiology

AS affects 0.9% to 1.4% of whites, which is equal to the prevalence for RA.[1] A strikingly high association between HLA-B27 and AS has been shown. HLA-B27 is present in more than 90% of white patients with AS compared with a frequency of 7% to 8% in a normal white population.[2] In North American whites, with a prevalence of HLA-B27 of 7%,.[3] A positive family history of AS or related spondyloarthropathy increases the risk to 30% among HLA-B27–positive first-degree relatives compared with HLA-B27–positive control subjects (1%–4%).[4]

The male-to-female ratio is reported in the range of 2:1.[5] Women tend to be less symptomatic, however, and develop less severe disease. Women may also present more often with cervical spine disease with minimal lumbar spine symptoms or more peripheral joint involvement. The overall pattern of illness may be similar in men and women.[6]

Pathogenesis

The pathogenesis of AS is unknown. A genetic predisposition to AS and to the seronegative spondyloarthropathies in general exists. A genetically determined host response to an environmental factor in genetically susceptible individuals seems to be the most likely basis for the pathogenesis of the spondyloarthropathies. The presence of HLA-B27 is not sufficient to develop AS; this is supported by the facts that not all individuals with HLA-B27 develop disease, that HLA-B27 even in a homogeneous form does not cause disease, and that a few patients with AS do not have HLA-B27.[7]

Enthesitis (inflammation of an enthesis—attachment of tendon to bone) is the hallmark that distinguishes the spondyloarthropathies from other forms of arthritis.[8] An enthesis is a dynamic structure undergoing constant modification in response to applied stress. This area is a target for inflammation by the activation of resident IL-23–sensitive T cells. Subsequent downstream activation of IL-17 and IL-22 results in characteristic spondyloarthritic modification of skeletal structures.[9] Although entheses are primarily affected in the spondyloarthropathies, inflammation of these structures is insufficient to explain the alterations that occur in (sacroiliac) joints. Synovitis plays an important role. Synovitis may be a secondary event, however, after initiation with an enthesitis.[10]

AS is a disease of the synovial and cartilaginous joints of the axial skeleton, including sacroiliac joints, spinal apophyseal joints, and symphysis pubis. The large appendicular joints, hips, shoulders, knees, elbows, and ankles are also affected in 30% of patients. The inflammatory process is characterized by chondritis (inflammation of cartilage) or osteitis (inflammation of bone) at the junction of the cartilage and bone in the spine. As opposed to RA, which is associated with osteoporosis as an early manifestation of disease, the inflammation of AS is characterized by ankylosis of joints and ossification of ligaments surrounding the vertebrae (syndesmophytes) and other musculotendinous structures, such as the heels and pelvis.

Clinical History

The classic AS patient is a man 15 to 40 years old with intermittent dull low back pain. The associated stiffness is slowly progressive, measured in months to years. AS rarely occurs in individuals older than 50 years. Patients with spondyloarthropathy initiated after age 50 years are more likely to have a non-AS spinal inflammatory disorder, such as psoriatic spondylitis.[11] Back pain, which occurs throughout the disease in 90% to 95% of patients, is greatest in the morning and is increased by periods of inactivity. Patients may have difficulty sleeping because of pain and stiffness; they may awaken at night and find it necessary to leave bed and move about for a few minutes before returning to sleep. Fatigue can be a major symptom and correlates with level of disease activity, functional ability, global well-being, and mental health status.[12]

Back pain improves with exercise. The mode of onset is variable, with most patients developing pain in the lumbosacral region. Peripheral joints (hips, knees, and shoulders) are initially involved in a few patients; occasionally, acute iridocyclitis (eye inflammation) or heel pain may be the first manifestation of disease. Occasionally, individuals older than 50 years may present with mild symptoms despite extensive spinal involvement.[13] Conversely, back pain may be severe, with radiation into the lower extremities, mimicking acute lumbar disc herniation. Patients have symptoms related to the piriformis syndrome. The belly of the piriformis muscle crosses over the sciatic nerve. Inflammation in the sacroiliac joint, where the muscle attaches, results in muscle spasm and nerve compression. There are no abnormal, persistent neurologic signs associated with the sciatic pain. The symptoms are reversible with medical therapy that relieves joint inflammation. This symptom complex of radicular pain is referred to as *pseudosciatica*.

Patients usually have a moderate degree of intermittent aching pain localized to the lumbosacral area. Paraspinal musculoskeletal spasm may also contribute to the discomfort. With progression of the disease, pain develops in the dorsal and cervical spine and rib joints.

Flattening of the lumbar spine and loss of normal lordosis are consistent with spinal involvement. Thoracic spine disease causes decreased motion at the costovertebral joints, reduced chest expansion, and impaired pulmonary function. In 81% of patients, the initial symptoms are back pain; back stiffness; thigh, hip, or groin pain; and sciatica. Pain in peripheral joints is the initial complaint in 13% of patients, pain in the chest is the initial complaint in 2%, and generalized aches are the initial complaint in 1%.

Cervical spine disease occurs less frequently than lumbosacral involvement in AS and at a later time in the course of the illness. Studies of large groups of AS patients report cervical spine involvement to range from 0% to 53.9%. The primary symptom of cervical spine disease is neck stiffness and pain. Patients may develop intermittent episodes of torticollis. Involvement of the cervical spine causes the head to protrude forward, making it difficult to look straight ahead.

Peripheral joint arthritis (hips, knees, ankles, shoulders, and elbows) occurs in 30% of patients within the first 10 years of disease. Hip disease is the most frequent limiting factor in mobility rather than spinal stiffness. Ankylosis may also occur in cartilaginous joints, such as the symphysis pubis, sternomanubrial, and costosternal joints. Erosions of the plantar surface of the calcaneus at the attachment of the plantar fascia result in an enthesitis. This inflammation causes a fasciitis and periosteal reaction, which causes heel pain and the formation of heel spurs. Achilles tendinitis is another enthesitis associated with heel pain and AS.

Neurologic Complications

Atlantoaxial Subluxation

Neurologic complications of AS are secondary to nerve impingement or trauma to the spinal cord. In a study of 33 patients with AS and neurologic complications, cervical abnormalities were the most common cause of neurologic

compromise.[14] Atlantoaxial subluxation occurs in the setting of AS but less often than in RA.[15] In a study of 103 AS patients, 21% had atlantoaxial subluxations. Vertical subluxation is a rare complication. About one-third of patients have progression of subluxations. Five of the 22 patients with subluxation required surgical fusion.[16] Rarely, symptoms of atlantoaxial subluxation may be the presenting manifestation of AS.[17] Significant instability may occur without symptoms in RA because of generalized ligamentous laxity and erosion of bone. AS patients have symptoms and signs of nerve impingement more frequently in the setting of instability secondary to the immobilized state of the calcified structures surrounding the spine. Spinal cord compression is associated with myelopathic symptoms, including sensory deficits, spasticity, paresis, and incontinence. AS patients who are at increased risk are those with elevated C-reactive protein (CRP), peripheral arthritis, and lack of response to NSAIDs.[18]

Spinal Fracture

The other change is the loss of normal flexibility because of ankylosis of the spinal joints and ligaments. The spine in this ankylosed state is much more brittle and is prone to fracture, even with minimal trauma. The most common location for fracture is the cervical spine, although dorsal and lumbar spine fractures have also been described.[19,20] The occurrence of traumatic cervical spine injury is 3.5 times greater in AS patients than in the normal population.[21] The risk for fracture may be present within the first 2.5 years of diagnosis.[22] The lower cervical spine (C6–C7) is the most frequent location for fracture, which is often associated with a fall. Patients who develop fractures may complain of nothing more than localized pain and decreased or increased spinal motion, but severe sensory and motor functional loss corresponding to the location of the lesion may develop. The onset of neurologic dysfunction may be delayed for weeks after initial trauma.

The diagnosis of fracture may be delayed because of the difficulty of detecting fractures in osteoporotic bone with plain radiographs. Computed tomography (CT) may be needed to identify the location of the fracture.[23] Neurologic deficits may persist despite surgical intervention in 85.7% of patients.[24] A mortality rate of 35% to 50% may be found, particularly in AS patients who are elderly, who have complete cord lesions, or who develop pulmonary complications after fracture.[25]

Spondylodiscitis

Another complication of AS is spondylodiscitis, a destructive lesion of the disc and its surrounding vertebral bodies. These lesions occur in individuals with younger age at disease onset.[26] This lesion may be associated with new onset of localized pain in the spine, which uncharacteristically for a patient with AS is improved with bed rest. The cause of these lesions may be localized inflammation or minor trauma.[27] MRI evaluation reveals increased activity in the central portion of the vertebral endplate, confirming this area as an area of enthesitis. In most cases, external immobilization is effective in controlling symptoms; thus, surgical fusion is reserved for more severely affected patients.

Extraarticular Manifestations

AS is also associated with many nonarticular abnormalities. Constitutional manifestations of disease—such as fever, fatigue, and weight loss—are seen in a few patients with active disease, particularly patients with peripheral joint manifestations. Iritis, inflammation of the anterior uveal tract of the eye, may be the presenting complaint of 25% of patients with AS and is present in 40% of patients over the course of the disease. Cardiac involvement occurs in 10% of patients, with disease durations of 30 years or longer. A fibrosing lesion causes the aortic valve and proximal root to thicken. Aortic disease may be more common in patients with peripheral arthritis. Mild features include tachycardia, conduction defects, and pericarditis. AS causes cardiac conduction disturbances, particularly bradyarrhythmias. The most serious cardiac abnormality is proximal aortitis, which results in aortic valve insufficiency, heart failure, and death. Prosthetic valve replacement may forestall cardiac deterioration. Pulmonary involvement is manifested by decreased chest expansion, which limits lung capacity, particularly with severely kyphotic individuals.

Physical Examination

A careful musculoskeletal examination is necessary, particularly of the lumbosacral spine, to discover the early findings of limitation of motion of the axial skeleton, which is especially noticeable with lateral bending or hyperextension. Percussion over the sacroiliac joints elicits pain in most circumstances. Other tests that may be helpful in identifying sacroiliac joint dysfunction place stress on the joint. The tests to be considered include a FABER (flexion abduction and external rotation of the hip) maneuver, Gaenslen test (pressure on a hyperextended thigh with a contralateral flexed hip), Yoeman test (hyperextension of the thigh with a prone patient), and distraction of the pelvic wings anteriorly and posteriorly.

Measurements of spinal motion, including the Schober test (lumbar spine motion), lateral bending of the lumbosacral spine, occiput to wall (cervical spine motion), and chest expansion, are important in ascertaining limitations of motion and following the progression of the disease. Paraspinous muscles may be tender on palpation and in spasm, resulting in limitation of back motion. Finger-to-floor measurements should be done but are more to determine flexibility, which is more closely associated with hip motion than with back mobility. Rotation may be checked with the patient seated. This position fixes the pelvis, limiting pelvic rotation. Chest expansion is measured at the fourth intercostal space in men and below the breasts in women or at the xiphoid process. Patients raise their hands over their head and are asked to take a deep inspiration. Normal expansion is 2.5 cm or greater. Cervical spine evaluation includes measurement of all planes of motion. Peripheral joint examination is also indicated. Careful hip examination is necessary to determine the potential loss of function involved with simultaneous arthritis of the back and hip. Examination

of the eyes, heart, lungs, and nervous system may uncover unsuspected extraarticular disease.

Laboratory Data

Laboratory results are nonspecific and add little to the diagnosis of AS. Mild anemia is present in 15% of patients. The erythrocyte sedimentation rate is increased in 80% of patients with active disease. Patients with normal sedimentation rates with active arthritis may have elevated levels of CRP.[28] Rheumatoid factor and antinuclear antibody are characteristically absent. Histocompatibility testing (for HLA) is positive in 90% of AS patients but is also present in an increased percentage of patients with other spondyloarthropathies (reactive arthritis, psoriatic spondylitis, and spondylitis with inflammatory bowel disease). It is not a diagnostic test for AS. HLA testing may be useful in a young patient with early disease for whom the differential diagnosis may be narrowed by the presence of HLA-B27.

Radiographic Evaluation

Characteristic changes of AS in the sacroiliac joints and lumbosacral spine are helpful in making a diagnosis but may be difficult to determine in the early stages of the disease.[29] The areas of the skeleton most frequently affected include the sacroiliac, apophyseal, discovertebral, and costovertebral joints. The disease affects the sacroiliac joints initially and then appears in the upper lumbar and thoracolumbar areas. Subsequently, in ascending order, the lower lumbar, thoracic, and cervical spine are involved. The radiographic progression of disease may be halted at any stage, although sacroiliitis alone is a rare finding except in some women with spondylitis or in men in the early stage of disease.

The European League Against Rheumatism (EULAR) has issued guidelines for the evaluation of spondyloarthritis.[30] Evaluation of the sacroiliac joints should be with a conventional anteroposterior supine view of the pelvis and should be the first imaging method to diagnose sacroiliitis.[30] Other conventional radiographic views do not offer greater sensitivity for the increased exposure to radiation.

Sacroiliitis is a bilateral, symmetrical process in AS. During the next stage, the articular space becomes "pseudowidened" secondary to joint surface erosions. With continued inflammation, the area of sclerosis widens and is joined by proliferative bony changes that cross the joint space. In the final stages of sacroiliitis, complete ankylosis with total obliteration of the joint space occurs (Fig. 83.1). Ligamentous structures surrounding the sacroiliac joint may also calcify. The radiographic changes associated with sacroiliitis may be graded from 0 (normal) to 4 (complete ankylosis).

In the lumbar spine, osteitis affecting the anterior corners of vertebral bodies is an early finding. The inflammation associated with osteitis causes loss of the normal concavity of the anterior vertebral surface, resulting in a "squared" body (Fig. 83.2).

While osteopenia of the bony structures appears, calcification of disc and ligamentous structures emerges. Thin, vertically oriented calcifications of the anulus fibrosus and anterior and posterior longitudinal ligaments are termed *syndesmophytes*. *Bamboo spine* is the term used to describe the spine of a patient with AS with extensive syndesmophytes encasing the axial skeleton (Fig. 83.3).

The apophyseal joints are also affected in the illness. As the disease progresses, fusion of the apophyseal joints occurs. Radiographs of the spine may show the loss of joint space and complete fusion of the joints. Cervical spine ankylosis may be particularly severe (Fig. 83.4). Complete obliteration

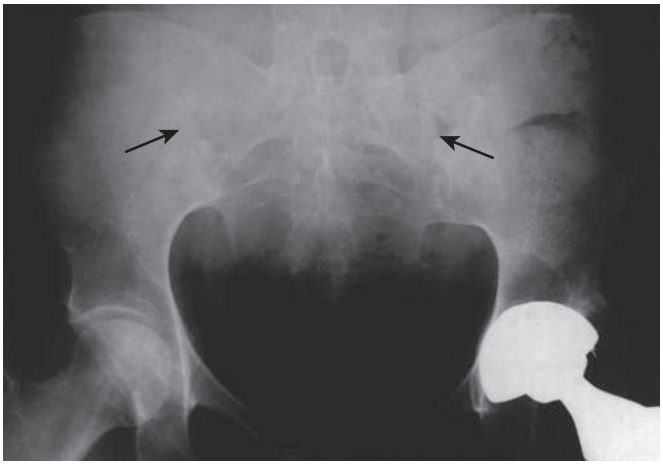

FIG. 83.1 Ankylosing spondylitis. Anteroposterior view of the pelvis of a 38-year-old woman with a 15-year history of ankylosing spondylitis shows bilateral fused sacroiliac joints (*arrows*). She underwent hip replacement because of destructive disease secondary to spondyloarthropathy.

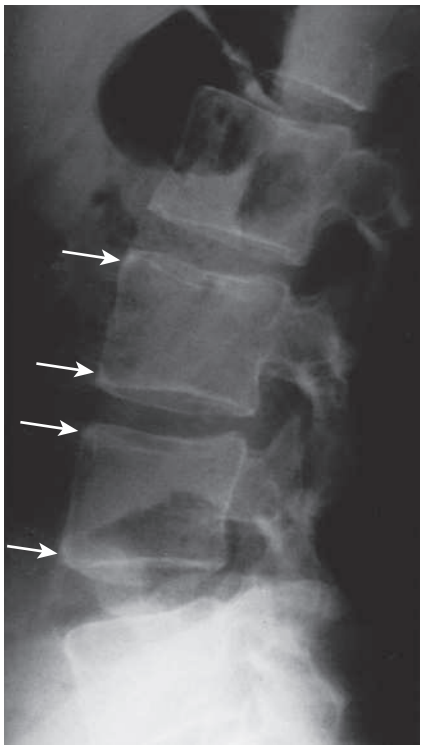

FIG. 83.2 Ankylosing spondylitis. Lateral view of the lumbosacral spine shows "squaring" of all lumbar vertebral bodies (*arrows*).

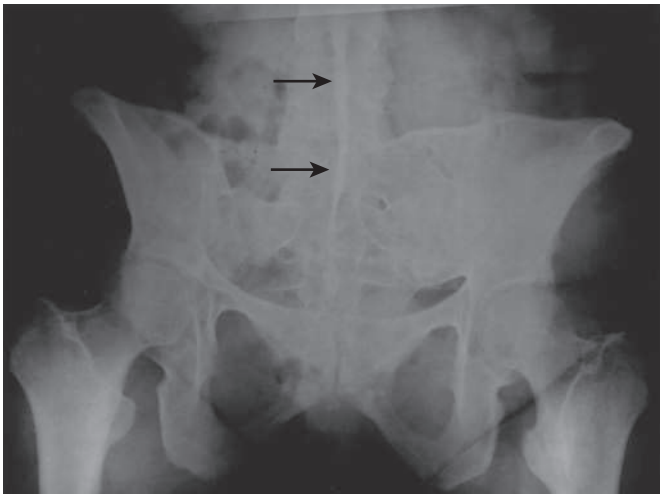

FIG. 83.3 Ankylosing spondylitis. Anteroposterior view of the pelvis of a 64-year-old man with 40 years of ankylosing spondylitis and bamboo spine. Sacroiliac joints are fused and interspinous ligaments are calcified (*arrows*).

BOX 83.1 Modified New York Diagnostic Criteria for Ankylosing Spondylitis

Clinical Criteria

1. Limitation of motion of lumbar spine in anterior flexion, lateral flexion, and extension
2. History of or presence of pain at dorsolumbar junction or in lumbar spine
3. Limitation of chest expansion to ≤1 inch

Radiologic Criteria (Sacroiliitis)

Grade 3: Unequivocal abnormality, moderate or advanced sacroiliitis with one or more erosions, sclerosis, widening, narrowing, or partial ankylosis

Grade 4: Severe abnormality, total ankylosis

Diagnosis

Definite grade 3-4: Bilateral sacroiliitis + one clinical criterion

Grade 3-4: Unilateral or grade 2 bilateral sacroiliitis with clinical criterion 1 or 2 and 3

Probable grade 3-4: Bilateral sacroiliitis alone

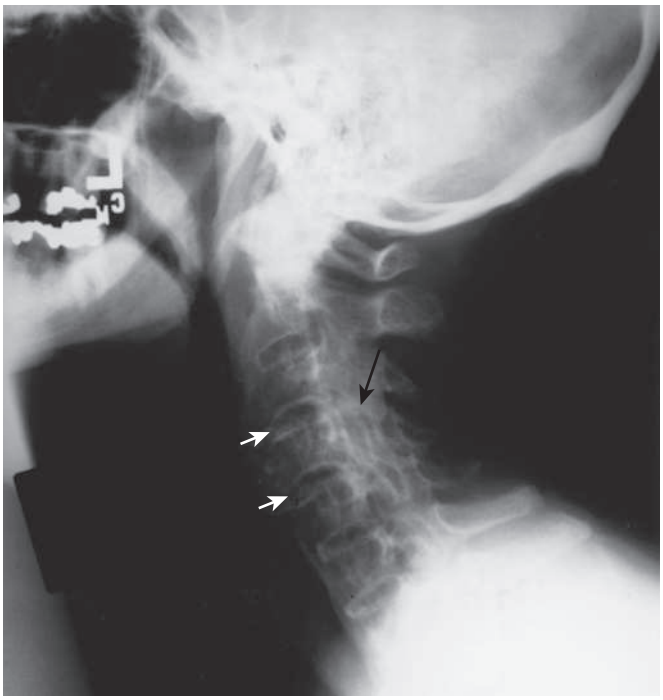

FIG. 83.4 Ankylosing spondylitis. Lateral view of the cervical spine of the patient in Fig. 83.3. Radiograph shows anterior syndesmophytes (*white arrows*) and fusion of posterior zygapophyseal joints (*black arrow*).

of articular spaces between the posterior elements of C2–C7 results in a column of solid bone. Patients with complete ankylosis of the apophyseal joints and syndesmophytes may develop extensive bony resorption of the anterior surface of the lower cervical vertebrae late in the course of the illness. Bone under the ligaments connecting the spinous processes may also be eroded in the setting of apophyseal joint ankylosis.

The C1–C2 joints may become eroded and partially dislocated. Synovial tissue around the dens may cause erosion of the odontoid process. Further damage of the surrounding ligaments results in instability that is measured by the movement of the odontoid process from the posterior aspect of the atlas with flexion and extension views of the cervical spine. Widening of the space is indicative of a dynamic subluxation. No movement of the distance between the atlas and axis suggests a fixed subluxation. In addition to atlantoaxial subluxation, migration of the odontoid into the foramen magnum and rotary subluxation may occur. Subaxial subluxation is more characteristic of RA than AS.

MRI with fat saturation or contrast medium–enhanced images are able to detect early inflammatory lesions in the sacroiliac joints and the lumbar spine before conventional radiographs.[31] MRI is able to identify this group, which has been classified as suffering from nonradiographic spondyloarthritis. From a diagnostic and clinical perspective, plain radiographs normally provide adequate information at a reasonable cost. Plain radiographs remain the usual radiographic technique used for the diagnosis of AS. MRI is a good choice for young women with suspected sacroiliitis as a means of decreasing radiographic exposure and detection of earlier lesions.

Differential Diagnosis

Diagnostic criteria exist for the diagnosis of AS. The modified New York criteria require alterations in the sacroiliac joints (Box 83.1). The criteria include a grading system for radiographs of the sacroiliac joints in addition to limited spine motion, chest expansion, and back pain.[32] Although these criteria are used mostly for studies of patient populations, they are helpful in the office setting. The Assessment of Spondyloarthritis International Society has proposed classification criteria based on clinical or imaging findings (Table 83.1).[33]

Although spondyloarthropathies are a common inflammatory musculoskeletal disorder, this group of illnesses is frequently overlooked by nonrheumatologists. A delay in diagnosis from the onset of symptoms and referral to a rheumatologist ranged from 6 to 264 months. Individuals

who are misdiagnosed by primary care physicians have mild to moderate disease, with atypical presentations, and are women.[34] The differential diagnosis of spinal pain includes other spondyloarthropathies, rheumatoid arthritis, and herniated intervertebral disc. Characteristics of these specific diseases are listed in Table 83.2. The inflammatory disorders are discussed briefly here.

Psoriatic Arthritis

Patients with psoriasis who develop a characteristic pattern of joint disease have psoriatic arthritis.[35] The prevalence of psoriasis is 1% to 3% of the population. Classic psoriatic arthritis is described as involving distal interphalangeal joints and associated nail disease alone.[36] This pattern occurs in 5% of patients. The most common form of the disease, affecting 70% of patients with psoriatic arthritis, is an asymmetrical oligoarthritis; a few large or small joints are involved. Dactylitis, diffuse swelling of a digit, is most closely associated with this form of the disease. Skin activity and joint symptoms do not correlate, and patients with little skin activity may experience continued joint pain and stiffness.

Psoriatic spondyloarthropathy is found in 5% to 23% of patients with psoriatic arthritis. Patients who develop axial skeletal disease, sacroiliitis, or spondylitis are usually men who have onset of psoriasis later in life. HLA-B27 is more common in individuals with axial disease. Sacroiliac involvement may be unilateral or bilateral. Percussion over the sacroiliac joints can elicit symptoms over the affected side. Patients may develop spondylitis in the absence of sacroiliitis, which has maximal tenderness with percussion over the spine above the sacrum. In the cervical spine, limitation of motion is a primary manifestation of neck involvement. Rarely, patients with psoriatic arthritis may develop atlantoaxial subluxation with evidence of cervical myelopathy. Fracture after minor trauma may be overlooked for an extended period.[37]

Spondylitis on radiographs is characterized by asymmetrical involvement of the vertebral bodies and nonmarginal syndesmophytes. Joint ankylosis occurs less commonly than in AS. Of patients, 25% can have sacroiliac involvement manifested by sacroiliitis, which can be unilateral or bilateral. Sacroiliitis may occur without spondylitis. Spinal disease progression occurs in a random rather than orderly fashion, ascending the spine as commonly noted in AS. Cervical spine disease may occur in the absence of sacroiliitis or lumbar spondylitis. Alterations in the cervical spine include joint space sclerosis and narrowing and anterior ligamentous calcification (Fig. 83.5).

The Classification of Psoriatic Arthritis study group proposed classification criteria for psoriatic arthritis. These criteria include the presence of psoriasis, nail changes, dactylitis, juxtaarticular new bone formation, and the absence of rheumatoid factor. These criteria have excellent sensitivity in early and late disease.[38]

TABLE 83.1 ASAS Criteria for Axial Spondyloarthritis (SpA) in Patients With Chronic Back Pain and Age of Onset of Back Pain <45 Years

Sacroiliitis on Imaging Plus ≥1 SpA Feature	*or*	HLA-B27 Plus ≥2 Other SpA Features
Active (acute) inflammation on MRI highly suggestive of sacroiliitis associated with SpA		Inflammatory back pain Arthritis Enthesitis (heel) Uveitis Dactylitis Psoriasis Crohn disease Good response to NSAIDs Family history of SpA HLA-B27 Elevated CRP
Definite radiographic sacroiliitis according to New York criteria		

ASAS, Assessment of Spondyloarthritis International Society; CRP, C-reactive protein; HLA, human leukocyte antigen; NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 83.2 Differential Diagnosis of Ankylosing Spondylitis

	Ankylosing Spondylitis	Psoriatic Arthritis	Reactive Arthritis	Enteropathic Arthritis	Rheumatoid Arthritis	Herniated Disc
Sacroiliitis	Symmetrical	Asymmetrical	Asymmetrical	Symmetrical	–	–
Axial skeleton	+	±	±	+	–	–
Peripheral joints	Lower	Upper	Lower	Lower	Upper and lower	–
Enthesopathy	+	+	+	–	–	–
ESR	Elevated	Elevated	Elevated	Elevated	Elevated	Normal
Rheumatoid factor	–	–	–	–	+	–
HLA-B27	90%	60%	90%	50%	8%	8%
Course	Continuous	Continuous	Self-limited	Continuous	Continuous	Episodic or continuous
Therapy	NSAIDs, DMARDs	NSAIDs/DMARDs, NSAIDs/antibiotics	NSAIDs	Steroids	NSAIDs, DMARD	NSAIDs
		TNF	Biologics	Biologics	Biologics	Epidural steroids
Disability		Hip	Lower extremity	Lower extremity	Extremities	Radiculopathy

DMARDs, disease-modifying antirheumatic drugs; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; NSAIDs, nonsteroidal antiinflammatory drugs; TNF, tumor necrosis factor.

Treatment of psoriatic arthritis is directed at reducing inflammation and preventing structural damage with early intervention. The EULAR has published recommendations for the pharmacologic therapy of psoriatic arthritis.[39] Immunosuppressive agents and TNF-α inhibitors are listed in Table 83.3. Treatments are used indefinitely.

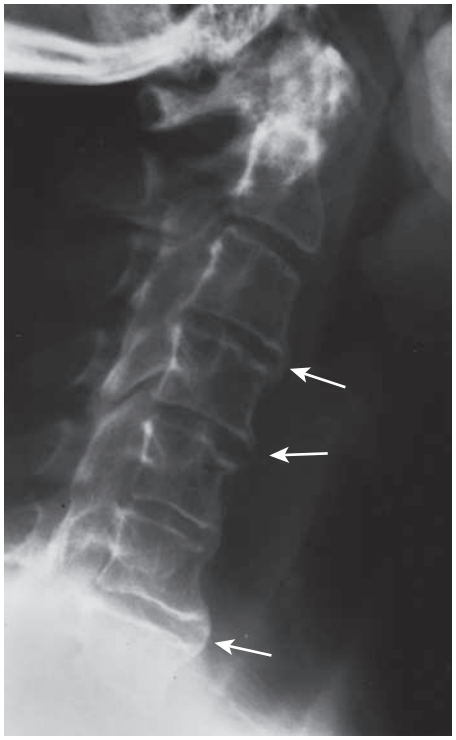

FIG. 83.5 Psoriatic arthritis. Lateral view of the cervical spine of a 45-year-old woman with psoriasis shows anterior syndesmophytes at levels C3–C4, C4–C5, and C6–C7 (*arrows*).

Reactive Arthritis

Reactive arthritis is associated with an infectious agent causing an aseptic inflammation in joints and other organs. This disorder has been associated with the triad of urethritis (inflammation of the lower urinary tract), arthritis, and conjunctivitis formerly referred to as *Reiter syndrome,* a form of reactive arthritis. Reactive arthritis is the most common cause of arthritis in young men and primarily affects the lower extremity joints and the low back. Involvement of the cervical spine is rare. The disease results from the interaction of an environmental factor, usually a specific infection, and a genetically predisposed host. Approximately 3% of patients with the common infection nongonococcal urethritis develop the syndrome. The syndrome develops in 0.2% to 15% of all patients with enteric infections secondary to *Shigella, Salmonella, Campylobacter,* and *Yersinia*. The male-to-female ratio in venereal infection is 10 : 1, and the ratio is 1 : 1 in large outbreaks secondary to enteric infection.

Reactive arthritis is associated with HLA-B27 in 60% to 80% of individuals. The classic patient with reactive arthritis is a young man about 25 years old who develops urethritis and a mild conjunctivitis, followed by the onset of a predominantly lower extremity oligoarthritis. The conjunctivitis is usually mild and is manifested by an erythema (redness) and crusting of the lids. Arthritis may occur 1 to 3 weeks after the initial infection. In many patients, arthritis is the only manifestation of disease.[40] Back pain is a frequent symptom of patients with reactive arthritis. During the acute course, 31% to 92% of patients may develop pain in the lumbosacral region. Occasionally, the pain radiates into the posterior thighs but rarely below the knees; it may be unilateral. Spondylitis affecting the lumbar, thoracic, and cervical spine occurs less commonly than sacroiliitis, with 23% of patients with severe disease showing such involvement.[41]

TABLE 83.3 Disease-Modifying and Biologic Antirheumatic Drugs

Drug	Availability (mg)	Dose (mg)	Toxicities	Comment
Disease Modifying				
Hydroxychloroquine	200	200–400	Retinopathy	Requires 6 mo to work
Sulfasalazine	500	1000–2000	Gastrointestinal, anemia	Sulfa allergy
Methotrexate	2.5, 5, 7.5	5–25	Hepatitis, anemia	Requires 6 wk to work
Azathioprine	50	50–300	Hepatitis, leukopenia	Requires 3 mo to work
Leflunomide	10, 20, 100	20	Diarrhea, alopecia	100 × 3 initially; onset at 4 wk
Biologics				
Etanercept	25, 50	50 (IM)	Injection pain, infections	Requires 6 wk to work
Adalimumab	40	40 every 1–2 wk (IM)	Injection pain, infections	Requires 6 wk to work
Infliximab	100	3–10 mg/kg 4–8 wk (IV)	Infusion reactions, infections	Best with methotrexate
Certolizumab	200	200 every 2 wk or 400 every 4 wk (IM)	Infections	Less injection pain
Golimumab	50	50 IM monthly, 50 IV monthly	Infections	Best with methotrexate
Tocilizumab	4, 8, 162 (SQ)	4 or 8 mg/kg IV or 162 mg IM every 2 wk	Infections	Monotherapy
Abatacept	500, 750, 1000 IV, 125 SQ	Depending on weight, every 4 wk or 125 SQ weekly	Infections	Not to be used with TNF inhibitors
Rituximab	500	1000 for 2 doses 2 wk apart, repeated at 6 mo	Infusion reaction	May be repeated
Anakinra	100	100, daily injection	Injection pain	Given same time every day
Toficitanib	5	5 twice daily	Infections, hyperlipidemia	With or without methotrexate

IM, intramuscular; IV, intravascular; SQ, subcutaneous; TNF, tumor necrosis factor.

Neck pain is a rare symptom of patients with reactive arthritis. Constitutional symptoms occur in about one-third of patients and include fever, anorexia, weight loss, and fatigue.

On examination, men tend to have involvement in the knees, ankles, and feet; women have more upper extremity disease. Percussion tenderness over the sacroiliac joints may be unilateral, correlating with asymmetrical involvement in reactive arthritis. The mobility of the lumbosacral and cervical spine should be measured in all planes of motion. Evaluation for enthesopathy, heel pain, or Achilles tendon tenderness is also required.

Sacroiliac involvement may mimic AS (symmetrical disease) or may be asymmetrical in severity of joint changes. Unilateral sacroiliac disease occurs early in the disease process. Variable amounts of sclerosis are associated with erosions. The progression of radiographic changes shows widening of the joint (erosion), then narrowing (fusion). Fusion of the joints occurs less frequently than in AS. Sacroiliitis may be detected in 5% to 10% of individuals early in the illness and in 60% in prolonged illness. Spondylitis is discontinuous in its involvement of the axial skeleton (skip lesions) and is characterized by nonmarginal bony bridging of vertebral bodies. These vertebral hyperostoses are markedly thickened compared with the thin syndesmophytes of AS. Cervical spine disease is associated with hyperostoses at the anteroinferior corners of one or more cervical vertebrae.

The joint and enthesopathic manifestations of reactive arthritis respond to NSAIDs. The drugs are continued as long as the patient remains symptomatic. Oral corticosteroids have some efficacy. The role of antibiotic therapy in the acute phase of reactive arthritis is controversial. Antibiotics may be ineffective for *Chlamydia*-associated reactive arthritis.[41] Sulfasalazine has been reported to improve spinal pain and swollen joints in patients with reactive arthritis. The usual dose of sulfasalazine is 2 g/day in divided doses. The immunosuppressive methotrexate is reserved for patients with uncontrolled progression of joint disease and unresponsive, extensive skin involvement. The dose of methotrexate ranges from 7.5 to 25 mg/week. The role of anti-TNF drugs remains controversial in an illness that is associated with infection as its initiating factor.[41]

The course of the illness is unpredictable. A self-limited illness, lasting 3 months to 1 year, occurs in 30% to 40% of patients. Another 30% to 50% develop a relapsing pattern of illness with periods of complete remission. The final 10% to 25% develop chronic, unremitting disease associated with significant disability.

Enteropathic Arthritis

Ulcerative colitis and Crohn disease are inflammatory bowel diseases. Ulcerative colitis is limited to the colon; Crohn disease, or regional enteritis, may involve any part of the gastrointestinal tract.[42] Inflammation of the gut results in numerous gastrointestinal symptoms, including abdominal pain, fever, and weight loss. These inflammatory diseases are also associated with extraintestinal manifestations, including arthritis. Articular involvement in inflammatory bowel disease includes peripheral and axial skeleton joints. Peripheral arthritis is generally nondeforming and follows the activity of the underlying bowel disease.[43] Axial skeleton disease is similar to AS and follows a course independent of activity of bowel inflammation.

Symptomatic ulcerative colitis usually occurs in adults 25 to 45 years old. Crohn disease occurs in all races and is distributed worldwide. In the United States, the annual incidence of the disease is 4 per 100,000. The disease occurs most often in individuals 15 to 35 years old. The frequency of peripheral arthritis is 11% in ulcerative colitis and 20% in Crohn disease. Spondylitis occurs in 3% to 4% of both diseases, and radiographic sacroiliitis occurs in 10%. Axial arthritis of inflammatory bowel disease may be a hereditary accompaniment of the disease and not a manifestation of activity of bowel disease itself. Non–HLA-related factors and HLA-B27 may play a role.

Early symptoms of ulcerative colitis are frequent bowel movements with blood or mucus. Mild disease is associated with some abdominal pain and a few bowel movements per day. Severe disease is characterized by fatigue, weight loss, fever, and extracolonic involvement. Crohn disease is frequently an indolent illness characterized by generalized fatigue, mild nonbloody diarrhea, anorexia, weight loss, and cramping lower abdominal pain. Patients may have symptoms for years before the diagnosis is made.

Articular involvement in inflammatory bowel disease is divided into two forms: peripheral and spondylitic. Axial skeleton involvement in ulcerative colitis and Crohn disease is similar. Spondylitis antedates bowel disease in about one-third of patients. This interval may be 10 to 20 years. Of patients, 70% are HLA-B27 positive, 68% have radiographic changes of spondylitis, and 25% have iritis. The spondylitis of inflammatory bowel disease has a course totally independent of the course of the bowel disease. The clinical and radiographic findings are similar to findings of AS, including involvement of shoulders and hips.

On examination, patients with spondyloarthropathy may have decreased motion of the spine in all planes and percussion tenderness over the sacroiliac joints. Rarely, chest expansion is diminished. Patients with more extensive disease have limitation of motion of the cervical spine. Occiput-to-wall measurements document the immobility of the entire axial skeleton, including the cervical spine.

The radiographic changes of spondylitis in inflammatory bowel disease are indistinguishable from classic AS (Fig. 83.6). Findings include squaring of vertebral bodies; erosions; widening and fusion of the sacroiliac joints; symmetrical involvement of sacroiliac joints; and marginal syndesmophytes involving the lumbar, thoracic, or cervical spine.

The factors that help make the diagnosis of enteropathic spondyloarthropathy are the pattern of peripheral arthritis if present (upper extremity disease is uncommon in AS and reactive arthritis; bilateral ankle arthritis is uncommon in psoriatic disease), erythema nodosum, and iritis. Therapy for enteropathic spondylitis is similar to therapy for classic AS. TNF-α inhibitors are effective agents for bowel and articular disease.[44]

The ultimate course and outcome of these patients depend on the severity of bowel disease. Patients with severe ulcerative

FIG. 83.6 Enteropathic spondylitis: a lateral view of the lumbar spine demonstrates loss of lumbar lordosis, fusion of the facet joints (*white arrows*), and early syndesmophyte formation (*black arrow*) in a 25-year-old woman with a 9-year history of Crohn disease. (From Borenstein DG, Weisel SW, Boden SD. *Low Back and Neck Pain: Comprehensive Diagnosis and Management*. 3rd ed. Philadelphia: Saunders; 2004.)

FIG. 83.7 Diffuse idiopathic skeletal hyperostosis. Lateral view of the cervical spine shows large anterior, horizontally oriented osteophytes characteristic of this illness.

colitis have a mortality rate of 10% to 20% over 5 years. Patients with a severe initial attack, continuous clinical activity, involvement of the entire colon, and disease for 10 years or longer have a higher risk of developing cancer of the colon. These patients may require colectomy. Although Crohn disease is associated with frequent recurrences, the overall mortality rate of 5% for the first 5 years of disease is much less than in ulcerative colitis.

Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is another disease that may occur in the setting of spondylitis. Patients with AS and DISH should be easily differentiated by careful radiographic evaluation.[45] DISH may cause alterations of the sacroiliac joints.[46] CT of the sacroiliac joints differentiates the hyperostotic joint changes from changes associated with joint erosion and fusion (Fig. 83.7). Also of note is the occurrence of fracture in patients with DISH and patients with AS. The convergence of two common diseases in the same host, a middle-aged man, is likely. The occurrence of AS and DISH of the cervical spine has been reported.[47]

Treatment

The goals of therapy for AS, as with other forms of inflammatory arthritis, are to control pain and stiffness, reduce inflammation, maintain function, and prevent deformity with avoidance of undue toxicity. Patients require a comprehensive program of education, physiotherapy, medications, and other measures. In 2015, the American College of Rheumatology (ACR) published recommendations for the treatment of AS.[48] The publication lists nonpharmacologic and pharmacologic therapies and the strength of evidence for the recommendations. Nonpharmacologic recommendations include land-based active physical therapy interventions. Use of braces, splints, and corsets should be avoided.

Nonsteroidal Antiinflammatory Drugs

Medications to control pain and inflammation are useful to patients with AS. NSAIDs possess antipyretic, analgesic, and antiinflammatory characteristics. They are antiinflammatory and analgesic when given long term in larger doses. NSAIDs are effective at decreasing pain and improving movement but have not been proven to slow the progression of disease.

Cyclooxygenase-2 inhibitors are another class of NSAIDs with less gastrointestinal toxicity. These drugs should be used continuously in AS patients with high activity of disease.

Muscle Relaxants

Patients with acute AS may develop severe muscle spasm with associated limited motion that may hinder their return to normal daily activities. In these patients, the addition of muscle relaxant to NSAIDs helps decrease muscle pain

and muscle spasm and improve back motion. Muscle relaxants, such as cyclobenzaprine, at low dosages (5–10 mg/day) are helpful while limiting possible drug toxicity. The sleepiness associated with muscle relaxants with long half-lives can be limited by giving the medication 2 hours before bedtime.

Corticosteroids

Systemic corticosteroids are rarely needed and are ineffective for the spinal articular disease of AS. The ACR publication recommends against the use of systemic steroids.[48]

Anti–Tumor Necrosis Factor-α Inhibitors

TNF-α, an inflammatory cytokine, is associated with the inflammatory process that results in the phenotypic expression of AS. Anti–TNF-α therapies are available in the form of infliximab, etanercept, certolizumab, golimumab, and adalimumab, which inhibit the inflammatory effects of TNF-α.[49] Table 83.3 contains information about these biologic drugs and their use in rheumatic disease, including AS. Studies have demonstrated the greater efficacy of each of these agents in comparison to placebo in the treatment of AS patients.[49]

The full benefits of anti–TNF-α therapy in AS remain to be determined. The efficacy of these agents in disease of long duration is less certain. These agents are expensive and their availability is limited. Toxicities are associated with their use, including the activation of latent tuberculosis. Questions remain in regard to the potency of TNF drugs to inhibit calcification of the spine in active disease. Also, the ability of these agents to produce a remission and the opportunity to discontinue treatment remains an active area of research.

Prognosis

The general course of AS is benign and is characterized by exacerbations and remissions. Many patients with AS may have sacroiliitis with mild involvement of the lumbosacral spine alone. Limitation of lumbosacral motion may be mild. The disease can become quiescent at any time. Patients who go on to develop total fusion of the spine may feel better because ankylosis of the spinal joints is associated with decreased pain. In a study of 1492 patients for 2 years, the frequency of patients with a total remission of disease was less than 2%.[50]

Rheumatoid Arthritis

RA is a chronic, systemic inflammatory disease that causes pain, heat, swelling, and destruction in synovial joints. The joints characteristically affected by RA are small joints of the hands and feet, wrists, elbows, hips, knees, ankles, and cervical spine. Most patients with RA have cervical spine disease manifested as neck pain, headaches, or arm numbness. Signs of cervical spine disease include decreased neck motion with stiffness; undue prominence of the spinous process of the axis (C2); and neurologic dysfunction, including paresthesias, spasticity, incontinence, and quadriplegia. The diagnosis of RA is made in the setting of a history of persistent joint inflammation in the appropriate joints and the presence of specific serum antibodies (rheumatoid factor). The degree of cervical spine destruction in RA does not always correlate with patient complaints and is detected by radiographic evaluation. RA of the cervical spine responds to the same therapy that is effective for the peripheral joints. Surgical intervention with stabilization of the cervical spine is required for persistent neurologic abnormalities.

Epidemiology

The prevalence of RA is 1% of the US population.[51] RA is found in all racial and ethnic groups. The condition occurs in all age groups but is most common in adults 40 to 70 years old.[52] The male-to-female ratio is approximately 1:3. Symptoms of cervical spine disease occur in 40% to 80% of RA patients. Radiographic evidence of cervical spine involvement is found in 86% of RA patients, whereas neurologic symptoms from cervical spine disease occur less frequently in 10% of patients with radiographic changes. Cervical spine disease usually occurs in the setting of active peripheral disease; however, occasionally, neck symptoms may be the initial or predominant symptom without clinical signs of RA in other locations. The lumbar spine is rarely involved in the rheumatoid process. One study suggested that 5% of men and 3% of women with RA have lumbar spine involvement.[53]

Pathogenesis

RA is a chronic immune-mediated disease whose initiation and perpetuation are dependent on T-lymphocyte response to unknown antigens.[54] The interaction of genetic factors, the shared epitope in the HLA-DRB1 region, with environmental factors, such as smoking, periodontitis, and the gut microbiome, increase the risk for disease. Increased numbers of $CD4^+$ lymphocytes that activate B lymphocytes to produce immunoglobulin are frequently found in synovium from RA patients. The activation of macrophages results in the production of monokines, including TNF-α, interleukins, and intracellular signaling and transcription factors. These factors attract additional lymphocytes and neutrophils. Angiogenesis factors result in the growth of new capillaries. Synovial cells cause tissue destruction by release of activated metalloproteinases, including procollagenase and progelatinase. The inflammatory response is also enhanced by the production of arachidonic acid metabolites.

Clinical History

Patients with RA develop joint pain, heat, swelling, and tenderness. The joint involvement is additive and symmetrical. The joints at greatest risk of being affected by the disease process include the proximal interphalangeal, metacarpocarpal, wrist, elbow, hip, knee, ankle, and metatarsophalangeal joints. In the

axial skeleton, the cervical spine is most frequently affected. Patients have joint pain and stiffness, which are most severe in the morning. Activity improves symptoms. The phenomenon of stiffness of a joint with rest occurs frequently with active disease. As a component of systemic inflammation, afternoon fatigue, anorexia, and weight loss are common complaints.

Neck movement frequently precipitates or aggravates neck pain that is aching and deep in quality. Atlantoaxial disease is experienced in the upper part of the cervical spine; pain radiates over the occiput into the temporal and frontal regions with increasing disease of the C1–C2 joint. Occipital headaches are frequently associated with active rheumatoid involvement of the cervical spine. Other symptoms of C1–C2 subluxation include a sensation of the head falling forward with flexion of the neck, loss of consciousness or syncope, incontinence, dysphagia, vertigo, convulsions, hemiplegia, dysarthria, nystagmus, or peripheral paresthesias.[55] Peripheral joint erosion is a harbinger of C1–C2 subluxation. Development of cervical subluxation occurs in patients who have joint erosions of hands and feet, serum rheumatoid factor, and subcutaneous nodules.

Pain associated with RA in the subaxial segments of the cervical spine is located in the lateral aspects of the neck and clavicles (C3–C4) and over the shoulders (C5–C6). Neurologic symptoms include paresthesias and numbness. Paresthesias have a burning quality that may be attributed to an entrapment neuropathy (carpal tunnel syndrome) but is sufficiently different not to be confused with joint pain. Patients with sensory symptoms alone may have their symptoms ascribed to arthritis, delaying the diagnosis of cervical myelopathy.[56]

The appearance of spasticity, gait disturbance, muscular weakness, and incontinence (urinary or rectal) indicates significant compression of the spinal cord. Symptoms suggesting vertebrobasilar artery insufficiency include visual disturbances, dizziness, paresthesias of the face, ataxia, and dysarthria.

Cervical Subluxation

In the cervical spine, the structures lined with synovial membrane may be involved in RA. These structures include the atlantoaxial joint. This joint connects the atlas (C1) with the axis (C2) and is responsible for rotation of the skull on the cervical spine. Synovial tissue is located between the atlas and axis and between the ligaments and atlas. Other synovial joints include the zygapophyseal and uncovertebral joints.

RA causes disease in the cervical spine by causing chronic inflammatory changes to occur in the atlanto-occipital, atlantoaxial, zygapophyseal, and uncovertebral joints along with the discs and ligamentous and bursal structures. At the level of the atlantoaxial joint, synovial inflammation of the bursae and ligaments results in laxity of the transverse ligament that holds the atlas and axis together. Normally, the distance between the bones does not exceed 2.5 to 3 mm in adults. The relaxation of supporting ligaments results in excess motion of the axis in relation to the atlas-atlantoaxial subluxation.

Luxation of the atlantoaxial joint may occur anteriorly, posteriorly, superiorly or vertically, or laterally. Anterior subluxation is the most common form and results from insufficiency of the transverse ligament or fracture of the odontoid and occurs in 49% of patients.[57] Posterior subluxation occurs when C1 moves posteriorly on C2 and results from erosion or fracture of the odontoid; this occurs in 7% of patients. Vertical or superior subluxation results from destruction of the lateral atlantoaxial joints around the foramen magnum and is found in 38% of patients. Lateral subluxation occurs in 20%, with erosion of the lateral mass and odontoid. Abnormal motion of this joint in any direction may result in compression of the cervical spinal cord or medulla oblongata, resulting in the development of neurologic symptoms and signs of myelopathy, including paresthesias, muscle weakness, reflex changes, spasticity, and incontinence. Subluxation of the atlantoaxial joint by the odontoid process of the axis and the posterior arch of the atlas may compress the vertebral arteries. The vertebral arteries are compressed as they travel through the foramina in the transverse processes of C1 and C2. Vertebral artery compression may cause tetraplegia, coma, or sudden death.[56]

Subluxation may occur between cervical vertebrae below the atlantoaxial joint. Common levels include C3–C4 and C4–C5. Inflammation in the zygapophyseal joints and surrounding bursae undermines the stability of these joints, resulting in excessive motion and angulation of the cervical spine.[58] Intervertebral discs may be invaded by growing synovial tissue, resulting in disc space narrowing. The reported frequency of subaxial subluxation ranges from 7% to 29% of RA patients.[59]

Myelopathy may also occur in patients without atlantoaxial or cervical spine subluxation. The 10-year incidence of RA-associated cervical myelopathy in Olmsted County, Minnesota, was 0.7%.[60] In these patients, synovitis from the zygapophyseal joints along with intervertebral disc lesions may compromise the blood supply to the spinal cord through stenosis of vertebral vessels that feed the anterior spinal artery. Ischemic myelopathy is the result. Sudden death may also be a consequence of thrombosis of vertebral vessels.[61]

Physical Examination

Physical examination of a patient with RA with cervical spine disease reveals diffuse peripheral joint involvement characterized by heat, swelling, bogginess, tenderness, and loss of motion. Nodules over the extensor surfaces are noted in 20% of RA patients. Examination of the cervical spine may show tenderness with palpation over the bony skeleton and limitation of all spinal movements. Inspection may show fixation of the head tilted down and to one side. This lateral tilt is caused by the asymmetrical destruction of the lateral atlantoaxial joints. Normal cervical lordosis may also be absent. With the neck flexed, the spinous process of the axis may be prominent in the midline of the neck of a patient with atlantoaxial subluxation. Patients with subaxial subluxation may show abnormalities in the upper extremities. Compression of C6–C8 segments causes distinctive numb, clumsy hands and tactile agnosia.[62] Neurologic abnormalities are seen in approximately 7% of RA patients.

Laboratory Data

Abnormal laboratory findings include anemia, elevated erythrocyte sedimentation rate, and increases in serum globulin levels. Thrombocytosis is found in patients with active RA. Rheumatoid factors (antibodies directed against host antibodies) are present in up to 80% of patients with RA. Citrullination alters arginine and occurs in inflammatory environments, such as the gingiva and the lung.[63] Measurement of antibodies directed against cyclic citrullinated protein has specificity for RA in the range of 95%.[64] Antinuclear antibodies are present in 30% of RA patients. C-reactive protein, an acute-phase reactant, may be helpful when obtained in a serial manner to predict individuals who are at increased risk for joint deterioration and as a measure of response to therapy. Individuals with persistent elevations in C-reactive protein are at risk of progressive cervical spine subluxations.[65] Synovial fluid analysis shows inflammatory fluid characterized by poor viscosity, increased numbers of white blood cells, decreased glucose level, and increased protein level.

Radiographic Evaluation

Characteristic radiographic changes of RA in peripheral joints include soft tissue swelling, bony erosion without reactive sclerotic bone, joint space narrowing, and periarticular osteopenia. Radiographic evaluation of the cervical spine includes anteroposterior, lateral with flexion and extension, oblique, and open-mouth frontal projections.

The radiographic criteria for the diagnosis of RA cervical spine disease as proposed by Bland and colleagues[66] are (1) atlantoaxial subluxation of 2.5 mm or more; (2) multiple subluxation of C2–C3, C3–C4, C4–C5, and C5–C6; (3) narrow disc spaces with little or no osteophytosis; (4) erosion of vertebrae, especially vertebral plates; (5) odontoid, small, pointed, eroded loss of cortex; (6) basilar impression; (7) apophyseal joint erosion and blurred facets; (8) cervical spine osteoporosis; (9) wide space (>5 mm) between posterior arch of the atlas and spinous process of the axis (flexion to extension); and (10) secondary osteosclerosis of the atlantoaxial-occipital complex, which may indicate local degenerative change. The normal distance between the odontoid and atlas is 2.5 mm in women and 3 mm in men as measured from the posteroinferior aspect of the tubercle of C1 to the nearest point on the odontoid (Fig. 83.8).[67] The posterior atlanto-odontoid interval is the remaining distance between the posterior surface of the odontoid process and the anterior edge of the posterior ring of the atlas. RA patients with a posterior interval of more than 14 mm did not have neurologic deficits. Posterior subluxation may also occur if the atlas "jumps" over the axis, resting in a dorsal position resulting in posterior subluxation. Vertebrobasilar artery insufficiency associated with neurologic dysfunction is a manifestation of this form of subluxation.

Upward translocation occurs when the bony and ligamentous integrity of the atlanto-occipital articulations is disrupted. Disease of the occipital condyles, lateral masses of the atlas, and lateral articulations of the axis results in bony erosions or collapse. Erosion of the lateral apophyseal joints allows for a rotational head tilt. The open-mouth view may show narrowing of the atlanto-occipital and atlantoaxial joints and erosion of the odontoid. Subluxation occurs when the lateral masses of the atlas are displaced more than 2 mm with respect to masses of the axis. Bony erosion is the most important factor in the development of severe lateral subluxation.

FIG. 83.8 Rheumatoid arthritis. Lateral view of the cervical spine in a 56-year-old woman with more than 20 years of disease. She developed increasing neck pain and dysesthesias in the arms. She had significant dynamic subluxations. C1–C2 spinous processes were wired together; she has had resolution of her symptoms for the subsequent 5 years. (Reproduced with permission from Borenstein DG, Weisel SW, Boden SD. *Low Back and Neck Pain: Comprehensive Diagnosis and Management*. 3rd ed. Philadelphia: Saunders; 2004.)

In addition to changes in the upper cervical spine, radiographic abnormalities—including subaxial subluxation, apophyseal joint narrowing, and disc space narrowing—occur in the lower cervical spine. Subaxial subluxation is present in instances of malalignment of more than 3.5 mm. The stability of flexion and extension of the lower cervical spine depends on the integrity of the anterior and posterior longitudinal ligaments. Greater than 3.5 mm of malalignment is indicative of a mechanically unstable spine. Multiple subluxations may occur, producing a "staircase" appearance on lateral radiographs. Anterior subluxation is more frequent than posterior subluxation. Subaxial subluxation is most notable on a lateral flexion view of the cervical spine (Fig. 83.9). Apophyseal joint disease includes narrowing, erosions, and sclerosis. Disc destruction in the cervical spine is associated with disc space narrowing and is caused by extension of erosive disease from uncovertebral joints or by ongoing trauma to vertebral endplates secondary to instability. The final stage of apophyseal disease is fibrous ankylosis of one or more levels, which may rarely simulate the appearance of AS.

FIG. 83.9 Rheumatoid arthritis. Lateral view of the flexed cervical spine of a 45-year-old woman with 15 years of disease. She has neck and shoulder pain. The neck has anterior subluxation at C3–C4 (*arrow*). Cervical lordosis is reversed.

CT is a useful imaging technique for detecting the extent of bony destruction of structures that may not be easily visualized with plain radiographs. CT detects the position of an eroded odontoid process that may not be seen on open-mouth view radiographs.

MRI is a noninvasive method that is useful in detecting soft tissue abnormalities in the cervical spine of RA patients. It is able to detect pannus around the odontoid and alterations in the substance of the spinal cord. MRI may also be useful in documenting the response of pannus to therapy or the status of the spinal cord in the postoperative state. Compared with CT and plain radiographs, MRI with plain radiographs shows lytic lesions and odontoid erosions and vertical atlantoaxial subluxations more often, shows anterior subluxations as often, and shows lateral subluxations less often.[68]

Differential Diagnosis

RA is a clinical diagnosis based on history of joint pain, distribution of joint involvement, and characteristic laboratory abnormalities (rheumatoid factor). New classification criteria for RA were published by the ACR in partnership with the EULAR in 2010 (Table 83.4).[69] The focus of the new criteria is to identify individuals with earlier stages of disease. In the setting of generalized active disease, the finding of neck pain associated with multiple abnormalities—including atlantoaxial subluxation, apophyseal joint erosion without sclerosis, disc space narrowing without osteophytes, and multiple subluxations—is most appropriately attributed to RA. The cervical spine abnormalities of AS, psoriatic arthritis, reactive arthritis, enteropathic arthritis, osteoarthritis, and DISH are associated with new bone formation or ligamentous calcification that differentiate them from RA. Occasionally, atlantoaxial subluxation may occur alone in the setting of little peripheral disease. In those circumstances, other disease processes that may cause subluxation include AS, psoriatic arthritis, reactive arthritis, trauma, or local infection.

TABLE 83.4 American College of Rheumatology/European League Against Rheumatism Classification Criteria for RA

Criteria	Score
A. Joint Involvement	
1 large joint	0
2–10 large joints	1
1–3 small joints (with or without large joints)	2
4–10 small joints (with or without large joints)	3
>10 joints (at least 1 small joint)	5
B. Serology (At Least 1 Test Result Is Needed for Classification)	
Negative RF and negative ACPA	0
Low-positive RF or low-positive ACPA	2
High-positive RF or high-positive ACPA	3
C. Acute-Phase Reactants (At Least 1 Test Result for Classification)	
Normal CRP and normal ESR	0
Abnormal CRP or abnormal ESR	1
D. Duration of Symptoms	
<6 wk	0
>6 wk	1
TOTAL (score of ≥6/10 = definite RA diagnosis)	

ACPA, anti-citrullinated protein antibody; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RA, rheumatoid arthritis; RF rheumatoid factor.
From Aletaha D, Neogi T, Silman AJ et al. 2010 Rheumatoid Arthritis classification criteria: an American College of Rheumatology/European League Against Rheumatism collaborative initiative. *Arthritis Rheum*. 2010;62:2569-2581.

Treatment

The treatment of RA has undergone a paradigm shift with the advent of new drug therapies directed at control of the factors that mediate the immunologic destruction of joints. The ACR has reviewed all the available therapies and has proposed new options for the treatment of RA.[69,70] These new guidelines include data supporting the use of biologic agents in the therapy for RA.

Nonsteroidal Antiinflammatory Drugs

NSAIDs are medications that control pain and inflammation and are useful in patients with RA for symptomatic relief. However, NSAIDs do not prevent joint destruction and should be discontinued when disease activity is controlled with other forms of drug therapy.

Disease-Modifying Antirheumatic Drugs

Patients who have joint inflammation or damage (joint space narrowing, bony erosions, or cysts) are candidates for remittive therapy. Remittive agents have a delayed onset of action compared with NSAIDs. Table 83.3 lists DMARDs used for

the treatment of RA. Methotrexate at doses of 7.5 to 25 mg/week is effective in decreasing the inflammation of RA and may slow disease progression. Methotrexate may be given all at once during the week. It is effective over a long duration of therapy.

Leflunomide is an oral pyrimidine inhibitor used to treat RA.[71] The dose is 100 mg for 3 days, then 20 mg or 10 mg daily as tolerated. Toxicities include abnormal liver function tests and diarrhea. Leflunomide and methotrexate can be used together. Patients taking this combination need to be monitored closely for potential hepatotoxicity.[52]

Systemic corticosteroids are effective in controlling the inflammatory components of RA. Corticosteroids are the most powerful and predictable remedy, inducing immediate relief of joint inflammation in RA. Corticosteroids at low doses (5–10 mg) have a modest effect on reducing the rate of radiologically detected joint destruction. A prospective trial showed disease-modifying properties of 10 mg of prednisone over a 2-year period.[72] Corticosteroids are also associated with a wide range of toxicities, from hypertension and diabetes to cataracts and obesity.

Biologic Therapies, Including Anti–Tumor Necrosis Factor-α Inhibitors

A variety of biologic therapies are available for the treatment of RA (see Table 83.3).[70] No category of biologic therapy is clearly superior in efficacy compared to another. The decision to use one agent as opposed to another involves a number of issues, including the preferred method of administration (oral, injection, or infusion).

TNF therapies are efficacious in decreasing inflammatory signs and slowing joint damage. TNF drugs indicated for the therapy for RA include infliximab, etanercept, adalimumab, certolizumab, and golimumab. Infliximab is partly humanized mouse monoclonal antibody directed against TNF-α. It is administered intravenously. Infliximab is added to methotrexate to limit the production of neutralizing antibodies to the mouse component of the agent. In a 30-week trial, combined infliximab and methotrexate was more effective than methotrexate alone in patients with active RA.[73] In a 54-week study, infliximab, 3 mg/kg or 10 mg/kg, and a stable dose of methotrexate prevented radiographic progression to a greater degree than methotrexate alone.[74]

Etanercept is a recombinant form of the p75 TNF receptor fusion protein. Etanercept 25 mg is administered by subcutaneous injection twice weekly or 50 mg once a week. Etanercept is more effective than placebo in limiting joint activity in RA.[75] It is also effective and safe when added to methotrexate.[76] This drug is also effective over a 12-month period.[77]

Adalimumab is a fully human monoclonal TNF-α antibody given by subcutaneous injection every 2 weeks at a dose of 40 mg. This anti–TNF-α factor is effective with methotrexate in decreasing joint activity.[78]

Certolizumab pegol is a recombinant, humanized Fc-free, polyethylene glycol anti-TNF monoclonal antibody. Certolizumab 200 mg every 2 weeks or 400 mg every 4 weeks is administered by subcutaneous injection. Certolizumab with methotrexate is more effective than methotrexate and placebo in limiting joint destruction in active RA.[79]

Golimumab is a fully humanized monoclonal antibody to anti-TNF. Golimumab is administered 50 mg subcutaneously monthly or 2 mg/kg infused every 8 weeks. Golimumab plus methotrexate decreases signs and symptoms of RA to a greater degree than methotrexate alone.[80]

The concern with anti–TNF-α therapies are the toxicities. Blocking TNF-α increases the risk for serious infection. TNF-α helps to maintain containment of organisms in granulomas. Inhibition of TNF-α has been associated with the reactivation of tuberculosis.[81,82]

Other biologic therapies include inhibitors of interleukins, inhibitors of cellular stimulation, cell-directed therapies, and intracellular signal inhibitors. These therapies affect different components of the immune process that result in joint damage in RA.

Anakinra is a recombinant, nonglycosylated form of human IL-1 receptor antagonist. This agent works by competitively inhibiting IL-1 from binding to its receptor site. Anakinra 100 mg is given as a daily subcutaneous injection. It has been shown to be an effective agent in combination with methotrexate in the improvement of RA.[83]

Tocilizumab is a recombinant, fully humanized monoclonal antibody against IL-6 receptor, inhibiting IL-6 functioning. Tocilizumab is administered by infusion at a dose between 4 mg/kg to 8 mg/kg on a 4-week basis. Tocilizumab plus methotrexate inhibits joint damage to a greater degree than methotrexate alone.[84]

Abatacept is a soluble fusion protein composed of the extracellular domain of human cytotoxic T lymphocyte antigen 4 and a fragment of the Fc portion of human immunoglobulin G1. Abatacept is a selective costimulation modulator that functions to inhibit T-cell activation by preventing binding of CD86 to CD28 on the surface of T lymphocytes. Abatacept is administered as 10 mg/kg intravenously on a 4-week basis or 125 mg subcutaneously on a weekly basis. Abatacept plus methotrexate is more effective than methotrexate alone in decreasing disease symptoms and joint destruction that can be sustained.[85]

Rituximab is a genetically engineered, chimeric monoclonal antibody directed against the CD20 transmembrane protein on B cells, resulting in subsequent cell death and depletion of B cells. Rituximab is administered intravenously at a dose of 1000 mg separated by 15 days repeated at 6-month intervals. Rituximab is effective in controlling RA in patients who have failed TNF therapy.[86]

Tofacitinib is a small-molecule chemical inhibitor of Janus kinase 3, which is an activator of transcription molecules that upregulates immune function. Tofacitinib is an oral agent given as a 5-mg dose twice daily. Tofacitinib is effective in controlling active RA in comparison to placebo.[87]

Immunosuppressive Agents

Immunosuppressive agents are associated with severe toxicities (aplastic anemia and cancer), which limits their benefit to severely affected patients. Only a few patients with RA require

this therapy. Immunosuppressive agents used in RA include azathioprine, cyclophosphamide, and cyclosporine. A combination of cyclosporine and methotrexate may be effective for therapy of patients with severe disease.

Cervical Spine Therapy

Conservative treatment of RA of the cervical spine is supportive. Early aggressive medical management is important to prevent joint destruction. Early DMARD therapy results in better outcomes. Combination therapy used early in the course of RA can limit the development of atlantoaxial and vertical subluxations. Sulfasalazine, methotrexate, hydroxychloroquine, and prednisolone were more effective than a single DMARD with prednisolone in preventing cervical subluxation.[88] Soft cervical collars offer comfort but do not protect against progressive subluxations. Rigid collars can limit anterior subluxations but do not allow reduction of the subluxations in extension. They are poorly tolerated by RA patients with temporomandibular disease.[89]

Prognosis

The course of RA cannot be predicted at time of onset. Some patients develop sustained disease that is associated with joint destruction and resistance to therapy. Patients who are older with seropositive generalized disease with nodules are at greater risk of developing cervical spine disease. Not all patients develop subluxation. In a 5- to 14-year follow-up study, 25% of patients had an increase in subluxation, 50% had no change, and 25% had improvement. In a 5-year study of 106 RA patients, the prevalence of cervical spine subluxation increased from 43% to 70%. In subaxial disease, myelopathy was associated with narrowing of the canal, destruction of spinous processes, axial shortening, younger age of patient, longer duration of disease, higher dose of corticosteroids, and higher stage of disease. Sudden death remains a complication of RA cervical spine disease, particularly in patients with vertical subluxation. Individuals with subluxations had eight times the mortality as RA patients without subluxations.[90] In those RA patients who do develop neurologic deficits with cervical spine disease, surgical repair to relieve nerve compression and spinal stability is appropriate.[91]

PEARLS

1. Most HLA-B27–positive individuals (98%) do not have an inflammatory arthropathy of the spine.
2. Enthesopathy is a frequent mechanism of axial and peripheral arthritis in spondyloarthropathies.
3. Plain radiographs are the preferred imaging technique for identification of sacroiliitis.
4. New biologic therapies for treatment of RA and spondyloarthropathies may offer an opportunity to control inflammation before skeletal damage occurs in individuals who fail disease-modifying drug therapy.
5. AS and enteropathic arthritis share common clinical findings that differ from findings associated with reactive arthritis and psoriatic arthritis.

PITFALLS

1. Patients with spondyloarthropathy may have significant axial disease without pain.
2. A minimal amount of trauma can cause devastating fracture in a patient with a fused spine.
3. Atlantoaxial subluxation may occur without significant degrees of peripheral disease in RA.
4. Inflammatory arthropathies of the axial skeleton are chronic illnesses that do not have a cure.
5. A patient with stable AS of long duration may develop spondylodiscitis with spinal instability that is difficult to treat.

KEY POINTS

1. Inflammatory spinal arthritis is an important, relatively common form of specific low back and neck pain.
2. Most patients with inflammatory spinal arthritis may be identified based on historical and physical examination findings along with plain radiographs.
3. New biologic therapies directed at specific cytokines can control the signs and symptoms of inflammatory arthritis and may slow progression of the disease.

84 CHAPTER Surgical Management of Rheumatoid Arthritis

Shari Cui
Scott D. Daffner
Sanford E. Emery

Rheumatoid arthritis (RA) is a chronic, progressive, systemic disease with widespread involvement of connective tissues, primarily synovial joints. Females are affected two to three times more often than males, with the majority of cases presenting in the fourth or fifth decades. Improvements in medical management have correlated with a decrease in hospitalizations for severe rheumatoid disease over the years.[1] The effect of biologic medications and other disease-modifying antirheumatic drugs (DMARDs) on the incidence of cervical spine surgery, however, varies in literature, with some studies showing decreased incidence and others no significant change.[2,3] The cervical spine is involved in 25% to 90% of patients with RA, making it the most commonly affected site after the metatarsophalangeal and metacarpophalangeal joints.[4,5] In contrast to RA of the thoracic and lumbar spine, cervical spine involvement carries significant risks of spinal cord, medullary, and vertebral artery compromise, which can lead to sudden death.[6–8]

Patients with cervical instability may be asymptomatic or present with pain and/or neurologic complaints. Neva et al. attempted to define the prevalence of cervical subluxation in this population.[9] They evaluated 154 Finnish patients with RA who were awaiting an orthopaedic procedure and found that 44% of patients had radiographic evidence of cervical subluxation or prior surgical fusion. Excluding patients with fusions, 69% of the patients with radiographic subluxation reported neck pain compared to 65% of patients without subluxation. Rates of occipital, temporal, retro-orbital, and upper extremity radicular pain were similar, with or without cervical instability. Nazarinia et al. studied 100 asymptomatic rheumatoid patients and found cervical subluxation in 17% on dynamic radiographs.[10] The only meaningful correlation found was with elevated C-reactive protein (CRP). Unfortunately, a large proportion of patients with significant cervical involvement may be overlooked by the treating physician due to the lack of clear findings on physical examination. The physician must therefore be cognizant of the natural history, pathophysiology, clinical presentation, radiologic findings, and treatment options to avoid potentially significant consequences of rheumatoid disease of the cervical spine.

Historical Perspective

There is some evidence that RA was described in the 17th and 18th centuries.[11,12] However, a more concrete description was reported around 1800 by Landré-Beauvais, a French medical student, in his doctoral thesis.[13] Rheumatoid involvement of the cervical spine was described much later (in 1890) by A. E. Garrod.[14]

Reports on cervical instability increased in the 1950s and 1960s[15–18] and articles on its surgical treatment followed in the 1960s and 1970s.[19–23] For the most part, C1–C2 fusion with Gallie-type[24] wiring and graft techniques were utilized early on and later modified by Brooks,[25] Wertheim and Bohlman,[26] and Clark et al.[27] Other types of C1–C2 fixation emerged with the use of the Halifax interlaminar clamp,[28] Magerl transarticular screw,[29–34] and posterior C1 lateral mass–C2 pedicle screw fixation.[35]

Occipitocervical procedures were originally described by Foerster in 1927[36] and modified to include iliac crest bone graft by Kahn and Yglesias in 1935.[37] The addition of wiring by Hamblen in 1967 was described in four rheumatoid patients.[21] Brattström and Granholm modified the wiring technique for occipitocervical fusion by adding methylmethacrylate in a 1976 report.[19] Evolution of techniques continued in the 1980s with the emergence of the looped rod with iliac crest bone graft as described by Ransford et al.[38] and Flint et al[39] and later by occipitocervical plating, described by Grob et al.[29,40] and Smith et al.[41] Current use of plate or rod fixation extends to the subaxial spine, especially with fixation of the lateral masses as described by Magerl and Roy-Camille.[30,31,33]

Pathophysiology

The inflammatory process in the cervical spine mirrors that in other sites of the body and consists predominantly of T lymphocytes, macrophages, and plasma cells in a hypervascular synoviocytic pannus.[42,43] The inflammatory reaction has a predilection for synovial joints; as such, the facets, uncovertebral, atlanto-occipital, and atlantodens joints are preferably

affected over the discoligamentous structures in the cervical spine.[44] This is in contrast to the traditional pattern of age-related degenerative changes. The cervical spine relies heavily on ligaments and joint congruency for stability and thus is at greater risk for instability than the thoracic or lumbar spine. Cervical instability can result from inflammatory changes that cause pannus formation and erosion of joint surfaces and capsular structures. These manifest as atlantoaxial (C1–C2) subluxation (AAS), subaxial subluxation, cranial settling (also known as basilar invagination or atlantoaxial impaction), or a combination of these. Although biologic pharmaceuticals and other DMARDs have been credited with lowering the prevalence of cervical spine instability, modern medical treatment cannot prevent progression of preexisting damage.[45–48] Rheumatoid discitis may also occur at the discovertebral junctions with noninfectious erosion of the endplates.[6]

Atlantoaxial instability is the most common instability pattern in the rheumatoid cervical spine and associated with the development of a periodontoid pannus and progressive inflammatory joint destruction.[44,49,50] Pannus formation localizes around the synovial joint formed between the transverse ligament, the posterior arch of the atlas, and the base of the odontoid. The soft tissue may compress the spinal cord and often distends and erodes the surrounding periodontoid-ligamentous structures (alar, apical, and transverse ligaments), the odontoid process (dens), and the lateral articular masses between C1 and C2.[51] Erosion of the dens may even lead to the development of occult, atraumatic dens fractures.[52] Subsequent static or dynamic instability or subluxation occurred historically in 50% to 70% of patients.[23,53] Most often, the subluxation is anterior (70%), but lateral, posterior, and rotational subluxations can also occur.[54,55] Anterior subluxation of 0 to 3 mm is normal in adults, 3 to 6 mm suggests instability with disruption of the transverse ligament, and 9 mm or more suggests disruption of the entire periodontoid-ligamentous and capsular structures with gross instability.[23,56,57]

The combination of periodontoid pannus buildup and instability may cause spinal cord and root impingement leading to myeloradiculopathy and potentially sudden death. Delamarter and Bohlman[58] conducted postmortem studies suggesting that paralysis can be due to both mechanical neural compression and/or vascular impairment of the neural structures. Henderson et al.[59] reported that diffuse axonal injury with or without frank necrosis may irreversibly affect the spinal cord due to mechanical damage. These findings may partly explain the smaller diameter and cross-sectional area of the spinal cord found in patients with severe disease.[60] Surgical stabilization can result in pannus regression.[49,61]

Posterior atlantoaxial subluxation is rare and should raise the possibility of an anterior arch defect of the atlas or erosion, or fracture, of the odontoid.[57] Patients usually present with myelopathy and posterior kinking of the cord without radiographic compression.[62] Lateral subluxation is defined as more than 2 mm of lateral displacement of the C1–C2 lateral masses, occurs in up to 21% of atlantoaxial subluxations,[57] and is often accompanied by rotational deformity.[63]

Subaxial subluxation is the second most common instability pattern and results from destruction of the facet joints, interspinous ligaments, and discovertebral joints.[53,64] These pathologic changes can lead to longitudinal collapse, bony erosion, soft tissue hypertrophy, and multisegmental sagittal plane instability, causing a "step ladder" type of deformity pattern. Patients can demonstrate significant preoperative neurologic deficits, and improvements from surgical intervention are at times short lived. Worsening rheumatoid disease and complications can result in deterioration of outcome and mortality rates as high as 20% and 33% at 5 and 10 years, respectively, even after surgery.[65] Cranial settling is the least common, yet most ominous, form of instability and occurs primarily due to bone and cartilage destruction at the atlantoaxial and occipitoatlantal joints. Caudad settling of the cranium and apparent cranial migration of the odontoid are characteristic. As a result, there is an increased risk of sudden death from either static or dynamic stenosis of the foramen magnum and compression of the brain stem. Other sequelae include obstructive hydrocephalus or syringomyelia, presumably from obstructing the normal flow of cerebrospinal fluid. In some cases, fixed rotation of the head may occur due to unilateral joint destruction.

Natural History

It is difficult to study the natural history of RA since patients are usually treated at some stage of the disease. Studies have shown that inflammatory processes in the cervical spine begin early after the onset of RA and progress along with peripheral involvement. Atlantoaxial instability may be detected within 2 to 10 years of disease onset,[66] and there is a strong correlation between cervical spine subluxation and peripheral erosions of the hands and feet.[66] Although the spine is commonly affected, only approximately 10% of patients with cervical spine involvement will eventually require surgery.[67] The natural history of RA of the spine without surgical intervention, especially in patients with myelopathy, is one of progressive disability and risk of sudden death. Vertebral artery injury and positional occlusion can also result from progressive instability.[8,68] In one study of 21 rheumatoid patients treated medically, 76% showed deterioration at an average of 6 years of follow-up.[69] All patients in the study became bedridden within 3 years of developing myelopathy and all died within 7 years, with one-third dying suddenly for unknown reasons. Risk factors for progression include mutilating articular disease, history of high-dose corticosteroid use, high seropositivity (rheumatoid factor), rheumatoid subcutaneous nodules, vasculitis, and male gender. Other potential risk factors for cervical involvement include high serum CRP level and HLA-Dw2 or -B27 positivity.[70,71] As the disease progresses, pain, neurologic deficits, and sudden death are the primary risks.

Clinical Presentation

Neck pain is the most common symptom in patients with cervical spine involvement. Peripheral erosive changes similarly occur along the apophyseal joints and surrounding soft

tissues and may be a source of pain. Cervical instability may cause secondary impingement of the posterior rami of the lesser and greater occipital nerves, which may lead to occipital headaches. In general, pain in the suboccipital region suggests atlantoaxial pathology or cranial settling. Middle or lower cervical pain should suggest subaxial subluxation. Subaxial involvement may also lead to painful neck deformity with loss of sagittal plane supporting structures, which may later become fixed due to postinflammatory ankylosis. Patients may complain of a "clunking" sensation in the neck with neck motion. This condition/symptom is most common with C1–C2 instability due to spontaneous reduction of the subluxation with neck extension (Sharp-Purser test).[72]

Progressive instability can lead to decreased canal diameter and brain stem or cord compression. Myelopathy and vertebrobasilar dysfunction may result due to mechanical and ischemic damage to the white and gray matter evidenced on histologic specimens by long tract demyelinization, lateral column necrosis, and focal gliosis.[58] According to Bell,[73] C1–C2 instability may lead to a phenomenon termed "cruciate paralysis," characterized by upper motor neuron dysfunction of the upper extremities and normal lower extremities, similar to a mild central cord syndrome after trauma. Pathologically, there is selective injury to the decussating corticospinal tracts of the upper extremities at the level of the cervicomedullary junction with sparing of the uncrossed lower extremity pyramidal and extrapyramidal tracts.

Additional neurovascular changes may occur due to vertebral artery occlusion with decreased flow into the posterior inferior cerebellar artery and cephalad brain stem circulation. Without adequate collateral blood flow, these patients may develop Wallenberg syndrome or lateral medullary infarction. These clinical syndromes are characterized by ipsilateral cranial nerve palsies (cranial nerves V, IX, X, and XI), cerebellar ataxia, Horner syndrome (ptosis, miosis, anhidrosis, and enophthalmos), facial pain, and contralateral loss of pain and temperature sensation.[74] In rare instances, patients may develop quadriplegia, quadriplegia with facial muscle paralysis (locked-in syndrome),[75] and sudden death.[43,69]

Unlike pain symptoms, neurologic signs are less straightforward. Patients must be assessed keeping their global disease in mind. Progressive myelopathy may not be evident by loss of fine motor control, gait imbalance, or global numbness of the hands, but rather by the slow onset of deteriorating independence and becoming wheelchair bound. Often, hand deformities will mask motor deficits in the upper extremities and the patients' deteriorating ambulatory status may be attributed to large joint involvement rather than myelopathy. Progression of myelopathy, especially early disease, may be misinterpreted as progression of their peripheral disease. Therefore, a high index of suspicion is necessary to diagnose myelopathy, as these patients do poorly without early surgical intervention.[43,69]

The Ranawat grading system may provide some useful clinical information in assessing patients with neurologic deficits[76] (Table 84.1). This system classifies pain as none (grade 0), mild (1), moderate (2), or severe (3). Neurologic function falls into three classes: Class I has no neurologic deficit; class II has subjective weakness, dysesthesia, and hyperreflexia; and class III has objective weakness and long-tract signs. Class III is further subdivided into ambulatory patients (A) and quadriparetic nonambulatory patients (B). Casey et al. reported that only 25% of Ranawat IIIB patients who underwent surgical decompression and stabilization had a favorable outcome. The mortality rate was 13% after 30 days and 60% by 4 years.[77]

TABLE 84.1 Ranawat Criteria for Pain and Neural Assessment

Grade/Class	Description
Pain Assessment	
Grade 0	None
Grade 1	Mild, intermittent, requiring only aspirin analgesia
Grade 2	Moderate; a cervical collar is needed
Grade 3	Severe; pain could not be relieved by either aspirin or collar
Neural Assessment	
Class I	No neural deficit
Class II	Subjective weakness with hyperreflexia and dysesthesias
Class IIIA	Objective findings of paresis and long tract signs, but walking possible
Class IIIB	Quadriparesis with resultant inability to walk or feed oneself

Radiologic Evaluation

Plain radiographs are an effective screening tool for identifying patients with atlantoaxial instability, cranial settling, or subaxial subluxations. Standard anterior-posterior (AP), open mouth (odontoid view), lateral, and controlled flexion-extension plain views should suffice. The flexion–extension views are the most important in detecting whether there is dynamic or static instability in the upper or lower cervical spine and allow for measurement of the anterior atlantodental interval (AADI) and posterior atlantodental interval (PADI). The AADI is the transverse distance from the anterior surface of the dens to the posterior margin of the anterior ring of C1, while the PADI is the distance between the posterior surface of the dens and the anterior margin of the posterior ring of the atlas. Historically, the AADI was used to screen patients who required surgical stabilization for atlantoaxial instability based on an AADI greater than 9 mm, with 0 to 6 mm suggesting instability and 0 to 3 mm being normal.[57] The AADI is limited by the occasional difficulty of obtaining accurate measurements in some patients because of erosive changes that distort anatomy and because there is some variation in the size of the C1 ring. In contrast, Boden et al.[78] showed that the PADI more reliably predicts neurologic outcome since it represents the space available for the cord. Patients with a PADI of at least 14 mm were more likely to have neurologic recovery after surgical stabilization, while those with a PADI less than 10 mm had no neurologic recovery. Anatomically, this correlates to the dura taking up 1 mm on the anterior and

posterior sides, 2 mm of cerebrospinal fluid, and 10 mm for the cord for a total of 14 mm.[79] Neither measurement on plain films takes into account possible pannus formation with mass effect on the cord, which requires advanced imaging.

The open-mouth view is useful to identify lateral subluxation.[57,63] Erosive changes of the dens and C1–C2 articulations may also be visualized. Taniguchi et al. defined the atlantodental lateral shift (ADLS) as a means of assessing lateral atlantoaxial instability.[80] Utilizing dynamic open-mouth odontoid views (taken in maximal left and right lateral bending), the ADLS is calculated by dividing the distance from the center of the dens to the medial edge of the C1 lateral mass (in the direction of lateral bending) by the distance between the medial borders of the bilateral C1 lateral masses and is expressed as a percentage. In rheumatoid patients, the ADLS averaged 14.8% compared to 6.1% in control patients. Among patients with increased AADI, the ADLS averaged 20.6% versus 12.7% in patients without anterior atlantoaxial instability.

Posterior subluxation, though rare, may be seen on lateral radiographs of the cervical spine and should be suspected in patients with an absent or fractured odontoid process.[62] It is important to note that the AADI will decrease with worsening cranial settling as the arch of the atlas approaches the wider base of the odontoid process and is a potential source of mistaken radiographic improvement.

Cranial settling carries the greatest risk of neurologic deficits and sudden death, especially when superimposed on atlantoaxial instability. As a consequence, several measurement techniques have been utilized with varying sensitivity and specificity, based on lateral plain radiographs of the upper cervical spine[81] (Fig. 84.1). The majority of these techniques assess the relationship between the tip of the odontoid, the hard palate, and the base of the skull. Traditionally, the McGregor line (drawn from the posterior-superior tip of the hard palate to the caudad base of the occiput) has been widely used for its simplicity. Cranial settling occurs when the tip of the dens is more than 4.5 mm above this line. Erosive changes in the odontoid anatomy may make it difficult to analyze many of the measurement techniques; thus, Redlund-Johnell and Pettersson[82] described a technique that measured the vertical line from the midpoint of the caudad margin of C2 to the McGregor line. Cranial settling occurs when the distance is less than 34 mm in males or 29 mm in females. Ranawat et al.[76] described a similar technique in which the distance along the odontoid was measured from the C2 pedicle to the transverse axis of the ring of C1. This technique avoided problems with changes in odontoid anatomy and identifying the bony landmarks at the base of the skull and hard palate. Cranial settling was positive if the distance was less than 15 mm in males or 13 mm in females. Clark et al.[27] (Fig. 84.2) defined the "station of the atlas," which indicates the position of the anterior ring of C1 to parts of the body of the axis divided into thirds. Normally, the atlas is adjacent to the upper third (station I) of the axis. Riew et al.[81] noted that none of the current radiographic measurements alone had a high sensitivity, specificity, or negative or positive predictive value greater than 90% and therefore recommended the combination of the Clark station, Redlund-Johnell, and the Ranawat criteria with sensitivity and negative predictive values of 94% and 91%, respectively.

Subaxial subluxation can be evaluated on AP and lateral static and dynamic radiographs. White and Panjabi[83] defined radiographic cervical instability as 3.5 mm or more of vertebral translation and greater than 11 degrees of angular changes between adjacent motion segments, although their study is more representative of acute conditions. The space available for the cord should also be considered since critical stenosis may be present with or without instability. Boden et al.[78] correlated anatomic measurements with neurologic findings and reported that a sagittal diameter less than 14 mm is considered critically stenotic in the rheumatoid subaxial spine. This is in contrast to 13 mm in cervical spondylotic patients who do not have pannus in the canal.

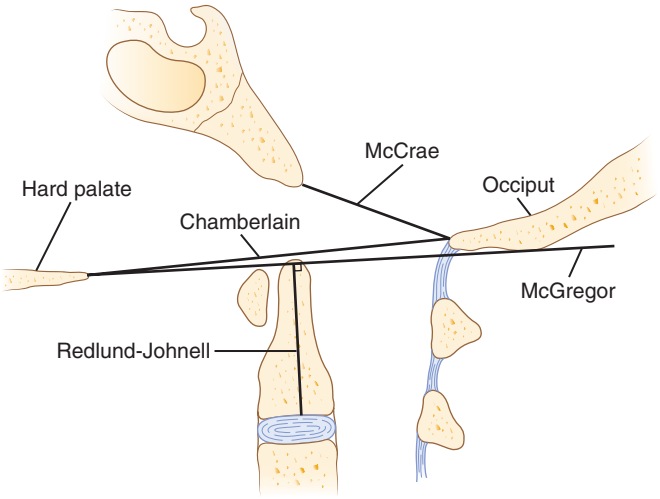

FIG. 84.1 Various measurements of basilar invagination. Chamberlain line: odontoid tip >6 mm above the line. McCrae line: odontoid tip above this line. McGregor line: males, odontoid tip >8 mm above the line; females, odontoid tip >9.7 mm above the line. Redlund-Johnell distance: males, <34 mm; females, <29 mm.

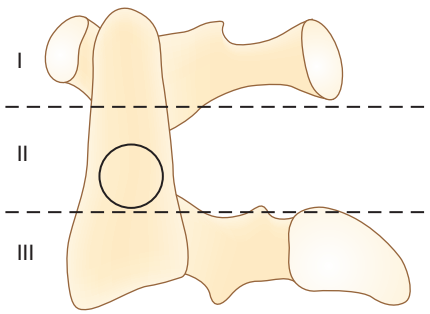

FIG. 84.2 The station of the atlas is determined by dividing the odontoid process into thirds in the sagittal plane. Normally, the anterior ring of the atlas should be adjacent to the cephalad third of the axis (station I). If the ring of the atlas is adjacent to the middle third of the axis, mild cranial settling is indicated (station II). If the anterior ring of the atlas is adjacent to the base of the axis, it is considered evidence of severe cranial settling (station III). (From Clark CR, Goetz DD, Menezes AH. Arthrodesis of the cervical spine in rheumatoid arthritis. *J Bone Joint Surg Am.* 1989;71:381-392.)

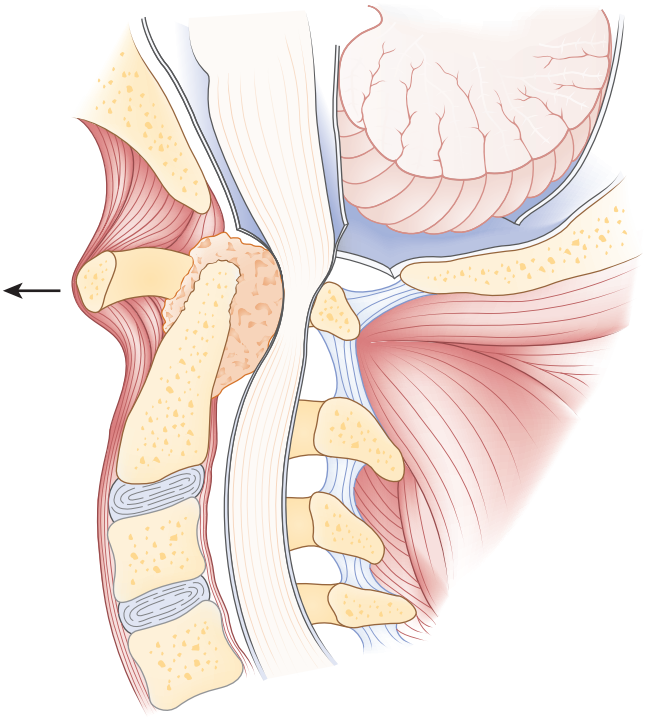

FIG. 84.3 Forward subluxation of the atlas on the axis, pannus formation around the odontoid process, and osseous erosions. There is severe compression of the spinal cord between the pannus anteriorly and the arch of the atlas posteriorly. (From Boden SD, Dodge LD, Bohlman HH, et al. Rheumatoid arthritis of the cervical spine: a long term analysis with predictors of paralysis and recovery. *J Bone Joint Surg Am*. 1993; 75:1282-1297.)

Patients with any radiographic instability, with or without symptoms or neurologic deficits, should be followed closely as existing instability of any subgroup (AAS, vertical subluxation, or subaxial subluxation) is at risk for accelerated progression to severe instability within 5 years.[84]

Computed tomography (CT), especially with intrathecal contrast, is a valuable addition to plain radiographs in delineating the bony anatomy and identifying cord compression and cranial settling. The degree of medullary compression on CT scans has been shown to correlate with myelopathy.[49] Static or dynamic magnetic resonance imaging (MRI), however, is the best option to assess the soft tissues and to look for the presence of periodontoid pannus (Fig. 84.3) and spinal cord or brain stem compression.[49,61,85–87] Myelopathic signs correlate with MRI findings[87] of a cervicomedullary angle of less than 135 degrees (normal, 135–175 degrees). This angle measures the intersection of vertical lines drawn along the anterior surface of the brain stem and the cord on a sagittal MRI.

Nonsurgical Treatment

Although life expectancy is lower in rheumatoid patients, many are living longer with advances in medical therapy that has slowed disease progression with fewer side effects.[70] Only a minority of these patients will eventually need surgical stabilization. Patients with early cervical disease and intermittent pain without radiographic instability or myelopathy can be managed with a soft cervical orthosis or trials of physical therapy. Medication options include nonsteroidal antiinflammatory drugs (NSAIDs), oral steroids (prednisone), and DMARDs such as methotrexate, gold, sulfasalazine, hydroxychloroquine, D-penicillamine, and azathioprine. Biologic agents such as tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1) antagonists have become more common. The addition of antiresorptive osteoporosis therapy may improve vertebral bone strength in rheumatoid patients.[88] Patients should be followed closely for neurologic or radiographic changes. Cervical collars provide support, warmth, some pain relief, and a feeling of stability; however, rigid collars are often poorly tolerated, especially in patients with temporomandibular disease, dental problems, and skin sensitivity and may have further detrimental effects by blocking spontaneous reduction of anterior atlantoaxial subluxation in extension.

Surgical Management

Indications

Patients with any one or more of the instability patterns described earlier—with or without associated pain, myelopathy, or neurologic deficits—should consider early surgery. Presence of mild or moderate instability should be followed closely due to high risk of progression to severe symptomatic instability.[84] As noted previously, radiographic indicators for surgery include an AADI of 9 mm or more, PADI of less than 14 mm, mobile subaxial subluxation greater than 3.5 mm, cord compression or space available for the cord of less than 14 mm, and cranial settling measured most accurately by the combination of the Clark station, Redlund-Johnell, and Ranawat criteria.[81] Computed tomographic myelograms and MRI demonstrating cord compression or a cervicomedullary angle of less than 135 degrees are suggestive of impending neurologic deficits and should be weighed heavily as an indication for surgery within the context of the remaining clinical picture. Patients with headaches in the distribution of the greater or lesser occipital nerve are likely to have atlantoaxial instability and may need C1–C2 arthrodesis for pain relief.

Timing of surgical intervention is crucial. In a retrospective review of 110 patients who underwent cervical spine fusion for RA, only three of 55 patients (5.5%) with early C1–C2 fusion for isolated AAS developed subaxial subluxation requiring surgery an average of 9 years later.[44] In contrast, 36% of patients who were stabilized for more progressive instability (atlantoaxial with cranial settling) developed recurrent cervical instability at a mean of 2.6 years. These authors recommended early surgery before cranial settling to decrease the risks of recurrent instability. In a series of 28 patients, Schmitt-Sody et al.[89] reported that seven of 10 patients who were Ranawat class II improved to class I following surgery, whereas only one of 11 class III patients improved (class IIIA to class II), and two patients deteriorated (class IIIA to class IIIB) postoperatively. Similarly, these authors recommended early surgical stabilization prior to the development of neurologic symptoms.

Preoperative Assessment

The goals of surgery should be pain relief, restoration of spinal alignment, decompression of neurologic deficits, and stabilization of the involved motion segments.

Thorough preoperative assessment is a prerequisite to good outcome in this often-fragile patient population. The quality of bone stock, presence of irreducible subluxations, and the overall medical condition of the patients should guide the preoperative decision-making process, including the potential need for awake fiberoptic nasal or endotracheal intubation.[90]

Patients with severe basilar invagination should be considered for preoperative skeletal traction using a halo ring (which can be incorporated into a halo vest after surgery) or cranial tongs. Preoperative traction can improve alignment and the resultant indirect decompression can improve neurologic symptoms and pain. Traction may be required for 3 to 7 days or longer, with wheelchair-halo configurations available to allow the patient greater mobility and avoid secondary problems, such as decubitus ulcers and pulmonary issues, associated with prolonged bed rest.[62,91,92] Gentle traction along the midline longitudinal axis with approximately 7 to 12 pounds, while avoiding hyperflexion or hyperextension, is recommended. Patients are monitored with frequent neurologic examinations (every 1–2 hours), and plain radiographs should be obtained to avoid overdistraction during the process. We have not felt the need to routinely use preoperative traction in atlantoaxial instability or subaxial subluxation. Many of these instabilities that moved little on preoperative flexion-extension views are better reduced when the patient is under general anesthesia positioned with the head holder (with concomitant use of neurophysiologic monitoring).

Once in the operating room, obtaining baseline neurophysiologic data, including somatosensory evoked potentials (SSEPs) and motor evoked potentials (MEPs), before and after positioning a myelopathic patient may alert the surgeon to impending spinal cord injury during or after positioning of the head and neck. Finally, the surgical approach should be determined by the underlying pathology and its location, in part analogous to the approach for compressive lesions in cervical spondylotic patients.[93,94]

Perioperative Management of Rheumatoid Medication

Approximately 80% of rheumatoid patients undergoing elective joint arthroplasty surgery are on corticosteroid therapy and 75% to 84% are on either traditional or biologic (anti-TNF-α) DMARDs.[95] Patients with rheumatoid spinal disease, in comparison, are typically older with greater disease progression, thereby making the possibility of medication complications even higher. Despite this potential, perioperative management of rheumatoid medications continues to be debated. Recommendations differ between rheumatologists and vary widely even among the rheumatology organizations; for example, anti-TNF-α discontinuation ranges from >1 week before surgery (American College of Rheumatology), to 2, 3, or up to 5 times the half-life of the drug (Canadian Rheumatology Association and British Society).[96–99] Commonly used agents range from potent antiinflammatories to immune modulators and have varying degrees of effect on wound healing and bony fusion, the latter of which continues to be poorly described in the literature. Stopping or resuming these medications requires walking the fine line between risking systemic flare-ups versus potential complications, such as wound infections, delayed healing, or delayed fusion. A flare in the postoperative period can also crucially impair a patient's ability to mobilize and rehabilitate. There continues to be a paucity of prospective research in optimal perioperative medication management, making true evidence-based recommendations difficult.

Because of the risk of increased bleeding time and potentially increased intraoperative blood loss, NSAIDs should be discontinued 3 to 5 half-lives prior to surgery.[100] In addition, NSAIDs have been previously shown to inhibit bone healing and therefore should be held as long as possible postoperatively so as not to impair formation of a spinal fusion.

Corticosteroids produce immunosuppression, which can adversely affect wound and bone healing. The risk of infection is also directly proportional to absolute and cumulative doses, with 100% of patients treated for 3 years or more developing an infection.[101] In addition, sudden stoppage of chronic corticosteroids may lead to adrenal insufficiency and hypotension, and patients are frequently given stress dosing. Several studies indicate, however, that patients receiving their usual dose of steroids responded to surgery (major and minor) with an increase in serum cortisol levels without signs of hemodynamic instability.[102–105] Most *spinal* procedures for this patient population, however, would be considered highly stressful, and patients on chronic moderate- to high-dose regimens (>20 mg/day of prednisone) should receive stress dose steroids on the day of surgery with rapid tapering over 1 to 2 days to their usual chronic dosage.[100,106]

Continued use of methotrexate in the perioperative period has not been shown to increase infection rates.[107] Previous studies linked methotrexate with nonunion following osteotomy of the extremities[108]; however, this result has not been found to be true in the existing spine literature.[109] Although withholding methotrexate may increase the likelihood of a flare-up of rheumatoid symptoms, we routinely discontinue its use 1 week preoperatively, and recommend that patients remain off of methotrexate postoperatively as long as symptomatology allows, up to 6 to 8 weeks.

Few studies exist to direct perioperative management of biologic agents such as TNF-α and IL-1 antagonists. Because of their strong immunoregulatory effects, these agents may predispose patients for opportunistic infections.[100,106] Early innate immune response to infection, particularly in the presence of orthopaedic implants, is heavily dependent on cellular defense mechanisms and activation by cytokines, such as TNF-α and IL-6.[110] In a recent meta-analysis of rheumatoid patients undergoing major orthopaedic surgery (the majority were joint arthroplasties), 3681 patients had a history of preoperative treatment by TNF-α inhibitors and 4310 patients did not. Exposure to an anti-TNF-α agent preoperatively was shown to favor infection. Odds ratios were 3.16 for studies

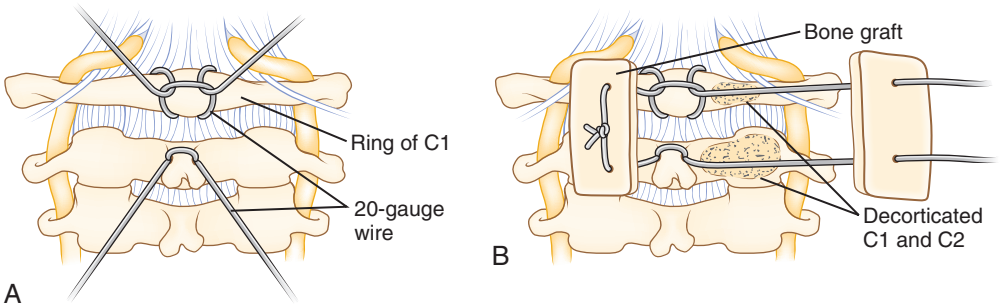

FIG. 84.4 Modified Gallie-type wiring for a posterior C1–C2 arthrodesis.

with confirmed rheumatoid diagnoses and 3.01 for studies meeting Centers for Disease Control and Prevention (CDC) criteria for infection. All studies included were retrospective. There are no data on these agents' effects on bone fusion; however, anti-TNF-α agents may allow expedited postoperative hemoglobin recovery.[111] Duration of discontinuation lacks high-quality evidence and control in the available literature, as cohorts are comprised of a heterogeneous mix of surgical procedures and variable arbitrary time intervals selected for withholding treatment.[112,113] Current recommendations are to discontinue biologic agents preoperatively (for 1.5 times the dosing interval),[114] and restart 10 to 14 days postoperatively at wound healing.

It is our practice to confer with the treating rheumatologist and individualize the duration of drug holiday, before and after surgery, based on patient factors (disease severity, duration, quality of disease control) and the extent of surgery required. As treatment with anti-TNF-α agents has been linked with neurologic adverse events such as demyelinating lesions and peripheral neuropathy, nontraditional manifestation of spinal disease should be worked up prior to surgery.[115,116] Postoperatively, patients should be monitored with daily laboratory tests due to baseline myelosuppression and placed on a regimen for nutritional optimization and vitamin/mineral supplementation.

Operative Procedures

Atlantoaxial (C1–C2) Instability

Posterior fusion is considered the standard treatment for C1–C2 instability.[35,117–119] The Gallie[24] and Brooks[25] wiring techniques require the presence of the posterior arch of C1, supplemental bone graft, and external immobilization. Claw-type constructs such as the Halifax clamp are rarely used today because of biomechanical limitations and better options. Transarticular screw fixation is popular because of its multidirectional rigidity, but it requires intraoperative fluoroscopy and preoperative axial imaging to visualize the vertebral artery anatomy. Direct screw fixation of the C1 lateral masses and C2 pedicles, pars, or lamina has become the most common and effective technique.[35,117–120]

Wire Techniques

Stand-alone wiring techniques have largely fallen by the wayside in favor of transarticular screw or direct screw-rod fixation techniques. Wiring techniques are frequently used as adjuncts to other fixation, particularly for securing bone graft material to help facilitate fusion or as a "bailout" in patients with anatomy unfavorable to other techniques. Sublaminar wire fixation is obtained on the C1 ring and around the C2 spinous process (Fig. 84.4). However, we recommend a modification of the Gallie technique. The patient's head is placed in a tong-type holder for rigid positioning with reduction checked by intraoperative imaging. The chin should be tucked to open the space between the occiput and C1 to facilitate passage of sublaminar wire. Note that an occiput–C2 fusion may be safer with or without a C1 laminectomy in cases of an inadequate posterior space available for safe wire passage of an unreducible C1 ring.

A posterior exposure is utilized, remaining close to the midline with approximately 1.5 cm lateral dissection in each direction on the C1 ring to avoid the vertebral artery and the venous plexus between C1 and C2. Cobb elevators are utilized to subperiosteally expose the base of the occiput to the caudad aspect of the C2 lamina at a minimum. Small curettes can be used to develop the plane under the C1 ring for wire passage. Loop a 20-gauge wire with the tip contoured for safe passage under the C1 ring. A nerve hook is used to engage the loop and pull it through approximately 2 cm. The free ends of the 20-gauge wire are then fed through the loop and the wire is cinched down tightly onto the C1 ring at the midline. Alternatively, sutures may be passed underneath C1 with a Mayo needle placed in a reverse manner with the blunt end from caudad to cephalad. Wires are then placed within the suture loops and passed underneath the lamina as the sutures are withdrawn caudally. A burr hole is made at the base of the C2 spinous process and a second 20-gauge wire is passed through the hole and looped beneath the spinous process and through the hole again to provide stress distribution. Two rectangular blocks of corticocancellous iliac crest bone graft can be harvested and placed over the laminae of C1 and C2 on either side of the midline. The grafts should be near full thickness to allow for tightening of the wires with less risk of breaking through the fragile bone. The wires are tightened over the graft while watching closely to prevent wire breakthrough. Cancellous chips can be placed around the bone blocks, especially on the ring of C1, where nonunions tend to occur. A drain is typically used and the wound closed in layers. If no supplemental internal fixation is used, a halo vest may be needed postoperatively to help maintain reduction. Care must be taken when tightening the wires in the unusual case of a

posteriorly subluxed C1 ring, as this action will tend to sublux the C1 ring posteriorly. We suggest a Brooks technique in this situation.

A Brooks-type modification of the Gallie technique utilizes bilateral sublaminar wires beneath C1 and C2 (Fig. 84.5). A laminotomy may be done between C2 and C3 to facilitate wire passage; a 20-gauge wire is looped and the looped end threaded beneath the lamina of C2 and C1 on either side of the midline. Near full-thickness corticocancellous iliac crest bone grafts are harvested and placed on the lamina of C1 and C2. The grafts should be contoured to fit snugly to reduce the risk of graft slippage. Alternatively, a full bone block may be used with a caudad notch to fit around the C2 spinous process. Decortication is not necessary and risks weakening the lamina. The wires are then tightened down in a longitudinal fashion over the bone block on either side. This fixation may provide more rotational stability over the Gallie technique because of fixation on both sides of the midline. A halo vest may be used at the discretion of the surgeon based on the need for maintaining reduction and the adequacy of intraoperative fixation.

Transarticular Screw Fixation

This technique provides rigid fixation for atlantoaxial fusion and can be used in conjunction with wire techniques to provide three-point fixation.[33] (Figs. 84.6 and 84.7) It rigidly fixes the C1 and C2 facets, minimizing the need for postoperative external immobilization. Preoperative CT scan is necessary to adequately define the vertebral artery anatomy. It also ensures that the C2 isthmus is wide enough to accept at least a 3.5-mm screw and that the lateral mass of C1 is reduced and aligned with the superior facet of C2. Other considerations that may preclude the use of this technique include significant thoracic kyphosis (which complicates screw placement), cranial settling with collapsed lateral masses, irreducible subluxations, substantial osteoporosis and osteopenia, comminuted fractures of the atlas and axis vertebrae, and an anomalous vertebral artery or foramen transversarium.

Patient positioning is similar to what has been described earlier, but the arm attachments from the tongs to the operating table should be radiolucent for intraoperative fluoroscopy. A longer incision may facilitate angling of the drill guide and screw placement. It is common to use bilateral percutaneous stab wounds about the level between the T2–T6 spinous process to achieve the correct angle for screw placement. The starting point for drill placement is 3 mm above the C2–C3 facet articulation and 2 to 3 mm lateral to the medial border of the C2 facet. The drill guide should be aimed 0 to 10 degrees medially and toward the dorsal cortex of the anterior arch of C1. Consider palpating the medial wall of the pedicle with a nerve hook or a small blunt elevator through a laminotomy between C1 and C2. Biplanar fluoroscopic images should be obtained prior to inserting the starting Kirschner wire and during drilling to ensure that the wire hugs the superior cortex of the isthmus to avoid the vertebral artery inferiorly. The vertebral artery is inferior on lateral views and parallel or slightly lateral to the cord on AP views. The tip of the wire should end about 3 mm short of the anterior cortex of C1 to avoid passing the drill into the oropharynx. Instrumentations are cannulated, which makes it easier to place screws. Usually, a 3.5- or 4.5-mm cannulated screw measuring 40 to 44 mm is adequate. Ideally, guide wires are drilled on both sides prior to placing the screws bilaterally. A Gallie-type posterior fixation technique with autologous iliac crest bone graft can be used to supplement the fixation. External immobilization devices should be prescribed based on the strength of the construct and bone quality. In many cases, a soft collar is all that is required.

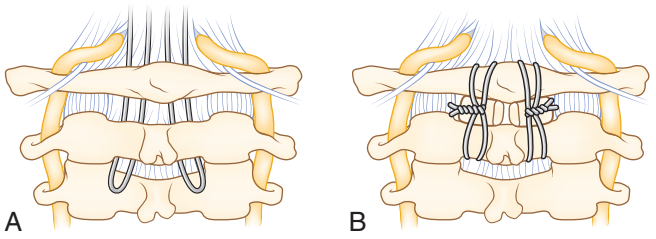

FIG. 84.5 Brooks-type wiring for a posterior C1–C2 arthrodesis. (A) Sublaminar wires are passed under both C1 and C2 and are tightened down over wedge-shaped, sculpted corticocancellous grafts. (B) The shaping of the grafts minimizes the chance of graft displacement into the canal.

Posterior C1–C2 Intraarticular Screw Fixation

A variation of this concept is the use of a C1–C2 intraarticular interference screw, as described by Tokuhashi et al.[121] In this technique, posterior dissection exposes the C1–C2 joints bilaterally. The joint capsule is dissected off the bone and retracted superiorly with the greater occipital nerve. When placing a screw on one side, atlantoaxial subluxation is reduced and maintained by application of a Halifax interlaminar clamp to the contralateral side. A 1-mm Kirschner wire is inserted

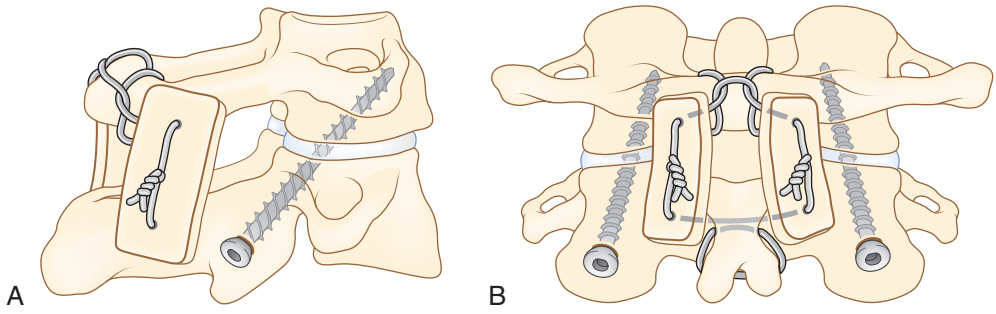

FIG. 84.6 Transarticular screw technique for C1–C2 arthrodesis.

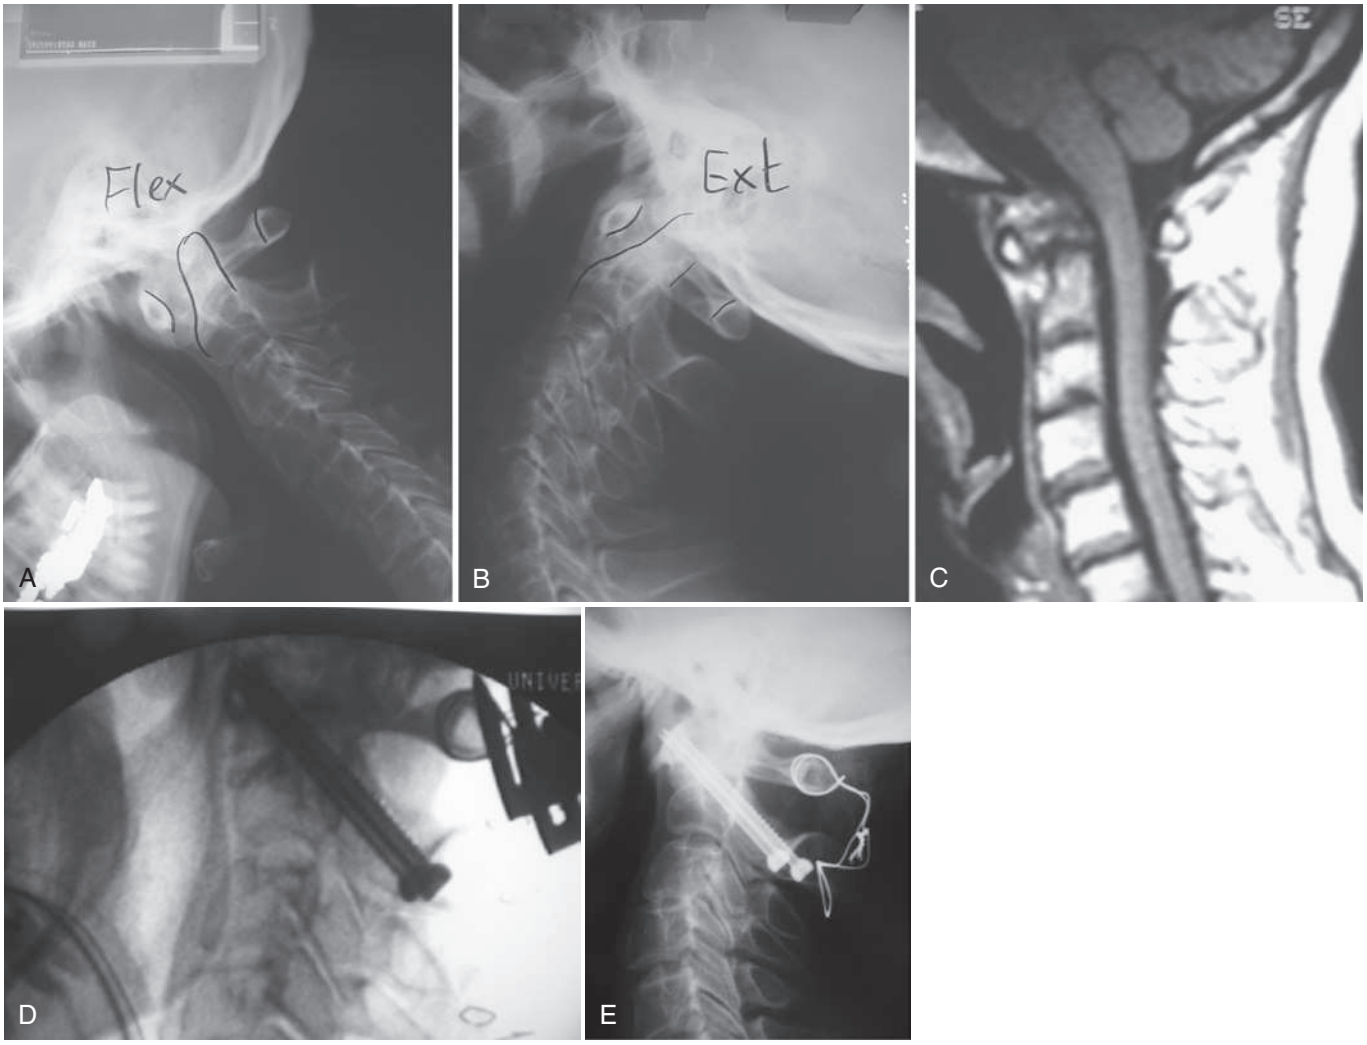

FIG. 84.7 A 52-year-old woman with long-standing rheumatoid arthritis had neck pain without evidence of frank myelopathy. (A–B) Flexion and extension lateral cervical spine radiographs show C1–C2 instability. There is incomplete reduction in extension. (C) A sagittal magnetic resonance image shows pannus around the dens. This is likely blocking complete reduction in extension. There is still enough space available for the spinal cord, however, as visualized on this image. (D–E) A lateral intraoperative fluoroscopic view of C1–C2 and postoperative lateral radiographic view following transarticular screw placement, modified Gallie-type wiring with bone grafting for posterior C1–C2 arthrodesis.

directly into the C1–C2 joint and a cannulated tap is used to prepare the site for insertion of the cannulated 5.6- or 6.5-mm titanium interference screw. These screws are typically 8 mm or 10 mm long. The procedure is then performed on the opposite side. Finally, corticocancellous bone graft is fashioned to fit the intralaminar space and is secured beneath bilateral Halifax clamps. Patients are placed in a cervical collar postoperatively. Tokuhashi et al.[121] used this technique in 22 rheumatoid patients, all of whom reported significant improvement in pain, and all patients who were Ranawat class IIIA or above improved neurologically by 2-year follow-up. Atlantoaxial reduction was maintained and bony fusion was noted in all patients; although four patients developed subaxial pathology, none required surgical intervention.

Posterior C1–C2 Screw-Rod Constructs

Several methods of posterior C1–C2 rigid instrumentation have been described. Harms and Melcher[35] reported a technique involving placement of 3.5-mm polyaxial screws directly into the lateral mass of C1 and into the pars interarticularis or pedicle of C2 bilaterally (Fig. 84.8). Vertical rods are then attached to these screws, followed by bone grafting for arthrodesis. Recently, the use of posterior C1–C2 screw-rod constructs has become the most commonly employed technique.[122] This method allows for direct manipulation and reduction of C1 on C2 as needed. The advantages of this technique includes rigid three-column fixation, high fusion rates (97.5%), low rates of implant failure, and the theoretical decreased risk to the vertebral artery compared to C1–C2 transarticular screws.[122,123] Bleeding from the venous lakes covering the C1 lateral masses can easily be encountered and is a disadvantage. This bleeding is usually minimized by meticulous subperiosteal dissection and can typically be controlled by hemostatic agents. Either technique requires an intimate knowledge of the anatomy by the operating surgeon aided by good fluoroscopic technique.

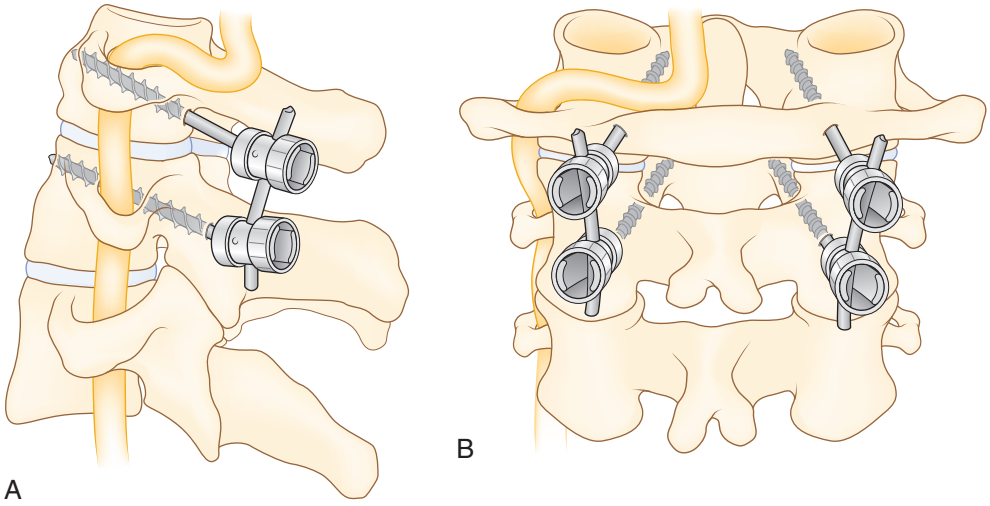

FIG. 84.8 Posterior C1–C2 fixation technique with polyaxial screws and rods. Screws are placed into the lateral masses of C1 and into the pedicles of C2.

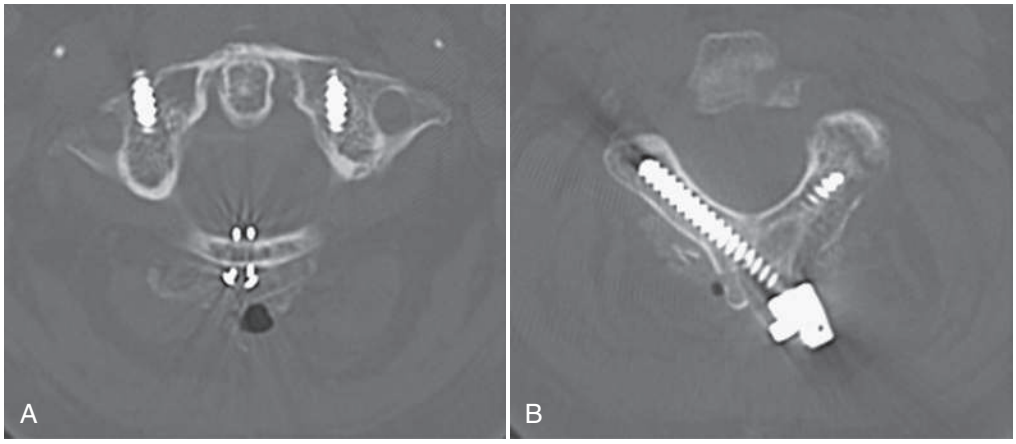

FIG. 84.9 Posterior C1–C2 fixation with placement of C1 lateral mass screws and C2 intralaminar screws. (A) Axial computed tomographic (CT) scan through C1 demonstrating location of lateral mass screws. (B) Axial CT through C2 laminae showing bilateral intralaminar screws. Note that because of the technique required for insertion, the screws are not in exactly the same axial plane.

After exposure, the C1–C2 joint is identified since this serves as the anatomic landmark for accurate placement of the C1 lateral mass screw. Removing a small amount of the caudal part of the C1 posterior arch with a burr will aid in visualizing the C1 screw starting point. The C2 nerve root can be gently retracted caudally for visualization or sacrificed, which has been shown to result in less neuralgia, decreased operative time, and decreased blood loss in studies. However, patients should be warned of postoperative numbness.[122,124] The screw is placed in the center of the lateral mass, first using a high-speed burr to create a dimple so that the drill bit does not skid while drilling. The pilot hole is drilled straight or slightly convergent and parallel to the C1 posterior arch in the sagittal direction. The drill hole is typically 18 to 22 mm, which should be confirmed with fluoroscopy. A longer screw than this will be needed since the polyaxial screw head will need to be elevated off of the cortex of the lateral mass in order to accommodate rod fixation. Typically, partially threaded screws are used, which allow the threads to remain within the bone of the lateral mass, while the nerve root then lies against the smooth shaft of the screw. The entry point for the C2 pedicle screw is in the upper and medial quadrants of the isthmus surface. The direction of the pilot hole is approximately 20 to 30 degrees in a convergent and cephalad direction. The medial border of the C2 pars interarticularis can initially be palpated with a small elevator or the edge of a nerve hook to help with accurate placement of C2 screws. A typical length for C2 pedicle screws is 22 to 28 mm, which should be confirmed with fluoroscopy. In their study, Harms and Melcher did not wire in grafts for their fusion technique[35]; however, this technique is certainly an option to augment the stability of the screw–rod construct and to help ensure a successful arthrodesis (see Fig. 84.7).

An alternative to the C2 pedicle or pars screw is placement of an intralaminar C2 screw (Fig. 84.9). As described by Wright, this technique provides excellent fixation of C2 with virtually no risk of injury to neurovascular structures.[117] Exposure is as described earlier for the placement of C1 lateral

mass and C2 pedicle screws. Placement of the C1 lateral mass screws is performed by the previously described technique. For placement of the C2 intralaminar screws, a high-speed burr is used to open a small cortical window at the cranial end of the junction of the C2 spinous process and lamina. A hand drill is then used to drill the intercortical space of the contralateral lamina to a depth of approximately 30 mm while maintaining alignment of the drill with the exposed dorsal aspect of the lamina. After palpation of the drill tract with a ball-tip probe, a 4.0 × 30 mm polyaxial screw is inserted. A starting hole is then burred in the contralateral side at the caudal junction of the spinous process and lamina and, using the same technique, an intralaminar screw is inserted. Care must be taken when inserting the screws to maintain the angle of insertion slightly shallower than the angle of the lamina; this technique will ensure that any cortical breach occurs dorsally rather than ventrally into the spinal canal. The polyaxial screw heads from C1 and C2 are then connected with a rod. In some instances, because of the angle of the screws relative to one another, offset connectors may need to be used to facilitate rod insertion. The laminae of C1 and C2 may then be decorticated and corticocancellous bone graft applied (and wired into place if desired).

A biomechanical study examined the relative stability of several C1–C2 screw-rod constructs in an odontoid fracture model.[125] Using cadaveric specimens, C1 lateral mass screws were placed and connected to either C2 intralaminar screws, C2 pars screws, or C2 pedicle screws. Insertional torque for C2 pedicle screws and intralaminar screws was similar, and both of these screw types were significantly higher than pars screws. Pullout strength was greatest for pedicle screws. In intact models, intralaminar screws provided superior resistance to axial rotation compared to pars screws and similar resistance to pedicle screws. After experimentally induced odontoid fracture, both pars and pedicle screws were superior in resisting lateral bending. Pedicle screws overall provided the greatest stability of C1–C2 in all planes, particularly after experimental odontoid fracture. Lapiswala et al.[126] noted similar results, with C2 intralaminar screws providing less resistance to lateral bending than C2 pedicle screws or C2–C1 transarticular screws. All posterior constructs, when supplemented with posterior cable fixation, provided similar stiffness in flexion–extension and axial rotation.

Cranial Settling or Atlantoaxial Subluxation With C1 Stenosis

Occipitocervical Fusion

The technique of choice to treat patients with cranial settling or fixed AAS with posterior cord impingement from the ring of C1 is occipitocervical fusion.[62,92,127] In the latter case, an occiput to C2 fusion with a C1 laminectomy is preferred. Patient positioning is same as with wire techniques. Particular care must be taken to ensure neutral alignment of the head in the sagittal and axial planes. Excess flexion or extension can lead to chronic pain, dysphagia, breathing problems, and functional impairment due to disruption of forward gaze. The skin incision extends proximally to the external occipital protuberance (EOP). Historical techniques include direct wiring of bone graft to the skull or the use of looped rods wired into place. Presently, rigid fixation with occipital plate-screw constructs is the standard treatment.

Wiring and Graft Technique

This technique utilizes corticocancellous bone blocks wired to the occiput and laminae[62,92,127] (Fig. 84.10). The prominent bony protuberance (inion) that is present approximately 2 cm below the EOP is the site of wire fixation (approximately 5–7 cm from the base of the skull). A 2-mm diamond burr is used to make unicortical holes to form a tunnel with a bridge of superficial cortical bone on each side of the midline. The holes are connected with a towel clamp between the inner and outer tables of the skull. A 20-gauge wire is passed through the tunnel and looped back under and out again to wrap around the bony bridge. A second wire is passed beneath the C1 lamina (if it has not been removed) and looped onto itself to cinch down on the lamina. A wire is passed transversely through the base of the C2 spinous process and looped around and passed back through to distribute stress. Other interspinous or sublaminar wires can be used in more caudad segments as needed. Long, thick corticocancellous posterior iliac crest grafts are harvested, typically 9 mm to 10 cm in length and 1.5 cm wide. For occiput to C2 fusions, a single block of graft may be used with the caudad end fashioned to fit around the C2 spinous process. A 1.5-mm drill bit is used to place holes through the graft. The wires are threaded through the graft with the cancellous side facing the exposed skull and laminae. The concavity of the central part of the iliac crest facilitates excellent contact between the occiput and the laminae. In severely osteopenic patients, a wire mesh may be placed over the cortical side of the graft to prevent the wires from cutting through the graft.[62] The wires are tightened down cautiously to prevent breakage or cutting through the graft. Cancellous bone chips may be added to the construct. A drain is typically used and the wound closed in layers. Without adjuvant fixation, most patients are managed in a halo vest postoperatively, but a two-poster brace or other cervical orthosis may be used based on the stability of the construct.

Occipitocervical Plating

This technique provides more rigid fixation compared with wiring techniques,[40,41,128,129] even in patients with significant osteoporosis. Current implants incorporate plate-rod hybrid constructs (Fig. 84.11). It may be technically challenging to produce the correct amount of contour required at the base of the skull. In longer fusions, it is recommended that fixation is achieved in and below C2 before fixation into the skull, since the distal fixation points require more precise placement. C2 fixation can be done with pedicle screws, transarticular screws, or intralaminar screws. Due to inferior pullout strength, C2 pars screws should not be used unless the fusion will be carried down into the subaxial cervical spine.

Fixation to the skull requires knowledge of the venous sinus anatomy to avoid bleeding complications. Screws should be placed distal to the transverse sinus, which lies at the level of the EOP. The thickness of the skull decreases laterally away

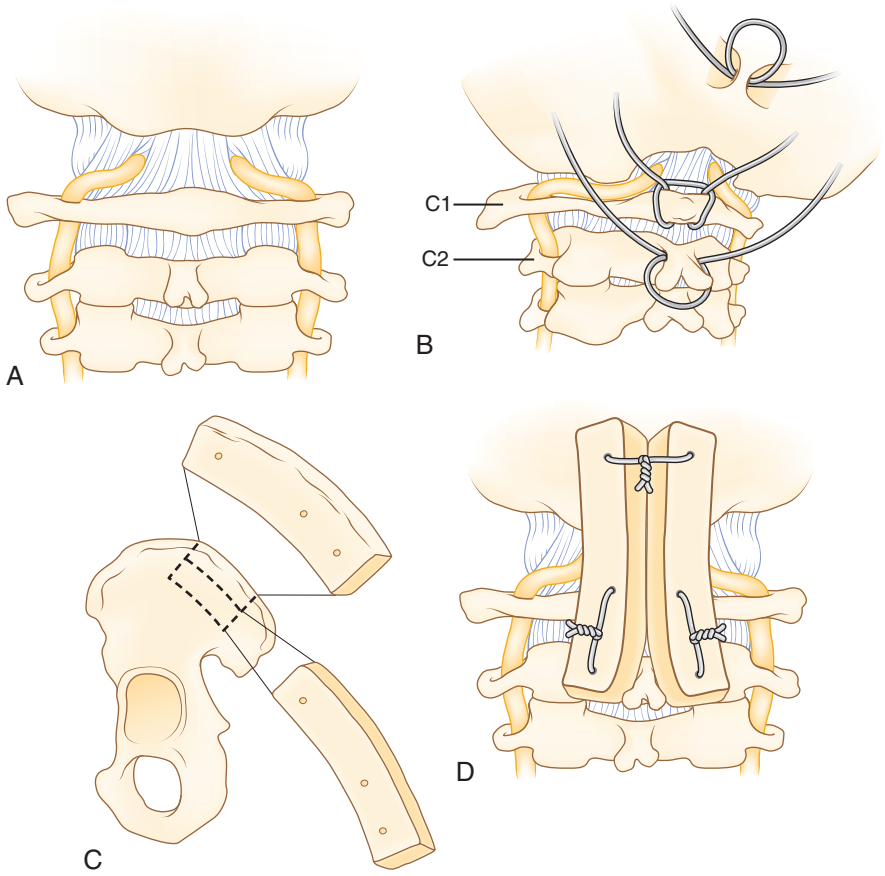

FIG. 84.10 Technique of posterior occipitocervical fusion. (A) A burr hole is made in the nuchal bony ridge, staying between the cortical table. (B) Twenty-gauge wires are passed down; looping the wire through a second time improves the grip and distributes the stress. (C) Near-full-thickness corticocancellous grafts are harvested from the ilium. (D) The grafts are wired in place as shown. Cancellous bone is also packed in the crevices. (Modified from Werthein SB, Bohlman HH. Occipitocervical fusion: indications, technique, and long-term results in thirteen patients. *J Bone Joint Surg Am*. 1987;69A:833–836.)

from the midline and closer to the foramen magnum.[130] Unicortical fixation is adequate in the thicker areas of the skull, but bicortical fixation can be performed safely. Two to three screws should be used on each side of the midline. A 2-mm diamond burr is used to minimize the chance of a spinal fluid leak common when using more aggressive carbide burrs. The holes are tapped and 3.5- to 4.5-mm screws between 6 and 12 mm in length are placed. In case of a spinal fluid leak, bone wax may be sufficient to stop the leak; otherwise, placing the screw usually tamponades the leak. There does not appear to be any adverse effect from breaching the inner table. Structural bone graft may be wired in or around the construct and augmented with cancellous bone. The head and neck are immobilized in a two-poster brace or a halo vest in osteoporotic patients with questionable fixation; in other patients, a hard cervical collar may be used. Patients are typically changed to a soft collar for comfort after 8 weeks.

Contoured Loop/Rod Techniques

This technique was first proposed by Ransford and colleagues[38] in 1986 and is used with segmental wiring to provide occipitocervical fixation.[38,131–133] The exposure is similar to that described earlier for plate fixation. Wires are placed in the occiput and beneath the lamina of C1 and the subaxial vertebrae. Earlier constructs relied on a horseshoe-shaped loop of 5/32 threaded stainless steel rods. The horizontal limb should be approximately 3.5 to 4 cm wide and the length of the occipital portion of the loop should be 2.5 to 3 cm. More recent constructs utilize a custom-contoured threaded titanium loop with titanium-threaded cables, which allows for postoperative MRI.

Resection of the Odontoid

Mild to moderate cervicomedullary compression can be treated with posterior C1 laminectomy and occipitocervical fusion as described earlier. The pannus will resorb with stabilization.[49] However, anterior decompression may be needed to treat an irreducible anterior extradural compression of the cervicomedullary junction by pannus or a severely migrated odontoid.[134,135] The transoral approach is associated with an increased risk of infection with mouth flora; the high retropharyngeal approach is a good alternative in many patients.[136] Supplemental posterior fusion is required unless there is a solid prior posterior fusion mass, in which case resection of the odontoid without grafting will suffice. In cases without prior posterior fusion, anterior strut grafting with iliac crest

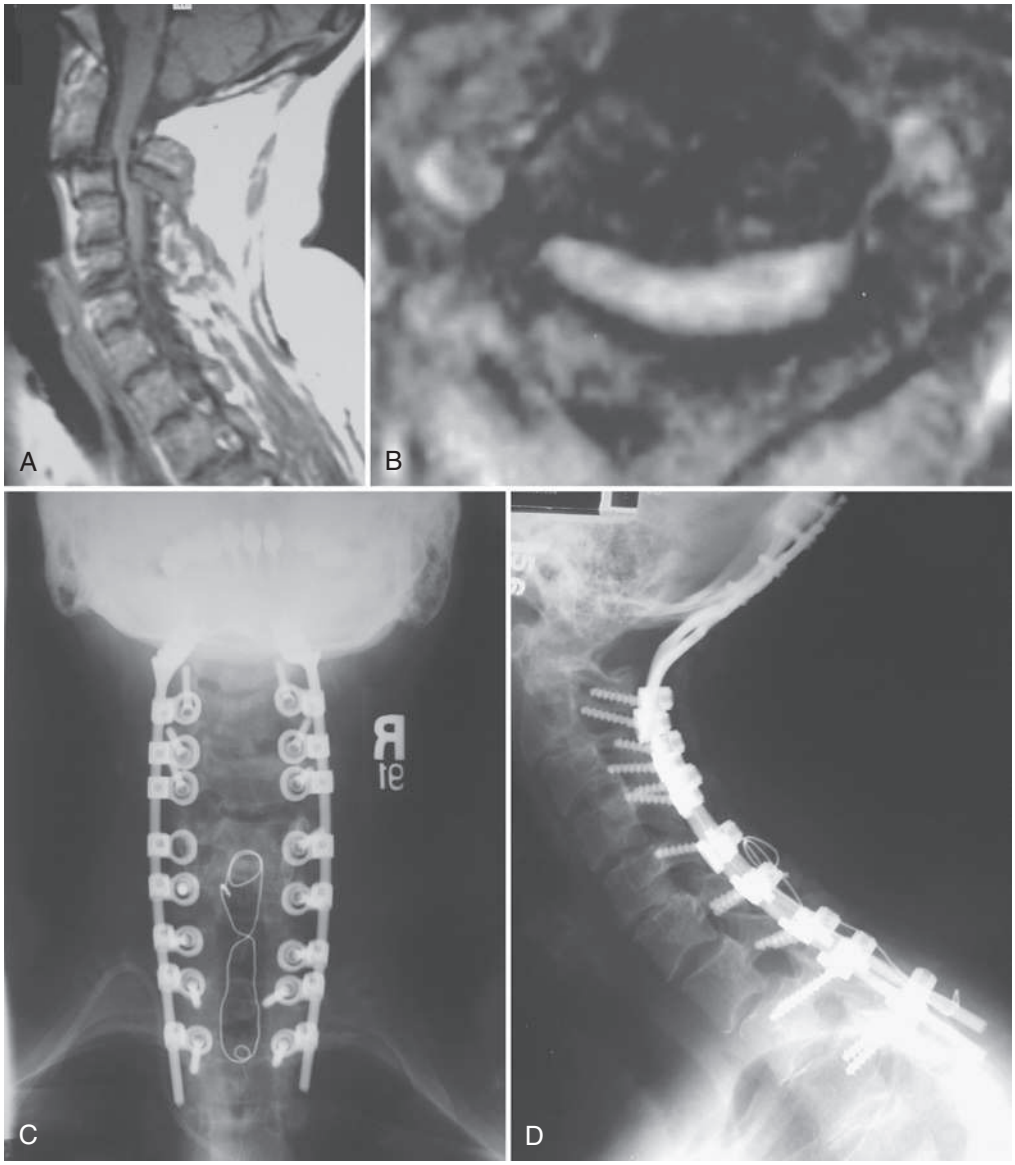

FIG. 84.11 This 46-year-old woman had a long history of rheumatoid arthritis since she was a young girl. She had chronic neck pain but developed worsening neck pain over the previous 6 weeks with increasing numbness of her arms and some truncal numbness. Some weakness of her upper extremities was evident on physical examination. (A–B) Magnetic resonance imaging showed severe cord compression, primarily at the C2–C3 level. She had multiple levels of subluxation in the subaxial spine, including C7–T1. (C–D) Anteroposterior and lateral postoperative plain films after a posterior decompression at C2–C3 followed by a long occipitocervical fusion with bone grafting and posterior instrumentation. Screws were placed in the pedicles of C7 and T1 for maximum fixation and osteoporotic bone.

or fibula is required between C2 or C3 and the clivus, followed by posterior occipitocervical fusion. Thorough preoperative assessment is necessary, which includes swallowing and respiratory function considerations, dental assessment, and the presence of a mobile temporomandibular joint to allow about 2.5 to 3 cm of opening.

Subaxial Subluxation

Subaxial subluxations may be fixed or mobile. The fixed types may be best treated with anterior decompression and fusion and strongly considered for supplemental posterior fixation since anterior column instability may occur from graft resorption or settling into the osteoporotic vertebral bodies. Mobile subluxations are best treated with traction to realign the spine and posterior instrumented fusion. Better reduction may be obtained after anesthesia when positioning of the head is done gently with neuromonitoring.

Anterior Fusion

Anterior decompression and fusion may be utilized for treatment of fixed cervical kyphosis or when needed to decompress

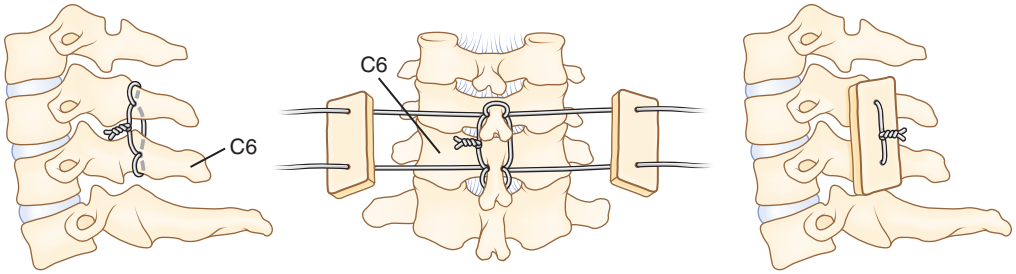

FIG. 84.12 Bohlman triple-wire technique for posterior cervical arthrodesis.

stenotic segments. These techniques may be performed as described for treatment of spondylotic disease elsewhere in this text. Because patients with RA frequently require multilevel procedures and because of the risk for graft settling into osteoporotic bone, consideration must be given to a supplemental posterior fusion.

Wiring Techniques

Posterior wiring and autogenous bone grafting may provide stable fixation at a high fusion rate. The preferred method for wire stabilization is the triple-wire technique described by Bohlman[136] (Fig. 84.12). The first 20-gauge wire is woven in a figure-of-eight fashion through holes burred into the base of the spinous processes of the involved vertebrae. This wire tethers the midline and is typically looped onto itself after passing through the spinous process to help distribute stress. Twenty-two-gauge wires can then individually pass through the same holes to loop around the spinous processes at the ends of the segments to be fused. The ends of these wires will pass through drill holes in the rectangular corticocancellous iliac crest autografts. The wires are tightened down on the graft to force the graft against the laminae. Decortication is not necessary; the wound is closed in layers over a drain. A two-poster cervical brace or halo is used for 6 to 8 weeks to allow solid fusion.

Lateral Mass Fixation

This treatment provides rigid fixation of the subaxial spine. Several modifications exist in the way the screws are angled in the lateral mass.[30–33] According to An,[30] 15 degrees of superior angulation and 30 degrees of lateral angulation best avoids violating the facet joints and nerve roots. All the techniques avoid the vertebral artery, which lies anterior to the lateral mass. The starting point is 1 mm medial to the center of the lateral mass. The screws average between 12 and 16 mm, depending on the size of the patient. The C7 lateral mass is thin and may require pedicle screw placement or supplemental posterior wiring between the C6 and C7 spinous processes, as described earlier. Fluoroscopy is helpful in placing C7 pedicle screws if the shoulders are not in the way, but a C7 laminotomy provides direct palpation of the medial wall of the pedicle for safer screw placement. A 25- to 30-degree medial angulation is recommended.[30] Pedicle screw fixation of all involved levels of the cervical vertebrae has been described frequently in other patient populations but has limitations of pedicle size and risks to the vertebral artery.[137] Because of the risk of subluxation with a long cervical fusion, consideration should be given to extending the fusion across the cervicothoracic junction.

Complications

Complications of cervical spine surgery in rheumatoid patients include dural tears, quadriplegia, infection, wound dehiscence, skin problems from external immobilization devices, nonunion, and subaxial subluxation above or below a fused segment. Anterior fusion procedures are at risk for graft resorption and anterior column collapse due to the inflammatory process and secondary osteoporosis of the vertebral bodies and may benefit from adjunctive posterior stabilization. The progressive nature of rheumatoid disease of the spine demands long-term follow-up to assess for the development of new symptoms in previously asymptomatic segments (see Fig. 84.12). In a study of 51 rheumatoid patients undergoing cervical fusion for instability, Clarke et al. reported that 39% of patients undergoing C1–C2 fixation developed subaxial subluxation at an average of 8 years.[138] No patient who underwent long posterior fusions (C1–C6 through T1) for combined atlantoaxial and subaxial instability required secondary procedures. In contrast, Tanouchi et al.[139] noted a 26% incidence of adjacent-level failures in 35 rheumatoid patients after occipitothoracic fusion. All failures were due to fracture at the distal junction. Including all involved unstable levels in the initial fusion procedure may reduce the risk of subsequent adjacent-level subluxation; however, fusion length and stress of the lever arm must be considered in these fragile patients. Age, presence of atlantoaxial instability, and perioperative complications are independent predictors of long-term mortality following cervical surgery in this population.[140]

Thoracolumbar Disease

Unlike the cervical spine, rheumatoid disease of the thoracic and lumbar spine less frequently leads to severe neurologic symptoms, thus has received less attention. Yet cases of thoracic myelopathy, lumbar radiculopathy, and cauda equina syndrome have been reported and appear to be due to bony destruction leading to instability and subluxation with or without the presence of pannus or nodules.[141–143] Radiographic

findings include poorly defined margins of the vertebral endplates and a relative lack of osteophytes.[6,7] Involvement of the facet joints may lead to spondylolisthesis and instability on flexion-extension films. Heywood and Meyers postulated that the pathologic process in the lumbar spine begins with synovitis of the facet joints causing functional incompetence, allowing AP and lateral translation.[6] This step is followed by discitis, which may start as an enthesopathy at the junction of the endplate and disc, resulting in loss of disc height and further contributing to instability. In the thoracic spine, the disease may also spread directly into the spine via the costovertebral joints. Nerve root impingement may be due to spinal instability as well as direct impingement from rheumatoid pannus.[6] To correlate radiographic findings with clinical symptoms, Kawaguchi et al. studied 106 rheumatoid patients and found a 40% rate of back pain, 18% had leg pain, and 12% exhibited symptoms of neurogenic claudication.[7] They reported abnormal radiographic findings in 57% of patients, most commonly disc space narrowing (37%), followed by coronal plane deformity (28%), spondylolisthesis (23%), and endplate or facet erosion (20%). They noted a high percentage of osteoporosis related to steroid therapy. Using MRI, Sakai et al.[144] reported a 45.2% incidence of lumbar involvement in RA and described two distinct patterns of disc destruction: narrowing, in which the disc space progressively collapsed, and ballooning, in which endplate changes gave the illusion of increasing disc height. Additionally, they found that the degree of lumbar involvement related to the severity of peripheral joint involvement.

Surgical treatment of the rheumatoid lumbar spine is tailored to the specific pathology involved; outcomes are similar to nonrheumatoid patients with similar pathology.[145] Complications, however, are more common and comprise screw loosening and cut-out, likely due to the relative osteoporosis of the population, and a greater risk of wound infections related to immune modulators used to treat the disease. Junctional breakdown can also occur.

Summary

The majority of patients with RA of the cervical spine can be managed nonoperatively. These patients, however, should be monitored closely since the progression of disease may be silent and the clinical findings nonspecific. Screening flexion and extension lateral radiographs should be done periodically before neurologic symptoms develop as well as prior to any planned surgical procedure that may require general anesthesia, intubation, or manipulation of the cervical spine. The benefits of early detection and surgical intervention in patients with progressive cervical instability cannot be overemphasized and should be done before the development of cranial settling or frank neurologic symptoms.[44,60,92] Otherwise, mortality and morbidity significantly increase as patients become less functional and fall under Ranawat class III criteria.[60,69,76,91,136] Although surgery in patients with quadriparesis may provide some neurologic and functional recovery, the results are not as predictable as with early surgery.

PEARLS

1. The periodontoid pannus begins to resorb as early as 6 weeks after atlantoaxial fusion.
2. Radiographic AADI 9 mm or greater confirms AAS and is a relative indication for cervical fusion.
3. A PADI less than 14 mm has a high sensitivity of predicting paralysis and is a more reliable radiographic criterion for cervical fusion than the AADI. A PADI less than 10 mm is associated with poor motor recovery after fusion, while a PADI greater than 14 mm has a higher likelihood of recovery.
4. A cervicomedullary angle of less than 135 degrees (normal, 135–175 degrees) correlates with myelopathic signs and suggests AAS as the source of myelopathy.
5. Patients with AAS have better outcomes if surgery is done prior to neurologic impairment.

PITFALLS

1. Anterior fusion procedures are at risk for graft resorption and anterior column collapse due to the inflammatory process and secondary osteoporosis of the vertebral bodies. Patients may therefore benefit from adjunctive posterior stabilization.
2. Radiologic improvement of AAS is a "radiographic illusion" and is due to worsening cranial settling of the anterior arch of C1 onto the base of the odontoid in reality.
3. Rheumatoid patients are at risk for late segmental instability below a previous fusion; therefore, they should be followed long term.
4. Myelopathy patients are at high risk for progression and sudden death if treated nonoperatively.
5. Perioperative upper airway complications are 14 times higher if intubation is done without fiberoptic assistance in rheumatoid patients undergoing posterior cervical fusion.
6. Attempts should not be made to pass sublaminar wires beneath a severely stenotic or unreduced C1 arch. Consider occipitocervical fusion with or without C1 laminectomy.
7. Commonly used rheumatic medications potentially place patients at risk for postoperative wound infections and their effects on spinal fusion are unknown. Most should be stopped preoperatively and held for as long as possible postoperatively. Close collaboration with the patient's rheumatologist is essential in balancing the need to minimize perioperative complications while preventing flares of rheumatoid symptoms.
8. Patients on chronic steroids may require perioperative stress dosing.

KEY POINTS

1. The cervical spine is involved in 25% to 90% of rheumatoid patients. Because cervical instability may be asymptomatic in many rheumatoid patients, the clinician must be vigilant in evaluating the cervical spine, especially preoperatively, for spinal or nonspinal procedures.
2. RA has a predilection for synovial joints, including the facet, occipitoatlantal, and atlantoaxial joints. The resulting joint erosion can lead to instability, of which the most common pattern is atlantoaxial, followed by subaxial and occipitoatlantal instability. Patients frequently present with pain but may also present with neurologic symptoms.
3. Surgical indications include the presence of myelopathy. Radiographic indicators include an AADI 9 mm or greater, PADI less than 14 mm, mobile subaxial subluxation greater than 3.5 mm, space available for the cord less than 14 mm, and cranial settling. A cervicomedullary angle less than 135 degrees

suggests impending neurologic deficit. Surgical intervention performed early, before clinically significant impairment, has the best functional outcomes.

4. Rheumatoid medications should be managed carefully in the perioperative period, as many mechanisms of action can increase the risk of infection, delayed wound healing, or affect fusion.
5. Modern rigid internal fixation should be used for surgical stabilization whenever possible. Because of variations in patient anatomy, the surgeon must be aware of different fixation options, such as C2 pedicle screws, C2 interlaminar screws, transarticular screws, or classical fixation techniques (e.g., wiring), as these may be the only available options at times. A clear understanding of the individual patient's anatomy and pathology is necessary to perform safe, effective surgery.

CHAPTER 85

Ankylosing Spondylitis

SECTION XII

Dheera Ananthakrishnan
Serena S. Hu

Ankylosing spondylitis (AS) was first described in the late 1800s by a group of French neurologists. It is currently classified as one of the spondyloarthritides. The hallmark of the disease is pain and stiffness of joints, mainly in the axial skeleton, with early inflammation in the sacroiliac joints and the spine and later findings of increased bone formation, leading to global and regional stiffness. The disease usually is diagnosed in men in their second and third decades of life. There is some debate about the true male-to-female ratio. It was previously thought that the ratio was almost 10:1. It is now accepted that the ratio is much lower, probably about 4:1. The disease affects males predominantly, with a 2:1 ratio. The disease in women is usually less severe, possibly leading to what may be perceived as a decreased incidence. AS is an autoimmune condition that often results in chronic pain, disability, deformity, and fractures, much of which is of a spinal etiology. In addition, large joints—most notably the hips, knees, and shoulders—develop early arthritic changes.

Pathophysiology

The association between the major histocompatibility complex antigen HLA-B27 and AS has been well established.[1–6] Approximately 90% of AS patients are positive for the HLA-B27 antigen, although less than 10% of patients who are HLA-B27 positive manifest the signs and symptoms of AS. First-degree relatives of AS patients who are HLA-B27 positive who are also positive for the antigen have a 30% risk of having AS in contrast to the prevalence in the general population, which is 1% to 2%. The exact mechanism of the AS and HLA-B27 connection is unknown, although a bacterial association has been proposed. Recent research has revealed complex associations of AS with cytokines, such as the interleukins and tumor necrosis factor; this research has led to new treatment algorithms for disease modification.

AS is an inflammatory disease in which joints become arthritic and eroded, followed by autofusion (ankylosis). Microscopic evaluation of early lesions shows lymphocytic infiltrates, plasma cells, and macrophages. The first joints to be affected are usually the sacroiliac joints, followed by the vertebral apophyses, followed by the costovertebral joints. When the costovertebral joints have been fused, chest expansion is much reduced, leading to a decrease in pulmonary function. Enthesopathies are also common, leading to inflammation and erosions of the junction of the anulus and the vertebral endplate. Subchondral marrow edema is a classic finding in enthesopathies associated with AS. Erosions lead to ossification of the endplates, which is manifested by the bridging syndesmophytes seen on plain radiographs. Ankylosis of the facet joints leads to the "bamboo spine" seen on plain radiographs. During the progression of facet ankylosis, patients tend to assume a kyphotic posture to unload the joints and relieve the pain. With time, this compensatory mechanism leads to the fixed deformities of cervicothoracic, thoracic, and lumbar kyphosis commonly seen in AS patients who present to spinal surgeons. These deformities lead to difficulty with horizontal gaze, ambulation, and activities of daily living.

When the spine has become completely ankylosed, it functions as a rigid, brittle beam, leading to an increased incidence of fracture with even minor trauma. These fractures represent the second pressing issue that spine surgeons must deal with when treating patients with AS. Osteoporosis also plays an important role in AS.[1,7–10] The greatest decrease in bone mass occurs early in the course of the disease, although the reason for this is unknown. Decreased bone density in AS patients is multifactorial: it results from the uncoupling of bone formation and resorption, stress shielding in the vertebral bodies, and decreased activity and decreased muscle mass.

AS affects peripheral joints as well. The most common joint involved is the hip joint, where protrusio acetabuli can be seen. Hip involvement is often bilateral and often occurs early in the course of the disease. In addition, the presence of thoracic and lumbar kyphosis compounds the problems seen with hip flexion contractures because these conditions contribute to an inability to stand upright. The shoulders, knees, wrists, and hands are also affected but to a much lesser degree.

Disease modifying antirheumatic drugs are currently being researched for treatment of AS.[10–12] In particular, tumor

necrosis factor blocking agents such as infliximab have been shown to improve clinical symptoms as well as decrease inflammatory markers and decrease appearance of inflammation on magnetic resonance imaging (MRI), all in the axial skeleton. These drugs have been promising, particularly when compared with traditional agents such as sulfasalazine, methotrexate, and nonsteroidal antiinflammatory drugs (NSAIDs), which have not been shown to be very effective in the axial skeleton, although they have been shown to help in the appendicular skeleton.

Nonorthopaedic Manifestations

Although it is the musculoskeletal system that is mainly affected by AS, there are other serious effects of the disease. The most common extraskeletal abnormality is anterior uveitis (approximately 25% of patients), which is usually treated with topical agents and rarely leads to vision loss. Ankylosis in the thoracic spine and at the costovertebral joints leads to markedly diminished chest wall expansion, resulting in restrictive lung disease with decreased lung volumes (vital capacity and total lung volume) and increased dependence on diaphragmatic excursion. Preoperative pulmonary function tests are recommended as is smoking cessation and aggressive postoperative pulmonary toilet. Some AS patients (25–30%) also have a component of ileitis or colitis, or both; regardless, all patients for whom surgery is being contemplated should have a preoperative nutritional assessment and should be considered for perioperative nutritional supplementation. The incidence of aortic stenosis and aortic valve insufficiency is increased in these patients as well; a preoperative echocardiogram is recommended routinely.

Physical Examination and Diagnosis

A patient with AS is most often a young man who gives a history of vague nonlocalizing back pain, morning stiffness, and possibly increasing difficulty with activities of daily living. Although women are affected with AS, men often present earlier or with more advanced disease. Upon physical examination, diminished spinal mobility, especially in the sagittal plane, is usually present. The Schober test is used to evaluate lumbar spinal motion: points 10 cm above and 5 cm below the lumbosacral junction in the midline are marked on the patient in the fully upright position. With full forward flexion, there should be at least 5 cm of excursion between these two points. Chest expansion is commonly limited to less than 2.5 cm of excursion and is typically measured at the fourth intercostal space. The modified New York diagnostic criteria for AS were outlined in 1984 and are as follows[13]:

1. Sacroiliitis confirmed by radiographs
2. Persistent low back pain greater than 3 months in duration
3. Diminished chest expansion (as just described)
4. Limited range of motion of the lumbar spine in the sagittal and coronal planes

The presence of sacroiliac inflammation and one of the other three criteria are generally considered enough to establish the diagnosis of AS.

Sacroiliitis is usually identified on an anteroposterior pelvis film (with or without a Ferguson view). It is widely accepted that the presence of sacroiliitis is crucial for the diagnosis of AS. Sacroiliac joint destruction is the earliest manifestation of AS. The earliest stages of sacroiliitis show some blurring of the cortical margins; this progresses to subcortical erosions (more commonly on the iliac side because it is less robust than the sacral side). In advanced stages, the sacroiliac joints become completely fused and the cortical erosions disappear. Sacroiliac joint involvement usually is symmetrical and bilateral. Studies have suggested that the use of bony pelvis computed tomography (CT) or MRI in conjunction with plain radiographs may lead to earlier diagnosis of AS.[8] It has yet to be determined whether this early diagnosis favorably affects clinical outcomes.

Management of Acute Injury

The spinal surgeon is usually not the physician making the initial diagnosis of AS but rather is called on to address spinal deformity caused by AS in the clinic and spinal trauma in an AS patient in an emergency setting. A trauma patient with AS also presents a great challenge to the spinal surgeon. The spine in AS functions as a long rigid beam, acting much like a long bone. This altered biomechanical state, plus the presence of osteoporosis and the lack of ligamentous constraints, significantly decreases the fracture threshold of the ankylosed spine. The key to detecting fractures in these patients is having a high index of suspicion, especially after minor trauma. Delay in diagnosis is common and is associated with secondary neurologic injury. The cervical and cervicothoracic regions are the most commonly affected, followed by the thoracolumbar junction. Plain radiography is neither sensitive nor specific in these instances; in many trauma centers, plain radiography has been replaced by CT as the initial radiographic evaluation for a suspected spinal injury. Epidural hematoma, spinal cord injury, and disc injury can be visualized with MRI as a secondary evaluation. The physician making the initial evaluation should keep in mind that often CT scan is not sensitive enough to pick up an occult fracture; given the high cost of missing these fractures, an MRI should be obtained in cases of clinically suspected fracture not visualized on CT scan.

A patient with AS may present with a progressive neurologic deficit without obvious bony injury or with progression of the spinal deformity and increased pain. This may be a missed spinal column injury that presents at a later time to the clinic or the emergency department with progressive neurologic deficit or worsening of deformity, or both. The evaluating clinician must also be aware of possible hyperextension through a fracture at a kyphotic segment, which may result in relatively normal sagittal alignment. Attempts to determine the patient's preexisting deformity from history and prior radiographs should always be made. There have been reports of neurologic injury in patients strapped to spine boards in a

position of hyperextension when compared with their preinjury alignment.[14,15] Because of the stiff and osteoporotic spine, minor trauma may result in acute angulation or moderately rapid deformity progression. One should refrain from attempting acute correction through such a fracture. The patient should be initially immobilized in a halo vest in the preinjury alignment. Every attempt to maintain the patient's preinjury posture while performing the evaluation should be made.

For a patient with a neurologic deficit, MRI is imperative. MRI may reveal an epidural hematoma, buckling of the ligamentum flavum, or a disc herniation. Hematomas can occur in these patients from minor trauma from the osteoporotic bone or from scarred epidural vessels adjacent to a fracture. Evacuation of a hematoma is essential in the presence of progressive neurologic deficit. The decompression required may significantly destabilize the AS patient; thus, the surgeon should be prepared to stabilize the spine at the same setting. Usually, rigid instrumentation is required, although rarely halo immobilization may be sufficient for some cervical cases. As with instrumentation for elective cases, the screw-bone interface is compromised because of osteoporosis and the overall spinal column can be extremely unstable in these situations. Both of these concerns warrant aggressive stabilization with multiple fixation points above and below the fracture site.

The incidence of neurologic injuries in these patients is quite high (58–65%) owing to excessive bleeding at the fracture site leaking into the confined epidural space and translation (displacement) at the fracture site. The translation causes direct injury to the spinal cord and persistent bleeding due to motion, resulting in an enlarging compressive hematoma. Most spinal injuries in AS patients are three-column injuries (because of the stiffness of the load-absorbing structures). These injuries are highly unstable because there are two long lever arms hinging at the fracture site. In addition, the presence of preinjury kyphosis increases the likelihood of translation at the level of the injury, which subsequently increases the likelihood of neurologic injury. Last, poor bone stock and difficult radiographic evaluation can lead to a delay in diagnosis and a secondary neurologic decline. Most of these injuries (60–75%) are at the cervicothoracic junction, which is notoriously difficult to evaluate with plain radiographs. If the surgeon uses lateral mass screws in the cervical spine, these constructs should generally be supplemented by external support, such as with a halo vest. Laminar hooks may be more rigid in many patients, but external bracing should still be considered.

It is generally accepted that AS patients sustain more spinal fractures and dislocations than individuals without AS, anywhere from 4 to 7 times the fracture rate of those unaffected by AS.[10–12,16–20] Carbone and colleagues[2] retrospectively looked at 158 patients in Rochester, Minnesota, with AS and found a sevenfold increase in the incidence of spinal fractures over that of a cohort of patients without AS. They found no such increase in extremity fractures. The patients with spinal fractures tended to be older and had a greater preinjury involvement of the spine than patients without fractures. Cooper and colleagues[16] also noted that this higher incidence was mainly during the first 5 years after diagnosis and suggested that this was due to a greater percentage of bone density loss during this period, resulting in a decreased fracture threshold. In addition, the dampening structures present in a normal spine have lost their load-absorbing qualities in the ankylosed spine. The intervertebral discs are stiff, as are the ligamentous structures, and the facet joints are ankylosed.

Whang and colleagues[21] compared a cohort of 12 patients with AS who sustained spinal injuries with 18 patients with diffuse idiopathic skeletal hyperostosis (DISH) who sustained spinal injuries. The DISH group represents a group of patients of similar age whose spinal condition results in stiff segments above and below any spinal fracture. Falls from a standing position were the most common mechanism of injury. There was a greater likelihood that the DISH patients did not incur any neurologic deficit (44.4%) compared with AS patients (25% of whom did not have a neurologic deficit). Complication rates were higher in the AS group (42% vs. 33% in the DISH group). There were two deaths in each group related to the injury or its treatment, all of which were considered to be related to the use of the halo vest (aspiration [two deaths], respiratory failure, and multisystem organ failure). Several patients died of unrelated causes during the follow-up period; however, all surviving patients were contacted and were classified as having excellent or good outcomes.

Caron et al.[22] looked retrospectively at 112 patients with AS and DISH who sustained 122 fractures. The majority of these were extension-type injuries, most at the C6–C7 disc level. Nearly 60% had a spinal cord injury. Nineteen percent of the patients had a delayed fracture diagnosis. Subgroup analysis noted no significant differences between the AS group and the DISH group (28 and 74, respectively). Two-thirds of the patients underwent surgery, which usually consisted of a posterior fusion with a minimum of three levels of fixation above and below the injury level. There was a high rate of complications (84%) as well as a high rate of mortality (32%), the latter of which correlated with advanced age (>70 years old). However, 34% of the patients with a spinal cord injury improved neurologically, and these authors did feel that surgery could be beneficial, though difficult, in these patients.

Westerveld et al.[12] did a literature review of fractures in patients with AS and DISH. Ninety-three articles were reviewed, with 345 ankylosing spondylitis patients and 55 DISH patients. They noted that most of the injuries were as a result of a low-energy insult (65–69%) and that most were cervical spine fractures (60–81%). Of the AS patients, 17% had a delay in diagnosis, with 14% of patients sustaining a secondary neurologic decline. Of the patients, 54% underwent surgery; the majority of these surgeries were posterior spinal fusions. They did note some unusual complications after surgery, such as aortic dissection, pseudoaneurysm, and tracheal rupture; however, the patients treated nonoperatively had a similar mortality rate compared to the surgically treated patients (11–13% vs. 6–7%, not significantly different from a statistical standpoint).

Finkelstein and colleagues[23] looked retrospectively at 21 AS patients with a diagnosis of spinal trauma. One-third of these patients had a delay in diagnosis; three had complete spinal cord injuries on presentation, and three experienced

neurologic deterioration to complete spinal cord injuries after admission. These authors recommended quick-screening cervical and thoracic MRI (one film) and screening lumbosacral spine MRI (one film) for diagnosis, in addition to minimal transfers and immediate stabilization. They did not comment on their definitive protocol for treatment of these patients (operative vs. nonoperative).

Hitchon and colleagues[24] retrospectively reviewed 11 patients with AS and thoracic and lumbar fractures. They found that 10 of these patients had sustained three-column injuries; 9 patients had extension-type injuries. More than half of these patients had a neurologic deficit (the specifics of which the study authors did not mention); half of these neurologically injured patients had some improvement in function. These authors recommended surgical intervention for stabilization of thoracic and lumbar three-column injuries because of their inherent instability.

The relatively recent adoption of minimally invasive techniques has been looked at in the AS population. Nayak et al.[25] looked at 11 consecutive patients with AS and/or DISH treated with minimally invasive surgery stabilization after hyperextension injuries of the thoracolumbar spine. The mean age was 77 years and the mean American Society of Anesthesiologists grade was 3. An average of 7 segments were instrumented. Of note is that the authors did not comment on whether they attempted a fusion in these patients or not. There were no revisions, and the clinical outcomes were similar to those of elective lumbar degenerative surgery.

Graham and van Peteghem[26] looked retrospectively at 15 patients over 6 years (1978–84) comparing types of injuries and treatments. Of the patients, 12 had cervical spine injuries; 9 of these had spinal cord injuries. The two patients with thoracic injuries had anterior cord syndromes. There were no compression-type injuries; most injuries resulted from a flexion-extension type of mechanism. The only patient treated with operative intervention was the patient with the lumbar injury, who had hardware failure and had to undergo revision. Two patients died, and three patients had pulmonary complications.

Apple and Anson[27] reviewed AS patients with spinal fracture and spinal cord injury, comparing operative versus nonoperative treatments. This study was a retrospective, multicenter study of 59 patients. In the operative group, 37 patients were treated with a variety of procedures. Patients in the nonoperative group were placed in halo traction followed by halo vests and placed on bed rest. There were no significant differences between the two groups with regard to motor recovery, fusion complications, or mortality rate (22% in both groups). The nonoperative group did have significantly shorter hospital stays. No analysis of the patients according to type of injury or treatment was done, and no discussion of the deaths was presented.

Hunter and Dubo[17] reviewed the cases of 19 AS patients who had sustained cervical spine fractures. Five of these patients had a complete spinal cord injury, and all of these patients died after their injury without having had any surgical intervention. All of these patients were treated nonoperatively. No patient developed neurologic deterioration, and all of the patients with incomplete cord injury regained some function. The authors concluded that nonoperative treatment worked well in these patients, although they suggested that surgery be considered in patients with grossly unstable injuries.

In a classic article, Bohlman[28] retrospectively reviewed 300 patients with cervical spine injuries.[28] He found only eight patients who carried a preinjury diagnosis of AS. Five of these patients died of pulmonary or gastrointestinal causes. Clinically significant epidural hematomas were found only in the AS patients. Bohlman recommended decompression for patients with progressive neurologic deficit. There was a delay in diagnosis in four patients, all of whom developed spinal cord injuries.

The generally accepted protocol with respect to the management of spine trauma in AS patients is as follows. If the clinician has even the slightest suspicion of spinal injury, the patient should be immobilized in the preinjury position. Plain radiography and fine-cut CT with reconstructions should be obtained. If the patient has a neurologic injury, MRI should be considered, looking for an epidural hematoma. If a fracture is detected and displacement or gross instability is noted, low-weight inline traction should be used in an attempt to facilitate a reduction to the preinjury alignment. If a reduction is obtained, the patient should be placed in a halo vest for definitive treatment. If a reduction cannot be obtained, internal fixation is recommended, with or without decompression if indicated by the patient's neurologic status. Postoperative immobilization in the form of a halo vest is then recommended. In a patient with a progressive neurologic deficit, MRI is likely to reveal the presence of a hematoma. In a patient with a stable deficit and no hematoma, the cord injury likely occurred at the time of injury; as long as the spine is stable, management of the neurologic injury should be expected. If the spine is unstable, reduction and stabilization either with traction followed by a halo vest or with surgery is recommended if the patient is medically able to tolerate surgery. If not, external immobilization, such as a halo vest or rigid thoracolumbar orthosis, can be used to manage these injuries, but in general the clinical outcomes are better with surgical intervention due to the high rate of unstable injuries. Despite some case reports to the contrary,[12,14] the standard of care for the AS patient with a spinal fracture is *not* to attempt a deformity correction at the same sitting as fracture stabilization. Rather, the two issues should be dealt with separately, allowing the patient to recover from the fracture and the surgery, then planning an elective deformity correction if it is warranted and the patient is able to tolerate it.

Complications can arise at the time of injury and from treatment of the injury. Deformity and neurologic injury can occur as a result of the injury; treatment with decompression and internal fixation carries risks of nonunion, hardware failure, failure of the bone-screw interface that results in loss of fixation, and infection. Halo management carries its own risk of complications. Skull fractures, pin tract infections, intracerebral hemorrhage, and intracranial air all have been reported with halo immobilization in these patients.[14,29] Taggard and Traynelis[30] described a posterior cervical fusion (lateral mass plating) that they used in seven AS patients who

had sustained fractures. The fusions were supplemented with autologous rib grafts. Postoperatively, the patients were immobilized in collars only, with the exception of one, who was placed in a sternal-occipital-mandibular immobilizer. Fusion occurred in all patients; there were two deaths in quadriplegic patients. The authors recommended operative intervention as a means of avoiding postoperative halo immobilization. Other complications that have been reported include cardiac issues, aortic rupture, postoperative dysphagia, and infection, to name a few.

Deformity

The deformities seen in AS are a result of excessive kyphosis throughout the spine and excessive flexion at the hip joints. All areas of the spine can be affected, with the lumbar spine affected most often, followed by the thoracic and cervical spine. If the physical examination and radiographic examinations indicate that the hip flexion contracture plays a significant role in the overall deformity, hip arthroplasty should be performed before spinal surgical intervention. In this manner, the less morbid operation is performed first; in addition, the spine surgeon can better assess the actual amount of sagittal imbalance attributable to the spine.

The spine surgeon must carefully examine the patient in the standing, seated, and supine positions to determine the major component of the deformity. If a major portion of the deformity corrects on moving from a standing to a seated position, the deformity is most likely arising from the hip joints or the lumbar spine and arthroplasty should be performed first. If the deformity persists on sitting but corrects in the supine position, the deformity is arising from the thoracic, thoracolumbar, or lumbar spine, and a lumbar osteotomy is usually indicated. If the deformity persists even in the supine position, the deformity is in the cervicothoracic area, and an osteotomy in this area is indicated.

From a radiographic standpoint, a full spine lateral radiograph with the neck in a neutral position and the hips in a fully extended position is crucial for surgical planning. This radiograph allows measurement of the chin-brow angle, which is formed by a line from the chin-brow to the floor vertical angle. This measurement is helpful when planning any osteotomy. Ideally, the chin-brow angle should be zero. Suk and colleagues[31] looked at the significance of the chin-brow measurement in assessing the success of surgical intervention. These investigators evaluated 34 AS patients undergoing lumbar or thoracolumbar osteotomies for correction of sagittal imbalance. Preoperative and postoperative chin-brow angles were measured. Clinical outcome assessment involved the Modified Arthritis Impairment Scales (AIMS). This questionnaire consists of three simple questions plus numerous subscales: function, indoor activity, outdoor activity, psychosocial activity, pain, and overall subjectivity. The authors found improved postoperative AIMS scores for questions involving looking forward, going up stairs, and going down stairs. There was a negative correlation between chin-brow angles and correction obtained but no correlation between chin-brow angle and clinical outcome. The patients who were overcorrected (to an angle <10 degrees) had worse scores with regard to looking forward and going down stairs; these results were found to be statistically significant.

Song et al.[32] investigated the optimal chin-brow angle for AS patients. They looked at 25 patients with AS who underwent surgical intervention for deformity correction, evaluating the final chin-brow angle as well as visual field–related life quality measurement scales and subjective appearance. In addition, they evaluated a number of indoor and outdoor activities. They found that the optimal chin-brow angle for best function and appearance was between 10 and 20 degrees.

When the location of the primary spine deformity is determined, the surgeon must decide what type of osteotomy would be most appropriate. It is preferable to place the osteotomy at the apex of the deformity, but this is not always possible. Thoracic and thoracolumbar osteotomies are limited by the rib cage, the spinal cord, and the conus medullaris. Deformities in these areas are often almost always treated with a lumbar osteotomy. By moving the osteotomy more caudally, one can obtain more sagittal plane alignment correction owing to a longer lever arm. By overcorrecting at the lumbar level, one can address the thoracic kyphosis and lumbar kyphosis. If overcorrection is to be performed, the surgeon should take into account what portion of the deformity is cervicothoracic because the patient's horizontal gaze would be affected and may not be restored. Of note, however, is that lumbar osteotomies present their own assortment of problems, such as difficulty with visualization and fewer points of fixation available distal to the osteotomy. These issues may lead the surgeon to perform an osteotomy or vertebral body resection in the thoracic spine, which carry their own set of risks and potential complications.

Preoperative Assessment

A careful history should yield information about the patient's lifestyle, habits, and medications. Smoking cessation is imperative in these patients; many surgeons do not undertake the operation while a patient is actively smoking. NSAIDs should be discontinued at least 2 weeks before surgery. Preoperative pulmonary function tests are indicated because most of these patients have restrictive lung disease. Preoperative echocardiography may also be indicated, as previously mentioned, although cardiac intervention is not often needed. Results of renal function tests should be obtained before surgery; an awareness of tenuous renal function would benefit intraoperative and postoperative fluid management. Many AS patients have a component of renal dysfunction because of long-term use of NSAIDs. Cervical spine flexibility should be assessed by the orthopedist and the anesthesia service before the procedure; fiberoptic intubation is usually needed because of concomitant ankylosis of the cervical spine.

Historically, most osteotomies in AS patients were performed with the patient awake or using a Stagnara wake-up test for evaluation of spinal cord function before, during, and after a correction. Somatosensory evoked potentials and motor

evoked potentials (epidural or transcranial) have become more reliable so that the wake-up test is less frequently needed. The anterior tracts are better monitored by motor evoked potentials. These tracts can be preferentially affected during an extension maneuver when addressing kyphotic deformities, either by direct compression or by impairing the vascular supply to the spinal cord. Of note is that in 2006, Simmons presented his 36 years of experience with his classically described cervicothoracic osteoclasis procedure performed in the seated position under local anesthesia alone.[61] He noted a slight change in technique in the latter years, with a larger area of bony resection laterally, but the anesthesia and surgical position remained the same. No instrumentation was used; rather, all patients were placed in a halo vest for 4 months. He reviewed 131 cases and noted three cases of intraoperative paraplegia, one of which resolved after the dura was split, one of which was thought to be related to a carotid artery distraction. The third did not recover significantly after splitting of the dura. Sixteen patients developed a C8 radiculopathy. Four patients died within 3 months of surgery from pulmonary and cardiac complications. Also noted were few complications of pseudarthrosis, pneumonia, deep vein thrombosis, and halo pin infections.

A preoperative nutritional assessment (albumin, prealbumin, total protein) should be performed; perioperative nutritional supplementation (tube feedings or parenteral nutritional assessment) may be indicated. Klein and colleagues[33] noted a significant increase in complications, such as deep wound infection in patients undergoing lumbar spinal fusion who were malnourished by nutritional parameters preoperatively. Hu and colleagues[34] and Lapp and colleagues[35] showed that supplementation in the form of parenteral nutrition is beneficial in reducing complication rates after reconstructive spine surgery.

Lumbar Osteotomies

The first lumbar osteotomy was described in 1945 by Smith-Petersen for use in the rheumatoid patient.[36] This osteotomy is an opening osteotomy, meaning that the apex of the wedge lies posteriorly, opening up the anterior column during correction (osteoclasis through ossified disc space and anterior longitudinal ligament). Smith-Petersen and colleagues performed multilevel osteotomies in six patients. These osteotomies were V-shaped in the coronal plane, with the point of the "V" at the midline in the interlaminar space. The osteotomies are carried out through the articular processes bilaterally at two or three levels. It is imperative that adequate amounts of lamina and flavum are resected before correction so that compression of the neural elements on closure does not occur.

Cauda equina syndrome has been reported by Simmons[37] as a result of a decrease in canal dimensions. The posteriorly based closing wedge type of osteotomy results in an anterior opening at the level of the disc space. This anterior opening can be better achieved in an AS patient than a patient without AS because of the stiffness of the disc space. Complications of an opening wedge osteotomy include superior mesentery artery syndrome and aortic rupture owing to stretching of the abdominal vasculature.[38,39] Vascular complications are rare and tend to occur in older patients with calcific, adherent abdominal vessels.

Lichtblau and Wilson[38] described a patient who underwent closed osteoclasis followed by cast placement. This patient died in the immediate postoperative period of an aortic rupture. His history was significant for a large dose of radiation that was used to treat the ankylosed spine. Fazl and colleagues[39] described an AS patient who sustained a fracture through the T12–L1 disc space. He was treated with Harrington rod instrumentation and fusion but died 2 days postoperatively from an aortic rupture at the level of the injury. Aortic necrosis was present at autopsy, as were adhesions of the vessels to the spine. More common complications reported include ileus, pneumonia, and root traction injury. Cauda equina syndrome with flaccid paralysis below the level of injury, although rare, was reported in these studies as well.

Patients originally were immobilized in plaster; segmental instrumentation currently is indicated for these patients. Many investigators have reported their results after multilevel Smith-Petersen osteotomies.[36,40,41] Nonunion rates resulting in recurrence and progression of deformity were significant. Soon after the original description of this technique, reports of "plugging up" the open disc spaces with interbody fusions showed increased fusion rates and decreased complications.[42] The complications associated with opening wedge osteotomies led to modifications of Smith-Petersen's techniques. In 1949, Wilson and Turkell[43] described a procedure similar to the Smith-Petersen procedure in which less bone is removed but more osteotomies are created. The anterior longitudinal ligament is not ruptured; the anterior column length is not changed. In 1985, McMaster[41] described the addition of Harrington compression instrumentation to Smith-Petersen osteotomies in 14 patients. This instrumentation was used to close the wedges produced after osteotomy. Postoperatively, the patients were placed in casts for 9 months. Mean correction was 33 degrees at final follow-up. Subjective improvement was found in horizontal gaze and height and posture. The author suggested that a slow controlled osteotomy closure was beneficial in terms of overall stability and protection of neural elements. Püschel and Zielke[44] also performed multiple wedge-shaped Smith-Petersen type osteotomies and used Zielke instrumentation to close the osteotomies. They also recommended a slow correction with a gradual lordosis.

After reports of nonunions and concerns about stretching of the abdominal vasculature and viscera, Thomasen[45] described a closing wedge osteotomy. He reported on 11 patients in whom he performed a complete laminectomy at L2, transected the transverse processes, and resected the ankylosed facets at L2–L3. The pedicles of L2 were removed in their entirety down to the posterior aspect of the vertebral body. The entire vertebral body was decancellated, followed by removal of the posterior cortex and osteotomies of both lateral cortices. After careful mobilization of the dura above and below L2, Thomasen[45] closed the wedge by gradual flexion of the table. Internal fixation (plates and wiring) was used in six patients; all patients were placed in casts. One patient

had a fracture-dislocation above the level of the osteotomy, resulting in a cauda equina syndrome. This patient had almost complete return of neurologic function after revision decompression and internal fixation. Correction ranged from 12 to 50 degrees. All patients had subjective improvement of posture and horizontal gaze.

Heinig's eggshell procedure[45a] was described in 1984 as a monosegmental osteotomy to be used in the same situations in which one would use Thomasen's procedure. Thomasen leaves the anterior vertebral body cortex intact, whereas Heinig actually describes fracturing this cortex, which decreases the length of the anterior column and the posterior column. As long as more bone is removed posteriorly, restoration of lordosis occurs.

Bradford and colleagues[46] reported in 1987 on a series of 21 patients with AS who underwent single-level or multilevel lumbar or thoracic osteotomies with or without anterior discectomies. All patients had internal fixation posteriorly with a thoracolumbosacral orthosis. Average corrections ranged from 9 to 36 degrees. Complications were noted more frequently in the closing wedge-type osteotomies (neurapraxias and fracture during hook placement). Wake-up tests were used in all patients. In addition, these authors recommended closing-type osteotomies to avoid traction on the spinal cord, wide decompression, and internal fixation to avoid neurologic complications.

In 1990, Hehne and colleagues[47] reported on 177 patients with AS in whom multisegmental opening wedge lumbar and thoracolumbar osteotomies were performed. These authors were the first to report on the use of pedicle screw fixation. Casting and bracing were used postoperatively. Average correction at follow-up (18–42 months) was 43 degrees, with horizontal gaze subjectively restored in all cases. Complications included deaths, transient paresis, transient and permanent nerve root injuries, implant failures, and infections. These authors suggested that pedicle screw fixation with multisegmental osteotomies can produce a smoother lordosis than that produced by a monosegmental osteotomy.

In 1992, Jaffray and colleagues[48] presented three patients in whom a decancellation closing wedge osteotomy was performed. They did not remove the entire pedicle; rather, the inferior aspect of the pedicle was preserved to ensure protection for the exiting nerve root. Pedicle screw fixation plus a postoperative cast was used. These authors recommended two-level osteotomies (L2 and L4) for patients who needed more correction. Horizontal gaze was corrected in two patients; one patient required a cervicothoracic osteotomy for complete gaze correction. Complications were not discussed.

The technique for lumbar osteotomy, whether via an opening wedge osteotomy or a closing wedge three-column osteotomy, begins similarly. The patient is positioned in the prone position on an operative table with the abdomen free to decrease venous congestion and bleeding. Often, an operative table that can be extended to facilitate correction is useful for these patients. Standard exposure of the areas to be instrumented is performed. Fixation points, usually pedicle screws at least three levels above and below the intended apex of the correction, are attained. Smith-Petersen osteotomies are performed as desired, gaining correction at each level, which can be facilitated by extending the operative table. A rod of the desired and intended configuration should be contoured in preparation for the correction. If a three-column osteotomy is needed, the laminectomy is performed at the desired level. This is most often L3 or L4, since the more distal correction will allow more improvement of the sagittal vertical axis but still allow three levels of fixation distally. The pedicle is skeletonized and then removed; the vertebral body is then decancellated in a wedge configuration. Often, a temporary rod is needed to prevent the osteotomy from collapsing prematurely. Decancellation of the osteoporotic spongy bone can result in significant bleeding and intermittent packing of the site with hemostatic agents is usually needed. Once the vertebra has been resected, the lateral body wall can be divided and the posterior body wall imploded into the defect. Placement of the contoured rod, supplemented by extension of the table, usually facilitates excellent correction. Once the spine has been stabilized, radiographs are taken to assess correction; if additional correction is needed, more bone can be removed or the rod or table further adjusted.

More recently, Van Royen and De Gast[49] mathematically analyzed the sagittal plane corrections of two patients and determined that the amount of correction needed depends on three parameters: sacral endplate angle, C7 plumb line, and chin-brow angle. The sacral endplate angle reflects the amount of sagittal plane deformity that can be attributed to the hip joints: as the flexion contracture at the hip increases, the pelvis must rotate posteriorly to keep the body center of mass over the pelvis, decreasing the sacral endplate angle. The chin-brow angle has been shown to be a quantifiable parameter that reflects the restoration of horizontal gaze.[40] A mathematical formula was found that determines the ideal location and angle for each particular patient for a closing wedge-type osteotomy centered on the anterior longitudinal ligament.

There have been many retrospective reviews of AS patients treated with various osteotomies for sagittal imbalance. Van Royen and De Gast[49] performed a meta-analysis of 856 AS patients. They found three different techniques described: multisegment (two to three levels) opening wedge osteotomies with rupture of the anterior longitudinal ligament (i.e., Smith-Petersen), multisegment closing wedge osteotomies (Wilson-Turkell), and closing wedge-type osteotomy with pedicle resection and an anterior hinge (Thomasen). After a thorough and careful review, the authors concluded that, although no single technique was clearly superior to the others, the complications associated with closing wedge osteotomies were less serious than the complications associated with the other two groups. In addition, loss of correction was more prevalent in patients treated with opening wedge and polysegmental wedge osteotomies and the closing wedge types.

A few studies have attempted to quantify results in terms of patient outcomes using a standardized grading system. In 1995, Halm and colleagues[50] used the modified AIMS questionnaire to evaluate 175 patients retrospectively after lumbar osteotomy. Treatment groups were multisegment Smith-Petersen with Harrington compression instrumentation (n = 34), multisegment Smith-Petersen with transpedicular fixation

(n = 136), and monosegmental Thomasen with segmental fixation (n = 4). The investigators found statistically significant improvement in 47 of 60 items. Kim and colleagues[51] used the AIMS questionnaire prospectively in 45 patients with AS who were treated with Thomasen osteotomies at one or two levels. Osteotomies were mainly performed in the lumbar spine (usually L3). Average increase in lumbar lordosis was 34 degrees, with no significant increase in thoracic kyphosis. All parameters measured were significantly improved. Clinical outcome scores were significantly improved in all five categories; no correlation was found between the amount of radiographic correction obtained and clinical outcome as measured by the questionnaire.

Berven and colleagues[52] looked at 13 patients undergoing transpedicular wedge resection. Three of these patients had AS and were having spine surgery for the first time. These investigators also used outcome measures (modified Scoliosis Research Society questionnaire) in a retrospective manner. After 2 years, most of these patients were satisfied and would have the surgery again. The changes in C7 plumb line and lumbar lordosis were statistically significant. Complications included dural tear, transient nerve root injury, pulmonary embolus, and loss of sagittal balance. None of the AS patients showed a loss of sagittal balance at follow-up.

Bridwell and colleagues[53] looked at 27 patients undergoing pedicle subtraction osteotomy, also in a retrospective fashion. Two of these patients had AS. Outcome data (Oswestry Disability Index [ODI] and Scoliosis Research Society 24-item questionnaire [SRS-24]) were also obtained retrospectively. These authors found a significant improvement in sagittal balance and lumbar lordosis and a high level of patient satisfaction. Complications included deep vein thrombosis, myocardial infarction, compartment syndrome, visual field loss, pseudarthrosis, loss of correction, urinary retention, and neurologic deficits (root lesions). The patients with the latter two complications all responded to a central canal decompression.

Liu et al.[54] looked retrospectively at 53 AS patients who had complex spinal reconstruction surgery for kyphosis. In addition to standard outcome measures of the ODI and the Scoliosis Research Society 22-item questionnaire [SRS-22], they looked at gastrointestinal function as measured by abdominal measurements from CT scans as well as bowel habits. They found significant clinical improvements in gastrointestinal function after pedicle subtraction osteotomy in addition to improvement in spinal outcomes.

Zhang et al.[55] evaluated lung volume changes after pedicle subtraction osteotomies in 26 patients with AS. They noted improved lung volumes (measured on CT scans) after osteotomy, and noted that the magnitude of improvement correlated with the improvement in sagittal balance.

Hu et al.[56] retrospectively compared single pedicle subtraction osteotomy (PSO) to dual PSO in 60 patients with AS. They looked at radiographic parameters as well as outcome scores and operative parameters such as operating room time, estimated blood loss (EBL), and complications. They found increased EBL and operative time for the two-level cases but no differences in the other parameters. They did make note of the inherent selection bias with this study, as the patients selected to have the two-level PSOs were those whose imbalance was worse and that the more unhealthy patients did not undergo surgery.

Liu and colleagues[57] performed a meta-analysis of AS patients undergoing deformity correction via a posterior column extension osteotomy versus pedicle subtraction osteotomy. Twenty-three studies were evaluated, with 979 patients total; 441 of those had an extension osteotomy (posterior column osteotomy [PCO]), 538 underwent a PSO. Most patients had a one-level osteotomy between T11 and L5; there were no significant differences in any of the group characteristics, including the pelvic parameters. The review noted no significant differences in correction between the two groups and no significant differences in terms of complications, but the PSO patients had a longer average operating room time and higher than average EBL. Also of interest is that aortic rupture occurred infrequently but exclusively in the PCO group; the authors recommended avoidance of this technique in patients over 50 years old and in those who have radiographic evidence of abdominal aortic plaques/calcifications.

In extreme situations, two-level osteotomies have been performed. Zheng et al.[58] looked at 48 patients who underwent two lumbar osteotomies. All of these patients had single-stage interrupted PSOs. There were no major complications and no pseudarthroses. All patients had significant improvements in their clinical outcome scores, and chin-brow angles and sagittal balance were significantly improved. The authors recommended this approach in the severely deformed patient, but cautioned against inexperienced surgeons performing the procedure.

Thoracic Osteotomies

Even when the deformity has been localized primarily to the thoracic spine, lumbar osteotomies are usually recommended. These can be performed below cord and conus level, and they have the advantage of large degrees of correction of the sagittal vertical axis with a long lever arm. Osteotomies performed in the thoracic spine are usually Smith-Petersen, although closing wedge osteotomies and vertebral column resections may be indicated in the thoracic and thoracolumbar spine.

Kawahara and colleagues[59] described a closing-opening wedge osteotomy in the thoracic and thoracolumbar spine. They used this procedure on seven patients with sagittal imbalance. The osteotomy consisted of a partial vertebrectomy with a large posterior wedge that is performed in a manner similar to a costotransversectomy. After bony resection, pedicle screw instrumentation plus temporary correction rods are used to facilitate a closing wedge correction of about 30 degrees. An opening wedge-type maneuver is facilitated, again through the instrumentation, and a spacer or allograft is inserted. The authors noted good improvement in kyphosis, lordosis, and plumb line. They had no neurologic complications, no nonunions, and no loss of correction (follow-up, 2.2–7.5 years).

Cervicothoracic Osteotomy

If the primary deformity has been determined to be in the cervical spine, an osteotomy at the cervicothoracic junction can be performed. Patients with these deformities, in addition to the problems with horizontal gaze, also can experience dysphagia and problems related to poor oral intake. The chin-brow angle is of paramount importance when planning a corrective osteotomy in the cervicothoracic region. A key point is not to overcorrect the horizontal gaze because this can lead to inability of patients to see the floor ahead of them. These patients may function better when corrected to a chin-brow angle of about 10 degrees. In 1958, Urist[60] described an osteotomy in the cervicothoracic region, noting that the canal at this level is quite large and that the C8 nerve root is quite mobile compared with the upper cervical roots. In addition, potential loss of the lower cervical roots is less morbid than loss of the upper cervical roots. Last, the vertebral arteries are typically extraosseous at these levels, making resection of the lateral masses less risky.

Careful preoperative planning with radiographic studies is of paramount importance when performing a cervicothoracic osteotomy. Full-length standing lateral spine radiographs are needed to measure the chin-brow angle. Lateral tomography or fine-cut CT with sagittal and coronal reconstructions is performed to delineate the anatomy.[37,60] Axial CT scans can be very helpful in characterizing the distorted anatomy often seen in patients with AS, especially with regard to placement of instrumentation. MRI can help to rule out occult fractures, which should be suspected if there is recent onset of pain or rapid progression of deformity; MRI should be obtained if there is any neurologic deficit. In addition, flexion and extension lateral cervical spine radiographs should be obtained to look for any instability occurring at the occipitocervical and atlantoaxial levels. A subset of AS patients develop instability in these areas as a result of excessive stiffness of the entire spinal column because the stress placed on these upper cervical areas can be quite high. Although the number of AS patients who have occipitocervical or atlantoaxial instability is not as high as the number of AS patients with rheumatoid arthritis, missing this instability can be catastrophic.

The surgeon must carefully examine the preoperative radiographs and CT scans to determine the amount of correction needed. The measured chin-brow angle should be transposed onto a neutral cervicothoracic film, with the apex of the angle centered on the posterior longitudinal ligament at the C7–T1 level. By extrapolation, the extent of posterior elements to be resected can be determined.

As originally described by Urist and popularized by Simmons, the procedure was performed under local anesthesia only, with the patient awake in a seated position, in seated halo traction. The seated position carries with it the risk of air embolus in a patient with a patent foramen ovale so that continuous cardiac monitoring is indicated during the procedure. With the widespread use of neurophysiologic monitoring, the awake seated position is almost never used for these procedures at the present time except in the case in which the severe spinal deformity precludes prone positioning. A baseline set of somatosensory evoked potentials and motor evoked potentials is obtained, and the patient's head is placed in a rigid head holder (three-pin Mayfield). After the flip, a repeat run of neurophysiologic monitoring is obtained.

After a wide and lengthy exposure, a wide cervical decompression at C7 and T1 is performed, including a dorsal unroofing of bilateral C8 nerve roots. The lateral masses at C7 are also resected; in addition, the pedicles at C7 are partially removed to ensure that the C8 nerve roots are not compressed after the correction. Sometimes, a portion of the superior aspect of the T1 pedicles must be removed as well. Before the widespread use of instrumentation, postoperative immobilization consisted of a halo vest or cast that was custom measured or fitted to the patient's torso preoperatively. Currently, sublaminar hooks or lateral mass and pedicle screw instrumentation can be used for rigid stabilization, which greatly reduces the likelihood of translation at the osteoclasis level and subsequent neurologic injury. Lateral mass screws generally do not hold well in these patients due to underlying osteoporosis and can be supplemented by halo vest immobilization if the surgeon prefers to use it, keeping in mind that this orthosis carries its own risks of complications. Instrumentation is placed three levels above and three levels below C7–T1 after the decompression but before osteoclasis.

After the instrumentation has been placed, a temporary rod is prepared. One surgeon breaks scrub and manipulates the head and neck via the halo ring, facilitating the osteoclasis. The neck is slowly extended about the C7–T1 level, while the scrubbed surgeon watches the decompression site for excessive dural compression. Neurophysiologic signals are carefully monitored during the correction. An audible crack is often heard; the manipulating surgeon should appreciate a decrease in resistance when the osteoclasis has been completed. If the decompression has been planned and executed properly, any residual lateral mass of C7 should be opposed to T1, the C8 nerve roots should be free, and the dura should not be excessively compressed. The halo or Mayfield is resecured to the operative table in the corrected position. The rods are secured into position.

Even with neurophysiologic monitoring, a wake-up test is often performed after correction. Adjustments can be made intraoperatively after the main correction has been obtained. After the instrumentation has been secured, the local bone resected during the osteotomy is used for grafting, supplemented by allograft if the surgeon believes this is indicated, and the wound is closed. The anterior soft tissues are usually tight after being in a shortened position for a long time. The patient is usually kept intubated until the soft tissue edema and the postoperative anterior hematoma lessen. Even with rigid segmental instrumentation, the patient's osteopenia may necessitate placement in a rigid halo vest for the duration of the healing period. Dysphagia is common and usually resolves with time. If the patient's caloric intake is borderline, as is common, it is imperative that the patient receive nutritional supplementation during the healing period in the form of either tube feedings or parenteral supplementation (Fig. 85.1).

FIG. 85.1 (A) Photographs of a 45-year-old female with known ankylosing spondylitis, difficulty with activities of daily living and horizontal gaze, chin-brow to vertical angle (CBVA) of 40 degrees, and mildly positive sagittal balance. She had no neurologic complaints. (B) Lateral radiograph and sagittal computed tomography (CT) myelogram showing flowing syndesmophytes in the cervical spine; no significant central stenosis noted.

The literature concerning cervicothoracic osteotomies in AS patients is not robust. Simmons in his original article[37] reported on 42 patients who underwent cervicothoracic osteotomy as described by Urist. The operations were performed in the seated position under local anesthesia, and postoperative immobilization consisted of a halo vest. Simmons reported two nonunions successfully treated with anterior fusion, one pulmonary embolus, two myocardial infarctions (one fatal), and one root injury treated with repeat decompression. The patients who did not experience complications all were quite satisfied with their outcomes and had their horizontal gaze restored.

In 2006, Simmons and colleagues[61] reported on 36 years of experience in performing cervicothoracic osteotomies. They looked retrospectively at 131 cases, 114 of which had the "conventional" technique, with the remainder undergoing the "current" technique. Both techniques include local anesthesia with the patient awake during the procedure in a seated position, with halo fixation alone (no internal fixation). The difference in the two techniques is in regard to the amount of bone resected. The current technique resects all of the C7 posterior arch, including the pedicles as well as some resection of the posterolateral portions of C6 and T1. The conventional technique does not remove the pedicle or any portions of C6

FIG. 85.1, cont'd (C) Patient positioned on the operating table preoperatively and postoperatively. Once the patient was in the final position on the operating table, the CBVA was recorded with radiographs and photographs. This allowed for a reasonable assessment of the degree of correction. Note that the position and angle of the operating table during surgery were not changed. (D) Preoperative and postoperative sagittal CT myelogram. Note fracture through the superior-posterior portion of the C7 vertebral body. (E) Preoperative and postoperative lateral cervical radiographs after C6–C7 osteoclasis and C4–T2 posterior cervical fusion with instrumentation.

and T1 other than the lamina. Both techniques were found to adequately correct chin-brow angle (the authors recommended correction to 10 degrees to allow for a functional position). Average correction was between 49 and 56 degrees. Two patients in the conventional group had intraoperative neurologic complications that did not resolve. There were 16 transient C8 radiculopathies in the conventional group, with two noted in the current group. Sixteen patients went on to nonunion in the conventional group, with none in the current group. There were four cases of deep vein thrombosis resulting in pulmonary embolism in the conventional group; none were noted in the current group. Four patients in the conventional group died within 90 days. The authors noted that most patients did well with these surgeries and were able to tolerate the awake seated procedure, but they cautioned against the average surgeon performing this type of procedure.

McMaster[61a] reported retrospectively on 15 patients with abnormal horizontal gaze who were treated with an extension osteotomy at the cervicothoracic junction. These surgeries were performed in the prone position with a halo jacket in place before the osteotomy. Only three patients had internal fixation. All patients had their horizontal gaze restored. Complications included one patient with delayed postoperative quadriparesis, two nonunions, a C8 nerve root lesion, and subluxation at the osteotomy site. McMaster also treated their nonunions with anterior fusion with subsequent good results.

Mummaneni et al.[62] described a "front-back-front" approach to cervical deformity, which they presented as a more controlled osteotomy than an osteoclasis. The violent maneuver of fracture for correction of the deformity is avoided, although the difficulty with intubation and anterior approach in the setting of cervical kyphosis is mentioned. They first performed an anterior cervical release, then a posterior instrumentation with resection of all posterior elements, followed by anterior instrumentation and grafting.

Hoh et al.[63] performed an extensive review of the literature regarding cervical deformity in the setting of ankylosing spondylitis. The authors looked at 183 patients who had extension osteotomies of the cervical spine, most of which were at the C7–T1 level due to the vertebral artery anatomy and the capacious spinal canal at this level. Five patients had a spinal cord injury, and 35 patients had postoperative issues related to the C8 nerve root, most temporary. Their conclusions were that the chin-brow angle should not be corrected to less than −10 degrees of flexion, usually a posterior-only approach was enough, multilevel segmental fixation avoided halo fixation, and that the modern techniques of propofol and neuromonitoring allowed for general anesthesia rather than local anesthesia as recommended by Simmons.

Etame et al.[64] also did a literature search to evaluate outcomes after cervicothoracic osteotomies for ankylosing spondylitis. They evaluated 227 patients (6 articles); the majority of these patients had a loss of horizontal gaze, causing severe limitations of activities of daily living. Total neurologic risk across these 6 studies was 23%, mainly related to the C8 nerve root. A majority of the root injuries were transient, resulting in a low incidence of permanent injury. The complication rate varied widely (27–88%), although the overall mortality rate was less than 3%. Interestingly, pseudarthrosis rate was low even in the studies that did not use internal instrumentation.

The remainder of the literature dealing with cervicothoracic osteotomies in AS patients is in the form of case reports. Sengupta and colleagues[65] addressed the complication of overcorrection resulting in the inability of the patient to look down. They performed a same-day, four-stage procedure in the lateral decubitus position with transparent drapes and reported restoration of horizontal gaze in one patient. They recommended this procedure only in extreme cases.

Summary

Spinal reconstructive surgery in patients with AS is a complex and high-risk procedure. These patients have significant disability from their spinal deformities, however, and can experience significant benefit from correction of their alignment and sagittal imbalance. Careful preoperative planning, a clear understanding of the characteristics of the spines of AS patients, and meticulous intraoperative and postoperative care can lead to measurable improvement in quality of life for these patients.

PEARLS

1. The progression of facet spondylosis causes compensatory kyphosis, which can lead to the fixed deformities of cervicothoracic, thoracic, and lumbar kyphosis commonly seen in AS. These deformities lead to difficulty with horizontal gaze, ambulation, and activities of daily living.
2. Initial immobilization of a patient with AS who has a spinal column fracture should be in the preinjury position because of the potential for injury to the spinal cord if hyperextension from the prior position is performed.
3. Determining the major component of the deformity requires examining the patient in the standing, seated, and supine positions. A truncal forward-flexed deformity that corrects when changing from a standing to a seated position is usually due to hip flexion contracture or lumbar deformity. If the deformity persists on sitting but corrects in the supine position, the deformity is arising from the thoracic, thoracolumbar, or lumbar spine, and a lumbar osteotomy is usually indicated. If the deformity persists in the supine position, the deformity is in the cervicothoracic area.

PITFALLS

1. When the spine has become completely ankylosed, it functions as a rigid, brittle beam, leading to an increased incidence of fracture with even minor trauma.
2. The incidence of neurologic injuries in these patients is quite high, owing to the potential for translation (displacement) at the fracture site. This translation causes direct injury to the spinal cord and persistent bleeding secondary to motion, resulting in an enlarging compressive hematoma.
3. Balancing the achievement of horizontal gaze with the improvement of sagittal balance requires proper planning and staging of lumbar osteotomies relative to cervicothoracic osteotomies when both are needed.

KEY POINTS

1. Recommended corrective lumbar osteotomies in AS patients are Smith-Petersen osteotomies if disc spaces are still mobile and PSOs if disc spaces are fully autofused.
2. Correction at the time of lumbar osteotomy can be facilitated by positioning the patient so that when the osteotomy is completed, the table can be extended, resulting in the controlled extension of the patient's spine. The use of a supporting frame where the trunk and shoulders are supported separately from the pelvis may be required.
3. For cervicothoracic osteotomy, the patient's head must be held rigidly in a halo or tongs, which can be manipulated to a corrected position after the osteotomy is completed. Osteotomy is best performed at C7 for maximum canal size, mobility of the nerve roots at this level, and the advantageous vertebral artery position.

CHAPTER 86

Tumors of the Spine

SECTION XII

Umesh Metkar
Swamy Kurra
William F. Lavelle

Introduction

Involvement of the spinal column by a tumor may lead to catastrophic outcomes. Thorough knowledge of the imaging and histologic characteristics of the tumor is of the utmost importance to obtain favorable outcomes. Spinal tumors are classified based on the location of the occurrence and the nature of the disease. Tumors that occur in the spine are termed primary spinal tumors. If the primary tumor origin is extraspinal and metastasized to the spine through a hematogenous or lymphatic route, these tumors are considered metastatic spinal tumors. Primary spinal tumors can be benign or malignant based on the growth rate and surrounding tissue expansion. Primary spinal tumors are far less common than metastatic tumors. Benign tumors are usually smaller in size and have well-defined sclerotic margins on radiographs. However, locally aggressive benign spine tumors, such as osteoblastomas, giant cell tumors, and aneurysmal bone cysts, have rapid growth rates, poorly defined borders, and aggressive cortex destruction and sometimes extend to surrounding soft tissues. Aggressive benign spinal tumors can grow to a significant extent, and the larger tumor size and aggressive cortex destruction can lead to pathologic fractures and/or compression of surrounding neurologic structures. Primary malignant spinal tumors are rare but can cause significant morbidity and mortality. Malignant tumors most commonly metastasize to the lungs. Metastatic spine tumors have a higher incidence than primary spine tumors.

Radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) are common imaging modalities used to determine size, location, staging, type, surrounding soft tissue expansion, and pathologic fractures. Imaging studies are used in the diagnostic process of the tumor. Diagnosis can be confirmed only through a tissue biopsy. This combined approach is used to manage tumors.

Various treatments are available for spinal tumors. The optimal treatment is determined by the location of the tumor, staging, and type of tumor. Radiation therapy, chemotherapy, embolization, and surgical resection are common treatments in the management of spinal tumors. Local control of the spinal tumor can be achieved through surgical resection. The type of excision and surgical approach are determined based on the nature of the tumor and its location. Spinal instability and neurologic compromise are potential complications associated with spinal tumors. Aggressive decompression helps achieve neurologic improvement. Spinal instrumentation is used with instability of the spine. Primary benign tumors have a good prognosis after surgical resection. For aggressive benign and malignant tumors, a good prognosis requires complete resection of the tumor, the preservation of neurologic function, adequate decompression of the neural elements, and avoidance of local and systemic metastases. All these factors depend on the size of the tumor and responsiveness of the tumor to treatment. Metastatic spinal lesions have a worse prognosis, which depends on the number of skeletal metastases, the presence of visceral metastases, the primary site of origin, and the overall health of the patient.

Imaging Techniques

Imaging modalities are essential for diagnosing the tumor and evaluating the extent of the tumor. Plain radiographs, CT scans, bone scans, and MRIs are the most commonly used imaging modalities for detecting the location of the tumor and its nature (benign vs. malignant primary vs. metastatic). Recent advancements in spine imaging studies aid in staging the tumors for optimal surgical treatment.

Although a plain radiograph is the first recommended imaging study for the diagnosis of spinal pathologies, radiographs have a limited contribution in the detection of spinal lesions. At least a 50% loss of the trabecular bone is required to visualize spinal bone lesions in plain radiographs. The classic presentations that can be seen on plain radiographs are osteolytic and osteoblastic lesions, mixed lesions, and fractures. Plain radiographs are also useful in determining the stability of the spinal column and assessing the overall alignment of the spinal column in an upright position. Pathologic

compression fractures can also be easily diagnosed on plain radiographs. However, radiographs have limited use in detecting latent lesions or skip lesions.

A bone scan (bone scintigraphy) is another diagnostic procedure performed by using radioisotopes. These scans detect the uptake of the radioisotope by bone-forming osteoblastic activity. Bone scans can identify lesions in symptomatic patients whose plain radiographs are negative or suspicious. Bone scans have a high sensitivity in diagnosing osteoblastic activity but have a low specificity because nonneoplastic conditions, like osteoarthritis, can produce an increase in the uptake of the radioisotope. The ability to scan the entire body makes bone scans advantageous to determine the extent of dissemination in patients with a known systemic disease and to define the most accessible lesion to biopsy in patients with an unknown primary malignancy. More recently, intraoperative bone scans have been used for osteoid osteomas to ensure complete resection and avoid recurrence.[1]

CT scans have a high sensitivity for abnormal bone mineralization compared with plain radiographs. CT scans can detect early osseous lesions, unlike radiographs. With the ability to obtain three-dimensional reconstructive imaging of the tumor mass, to detect minor variations in bone mineralization as well as soft tissue extent of the tumor mass, CT imaging has been an important tool in decision making for tumor surgery. CT scans are also important in defining the stability of the spinal column based on three-dimensional measurements of the tumor mass. With the advent of portable CT scanners, intraoperative CT scan imaging has become widely used in spine surgery. Because CT imaging provides excellent visualization of osseous pathology, it can be extremely helpful in the evaluation of tumor resections during complex spinal operations.

Myelography, once the only reliable way to assess spinal cord and nerve root compression, has now given way to MRI in most instances. In combination with CT, myelography remains a valuable tool for detecting neural compression due to bony impingement in patients unable to undergo MRI due to pacemakers or other metallic devices.

MRI scans have superior sensitivity and specificity for spinal lesions and can be done without any radiation exposure to the patient. MRI is the best imaging modality in spine oncology because of its ability to delineate the borders between the tumor and surrounding normal tissues. MRI is equally useful in detecting the extent of neural compression. Gadolinium contrast-enhanced MRI scans are helpful in distinguishing between intradural and extradural tumors as well as intramedullary and extramedullary tumors.[2] Gadolinium is also beneficial for assessing the extent of tumor necrosis present initially as well as tumor necrosis as a response to chemotherapy.

Summary of Imaging Appearance

The imaging appearance of primary bony tumors of the spine and simulating lesions of the spine have been described recently. Benign bone tumors are usually well circumscribed. As slow-growing lesions, they may present with a calcified or sclerotic matrix. Malignancy, on the other hand, is often characterized by permeative margins with bone destruction, cortical erosion, and associated soft tissue masses. CT is helpful in the characterization of the tumor matrix, exact location and extension of the tumor, and osseous changes. MRI is best for evaluation of the associated soft tissue mass, bone marrow infiltration, and intraspinal extension.[3]

Biopsy Techniques

Obtaining a tissue diagnosis is the next step in the treatment of spinal tumors. A biopsy is needed to obtain a tissue sample to diagnose an unknown spinal lesion or confirm the provisional diagnosis obtained through clinical and imaging workups. The tissue sample can be obtained through a fine-needle, core, incisional, or excisional biopsy.

Fine-needle aspiration and core biopsies allow percutaneous extraction of the tissue sample. The use of image guidance (fluoroscopy, CT, or MRI) has significantly improved the ability to obtain the tissue sample from the desired tumor region. CT-guided biopsy by an interventional radiologist has become a common practice at many cancer treatment centers. In certain instances, tissue diagnosis can only be obtained through a surgical procedure. In those situations, a tissue sample is sent for immediate tissue diagnosis, and followed by the complete excisional biopsy of the tumor with appropriate margin selection based on the nature of the tumor.

If definitive excision is considered after incisional biopsy, a new set of instruments and drapes is mandatory to prevent accidental tumor seeding. Similar precautions should be followed when harvesting graft material from another site.[4]

Primary Tumors

Primary tumors in the spine constitute less than 10% of all spinal tumors. Patients with spinal tumors usually present with pain, which can be local and/or radicular and is often worse at night. Other patients present with weakness from spinal cord or nerve root compression. Some tumors are incidental findings discovered in the imaging studies performed for other problems. Radiographs, CT, and MRI are used to determine the location, type of lesion (osteoblastic/osteolytic), soft tissue extension, fluid levels, and spine instability. Evolving imaging modalities have improved the ability to make a diagnosis of the tumor type without the need for biopsy; however, most tumors can only be definitively diagnosed through biopsy based on the histologic appearance. Only a few tumors can be diagnosed by combining clinical symptoms and imaging studies. Management of primary tumors in the spine varies and depends on whether they are benign or malignant, indolent or aggressive, and their location relative to the spinal cord and nerve roots. Follow-up observation, symptomatic treatment, chemotherapy, radiation therapy, embolization, and surgical resection with or without instrumentation are all commonly used modalities in the management and treatment of primary tumors.

Benign Tumors

Osteochondroma

An osteochondroma is the cartilaginous exostosis arising from a parent bone, containing a cartilaginous cap at the end. The growth of the tumor ends with skeletal maturity. These are the most common type of bone tumors, but they constitute only 4% of the primary benign tumors of the spine. In the spine, osteochondromas are either solitary or multiple (multiple hereditary exostosis). Multiple hereditary exostosis (MHE) occurs in an autosomal dominant fashion; the majority of patients have mutations in the exostosin-1 and exostosin-2 genes.[5,6] Osteochondromas are predominantly diagnosed in the third and fourth decades of life and have a higher incidence in males, but patients with MHEs most commonly present in adolescence. Within the spinal column, osteochondromas are most commonly seen in the cervical spine,[7] more commonly in C2 due to the presence of an osteocartilaginous growth plate (Fig. 86.1). Microtrauma to this growth plate leads to the displacement and subsequent growth of small cartilaginous remains, thus resulting in a predominance of cervical lesions.[8]

Patients with spinal osteochondromas usually present with pain over the affected areas, especially if the lesion is in the posterior elements. Osteochondromas originating from the lamina can grow into the spinal canal and can lead to spinal cord compression or nerve root compression and present with neurologic deficits and with local back pain.[8]

Radiographs have limited utility in diagnosing osteochondromas due to the predominant presence of cartilaginous elements and the typically small size of the lesions. CT scans can demonstrate the presence of a sessile or pedunculated mass arising from a parent bone with calcification. MRI aids in the assessment of the cartilaginous cap and its size. The cartilaginous cap can be seen as a hypointense structure on T1-weighted images and as hyperintense on T2-weighted images. MRI determination of the thickness of this cartilaginous cap also has prognostic significance. A cartilaginous cap thickness more than 3 cm signifies a malignant transformation of the osteochondroma. Studies have reported that the intracanal osteochondroma rate (20–27%) is greater in children with MHE; routine axial screening (MRI or CT) is recommended in this population for early detection of intracanal osteochondromas to prevent potential neurologic consequences.[8,9]

Histologically, the cartilaginous cap consists of hyaline cartilage, which continues through the process of endochondral ossification until skeletal maturity.

Treatment of osteochondromas mainly involves a complete surgical excision (Fig. 86.2) at the point of the cortical and marrow junction to the parent bone. A complete resection is usually curative, and recurrence is rare.[10] Approximately 10% of osteochondromas may undergo a malignant transformation to an osteosarcoma.[9,11]

Hemangioma

Hemangiomas are mostly asymptomatic, benign vascular tumors primarily located inside the vertebral bodies. Vertebral hemangiomas (VHs) are mostly incidental findings on MRIs performed for other pathologies. They are most commonly seen in the thoracic spine, and the estimated occurrence is greater than 10% in autopsy studies.[12,13] However, hemangiomas that extend into the posterior elements and surrounding soft tissues can become symptomatic. Clinical symptoms of symptomatic VH are pain and neurologic deficits from expansion. Pregnancy is a risk factor for symptomatic VH, and the thoracic vertebrae are most commonly affected.[14] VHs can also weaken the vertebral body and present as a pathologic compression fracture. Aggressive VHs can present with

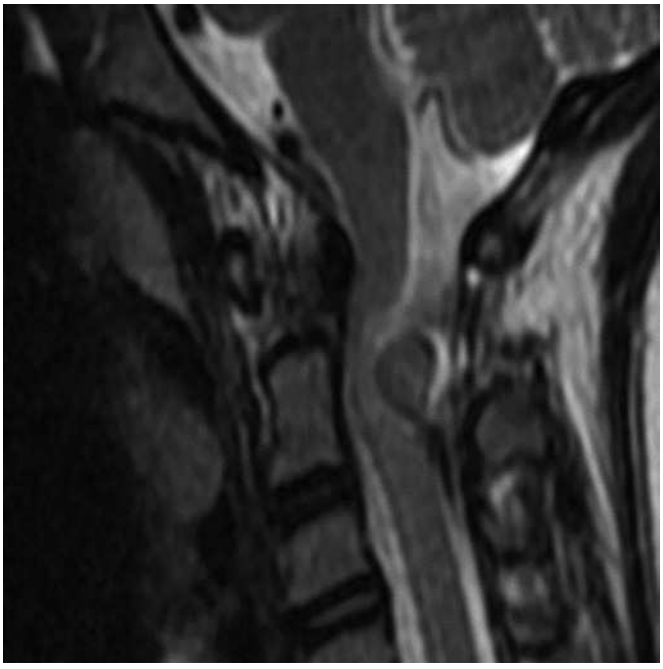

FIG. 86.1 Sagittal T2-weighted magnetic resonance image demonstrating C2 osteochondroma.

FIG. 86.2 Gross specimen showing en bloc removal of compressive C2 osteochondroma.

neurologic symptoms caused by canal compromise or nerve root impingement.

VHs can be diagnosed on radiographs, where they show a peculiar "corduroy pattern" with vertical striations. Axial CT images show a punctate, or "polka dot," appearance. MRI shows the presence of a hyperintense signal on both T1- and T2-weighted images.

Histologically, VHs appear as blood-filled, dilated vascular loops lined by endothelial cells. The loops are separated by trabecular bone. VHs can be capillary or cavernous according to the type of vessels involved.

Most VHs are asymptomatic and do not need to be followed clinically. Symptomatic VHs are rare and can be treated with endovascular embolization,[15-18] intralesional ethanol injections,[19-23] radiation therapy,[24] surgical intralesional resection, and vertebroplasty or kyphoplasty.[25-27] Embolization is used to treat painful VH or preoperatively to reduce intraoperative blood loss.[28,29] Vertebroplasty and kyphoplasty have been shown to potentially provide improvements in painful VH. Patients with pathologic compression fractures may be treated with either vertebroplasty or kyphoplasty. Patients presenting with neurologic symptoms caused by compressive VHs need surgical treatment based on the type and severity of the compression.

There is no consensus regarding the management of symptomatic VH in pregnant women. Chi et al[30] proposed a treatment algorithm for symptomatic VHs in pregnant women based on the week of gestation. At 36 weeks of gestation, observation is recommended and symptoms can be resolved after delivery or with postpartum treatment. If neurologic deterioration is seen, a cesarean section can be performed or labor can be induced followed by surgery with or without radiation, embolization, and/or sclerotherapy. Between 32 and 36 weeks of gestation, expectant observation may also be considered. If symptoms are severe and progressive, embolization or surgery without preterm delivery may be considered. For less than 32 weeks of gestation, observation is recommended for mild symptoms and surgery and/or embolization for severe neurologic deficits.

Eosinophilic Granuloma

Eosinophilic granulomas present as multifocal or unifocal lytic bony lesions. They commonly occur in children and adolescents. These lesions are formed due to the benign proliferation of Langerhans histiocytosis (dendritic cells).[31] Hand-Schüller-Christian disease (skull lesions, exophthalmos, and diabetes insipidus) and Letterer-Siwe disease (malignant) are two other systemic diseases affected by Langerhans histiocytosis (LCH) proliferation.[32] The skull is the most frequent site for occurrence in the skeletal system. In the spine, eosinophilic granulomas account for 6.5% to 25% of all skeletal LCH cases, and the thoracic vertebrae are the most commonly involved sites. Clinical presentation of eosinophilic granulomas includes back pain, rare neurologic deficits, kyphosis, and torticollis.

On radiographs, the lytic lesion in the vertebral bodies rarely extends to the posterior elements. Flattening of the vertebra (vertebra plana) is a typical radiographic feature of eosinophilic granulomas. On MRI, lesions appear as low to intermediate signal in T1-weighted images and as hyperintense in T2-weighted images.

CT scans show the lytic destruction of the involved vertebra. Osteomyelitis, aneurysmal bone cysts, neuroblastomas, chondromas, Ewing sarcomas, osteosarcomas, leukemia, and lymphoma comprise the differential diagnoses for eosinophilic granulomas. MRI is used to identify a paravertebral soft tissue mass, peridural compression, or edematous zone around the lesions. On MRI, the vertebra plana presents as a "dumbbell" and may be considered a feature of spinal LCH. A technetium bone scan or positron emission tomography/CT scan is recommended for multiple bony lesions or disseminated disease.

Clinical and radiographic findings are often enough to confirm the diagnosis. In a typical LCH, classic radiographic findings include vertebral collapse, maintenance of disc spaces, lack of extraspinal spread, and lack of a soft tissue mass. These findings provide sufficient evidence to avoid an unnecessary biopsy and the risk of inadvertently damaging the vertebral growth plates during biopsy. A biopsy is essential, however, in suspected cases of spinal Langerhans cell histiocytosis only if there are any atypical features such as a soft tissue mass, disc space involvement, or neurologic symptoms.[31,33]

Histologically, in immunohistochemical staining, tennis racquet–shaped Birbeck granules appear in the cytoplasm and are characteristic of eosinophilic granulomas. Significant eosinophilic infiltration can be seen in the lesion. Birbeck granules are plentiful in aggressive eosinophilic granulomas.[13]

Various modalities are used to treat eosinophilic granulomas, which often improve spontaneously and frequently reconstitute the lost vertebral height. These patients are managed with pain medications and rest and are followed clinically with radiographs. Systemic chemotherapy can be used for management of systemic or disseminated lesions. CT-guided corticosteroid injections may be helpful in symptomatic solitary eosinophilic granulomas. Most patients with spinal instability can be supported in an orthosis until sufficient reconstitution has occurred to restore stability. Surgery is the procedure of choice in patients who have an unstable spine segment that cannot be stabilized with an orthosis or have neurologic symptoms due to the compression of the neural elements from the collapsed vertebrae.

Osteoblastoma/Osteoid Osteoma

Osteoid osteomas are benign tumors frequently seen in children. These tumors have a slight male predominance and have a higher predilection for the posterior elements of the vertebrae. Osteoid osteomas are smaller in size, measuring less than 2 cm.

Patients with an osteoid osteoma typically present with back pain at the site of the lesion. The pain gradually worsens over a period of weeks and has a characteristic nighttime exacerbation. The pain responds well to nonsteroidal antiinflammatory drugs (NSAIDs), mainly salicylates. Patients with severely painful lesions may also present with scoliosis with an osteoid osteoma in the concavity of the curve. Due to the

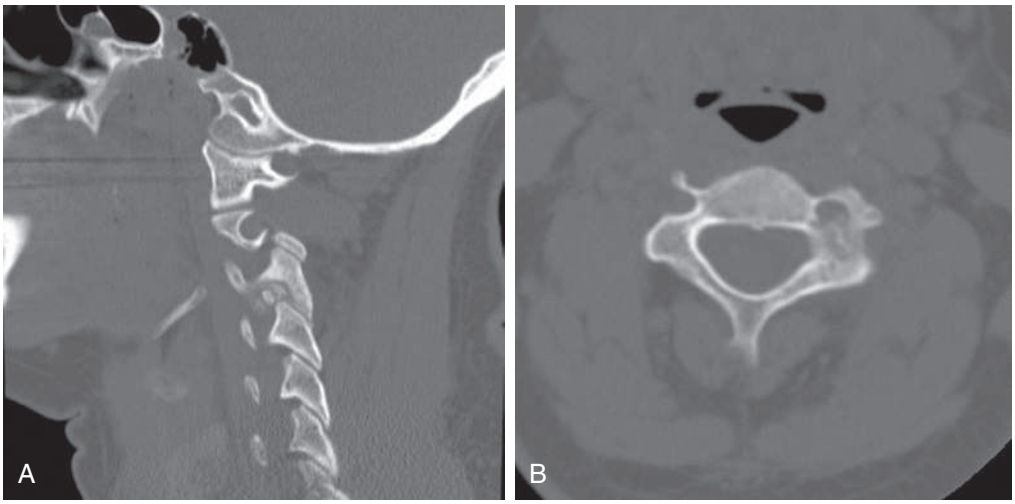

FIG. 86.3 (A) Sagittal and (B) axial computed tomographic views demonstrating discrete nidus consistent with osteoid osteomas.

smaller size of these lesions, they rarely cause significant bone destruction that would produce instability or neurologic deficits.

Osteoid osteomas are difficult to diagnose on plain radiographs unless there is a high suspicion of this diagnosis. The smaller size, radiolucency of the lesion, and common posterior element occurrence makes radiographic diagnosis challenging. On plain radiographs, they appear as radiolucent lesions in the posterior elements most commonly found in the lumbar spine with a calcified nidus. CT is considered to be essential in the diagnosis of these lesions. On CT scans, these lesions present as radiolucent lesions with or without a central calcified nidus (Fig. 86.3). Surrounding cortical thickening or sclerosis is also evident on these images. On MRI, osteoid osteomas present as a low- to intermediate-density lesion on T1-weighted images and as intermediate- to high-intensity lesions on T2-weighted images. MRI can be used to rule out canal compromise and for preoperative planning.[2]

Histologically, osteoid osteomas consist of a reddish nidus of woven bone with interconnected trabeculae. Intertrabecular spaces contain hypocellular fibrovascular tissue. The lesion may be surrounded by reactive bone with sclerosis.

Osteoid osteomas usually respond to NSAIDs, especially salicylates. For tumors that have not responded to conservative treatment or in patients with severe disabling pain, image-guided percutaneous thermal ablation (radiofrequency or laser ablation) has been shown to significantly reduce pain.[34-37] Surgeons have limited the use of thermal ablation techniques in the spine due to the risk of thermal injury to the proximal neural structures. With a minimum distance of 10 mm between the periosteum and neural elements, an intact thick cortex and thermal protection techniques can reduce thermal neural injury.[38,39] A complete resection is recommended for patients with neurologic compromise and those with secondary scoliosis. Surgical resection is also recommended for patients with severe refractory pain who are at risk of thermal injury from thermal ablation procedures (Fig. 86.4).[35,40]

Osteoblastomas are benign bone tumors and are histologically similar to osteoid osteomas; however, they are larger in size (>2 cm). They are usually found in the second and third decades of life, with a higher incidence in males. Osteoblastomas are more aggressive and often have a cortical breach and soft tissue extension and can undergo malignant transformation. Unlike other primary osseous tumors, osteoblastomas have a predilection for the spinal column and constitute about 32% to 45% of all osteoblastomas. Osteoblastomas commonly occur in the posterior elements, mainly the lamina and pedicles, and have a higher predilection for the lumbar spine.[41] Aggressive osteoblastomas can expand into the vertebral bodies; however, anterior vertebral body involvement is rare.[41] Osteoblastomas are usually slow-growing tumors, and malignant transformation to osteosarcoma is rare.[42] Due to their aggressive growth pattern, osteoblastomas have a higher risk of recurrence after excision. More aggressive lesions have an approximately 50% recurrence rate after excision.

Patients with osteoblastomas present with a dull, aching pain. However, the pain does not increase at night, and NSAIDs are not as effective in alleviating the pain as in the case of osteoid osteomas. More aggressive lesions may present with neurologic symptoms caused by the compression of neural structures.

On plain radiographs, osteoblastomas present as a radiolucent nidus with a surrounding sclerotic rim. They are more than 2 cm in size and are differentiated from osteoid osteomas based on their size and aggressive growth pattern. The nidus may have varying amounts of calcification. More aggressive lesions may show variable matrix calcifications, have an expansile appearance, and cause extensive destruction along with growth into the surrounding paraspinal soft tissues. Approximately 10% to 15% of osteoblastomas have an associated aneurysmal bone cyst. CT is the investigative method of choice and helps identify the multifocal calcifications in the nidus and the thin surrounding rim of sclerosis. MRI is considered helpful in preoperative planning to assess the soft tissue involvement and compression of the neural elements.[43]

Histologically, osteoblastomas are similar in appearance to an osteoid osteoma. The osteoblastoma has a characteristic

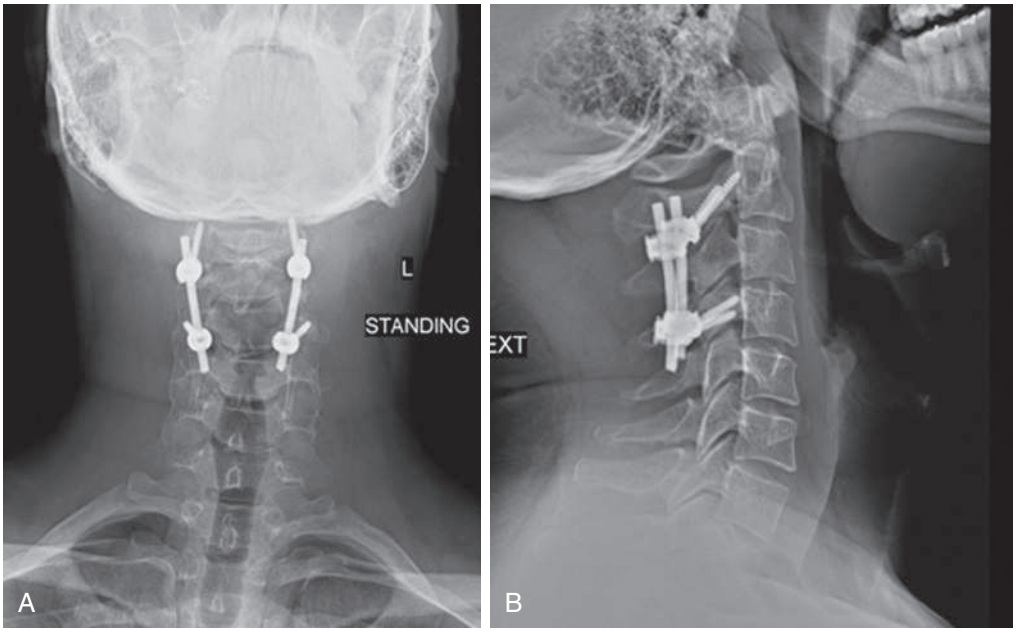

FIG. 86.4 (A) Anteroposterior and (B) lateral radiographs demonstrating posterior decompression and fusion of the osteoid osteoma.

reddish appearance due to the rich vasculature and consists of woven bone containing bone-forming osteoblasts.

Complete resection is the treatment of choice. A total en bloc resection is recommended whenever possible. The extensive resection necessary to completely remove these aggressive lesions usually causes significant spinal instability and requires fusion with instrumentation. In some cases, due to the location of the lesion, en bloc resection may not be feasible. In such cases intralesional curettage and cementing or bone grafting may be considered.[44] Postoperatively, patients need a close follow-up, every 3 months for the first 2 years, to detect recurrence. Approximately 10% to 15% of patients present with a recurrence of the tumor.[43,45] However, malignant transformation is rare.

Aneurysmal Bone Cyst

Aneurysmal bone cysts (ABCs) are benign cystic lesions affecting the bone. ABCs are peculiar in their pathologic appearance of an expansile bony lesion containing blood-filled cavities separated by fibrous septae or trabecular bone. Approximately 8% to 30% of ABCs occur in the spine, most commonly the lumbar spine. ABCs are more common in females. ABCs constitute approximately 15% of the primary benign tumors of the spine and are most commonly diagnosed in the second and third decades of life. ABCs are mainly seen in the posterior elements; however, they may extend into the vertebral bodies.

Patients with ABCs usually present with progressively worsening local pain. Patients with expansile lesions that cause neural compression may present with neurologic deficits. A palpable mass may be felt in a few patients.

Diagnosis of an ABC involves plain radiographs, CT, and contrast-enhanced MRI. ABCs show an expansile lytic lesion or "blown out" appearance on plain radiographs. They typically involve the posterior elements of thoracolumbar spine with expansion to the vertebral body. On CT, ABCs appear as multiloculated lytic lesions with a "soap bubble" appearance. Fluid-filled levels may occasionally be seen on CT scans. A pathologic fracture may be apparent on CT scans. Contrast-enhanced MRI is useful to detect soft tissue involvement and the status of neural structures, which are assessed in axial scans. Fluid levels can be seen on these axial scans. ABCs show increased signal intensity on both T1- and T2-weighted images, which can be attributed to the high concentration of methemoglobin in the fluid. The presence of a fluid level in a lytic expansile lesion aids in the confirmation of the diagnosis and also allows the physician to look for the presence of associated solid tumors to rule out a secondary ABC.

Differential diagnosis of ABCs includes other lytic lesions of the spine, namely giant cell tumors, malignant fibrous histiocytomas, and eosinophilic granulomas. ABCs can be secondary to the presence of a giant cell tumor or osteoblastoma. Histologically, ABCs show the presence of blood-filled cavities separated by septae, which consist of fibrous tissue, giant cells, and reactive trabecular bone.

The treatment of ABCs depends on the level of the tumor in the spinal column, the anatomic location of the lesion in the vertebra, the magnitude of bony destruction, the degree of instability of the spinal column, and the presence or absence of neurologic compromise. Treatment options for ABCs include local intralesional curettage with or without bone grafting, cryotherapy, radiotherapy, embolization, and an en bloc resection. An en bloc resection is the highest degree of cure; however, it is difficult to perform in many cases of ABCs. A complete piecemeal intralesional resection is the most commonly performed surgical treatment of ABCs. Aggressive curettage of the cyst wall using a high-speed burr is highly

recommended to minimize the risk of recurrence. Preoperative embolization of the tumor is also highly recommended.

Giant Cell Tumor

A giant cell tumor (GCT) is a locally aggressive benign tumor; approximately 7% to 15% of all GCTs are found in the spine. GCTs have a peak incidence in the second to fourth decades of life and are more commonly seen in females. GCTs are rare before skeletal maturity and are most commonly seen in the sacrum.

Clinically, pain is the most common symptom on presentation.[46] The expansion of a GCT can further lead to the development of neurologic deficits caused by either nerve root or spinal cord compression.

GCTs present radiographically as an expansile lytic lesion arising from the vertebral body that may involve the posterior elements. Expansion of the lesion can cause canal encroachment leading to spinal cord or thecal sac compression. The expansile lesion lacks a surrounding sclerotic rim and has a characteristic "soap bubble" appearance on radiographs. The lesion can spread to the paraspinal areas as well as the adjacent discs and/or vertebral bodies. On MRI, the majority of GCTs appear to have low to moderate intensity on both T1- and T2-weighted images. The presence of a fluid level on the MRI suggests presence of an accompanying ABC.[2]

A biopsy aids in confirmation of the diagnosis. Histologically, GCTs show the presence of osteoclast-like giant cells surrounded by mononuclear cells (Fig. 86.5). There is an absence of mineralization of the matrix, which is interspersed with hemorrhagic areas.[47]

Traditionally, GCTs are considered benign tumors. However, locally aggressive expansile lesions may cause significant destruction of the vertebral body and encroachment of surrounding soft tissue structures, including canal compromise. A malignant transformation rarely develops, leading to the formation of metastatic lesions. Such malignant lesions may metastasize hematogenously, predominantly to the lungs.[48,49]

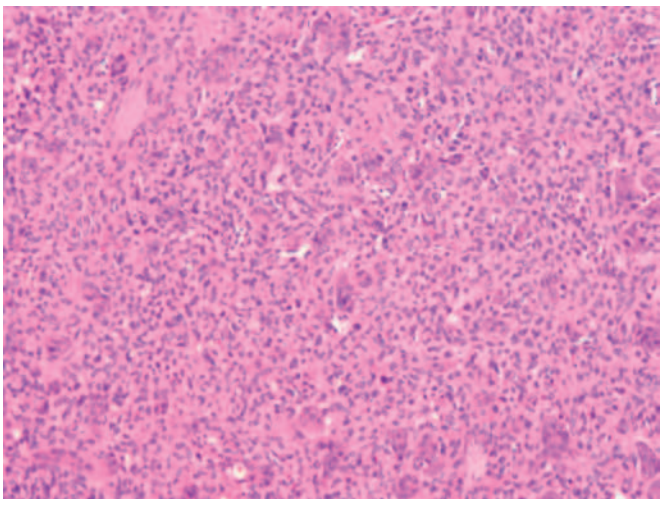

FIG. 86.5 Histologic appearance of a giant cell tumor.

An en bloc excision with a wide marginal resection is the treatment of choice for GCTs. An en bloc resection is recommended for patients with stage 3 Enneking GCTs.[50] Even with an en bloc resection with wide margins, the local recurrence rate is 0 to 14% (Fig. 86.6).[46] Although an en bloc resection may be feasible in the lumbar and thoracic spine, it may not be possible in lesions located in the cervical spine or sacrum. In such cases, intralesional curettage with phenol and cementing can be considered. Postoperatively, the local area can be treated with radiation to prevent local recurrence. Intralesional resections have higher recurrence rates even with adjuvant treatments (up to 71%).[2,51] An intralesional resection is recommended for Enneking stage 2 GCTs.[50] Radiation has been studied as a treatment for an incomplete resection or local resection. However, radiation poses a risk of malignant transformation in up to 25% of the patients.[52] The recurrence rate is higher in patients who undergo incomplete resection, which necessitates revision surgery or additional systemic treatment.

In the sacrum, resections must be stabilized whenever there is a suspicion for instability of the spine (Fig. 86.7). En bloc resection in the sacrum has been found to have a high incidence of postoperative neurologic deficits, especially with more proximal levels of tumor occurrence. Preoperative embolization followed by an intralesional resection has been shown to have a lower postoperative morbidity than en bloc resections.[46,53,53a] Serial arterial embolization has also been found to be an effective treatment modality in sacral lesions.[54,55] It can be considered in patients who are at risk for potential morbidities from other treatments. Preoperative embolization, followed by intralesional resection, should be the treatment of choice for patients with sacral GCTs that are too large for en bloc excision.[46]

FIG. 86.6 Sagittal T2-weighted magnetic resonance image demonstrating giant cell tumor recurrence.

FIG. 86.7 Lateral plain radiograph demonstrating fusion construct for stabilization before recurrence.

The treatment paradigm for patients with GCTs of the spine has been changed recently with the advent of monthly injections with denosumab, which is a fully human monoclonal antibody that targets and binds with high affinity and specificity to the receptor activator of nuclear factor-κB ligand. There is experience using it in recurrent GCTs of the spine, GCTs thought to be inoperative because of tumor size or location, and GCTs in patients who refuse surgery. A recent study showed a clinically beneficial radiologic response and an impressive histologic response in most, but not all, patients.[56–58] It will be important to keep this new treatment modality in mind as more studies become available, allowing better evaluation of the current GCT treatment algorithm.

Malignant Tumors

Osteosarcoma

Osteosarcomas (osteogenic sarcomas) are the most common primary malignant tumor of the bone; however, only 3% to 5% of these tumors are seen in the spine. An osteosarcoma of the spine is usually seen in the fourth decade of life. Osteosarcomas are slightly more common in males and are most commonly located in the thoracic and lumbar spine. Osteosarcomas are high-grade aggressive tumors that may present secondary to radiation therapy after the treatment of a primary tumor. They may also occur in patients with Paget disease, enchondromatosis, or fibrous dysplasia. Patients with a history of retinoblastoma also have a high probability of developing an osteosarcoma later in life.

Patients with an osteosarcoma present with local pain, a palpable mass, or a neurologic deficit caused by spinal cord or nerve root compression from growth of the tumor. Some patients may also present with metastatic lesions, mainly in the lungs, liver, or bone, at the time of diagnosis.

Osteosarcomas are predominantly osteosclerotic lesions. On plain radiographs they appear as a heterogeneous mass with mixed lytic and sclerotic components. This appearance is caused by the presence of ossified and nonossified parts of the tumor. A pathologic fracture may be visible. CT shows a permeative bone lesion with significant bone destruction, involvement of the surrounding soft tissue, and the presence of canal compromise. The appearance of the tumor on MRI depends on the amount of mineralization within the tumor. The mineralized part of the tumor appears hypointense in both T1- and T2-weighted images, whereas the nonmineralized part of the tumor gives a hyperintense appearance on T2-weighted images. MRI is useful in presurgical planning to determine the extent of soft tissue involvement, extent of canal compromise, and severity of compression of neural structures. Technetium and gallium scanning may be used to determine the presence of skip lesions, whereas positron emission tomography scans are the most effective tools to monitor the effects of the treatment and staging of the tumor.

Grossly, the tumor has a reddish granular appearance caused by the presence of calcifications. Histologic evaluation shows the presence of a woven bone formation by malignant osteoblasts. The woven bone masses are haphazardly present in a richly vascular stroma. Typical palisading of the osteoblasts seen in normal bone is characteristically absent. The osteoblasts are dispersed in the background of the spindle cell stroma. Hemorrhagic and necrotic areas are also present within the tumor. If osteoblasts are not seen in the histologic appearance, a diagnosis of malignant fibrous histiocytoma or fibrosarcoma should be considered.

Treatment of an osteosarcoma involves a multimodal approach. Significant advancements have occurred in the treatment of osteosarcomas of the long bones; these advances have been extrapolated to the treatment of osteosarcomas of the spine. The treatment of spinal osteosarcomas starts with imaging investigations to determine the presence of metastatic lesions and the staging of the tumor. The presence of micrometastasis is common in cases of osteosarcomas. Neoadjuvant chemotherapy has been an important tool in the treatment of osteosarcomas. The addition of neoadjuvant chemotherapy aids in the treatment of systemic micrometastases, prevention of further systemic spread, and reduction of the size of the primary tumor. Histologic studies of surgically resected primary tumors obtained after neoadjuvant chemotherapy help determine the effectiveness of chemotherapy on the primary tumor. These data can then be used to plan the postoperative chemotherapy regimen. In summary, an osteosarcoma of the axial skeleton can be effectively treated with a total spondylectomy or a wide marginal excision completed after neoadjuvant chemotherapy. Local external-beam radiotherapy is reserved for palliative treatment purposes. Harrop et al. reviewed the literature for evidence-based treatment of spinal osteosarcomas.[59] They studied the effect of

chemotherapy on local recurrence and the 5-year survival of patients and determined if the extent of surgical resection mattered when chemotherapy was used as part of the multimodal therapy. The authors found six studies that addressed these questions. Based on their review, they concluded that there was moderate evidence to support neoadjuvant chemotherapy and low evidence supporting en bloc resections. The authors strongly recommended the use of neoadjuvant chemotherapy as a multimodal treatment in addition to en bloc resection of the tumor. Despite recent advances, an osteosarcoma still has one of the lowest survival rates in pediatric cancers.

Ewing Sarcoma

Ewing sarcoma is a primary malignant tumor of neuroectodermal origin in the spine found in children and young adults.[60] Approximately 3% to 10% of all Ewing sarcomas arise in the spinal column.[61] Metastatic involvement of the spinal column from a primary tumor in an appendicular skeleton is much more common than a primary Ewing sarcoma in the spine. Ewing sarcoma is the most common nonlymphoproliferative malignant tumor of the spine. The tumor has a predilection for the sacrococcygeal region; however, it may also be seen in the lumbar and thoracic spine. Ewing sarcoma of the cervical spine is extremely rare. The tumors are most commonly seen in the pediatric age group (5–15 years of age).[62] The most common clinical symptoms in these patients include local pain and the presence of a neurologic deficit. Patients may also present with a soft tissue mass. Like other pediatric malignant tumors, systemic constitutional symptoms of weight loss and fever are also commonly seen. Sacral tumors may grow to a significant extent before becoming symptomatic.

On plain radiographs, Ewing sarcoma shows a moth-eaten appearance with surrounding concentric layers of reactive bone formation, giving it a classic "onion ring" appearance. However, this appearance is not seen in the spine. Most patients show aggressive vertebral destruction and lysis with a large paraspinal soft tissue mass on plain radiographs. Defining margins are absent, and vertebra plana may be seen. CT is helpful in detecting the amount of bony destruction. MRI is used to study the extent of soft tissue involvement as well as any neurologic compromise. The tumor shows intermediate signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

Approximately 20% of patients present with a symptomatic metastasis, and the presence of micrometastasis is seen in a majority of the patients. The most common sites for metastasis are the lungs, long bones, and bone marrow. Bone scanning is used to detect the presence of metastatic lesions. The suspicious lesions should be confirmed with a biopsy.

On gross examination, the tumor appears as a firm, gray, friable mass with areas of hemorrhage and necrosis. Histological examination shows the presence of characteristic small round cells that form large sheets separated by septae. There is an abundance of collagen in the tumors. Patients with Ewing sarcoma or other types of peripheral neuroectodermal tumors of the bone have a translocation mutation. The diagnostic workup should include investigations into immunohistochemistry, cytogenetic, and molecular genetic testing.

Initial treatment of Ewing sarcoma involves chemotherapy. The survival rate with six-drug chemotherapy has been shown to be as high as 80%, which is significantly higher than four-drug chemotherapy. The cure rate with a multimodal treatment has been shown to be more than 50%. Patients with systemic metastatic disease do not respond favorably to chemotherapy and pose a therapeutic challenge to the treating physician. The 5-year survival rate is only 20% despite advances in treatment. Treatment of the local tumor can be done with surgical resection or radiation. The size of the tumor, older age at onset, and presence of systemic metastatic lesions have been thought to be poor prognostic signs. A review of literature by Harrop et al.[59] considered the evidence-based recommendations for the treatment for Ewing sarcoma. The authors studied the effects of neoadjuvant chemotherapy in local control, long-term survival of patients with Ewing sarcoma, and how the extent of a local surgical resection affects local control and long-term survival. The authors strongly recommended neoadjuvant chemotherapy as a first-line treatment modality but only had moderate evidence to support this line of treatment. The authors also recommended the use of surgical resections for local control of the tumor with low-quality supporting evidence. Radiation was believed to be a useful treatment modality in the cases of incomplete resections.

Chordoma

Chordomas are primary malignant tumors arising from the notochordal remnants in the spinal segments from the clivus to the coccyx and account for 2% to 4% of primary malignant bone tumors. They are the most common primary malignant tumor affecting the sacrum. The tumor is most frequently seen in the sacrococcygeal location (50%) followed by the sphenooccipital location (35–40%). Chordomas can be seen at almost any age; however, they are most commonly found in the fifth to sixth decades of life. It is the most common nonlymphoproliferative primary malignant tumor of the spine in adults. The tumor is more common in men than women, with a ratio of 2 : 1. Chordomas are considered to be slow-growing, locally aggressive tumors and may arise from the vertebral bodies and grow posteriorly, causing compression of the neurologic structures. They may also grow anteriorly into the paraspinal soft tissues. Within the sacrum, the tumor most commonly affects the fourth and fifth sacral segments and protrudes into the pelvis as it grows. Involvement of the pelvic bones is rare. Metastatic lesions can be seen in approximately 30% of sacrococcygeal chordomas.

Patients with chordomas that affect the sacrococcygeal region present with an insidious onset of back pain. The pelvis and sacral canal can accommodate the enormous growth of the tumor before it becomes symptomatic. Patients most often present with low back pain or sciatic pain, constipation from compression of the rectum, or a neurologic deficit caused by compression of the sacral nerve roots. Patients may also present with a gluteal or sacral mass. Chordomas of the mobile spinal column present earlier with a neurologic

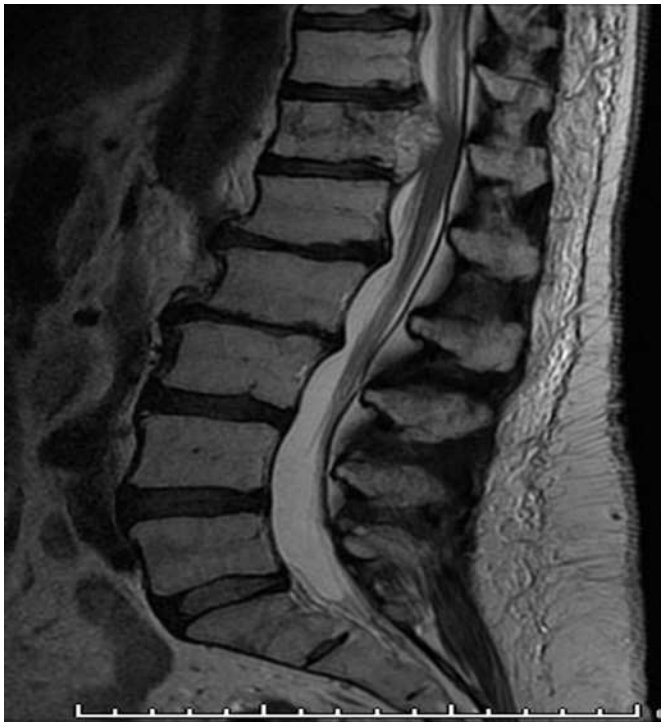

FIG. 86.8 Sagittal magnetic resonance image demonstrating expansile thoracic tumor proven by biopsy to be a chordoma.

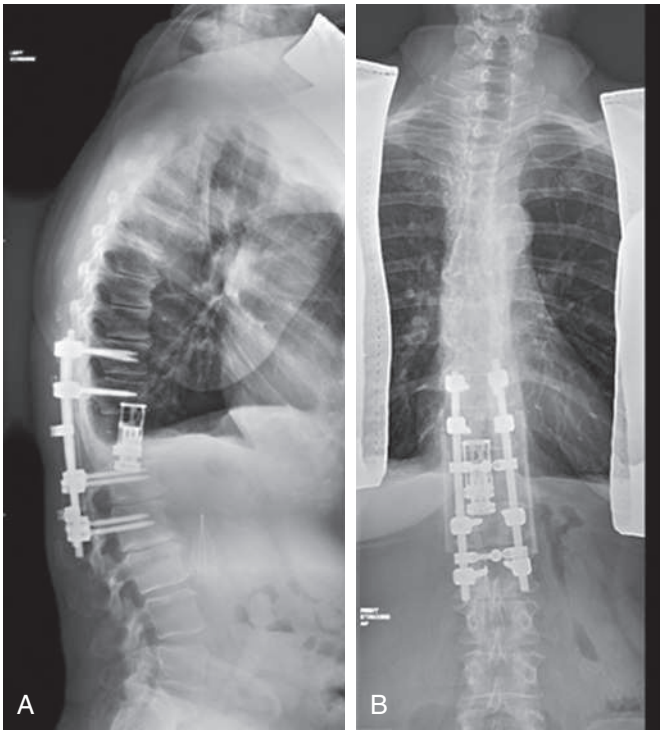

FIG. 86.9 (A) Posteroanterior and (B) lateral long standing films demonstrating postoperative reconstruction after an en bloc spondylectomy.

deficit compared with sacrococcygeal tumors. Chordomas in the cervical region may present with symptoms of dysphagia, breathing difficulty, or neurologic deficits.

Chordomas usually appear as lytic lesions with a large associated soft tissue mass. The majority of chordomas present with calcifications throughout the tumor. Unlike other malignant tumors of the vertebral bodies, chordomas (along with GCTs) are the only tumors that involve the adjacent intervertebral disc as they spread to the adjacent vertebral bodies. Chordomas give a uniform appearance of the soft tissue mass with the occasional presence of lucencies indicating the areas of necrosis. Sacral chordomas often show the presence of mottled densities/calcific debris within the tumor mass. MRI helps delineate the tumor extent, especially on T2-weighted images (Fig. 86.8). It also aids in defining the presence or absence of the plane of separation between the tumor and the rectum. Tumors appear hyperintense to the surrounding muscles on T2-weighted images. On gadolinium-enhanced images, the tumor shows signal enhancement with areas of attenuation around the calcifications.

Workup should involve investigations to diagnose the presence of local and systemic spread of the tumor. CT scans of the chest, abdomen, and pelvis and a bone scan may aid in determining the spread of the tumor. The tumor usually shows normal or a decreased uptake on the bone scans. Tissue diagnosis is equally important and requires a biopsy. Chordomas are notoriously known to spread along the biopsy needle tracks, and care should be taken to avoid other body cavities while doing the biopsy. The tissue sample allows for the diagnosis and determination of the tumor's aggressiveness.

On gross examination, the tumor appears as a gray, soft to firm mass with a lobulated structure and a translucent surface. The tumors are well circumscribed due to the presence of a pseudocapsule formation. Within the bone, the tumor appears as a lytic lesion with a clear margin of reactive bone. Histologically, the tumor shows the presence of a lobular architecture with signet ring cells separated by fibrous septae. The septae are densely infiltrated with lymphocytes.

Effective treatment of a chordoma requires en bloc resection of the tumor with the resection of the circumferential margin of normal tissue. Resection with a wide margin is important to decrease the risk of local recurrence. For sacral chordomas, complete resection of the sacrum is occasionally required. Due to the complex anatomy of the sacrum and surrounding structures, surgical treatment involves a combined approach with the assistance of multiple specialties. A resection of the chordoma involves a combination of various surgical approaches. Usually, posterior elements are resected through the posterior approach. The anterior tumor mass is separated from the thecal sac. Posterior stabilization is carried out using instrumentation to the pelvis if the entire sacrum or all of the sacrum distal to S1 is resected. This is followed by an anterior resection of the vertebral body. The anterior column is then reconstructed using an expandable titanium biomechanical device with or without allograft (Fig. 86.9). Resection of sacral chordomas may necessitate the sacrifice of the sacral nerve roots, resulting in a postoperative neurologic deficit and the loss of bowel, bladder, and sexual function. Preservation of at least one of the S2 nerves allows the patient to retain control of the bowel or bladder function. Resection of the sacrum at or above S1 leads to significant neurologic deficits and the need for a specialized postoperative treatment plan. Adjuvant treatment with radiation is reserved for palliative

treatment for local recurrences. Chordomas are thought to be radioresistant tumors. Due to the slow-growing nature of the tumor, chemotherapy has a limited role in the treatment of chordomas.

Chondrosarcoma

Chondrosarcomas are cartilage-forming malignant tumors that affect the spinal column. Tumor osteoid formation is characteristically absent. Spinal chondrosarcomas are extremely rare. Chondrosarcomas can present de novo or can develop secondary to a preexisting benign tumor of the spine. They can also be associated with multiple hereditary osteochondromatosis. Chondrosarcomas are more common in males, with a ratio of 2 to 4:1. The average age at diagnosis is between the fourth and fifth decades of life, but they can be seen at any age. The tumor is more commonly found in the posterior elements than anterior elements. The most common location in the spinal column is the thoracic spine.

Patients with a chondrosarcoma present with an insidious-onset pain over the tumor site. Neurologic deficits in the form of radiculopathy or myelopathy are commonly seen and present in up to 50% of patients. Patients with posterior element involvement may also have a palpable mass as the tumor grows in size.

Lytic lesions with occasional calcifications (arc and ring patterns) are common presentations in radiographs and CT scans. A lobulated soft tissue mass has low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 86.10). CT and MRI studies demonstrate the tumor's extension and are helpful for preoperative planning.[63-65] Because chondrosarcomas are avascular in nature, they are resistant to chemotherapy and radiation. Chondrosarcomas show cortical destruction and soft tissue extension. Most of these tumors are low grade and slow growing, but once metastatic they have a poor prognosis. Chondrosarcomas are classified based on origin (intramedullary and periosteal) and histologic appearance (conventional and variant types). Variant subtypes seen are clear cell, dedifferentiated, mesenchymal, and myxoid. Conventional chondrosarcomas have a higher incidence rate than variant chondrosarcomas.[66]

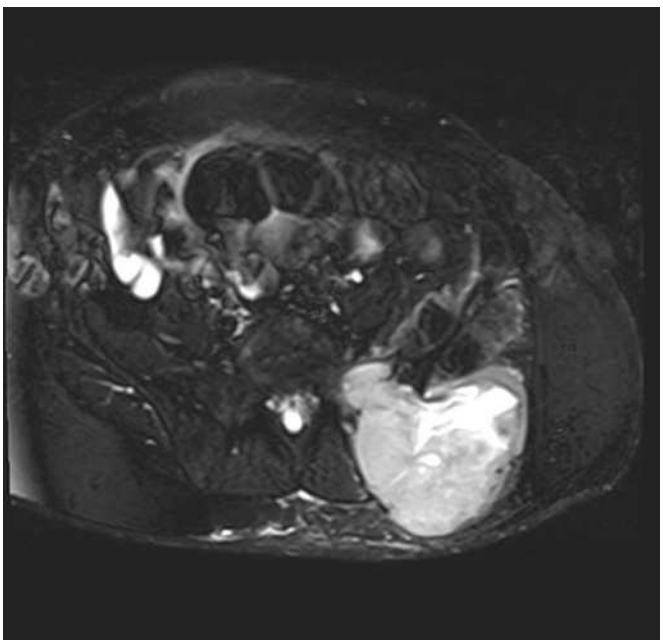

FIG. 86.10 T2-weighted axial magnetic resonance image showing chondrosarcoma involvement of the left sacrum and ilium.

Chondrosarcomas are primarily managed by en bloc excision with wide margins. A wide marginal resection is sometimes impossible due to the size and extension of the tumor into the surrounding important structures and risks the stability of the spine. Stener pioneered en bloc excision of the chondrosarcoma of the spine in 1971.[67] Since then, all subsequent series have demonstrated the importance of obtaining negative margins in an en bloc fashion to increase disease-free survival.[68] The prognosis of the tumor depends on histologic grading and surgical resection.[68] Incomplete surgical resection results in local recurrence and a much worse prognosis. Although chondrosarcomas are resistant to radiation therapy, Harwood et al.[69] reported that high radiation dosage (5000 cGy) for 4 to 5 weeks is helpful for long-term control of the local disease. They recommended radiation therapy only in patients in whom surgical resection was impossible. Negative marginal resections are uncommon in en bloc excision, and adjuvant radiation therapy is recommended to control local recurrence.[70]

When the management of sacral tumors requires partial or complete sacrectomy (Fig. 86.11), reconstruction of the lumbosacral junction is necessary. A staged anterior/posterior en bloc sacrectomy with a Galveston L-rod pelvic ring reconstruction or more modern variation is often required. Understanding the anatomy and biomechanics of the spinopelvic apparatus and the lumbosacral junction, as well as having a familiarity with the various techniques available for carrying out sacrectomy and pelvic ring reconstruction, enables the spine surgeon to effectively manage sacral tumors.[1]

Multiple Myeloma and Solitary Plasmacytoma

Multiple myeloma is a hematologic malignancy with a primary bone origin constituting multifocal plasma cell neoplasms that commonly involve the spine. The plasma cells undergo a malignant transformation, producing an excess amount of immunoglobulin. This leads to the activation of osteoclasts and inhibition of osteoblastic activity, which also leads to the formation of multiple lytic lesions throughout the skeletal system. Multiple myeloma constitutes approximately 1% of all malignant diseases. The most common age of presentation is in the sixth decade of life. Skeletal involvement is a very common mode of presentation. More than 70% of patients have bone involvement and pain at the time of presentation. Patients with multiple myeloma present with multiple lytic lesions in the spine as well as the appendicular skeleton. They have bone pain and a vertebral compression fracture, but rarely have neurologic symptoms or deficits. However, patients with extension of the tumor to the epidural space or compression fractures with severe canal compromise may present with neurologic deficits. They may have associated

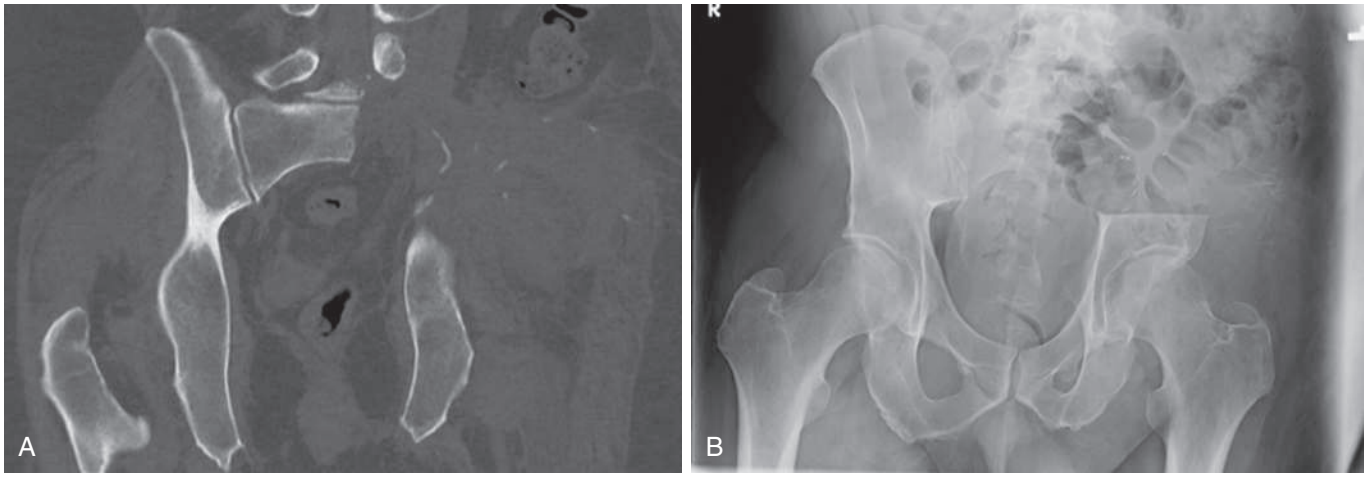

FIG. 86.11 (A) Coronal computed tomography and (B) plain radiograph demonstrating hemisacrectomy and hemipelvectomy without reconstruction.

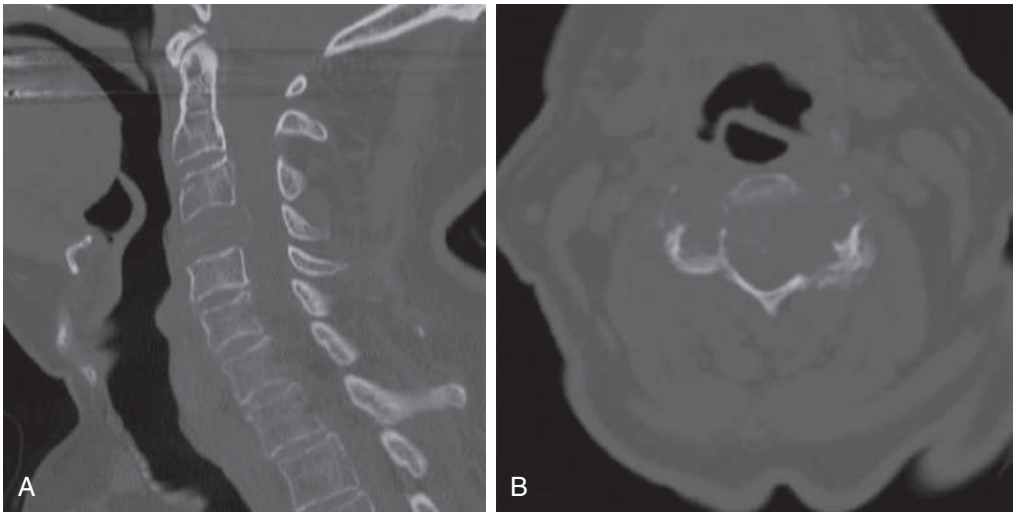

FIG. 86.12 (A) Sagittal and (B) axial computed tomographic images of C4 vertebra showing complete destruction of the vertebral body with infiltration of the posterior elements.

systemic symptoms in the form of fatigue, recurrent infections, and severe life-threatening anemia.

Plain radiographs are used for a skeletal survey when multiple myeloma is suspected. The radiographs show the typical lytic lesions, with a sharp zone of transition and lack of reactive bone formation giving the appearance of "punched out" lesions. Pathologic compression fractures are most commonly seen in the thoracolumbar region. Due to the suppression of osteoblastic activity, a bone scan has a very limited role in the diagnosis of multiple myeloma lesions. CT scans are used to detect the amount of bony destruction and assess spinal stability (Fig. 86.12). CT scans are useful when the lesions are not well visualized on radiographs. Typical CT findings include classic lytic lesions, a soft tissue mass, pathologic fracture, or an epidural mass. MRI is useful to assess the extent of neurologic compression (Fig. 86.13). The tumor appears as hypointense on T1-weighted images and hyperintense on T2-weighted images. Fluorodeoxyglucose positron emission tomography (FDG-PET) scan has become the investigative tool of choice and has replaced MRI as a tool in the early detection and staging of multiple myeloma. Schirrmeister et al. reported these scans to be 92% sensitive in the early detection of lesions that were not seen on radiographs.[71] MRI or FDG-PET scans are also important to look for other skeletal lesions when the diagnosis of a solitary plasmacytoma is considered.

The treatment of multiple myeloma involves a thorough investigation to assess the severity of the disease. These assessments are carried out to determine the neurologic status of the patient, oncologic assessment, assessment of mechanical stability, and systemic disease assessment. These fundamental assessments help in deciding the most appropriate treatment modality (radiotherapy, chemotherapy, or surgery) for the patient. Thorough assessment of the neurologic status is important to determine the presence of radiculopathy or myelopathy and the extent of canal compromise. An oncologic assessment is necessary to determine the tumor's response to radiotherapy or chemotherapy. Mechanical stability can be

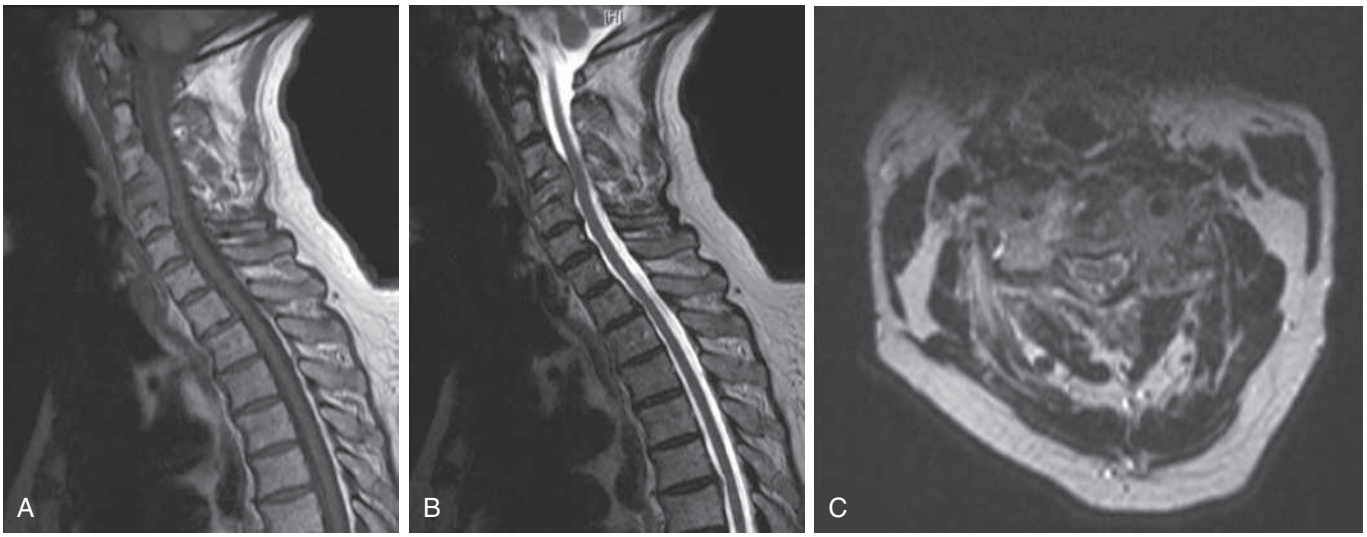

FIG. 86.13 (A) T1-weighted and (B) T2-weighted sagittal images and (C) T2-weighted axial magnetic resonance images of a solitary plasmacytoma presenting as a lytic lesion of the C4 vertebra.

assessed based on the extent of bone destruction. A systemic assessment involves the determination of the extent of the disease and other medical comorbidities.

Radiation therapy, in addition to surgery, has been shown to increase the long-term survival rate. It has been the frontline treatment modality for multiple myelomas. Patients with minimal epidural canal compromise with or without neurologic symptoms can be treated with image-guided, intensity-modulated radiation therapy. However, patients with severe canal compromise or the presence of neurologic deficits are initially treated with radiation therapy. Patients who present with compression or burst fractures are treated with vertebroplasty or kyphoplasty. These procedures should be avoided in patients with a breach in the posterior vertebral cortex or significant epidural disease. Cement augmentation procedures have been shown to improve pain and the functionality of patients with multiple myeloma.[72] Patients with significant spinal instability need surgical treatment. Due to accompanying osteopenia/osteoporosis, a stabilization and reconstruction procedure often involves anterior column reconstruction as well as posterior instrumented spinal fusion (Fig. 86.14).

FIG. 86.14 Postoperative upright radiograph showing spinal column reconstruction after a cervical corpectomy and excision of tumor.

Metastatic Tumors

Metastatic lesions are the most commonly seen malignant tumors of the spine, and symptomatic metastatic lesions are the initial manifestation in up to 20% of patients with malignancy. The spinal column is the third most common site of malignancy after the lungs and liver and is the most common site of skeletal metastasis. With an increase in the life span of the current population, the incidence of cancer and spinal metastatic lesions is on the rise. The most common primary tumors that metastasize to the spine are breast, prostate, lung, kidney, and thyroid. Within the spinal column, the thoracic spine is the most common site for metastasis (70%) followed by lumbosacral (16–22%) and cervical (8–15%).

Pathophysiology of Metastasis

The process of metastasis involves the dissociation of tumor cells from the primary tumor, the penetration of the surrounding matrix, followed by the invasion of vascular or lymphoreticular channels. Tumor cells act as emboli and travel to the distant organ site where they invade through the walls of the blood or lymphatic vessels and eventually adhere to the extracellular matrix. Various chemical modulators secreted by the tumor cells then promote neoangiogenesis. In the skeletal system, the tumors most often stimulate osteoclasts, leading to lytic lesion formation, or less commonly stimulate osteoblasts, leading to an osteoblastic lesion. Spinal metastasis most

frequently occurs through a hematogenous route either through the segmental vessels or the retrograde spread through the valveless Batson's venous plexus. Lung tumors spread to the vertebral column through the segmental arteries, whereas breast, gastrointestinal, and prostate carcinomas spread through the Batson's venous plexus. The expression of surface protein and receptors has also shown to contribute to the selectivity of tissues for metastatic lesions.

Clinical Presentation

Axial pain is the most frequently reported symptom in patients with a spinal metastasis. The pain caused by the metastatic lesion is usually nonmechanical in nature and is associated with a characteristic nighttime aggravation. Patients may also present with pathologic compression fractures with aggravation of axial back pain. Another patient presentation is neurologic symptoms that may include the presence of radiculopathy or myelopathy. The symptoms may be caused by a direct extension of the tumor to the epidural space or compression of the neurologic structures caused by retropulsed fragments and deformity created by the pathologic fractures. Spinal metastatic lesions can also be asymptomatic and may only be detected in a general workup for a visceral malignant tumor.[73]

Diagnosis

Evaluation of the patient with metastatic lesions should begin with a thorough clinical examination. Patients should be evaluated for the presence of local tenderness, deformity, neurologic deficits, and instability. A thorough neurologic examination is very important to diagnose spinal cord or nerve root compression. Signs of myelopathy commonly seen in these patients are exaggerated reflexes, a positive Babinski sign, and gait disturbances.

The next step in the management of metastatic lesions involves imaging investigations to determine the extent of local involvement and the source of the primary tumor.

The imaging investigations start with a series of biplanar plain radiographs. The images should be evaluated for the presence of spinal stability, alignment, pathologic compression fractures, as well as any lytic or sclerotic lesions. However, plain radiographic evaluations have limitations posed by the location in the spinal column as well the overall bone quality of the patient. Fifty percent of the trabecular bone must be lost before the lesion can be diagnosed as a lytic lesion on a plain radiograph. Lytic lesions involving the pedicle may give the appearance of a "winking owl" sign. CT or MRI is necessary to diagnose metastatic lesions. CT scans provide information about the extent of bony destruction caused by the lesion (Fig. 86.15). CT scans can assess the bone destruction in the sagittal, coronal, and axial planes, which aids in the determination of potential spinal instability. CT scans also show involvement of surrounding paraspinal structures. In addition, CT myelogram can be used to determine the extent of neurologic compromise. MRI is routinely used in the evaluation of spinal metastatic lesions. MRI of patients with metastatic lesions involves T1- and T2-weighted images and short tau inversion recovery sequences. MRI is useful in differentiating metastatic compression fractures from osteoporotic compression fractures. T2-weighted images show hyperintense signal in both types of fractures (Fig. 86.16), whereas T1-weighted images of metastatic lesions show diminished signal due to marrow involvement by the tumor. Osteoporotic fractures appear isointense on T1-weighted images (Fig. 86.17). Gadolinium contrast-enhanced imaging sequences help evaluate soft tissue involvement and epidural space involvement. MRI is a very important tool when surgical treatment is contemplated. It aids in the evaluation of adjacent and distant vertebrae so that a reliable point of fixation can be obtained. MRI of the entire spine is conducted to detect the presence of metastatic lesions. It has a high specificity in diagnosing noncontiguous multiple foci of metastatic lesions and a very high specificity and a low false-positive rate. Bone scans may also be used for a similar purpose due to their high sensitivity, but they have a higher false-positive rate.

Obtaining a tissue diagnosis is of the utmost importance in differentiating a primary tumor from a metastatic lesion.

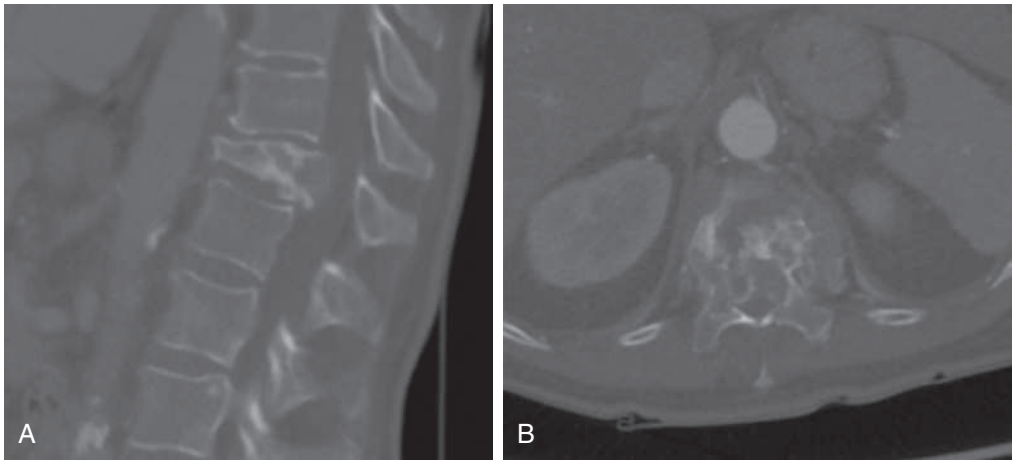

FIG. 86.15 (A) Sagittal and (B) axial computed tomographic images showing a lytic lesion in the T12 vertebra with pathologic fracture, retropulsion, and canal compromise.

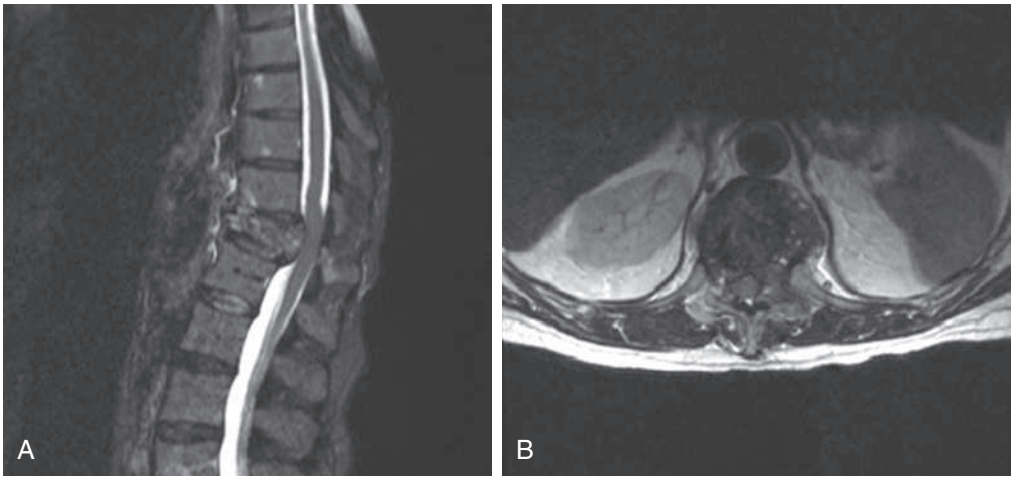

FIG. 86.16 (A) Sagittal and (B) axial T2-weighted images showing a hypointense lesion causing spinal cord compression and infiltration of the pedicle and vertebral body along with posterior elements by the metastatic lesion.

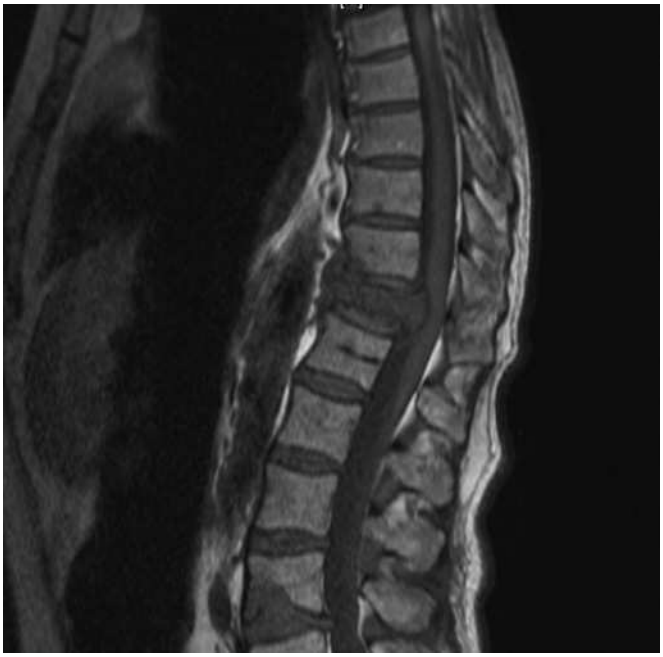

FIG. 86.17 T1-weighted image showing presence of marrow infiltration by the lesion appearing as hypointense signal intensity compared with surrounding bone marrow.

CT-guided biopsy usually provides an adequate sample for tissue diagnosis in 93% of lytic and 76% of sclerotic lesions and has obviated the need for an open biopsy.

Treatment

Most surgeons agree that metastatic spine tumor surgery should be limited to patients who have an estimated life expectancy of greater than 3 months. Treatment outcomes are highly dependent on the prognosis of the primary tumor. An early study estimated the average survival for patients with metastatic spinal cord compression to be between 3 and 7 months, with a 36% probability of survival to 12 months.[74] In an effort to better determine a patient's life expectancy, Tokuhashi et al.[75] presented a scoring system to be used in the preoperative evaluation of patients with metastatic spine tumors. Scores of 0 to 2 points are assigned to each of six parameters. The patient's general health condition, number of extraspinal skeletal metastases, number of metastases to the spine, status of metastases to internal organs, site of primary tumor, and the patient's neurologic status are all weighted parameters. The same study group later published a revised system of scoring that slightly increased the weight of the primary site of cancer,[76] which is commonly used as an indication for patient survivability (Table 86.1). Regardless of the type of scoring system used, spine surgeons are encouraged to consult with the patient's medical and radiation oncologists because multimodal treatment may offer the patient even longer survival than otherwise predicted.

The treatment of metastatic spinal tumors requires a multidisciplinary approach that integrates surgery, radiation and medical oncology, and interventional radiology. Recently, a multidisciplinary team at Memorial Sloan Kettering Cancer Center established the NOMS decision framework to incorporate four fundamental assessments: neurologic, oncologic, mechanical instability, and systemic disease. This framework established guidelines in the decision-making process to administer conventional external-beam radiation, stereotactic radiosurgery, surgical intervention, separation surgery, or a combination of these treatment modalities based on the most recent advancements in technology and outcomes based on the literature. In NOMS, the neurologic consideration is an assessment of the degree of epidural spinal cord compression, myelopathy, and/or functional radiculopathy. The degree of epidural spinal cord compression is based on a 6-point scale that incorporates gradations of the thecal sac impingement. A grade of 0 indicates only bone disease. Grade 1a indicates epidural impingement without deformation of the thecal sac; grade 1b indicates deformation of the thecal sac without spinal cord abutment; and grade 1c indicates deformation of the thecal sac with spinal cord abutment but without cord

compression. A grade of 2 indicates spinal cord compression but with visible cerebrospinal fluid around the cord; grade 3 indicates spinal cord compression with no cerebrospinal fluid visible around the cord.[77] The oncologic consideration is predicated on the expected tumor response and the durability of the response to available treatments. Mechanical instability takes into account the integrity of the spinal column and the extent of pathologic fractures to determine whether to use conservative management with a brace or surgical intervention. The final consideration of systemic disease and medical comorbidities is to evaluate the ability of the patient to tolerate a proposed treatment and the overall survival based on tumor histology and extent of disease. Table 86.2 provides a guide to the current NOMS decision framework.

TABLE 86.1 Tokuhashi Scoring System for Preoperative Evaluation of Patients With Metastatic Spinal Tumors

Parameter	Score
General Condition	
Poor	0
Moderate	1
Good	2
Number of Extraspinal Bone Metastases	
>3	0
1 or 2	1
0	2
Number of Metastases in the Spine	
>3	0
2	1
1	2
Metastases to Major Internal Organs	
Irremovable	0
Removable	1
None	2
Primary Site of Cancer	
Lung, osteosarcoma, stomach, bladder, esophagus, pancreas	0
Liver, gallbladder, unidentified	1
Others	2
Kidney, uterus	3
Rectum	4
Thyroid, breast, prostate, carcinoid tumor	5
Myelopathy	
Complete	0
Incomplete	1
None	2

Treatment

The goal of treatment for patients with spinal tumors is to provide a possible cure, palliation, and early return to activity. If this is not possible, the goal is to provide a stable spinal column and normal or improved neurologic function. Table 86.3 provides a general outline for the treatment of spinal tumors.

Indications for Surgery

Not all patients with spinal tumors require surgery. Patients with clearly benign tumors and those with diffuse metastases in which the primary tumor is known can simply be observed. With the acceptance of more aggressive surgical methods, surgical indications have been expanded to include (1) isolated primary or metastatic lesion or a solitary site of relapse, (2) pathologic fracture or deformity with bony impingement producing neurologic symptoms or pain, (3) radioresistant tumor (metastatic or primary), (4) tumor progression despite or after radiotherapy, (5) segmental instability with significant pain or impending neurologic injury, and (6) inability to obtain tissue diagnosis by other means. All these presume a patient who is healthy enough to survive surgery but are not incumbent on a long-expected survival.

Staging

The initial diagnostic workup allows spine surgeons to determine the nature, extent of the tumor, extent of soft tissue

TABLE 86.2 NOMS Decision Framework

Neurologic	Oncologic	Mechanical	Systemic	Decision
Low-grade ESCC + no myelopathy	Radiosensitive	Stable		cEBRT
	Radiosensitive	Unstable		Stabilization followed by cEBRT
	Radioresistant	Stable		SRS
	Radioresistant	Unstable		Stabilization followed by SRS
High-grade ESCC + myelopathy	Radiosensitive	Stable		cEBRT
	Radiosensitive	Unstable		Stabilization followed by cEBRT
	Radioresistant	Stable	Able to tolerate surgery	Decompression/stabilization followed by SRS
	Radioresistant	Stable	Unable to tolerate surgery	cEBRT
	Radioresistant	Unstable	Able to tolerate surgery	Decompression/stabilization followed by SRS
	Radioresistant	Unstable	Unable to tolerate surgery	Stabilization followed by cEBRT

Low-grade ESCC is defined as grade 0 or 1 in the Spine Oncology Study Group scoring system. High-grade ESCC is defined as grade 2 or 3 in the Spine Oncology Study Group scoring system. cEBRT, conventional external-beam radiation therapy; ESCC, epidural spinal cord compression; SRS, stereotactic radiosurgery.
Modified from Laufer I, Rubin DG, Lis E, et al. The NOMS framework: approach to the treatment of spinal metastatic tumors. *Oncologist.* 2013;18(6):744-751.

TABLE 86.3 General Treatment Approach for Spine Tumors

Therapy	Indication
Observation	Indolent and clearly benign tumors (hemangioma, osteochondroma, bone island, bone infarct)
Radiotherapy	Metastatic lesions from a known radiosensitive primary (multiple myeloma, breast carcinoma)
Chemotherapy	Metastatic lesions from a known chemosensitive primary (thyroid)
Intralesional excision, curettage	Benign tumors with limited potential for recurrence (aneurysmal bone cyst, osteoblastoma), radiosensitive metastatic lesions with adjuvant radiation therapy
Marginal excision ± adjuvant cryotherapy or radiotherapy	Locally aggressive benign lesions (giant cell tumor), radiosensitive primary and metastatic lesions (plasmacytoma, breast and prostate carcinoma), low-grade malignancies
Wide excision	All primary malignancies without known metastases (osteosarcoma, chondrosarcoma, chondroma); solitary metastases with likelihood of prolonged survival (breast, prostate, renal cell carcinoma); locally aggressive benign tumors (giant cell tumor)

involvement, stability of the spinal column, and extent of neurogenic compromise. This information can then be used to stage the tumor. Boriani et al. published a novel system for staging primary spinal tumors.[78] According to the Weinstein-Boriani-Biagini staging system, the affected vertebra is divided into 12 radiating zones, numbered 1 to 12 in a clockwise manner starting from the left side of the spinous process, and five concentric layers (labeled A to E) starting from the paravertebral extraosseous region to the dural involvement. Layer A corresponds to the extraosseous soft tissues, B is the intraosseous superficial layer, C is the intraosseous deep layer, D is the extraosseous extradural layer, and E is the extraosseous intradural layer.[78,79] CT, MRI, and angiography techniques are used to stage the tumor. These investigations also help determine the longitudinal extent of the tumor.

Surgical Approach

The primary goals of surgery are local control of the tumor, neurologic improvement, and maintenance of spinal stability. The surgical approach must provide sufficient access for both tumor excision and stabilization of the spine. A complete radiographic evaluation should be performed to determine the accurate location of the tumor and its extension to the surrounding tissues. Additional laboratory and screening studies should focus on further differentiation, allowing the surgeon to plan an operation that will adequately treat the tumor without exposing the patient to needless risks. The approach and extent of surgery depend on the location of tumor in the vertebrae and the extent of the disease. General approaches for spinal tumors are described below.

A dorsal approach is recommended for a dorsal element tumor (lamina and spinous process) or lesions in radiating zones 10 to 3. Studies have reported that an aggressive dorsal decompressive laminectomy provides more neurologic improvement than a simple decompressive laminectomy.[80,81] At all vertebral levels, dorsal elements can be accessed through a midline incision.

Lesions that involve the posterior elements and pars (zones 2 to 5 and 7 to 11) can be excised through a dorsal or dorsolateral approach. Most tumors need both a ventral and dorsal approach. In such cases, a dorsolateral approach is considered to avoid a two-stage surgery. In the upper thoracic and thoracolumbar junction, lateral vertebrae are exposed through a costotransversectomy approach for both ventral and dorsal decompression and segmental dorsal fixation.[81] This approach exposes half of the ventral body. For dorsal decompression, concomitant thoracic laminectomy and resection of the facet joints and pedicles are needed. The surgeon may consider sacrificing at least one single nerve for extensive ventral decompression and spinal instrumentation. Care should be taken to protect the underlying pleural structures, and the patient's mean arterial pressure should be maintained at greater than 75 mm Hg to protect the spinal cord from ischemia during the procedure.

Lesions involving the anterior and posterior halves of the vertebral body (zones 5 to 9 and 4 to 8) are resected using anterior approach techniques, especially for benign tumors. However, dual-approach techniques are needed in cases of malignant lesions. The majority of malignant tumors affecting this region require a vertebrectomy, which is performed with a dual approach. The standard surgical approach is determined according to which vertebral levels are involved. For the upper cervical lesions, transoral and extraoral ventral approaches are used.[82,83] For lower cervical tumors, most surgeons use the Southwick-Robinson anterior approach.[84] In the thoracic region, a right- or left-sided approach is usually determined by the area of the compressed tumor. If neither side is more involved, the spine is often approached from the right side at or above T5 to avoid the arch of the aorta. Below T5, the spine is approached from the left to minimize retraction on the liver. Surgeons typically select the intercostal space one or two segments above the targeted vertebral body approach. The upper part of the thoracic spine from the first to the third thoracic vertebrae can be exposed using a thoracoplasty approach by mobilizing the scapula ventrally and resecting the second vertebra. As described by Harrington, the major advantage of a ventral approach is the surgeon's ability to resect the tumor directly, decompress the neurologic structures from the side of their compromise, and "jack" open the collapsed vertebral space, thereby correcting the typical kyphotic deformity at its source.[85,86] In the thoracolumbar junction, both a thoracotomy and lumbar retroperitoneal approach must be completed for a ventral approach.[87,88] The most common approach is through the rib just proximal to the area of interest. Lumbar spine tumors can be accessed ventrally through a retroperitoneal approach.[89] Care should be taken to protect the genitofemoral nerve and ureter from injury during the procedure.

Resections

En bloc and intralesional resections are the two general types of surgical resections classified based on the type of margin achieved during surgery. In intralesional resections, the surgeon removes the tumor from within the tumor mass. An intralesional resection has a high recurrence rate compared with en bloc resections. The high recurrence rate is due to the presence of the residual tumor or an incomplete resection. Radiation therapy is often used after intralesional resections to facilitate local control. En bloc resection is the surgical removal of the tumor in a single piece, fully encased within a layer of healthy tissue. En bloc resections can be marginal, wide, or radical. Marginal resection means the removal of the entire tumor with or without a thin healthy tissue layer. En bloc resection in the spine may still have recurrences from positive tumor margins. A wide margin resection means the complete removal of the tumor with the continuous shell of healthy tissue. Wide resections are not always possible in the spine and often lead to spine instability and morbidities. Wide resections have a lower recurrence rate. A radical resection is the removal of an entire organ along with the blood and lymph supply to the organ and is almost always impossible in the spine.[90]

Decompression

Metastatic tumors of the spine cause more spinal cord compression than primary benign and malignant tumors. Spinal metastasis is seen in 70% of cancer patients, and up to 10% of cancer patients develop metastatic cord compression.[91] Spinal cord compression may result from one of four types of processes: (1) direct compression from an enlarging soft tissue mass, (2) pressure due to fracture and retropulsion of bony fragments into the canal, (3) severe kyphosis after vertebral collapse, and (4) pressure due to intradural metastases. The most common cause of cord compression is mechanical pressure from the tumor tissue or bone extruded from the collapsing vertebral body.

Primary tumor compression is often effectively addressed during resection of the tumor by decompression techniques. Spinal cord decompression can provide dramatic improvement in neurologic function, even in advanced states. Decompression can be achieved through radiation therapy, surgical decompression or, occasionally, serial arterial embolization.

Radiation therapy alone can be used to treat spinal cord impingement, especially for spinal metastatic tumors. Studies have reported positive neurologic outcomes and retained ambulatory status in patients who underwent radiation therapy after surgical decompression compared with radiation therapy alone.[92,93] Recent advancements such as stereotactic radiosurgery have been effective in treating radioresistant solid spinal metastatic tumors.[94] One prospective study demonstrated the safety and effectiveness of spinal stereotactic radiosurgery as a first-line therapy for spinal metastasis in the absence of significant spinal cord compression.[95]

Surgical decompression is necessary for progressive neurologic deficits. Surgical decompression can be achieved either by dorsal or ventral approaches.[96] Studies reported that neurologic status, ambulatory status, and functional status improved in patients who underwent ventral surgical decompression.[97-100]

Posterior decompression and stabilization for metastatic spinal cord compression in the cervical spine is less likely to improve or maintain motor function compared with metastatic spinal cord compression in the thoracic and lumbar spine after posterior decompression and spine stabilization.[101]

Important factors in determining the prognosis for the neurologic outcome include tumor biology, pretreatment neurologic status, and tumor location within the spinal canal.

Spine Stability

Aggressive tumor resections, aggressive decompression techniques, severe bone destruction by the tumor, and associated pathologic fractures predispose the vertebral column to mechanical instability and the risk of neurologic injury. Planning for tumor surgery should include optimal reconstruction techniques to maintain the stability of the spinal column. The Spine Oncology Study Group created a novel classification to study spinal stability in neoplastic spinal lesions.[102] The spine instability neoplastic score (SINS) created by the group aids in the assessment of spinal stability and the determination of the need for a surgical consult. This classification system is primarily useful with metastatic involvement of the spine compared with primary or benign tumors of the spine. However, the classification system provides a thorough insight into key elements of spinal stability. Surgical treatment of aggressive benign lesions or primary malignant lesions involves resection of a majority of the vertebral body and stabilizing structures. In such cases, surgical treatment involves reconstruction techniques that use expandable biomechanical devices that help restore the sagittal alignment of the patient and anterior column reconstruction. However, stand-alone anterior column reconstruction is considered suboptimal when aggressive resections are contemplated. In most cases anterior column resections are reinforced with posterior instrumentation of the spinal column using various fixation techniques depending on the level of involvement in the spinal column.

Assessment of any potential spinal instability can be achieved by looking at key elements of the SINS classification system. The scoring system grades stability based on six parameters: tumor location within the spinal column (junctional, mobile, rigid, or semirigid part of the spinal column), pain-related response from the mechanical loading and unloading of the spinal column (alleviation of pain on recumbency and reproduction in upright posture), quality of the bone lesion (lytic, mixed, or blastic), radiographic spinal alignment (subluxation, kyphosis/scoliosis versus normal), percentage of vertebral body collapse, and the involvement of posterolateral spinal elements (pars, pedicle, and facet joints). Scores of 0 to 6 denote stability, 7 to 12 denote indeterminate or impending instability, and 13 to 18 denote definite instability of the spinal column.

A minimally invasive spine stabilization technique can be an alternative to conventional open surgery for metastatic spine tumor patients with a short life expectancy.[103]

Summary

Primary and metastatic lesions of the spinal column present a unique challenge to the treating surgeon. The treatment of these complex pathologies requires a team approach and expertise. A thorough clinical evaluation and a high suspicion for a tumor are very important to achieve early detection and better outcomes. Advances in imaging technologies have also promoted early tumor detection and the accurate assessment of tumor extent in spinal tumors, but the treatment of primary malignant tumors continues to pose a challenge to spine surgeons.

Development of newer chemotherapy medications and advancements in radiotherapy delivery mechanisms have also improved survival rates in these patients. Due to the increased survival in these patients, preservation of neurologic function and spinal stability is of utmost importance to maintain the functional independence and dignity of the patient.

Advancements in rehabilitative technologies allow patients with residual deficits to be independent as well. Surgery should be offered to the patients who can tolerate surgery.

Advances in surgical techniques and instrumentation systems have considerably decreased the morbidity of the surgical procedures. These newer techniques also provide correction and prevention of deformity. The widespread use of posterior-only vertebral column resection techniques has negated the need for multistage procedures and the morbidities that came with it. The widespread use of percutaneous fixation techniques as well as robotic- and navigation-guided surgical techniques will further improve the outcomes of tumor surgery and fusion in these patients.

Advances in interventional radiology techniques have allowed preoperative embolization of hypervascular tumors. This has been beneficial for spinal surgeons and has significantly reduced the perioperative morbidity of tumor surgery. With all these advances, vertebrectomy has become a common procedure and has improved the outlook of tumor surgery.

KEY POINTS

1. Spinal surgery, if well planned, properly executed, and combined with contemporary radiotherapy and chemotherapy, can reduce pain, improve neurologic function, greatly enhance survival, and provide greater opportunity for a curative treatment in patients with spinal tumors. Hence it is imperative that physicians recognize the presence of spinal neoplasia with early detection and carefully observe the principles of tumor staging and management.
2. A diagnostic workup should include imaging investigations to study the extent of the tumor as well as its distant spread. Tissue diagnosis is equally important and can be completed with CT-guided biopsy at a facility equipped to perform spine tumor surgery and by a surgeon who will ultimately do the surgical resection.
3. Treatment of primary benign or malignant tumors involving the spinal column is aimed at obtaining a tissue diagnosis, preserving neurologic function, and maintaining or restoring spinal alignment and stability.
4. MRI has become a key imaging tool to define tumor characteristics. It has a superior sensitivity and specificity in defining the extent of the tumor, soft tissue involvement, and extent of canal compromise. MRI is also useful in detecting noncontiguous lesions in metastatic lesions.
5. Tissue diagnosis is of the utmost importance and forms the basis of the treatment algorithm. CT-guided biopsy has become the procedure of choice to obtain tissue samples. The adequacy of the tissue sample should always be verified. A frozen section, taken at the time of biopsy, can help obtain the most diagnostic sample from the tumor. A biopsy should be performed by the surgeon who will perform the final excision. Biopsy needles should not cross any body cavities. The tumor biopsy should be approached in an optimal way.
6. Benign tumors of the spinal column can be treated with resection of the tumor and reconstruction of the spinal column in cases of instability. However, GCTs are locally aggressive tumors and may have an associated large soft tissue mass that rarely metastasizes to the lungs. They are associated with a high local recurrence rate of en bloc resection is not possible due to location. Aggressive surgical resection is important to prevent local recurrence. Patients with a local recurrence have associated poor outcomes. New medical modalities such as serial intravenous denosumab injections show evidence of radiologic and histologic improvement in these patients and may change the current algorithms for treatment of GCTs.
7. Primary malignant tumors are very rare but need an extensive planning and team approach to prevent recurrence. Primary osteogenic sarcomas are associated with aggressive local growth and metastasis. They are most commonly seen in the vertebral body. Secondary osteosarcomas can present in patients with long-standing Paget disease or patients who have had radiation for treatment of benign tumors such as GCTs. A multimodal approach and neoadjuvant chemotherapy have decreased the incidence of local recurrences and have improved the disease-free survival rate.
8. Locally aggressive benign tumors such as GCTs and malignant tumors such as chordomas are associated with a high local recurrence rate. Aggressive local resection with wide margins is of utmost importance. En bloc resection has been shown to decrease the risk of local recurrence and is thought to be curative if a wide marginal resection can be obtained. Local recurrence is associated with poor outcome.
9. Metastatic tumors are the most common type of malignant tumors that affect the spinal column. Tumors that commonly metastasize to the spine include breast, lung, kidney, and prostate tumors. Treatment of the metastatic lesion depends on the overall prognosis of the patient. Radiation therapy is the mainstay of treatment. However, surgical treatment may be necessary in patients who have the potential for spinal instability or neurologic compression.
10. Multiple myeloma is a plasma cell disorder that commonly affects the spinal column. The lesions have a characteristic "punched out" lytic appearance on plain radiographs. The tumors are highly radiosensitive, and radiotherapy can be curative. However, surgical treatment may be needed when there is neurologic compromise or the potential for spinal instability after radiotherapy.
11. Surgical treatment is necessary in spine tumor patients mainly to obtain local control of the lesion. Surgical treatment helps obtain a definitive tissue diagnosis, allows thorough decompression of the neural structure, and helps maintain or restore spinal stability.

12. Neurologic compromise can lead to catastrophic outcomes and warrants prompt treatment. Compromise most commonly results from retropulsed fragments from a pathologic compression fracture or the presence of an epidural mass causing direct compression of the neural structures. Radiotherapy is the initial treatment of choice if the tumor is radiosensitive and the neural progression is gradual; however, surgical treatment may eventually be needed in the presence of potential spinal instability. Surgical treatment is necessary if progression is rapid, if the tumor is known to be radioresistant, and/or the neural compression is caused by retropulsed bone fragments.

CHAPTER 87

Infections of the Spine

SECTION XII

Jason C. Eck
Choll W. Kim
Bradford L. Currier
Frank J. Eismont

Infections of the Spine

Historically, spine infections were devastating diseases with exceedingly high morbidity and mortality rates. With the advent of new diagnostic techniques, multidrug antimicrobial chemotherapy, and improvements in surgical techniques, the prognosis has improved dramatically in recent years. Successful management of spine infections requires a high level of diagnostic acuity to avoid delays in diagnosis, use of appropriate antibiotic therapy as directed by biopsy results, and institution of appropriate surgical intervention when indicated.

There are numerous ways to classify spine infections. The most basic is by the histologic response of the host to the specific organism. Most bacteria cause a pyogenic response, whereas *Mycobacterium,* fungi, *Brucella,* and syphilis induce granulomatous reactions. Infections may be classified by their primary anatomic location—vertebral osteomyelitis, discitis, or epidural abscess. Another way to categorize spine infections is by cause; the main routes of infection are hematogenous, direct inoculation (postoperative and traumatic), and spread from a contiguous source. Finally, age may be the determinant and infections may be classified as occurring in pediatric or adult populations. Each of these classifications has implications with regard to evaluation, treatment, and prognosis.

Historic Perspective

The first recorded descriptions of spine infections were those in the Hippocratic texts on tuberculous spondylitis written between the 4th century BC and the 1st century AD. Sir Percival Pott's description of paralysis in association with tuberculosis of the spine in the 18th century led to the eponym "Pott paraplegia." His frustration with the inadequate treatment options available to him was shared by physicians for another 150 years: "To attend to a distemper from its beginning through a long and painful course, to its last fatal period, without even the hope of being able to do anything which shall be really serviceable, is of all tasks the most unpleasant."[1]

Before the advent of antimicrobial therapy, the treatment of tuberculosis of the spine was based on bed rest, often in a plaster cast, with attention to diet and exposure to fresh air and sunlight. Laminectomy was the mainstay of surgical treatment in the late 1800s and the early part of the 20th century but was later condemned by Seddon and others because it did not address the anterior disease and led to further instability.[2] In 1911, Hibbs[3] and Albee[4] independently described the use of posterior fusion to hasten the recovery. The idea evolved from the demonstration that ankylosis of peripheral joints led to remission of local disease. Unfortunately, posterior fusion did not prevent progressive kyphosis or address the lesion that was causing paralysis, and the technique was later abandoned. The mortality rate for children treated by these various techniques was 40%.[5] In 1894, Menard described a series of patients with Pott paraplegia successfully treated with decompression by costotransversectomy.[6] The technique fell into disfavor because of a high rate of secondary infection; it did not gain acceptance until Girdlestone reintroduced it in 1931 with aseptic technique.[7]

Ito and colleagues[8] described the anterior approach to the lumbar spine in 1934, demonstrating that it provided wider exposure and allowed more radical debridement and fusion. Hodgson and colleagues[9,10] popularized the anterior approach for the management of tuberculosis of the spine and stressed radical excision and strut-graft fusion to prevent kyphosis and late-onset paraplegia.

Antituberculous chemotherapy became available in 1945 and was found to be capable of curing the disease even without surgery.[11–15] Faced with a number of widely divergent regimens for the treatment of the disease, a group of investigators formed the British Medical Research Council Working Party on Tuberculosis of the Spine. This group set out to perform a number of large-scale, controlled prospective trials of treatment methods. These studies, as well as others to be described later, helped to determine the current treatment recommendations for this disease.

The first recorded description of a pyogenic spine infection was by Lannelongue in 1897.[16] Although pyogenic spine infections differ in many ways from tuberculous spondylitis, the

surgical treatment of the former has been influenced a great deal by the developments in the management of tuberculosis. The introduction of penicillin and streptomycin revolutionized the treatment of all spine infections. As more powerful antimicrobial agents were developed and combinations and dosages were refined, the relative effectiveness of surgical treatment decreased.

The introduction of needle biopsy of the spine obviated the need for open biopsy in many cases. Greater awareness of spine infections and greater availability of better diagnostic modalities have shortened the delay in diagnosis and have diminished the role of surgery in prevention or treatment of deformity. However, patients with a neurologic deficit and/or progressive deformity are still managed best with surgical debridement and reconstruction. In this area as well, significant advances in surgical techniques, development of specialized implants, and application of biologic adjuncts have significantly improved the treatment outcomes for patients with severe spinal infections.

Pyogenic Infections

Postoperative Wound Infections

See Chapter 99.

Spinal Intradural Infections

See Chapter 91.

Vertebral Osteomyelitis

Epidemiology

Although the incidence of tuberculous spondylitis has decreased dramatically in recent years, the incidence of pyogenic vertebral osteomyelitis appears to have increased.[17,18] Various reports have stated that vertebral osteomyelitis represents 2% to 7% of all cases of osteomyelitis.[19–22] The disease may occur from infancy to old age but has a predilection for the elderly.[17,21,23–32] Approximately one-half of the patients with spine infections are more than 50 years old and two-thirds are male.[31] The mean age is 66 years, but the incidence may be higher in younger patients who are intravenous (IV) drug abusers.[2] There is a median length of stay of 31.5 days with increased mortality associated with elevated C-reactive protein (CRP), advanced age, and a Charlson Comorbidity index greater than 2.[33]

Etiology

Any condition that causes a bacteremia may lead to hematogenous vertebral osteomyelitis. Approximately 50% of cases are thought to seed the vertebral column through arterial or venous conduits at the intervertebral disc or endplates. Another 40% are from direct inoculation, such as after a spine procedure. The remaining cases are from local extension from adjacent areas of infection.[34] The most frequent sources are urinary tract infections and the transient bacteremia caused by genitourinary procedures.[18,24,26,30,35–37] Of 198 cases in the literature in which the probable source of infection was noted, it was the genitourinary tract in 29%, soft tissue infections in 13%, and respiratory tract infections in 11%; 1.5% of the infections occurred in IV drug abusers,[31] but this association is being reported with increasing frequency.[31,38–43] Vertebral osteomyelitis may also be caused by direct inoculation of bacteria into the spine by penetrating wounds, spine surgery, chemonucleolysis, or discography.[31,44–53] The source of infection could not be identified in 37% of cases.[31] Immunocompromised hosts appear to be particularly susceptible to spine infections.[24,31,35,37] In particular, diabetic patients have a high incidence of vertebral osteomyelitis.[18,23,35,54] Those who are human immunodeficiency virus (HIV) positive are also predisposed to develop spinal infections even when IV drug users are eliminated from the study group.[55] In a recent series of 253 patients from the Cleveland area, 33% of infections were acquired in the hospital. In total, 51% of patients had predisposing extravertebral infections with most due to hematogenous spread from urinary tract, skin and subcutaneous tissues, infected vascular access sites, endocarditis, and bursitis of septic arthritis.[56] Kulowski thought that trauma was a predisposing factor in pyogenic vertebral osteomyelitis.[29] More recent studies have not supported that association.[2,30,35] In Sapico and Montgomerie's[31] review of 207 literature cases in which the presence or absence of blunt trauma was discussed, in only 5% was there a history of trauma.

Bacteriology

In 1931, Hatch reviewed the literature and reported that the causative organism was almost exclusively *Staphylococcus aureus*.[57] There has been an increase in the number of gram-negative bacillary infections.[26] In the series from Cleveland, gram-negative bacilli accounted for 23% of infections.[56] From data reported in the postantibiotic era, Sapico and Montgomerie[31] found that 67% of 222 patients were infected with gram-positive aerobic cocci; *S. aureus* constituted 55% of the total. The emergence of tolerant *S. aureus* is a concern, and such strains may become more prevalent with the widespread use of antibiotics.[58] Gram-negative organisms are responsible for approximately 13% of cases. The most frequently isolated gram-negative organisms are *Escherichia coli, Pseudomonas* species, *Haemophilis influenzae*, *Klebsiella pneumoniae*, and *Proteus* species.[59] These are frequently found in association with genitourinary tract infection.[26,35,36,60–62] *Pseudomonas aeruginosa* is frequently isolated from heroin abusers.[38,40,42,63–65] In a review of 67 reported cases, gram-negative aerobic bacilli were isolated in 82% of the cases and *Pseudomonas* was the pathogen in 66%.[42] However, one series included 15 IV drug abusers with pyogenic vertebral osteomyelitis; all 11 with positive cultures were infected with *S. aureus*.[24] Isolating an organism in the blood is most likely when fever is present. In the absence of a fever, bacteremia can be detected in only 21% of patients.[56]

Salmonella osteomyelitis is uncommon. It generally occurs after an acute intestinal infection, but the interval between the

gastroenteritis and the onset of osteomyelitis may be quite long[66]; in some cases, no previous infection can be identified.[67] *Salmonella* has a strong tendency to localize in tissues where there is preexisting disease.[66,68] Infection with anaerobic bacteria is unusual and is generally associated with foreign bodies, open fractures, infected wounds, diabetes, or human bites.[31,69]

Infection caused by multiple organisms is encountered in up to 8% of cases.[31,70] Infection with *Haemophilus* species has been reported but is extremely rare in adults.[71,72] Low-virulence organisms, such as diphtheroids and coagulase-negative staphylococci, may cause indolent infections with delayed diagnosis.[73] These organisms may grow slowly; thus, cultures should be held for 10 days before they are considered to be negative. Low-virulence organisms should not be dismissed as contaminants in patients suspected clinically to have vertebral osteomyelitis.[73] In one series of 111 cases of pyogenic vertebral osteomyelitis, low-virulence organisms caused 48% of the infections in the 61 patients who were 60 years of age or older and 55% of the 44 patients who had an impaired immune system.[24]

Pathogenesis/Pathology

Although the nucleus pulposus is an avascular tissue, it is relatively active metabolically.[74] It receives its nutrition via diffusion across the endplates and from blood vessels at the periphery of the anulus fibrosus.[74] In the developing spine, orderly arranged cartilage canals within the endplate contain vascular organs resembling glomeruli.[75,76] Earlier studies suggested that blood vessels penetrate the nucleus pulposus in human fetuses and neonates.[77] However, elegant studies by Whalen and colleagues[76] demonstrated that the nucleus pulposus is always avascular. Coventry and colleagues[78] demonstrated that, after birth, the cartilage endplates become progressively thinner and the vessels within the cartilage canals become obliterated. Some persist up to age 30 years, but by adulthood, most of the vessels within the endplate itself have disappeared.[78]

Wiley and Trueta[79] demonstrated the rich arterial anastomosis within the vertebral body, with end arterioles in the metaphyseal region. Spinal arteries enter the canal through the intervertebral foramen at the level of the disc. Branches ascend and descend, supplying the vertebral bodies above and below. Through their injection studies, Wiley and Trueta demonstrated how bacteria could easily spread hematogenously to the metaphyseal region of adjacent vertebrae. The infection may also start in the metaphyseal region of one vertebra and either spread across the avascular disc by lysosomal destruction of the nucleus pulposus or through vessels anastomosing on the periphery of the anulus fibrosus.[79]

It has been suggested that Batson's plexus may be the route of hematogenous spread of infection. Batson demonstrated, in injection studies, that dye flows into the valveless vertebral venous plexus when pressure is applied to the lower abdominal wall.[80] The distribution of veins within the vertebral body is an arborization of vessels. Minute tributaries draining the metaphyseal region empty into large, valveless, venous channels that drain into the loose plexus lining the canal. Wiley and Trueta demonstrated that it takes considerable force to fill the small metaphyseal vessels in a retrograde fashion compared with the ease of injection of the metaphyseal arterioles; this suggests that the former is an unlikely route of hematogenous seeding.[79]

Once microorganisms lodge in the low-flow vascular arcades in the metaphysis, infection spreads. The disc is destroyed by bacterial enzymes in a manner similar to the destruction of cartilage in septic arthritis. This is in contrast to tuberculous infections (described later), in which the endplates and bone are destroyed, but the disc is frequently better preserved.[81] In children, the cartilage canals allow microorganisms nearly direct access to the disc, which probably explains the clinical differences between spine infections in children and adults. In adults, disc space infection may occur by direct inoculation of the disc as a result of surgery, chemonucleolysis, or discography but is less likely to occur spontaneously.[82,83]

Some authors have suggested that discitis in adults is a separate entity from vertebral osteomyelitis.[28,84] Ghormley and colleagues[84] stressed the benign nature of this variation, but in Kemp and colleagues'[28] series, the disease was quite severe, with a high rate of irreversible paralysis. It is conceivable that adult discs could receive blood directly through persistent vascular channels in the endplate, degenerative defects in the endplate, or vessels anastomosing on the peripheral anulus fibrosus and perhaps gaining access through rents in the anulus. When adult discitis occurs, it appears that hematogenous involvement of the metaphysis is far and away the most common mechanism and, whether the infection begins in the metaphysis and spreads across the disc or vice versa, the clinical manifestations and treatment are the same.

The upper cervical spine has a peculiar blood supply. Parke and colleagues[85] have demonstrated a venous plexus around the odontoid, called the "pharyngeal vertebral vein," which frequently has lymphovenous anastomoses. This venous plexus may be responsible for hematogenous spread to the upper cervical spine.[85,86] Abscesses may drain into the soft tissues surrounding the spine or into the spinal canal itself. In the cervical spine, a retropharyngeal abscess may invade the mediastinum.[29,87] In the thoracic spine, an abscess may be paraspinous or retromediastinal.[29] Infection in the lumbar spine may cause a psoas abscess or, less commonly, an abscess pointing through the Petit triangle.[29] Occasionally, an abscess may create a tract through the greater sciatic foramen and appear in the buttock beneath the piriformis fascia, in the perirectal region, or even in the popliteal fossa.[29] The more virulent organisms may not follow fascial planes and may extend into visceral structures. They also are more likely to produce spinal deformity. An abscess that enters the spinal canal is considered to be an epidural abscess and is discussed later. Infection may cross the dura, causing a subdural or intradural abscess or meningitis.[29,88]

The pathogenesis of neural compromise may be related to direct compression by epidural pus, granulation tissue, or bone and disc from the development of spinal deformity and instability. In addition, the cord or nerve roots may suffer ischemic damage from septic thrombosis or may be damaged by inflammatory infiltration of the dura (Figs. 87.1 and 87.2).[28,29,31]

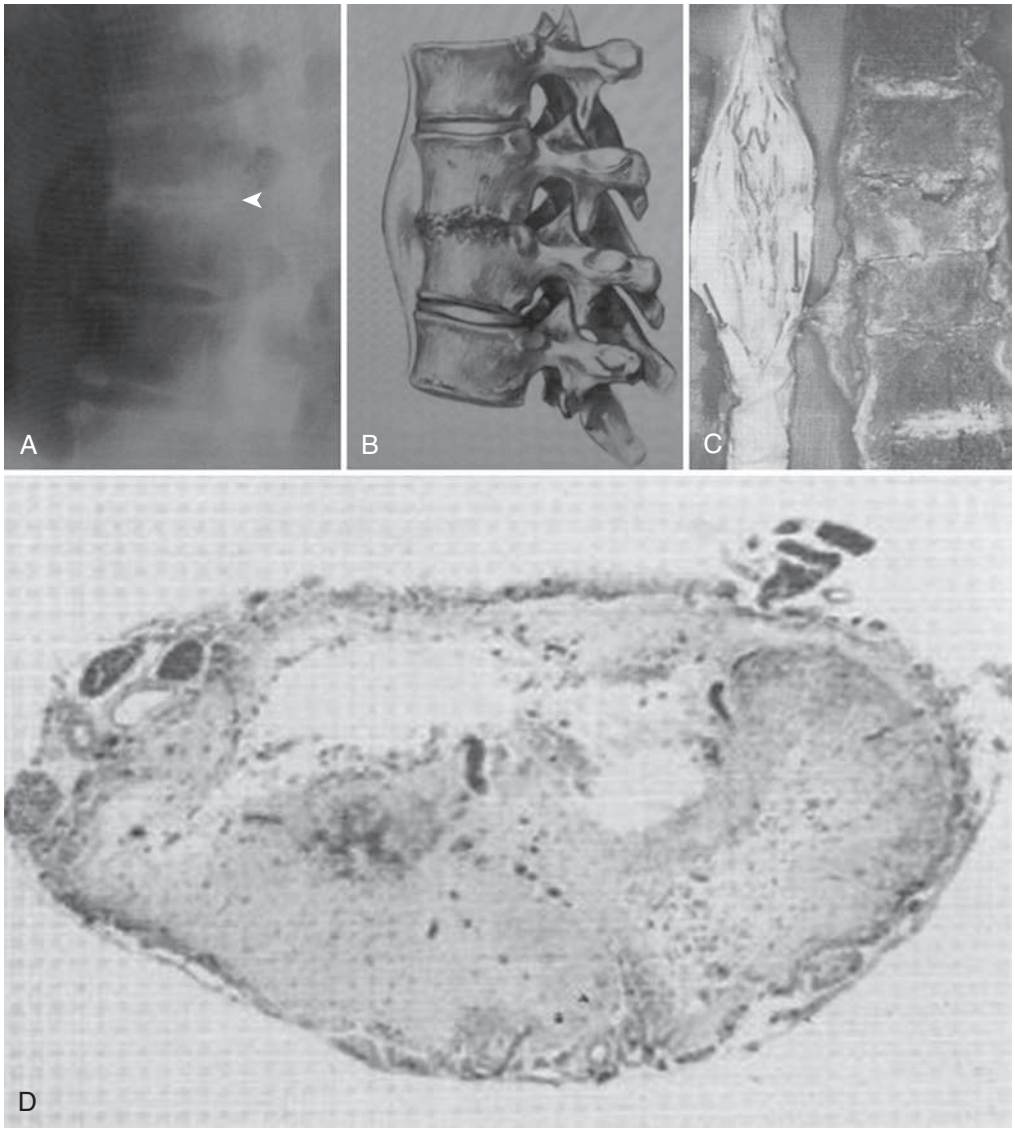

FIG. 87.1 This patient with a T7–T8 disc space infection with associated vertebral osteomyelitis developed progressive paraplegia and died as a result of overwhelming sepsis associated with antibiotic-induced neutropenia. (A) Lateral radiograph showing marked narrowing and sclerosis at the T7–T8 interspace (*arrowhead*). (B) Artist's rendition of the pathology shows the collapse centered at the T7–T8 interspace and associated paraspinal abscess. (C) Two months later, infection spread down to the T9–T10 interspace, with marked narrowing at that level. Gross destruction of the disc can be seen on this gross pathology specimen at the T7–T8, T8–T9, and T9–T10 levels. (D) This microscopic section of the spinal cord has been taken at 11.5 times normal magnification. The dorsal aspect of the spinal cord is at the top of this figure. The patient was completely paraplegic. This is consistent with the changes seen within the spinal cord. (Courtesy Dr. H.H. Bohlman, Cleveland, Ohio.)

An unusual association between vertebral osteomyelitis and compression fractures secondary to osteoporosis has been described. It is theorized that the osteomyelitis may develop as a complication of the fracture because the fracture creates a favorable environment for the hematogenous infection. Alternatively, the osteomyelitis may develop within the central portion of an osteoporotic vertebral body, perhaps because the bone is more hyperemic or because of vascular stasis. Infection may then lead to a pathologic fracture of the vertebra without the usual involvement of the disc space.[89]

Clinical Presentation

The clinical manifestations of spine infection are determined by the virulence of the organism and the resistance of the host. The presentation may be acute, subacute, or chronic.[28,29] Before the antibiotic era, most patients had acute osteomyelitis, and in 68% of the cases the disease was fulminant with severe toxemia.[57] The mortality rate ranged from 25% to 71%.[29,57] A literature review in 1979 found that only 20% of the patients had symptoms for less than 3 weeks before presentation, 30%

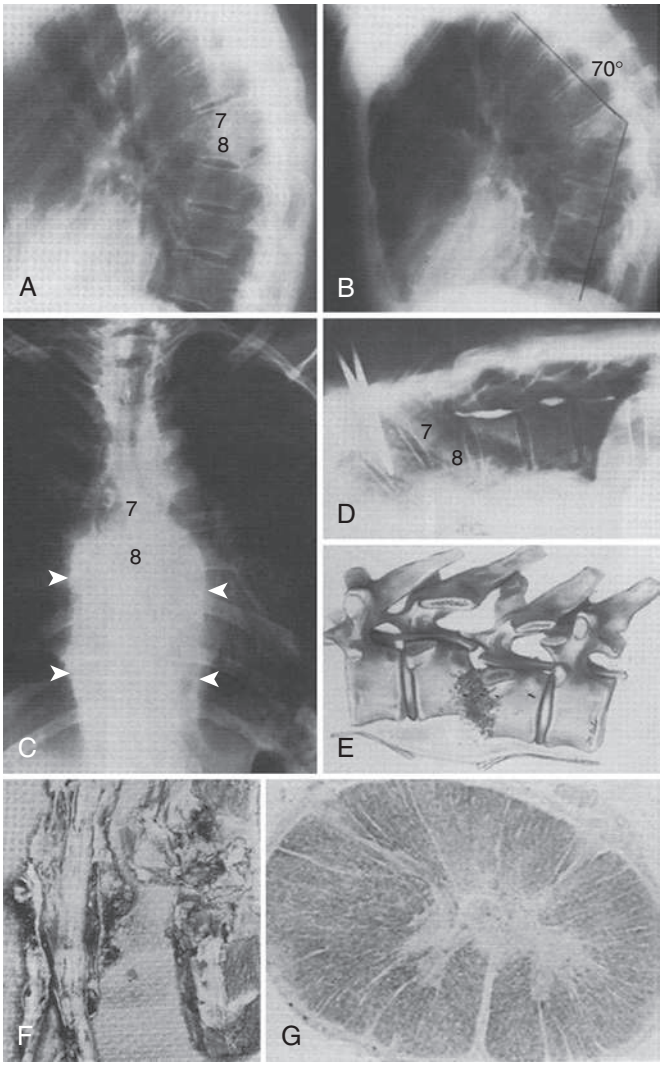

FIG. 87.2 This patient died with thoracic vertebral osteomyelitis secondary to overwhelming meningitis associated with the spine infection. (A) The patient developed a T7–T8 disc space infection with associated vertebral osteomyelitis following a urologic operation with associated postoperative sepsis. He was treated initially with oral antibiotics. (B) One month later, there is an obvious increasing kyphosis secondary to the spine infection. The patient is still being mobilized despite this deformity. (C) This anteroposterior radiograph at the time of transfer to our institution reveals a large paraspinous abscess (*arrowheads*). At this time, the patient had an incomplete paraplegia. (D) This lateral intraoperative radiograph demonstrates gross instability of the thoracic spine with the T7 vertebra 50% retrolisthesed on the T8 vertebra. At this time, the patient still had an incomplete paraplegia. Surgery was undertaken in order to drain the paraspinal abscess. (E) Extent of destruction at the T7–T8 interspace. The retrolisthesis of T7 on T8 is well demonstrated. The paraspinous abscess is also clearly shown. (F) The gross destruction of the anterior vertebral column is well demonstrated in this pathology specimen. (G) This transverse section of the spinal cord has been magnified 11.5 times. Although there are significant changes within the neural tissue, this patient had an incomplete paraplegia at the time of death. (Courtesy Dr. H.H. Bohlman, Cleveland, Ohio.)

had symptoms for 3 weeks to 3 months, and 50% had symptoms for longer than 3 months.[31] Greater awareness of the disease and improved diagnostic modalities (especially magnetic resonance imaging [MRI]) have shortened the delay in diagnosis. In one series reported in 1997, 68 of 111 patients were diagnosed within 28 days of the onset of their symptoms and only 8 patients were diagnosed more than 3 months after their symptoms began.[24] In an urban setting, the infection is discovered within 1 month in only 28% and the median time to diagnosis is 1.8 months.[5] More recently, the mean time from onset of symptoms until diagnosis was 30.2 days in culture-positive cases and 72.2 days in culture-negative cases.[90,91]

Fever is present in only 52% of the patients overall, 85% in culture-positive and 32% of culture-negative patients. Pain in the back or neck is a much more common finding, occurring in approximately 90% of patients.[31,91] Concomitant infections are found in 47% of culture-positive cases and 4% of culture-negative cases.[90] Patients with acute infection commonly present with fever, local spine pain, severe muscle spasm, and limitation of motion of the spine. With lumbar spine involvement, there may be a positive straight-leg raise test, reluctance to bear weight, and hip flexion contracture due to psoas irritation. Hamstring tightness and loss of lumbar lordosis may be noted. Torticollis and fever may be the only presenting signs with cervical osteomyelitis.[86,92]

Subacute and chronic infections may be much more insidious, and these patients have a vague history. Pain may be the only symptom, especially with an occult infection by a low-virulence organism.[73] Approximately 15% of the patients have atypical symptoms such as chest pain, abdominal pain, hip pain, radicular symptoms, or meningeal irritation.[18,31,93] These unusual and often vague complaints have led to unnecessary exploratory laparotomies before the diagnosis has been made.[31,93] A significant delay in diagnosis is common with chronic infections.[18,23,25–27,31,94,95]

Vertebral osteomyelitis is more common in the lumbar region. In Sapico and Montgomerie's[31] literature review, in 48% of 294 cases the involvement was lumbar, in 35% thoracic, in 6.5% cervical, and in approximately 5% thoracolumbar and lumbosacral. Vertebral osteomyelitis at noncontiguous levels is uncommon, occurring in approximately 3% (Fig. 87.3).[91] With the advent of antibiotics, significant spine deformity is not as common as it was in the past, but significant kyphosis still may occur.[26,29] Bacterial infection in the vertebral body can lead to increased intraosseous pressures and impede blood flow to the vertebrae and discs, leading to ischemic necrosis and subsequent deformity. Additionally, production of hyaluronidase by certain bacteria can invade the anulus fibrosus and cause proteolytic breakdown and subsequent biomechanical instability and deformity.[96]

Abscesses are not encountered as frequently now as they were before the antibiotic era but should still be sought in the paraspinous region, psoas region, and in remote areas.[29] A tender or pulsatile abdominal mass may be caused by a mycotic aneurysm, a dilatation of the wall of an artery resulting from an infection.[97] In the lumbar spine, abscesses in the psoas muscle are common and help to distinguish spinal infections from other lesions, such as tumors or trauma (Fig. 87.4).

Approximately 17% of the patients present with a neurologic deficit secondary to nerve root or spinal cord involvement.[31] Eismont and colleagues identified several factors that predisposed patients to paralysis, including diabetes,[18,29,54,98] rheumatoid arthritis,[98] increased age,[98,99] and a more cephalad

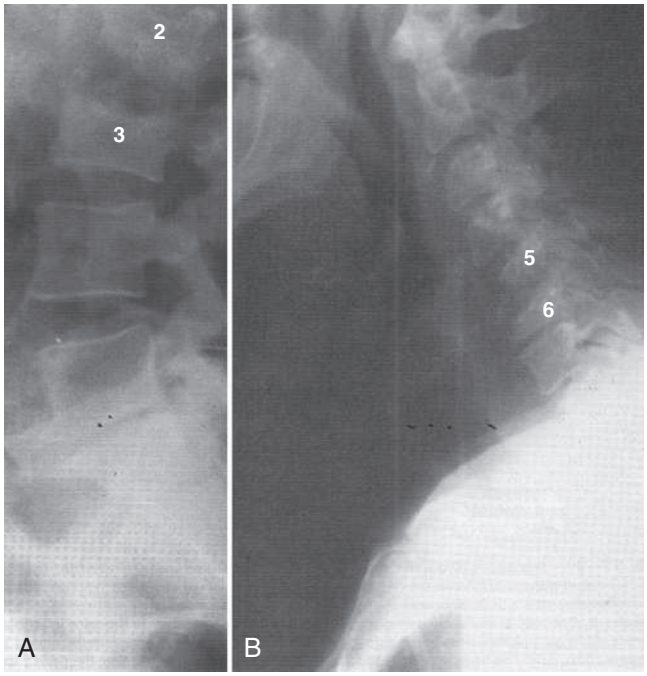

FIG. 87.3 Although uncommon, some patients present with vertebral osteomyelitis at noncontiguous levels. This diabetic patient had an infection of the cervical spine as well as the lumbar spine secondary to *Staphylococcus aureus*. (A) The patient has an obvious disc space infection at L2–L3, with an associated vertebral osteomyelitis. (B) This lateral radiograph of the cervical spine demonstrates a disc space infection at C5–C6 with destruction of the adjacent bone. The patient had a quadriparesis as a result of this infection.

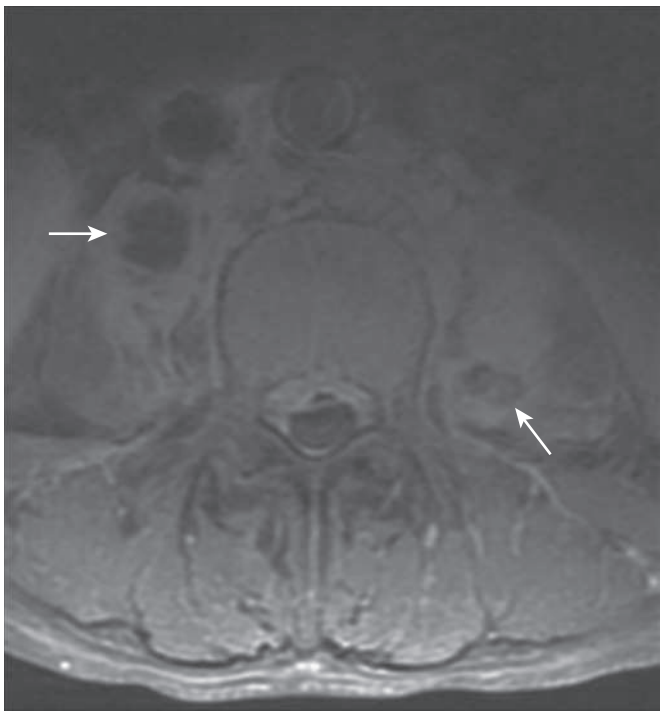

FIG. 87.4 T1-weighted contrast-enhanced magnetic resonance axial image through lumbar spine. Increased signal intensity can be seen diffusely in the psoas muscle bilaterally with low signal intensity abscess pockets (*arrows*).

level of infection.[41,98] Patients on systemic steroid therapy are more likely to be paralyzed, and those infected with *S. aureus* seem to have the most severe degree of paralysis.[98] Some authors have noted that neurologic involvement is uncommon in patients infected with *Pseudomonas*.[63,65]

Infants and IV drug abusers are two subsets of patients who have slightly different presentations. Infants generally present acutely with high temperature, septicemia, and generalized signs of systemic illness.[99,100] The radiographic findings of vertebral osteomyelitis in infants is striking, with almost complete dissolution of the involved vertebral bodies and nearly normal adjacent endplates. The late radiographic appearance may be identical to that of congenital kyphosis (Fig. 87.5). Heroin abusers also present earlier than most patients. In a review of the literature, 81% of heroin abusers presented within 3 months after the onset of their symptoms, compared with 50% in the general population with vertebral osteomyelitis.[31,42,99,100] The authors postulated that the earlier presentation may be related to infection with more virulent organisms or the fact that their patients have less tolerance to pain or may be using their back pain as an excuse to receive more narcotics (Fig. 87.6).[42]

Diagnostic Evaluation

Laboratory Evaluation

The erythrocyte sedimentation rate (ESR) and Gram stain and culture are commonly used laboratory tests in the diagnosis of pyogenic spine infections.[25,31,35,82] The leukocyte count is increased on presentation in only 42% of cases and is usually normal in patients with chronic disease.[31,35,82] Conversely, the sedimentation rate was increased in 92% of 184 patients reported in the literature.[31] It is a nonspecific test, however, and the rate may be increased in pregnancy, malignancy, other infections, dysproteinemias, and connective tissue diseases. In addition, it is influenced by serum levels of fibrinogen and globulin.[31] The sedimentation rate may be normal in occult infections with low-virulence organisms.[73]

CRP has been shown to be helpful in the diagnosis of postoperative discitis[101] and has supplanted ESR as the laboratory study of choice for assessing the presence of infection. CRP was discovered in 1930 by Tillett and Francis in their studies of pneumonia. This acute-phase protein is a 187 amino peptide that can precipitate the C-fraction polysaccharide from *Streptococcus pneumoniae*.[102] With the onset of an infection or other inflammatory process, the CRP level increases within 4 to 6 hours, doubling every 8 hours and peaking at about 36 to 50 hours.[102] The half-life of CRP is 24 to 48 hours. The degree of increase can be up to 10,000-fold higher than normal, while ESR increases only 10- to 100-fold.[103] The ESR begins to increase only several days after onset of infection and peaks at 7 to 8 days.[102] An additional limitation of the ESR is the long period of recovery. The ESR has been useful in follow-up to assess the response to treatment.[17,25,26,28,31,104,105] In one small series, the sedimentation rate decreased to at least two-thirds of the original value at the completion of successful antibiotic therapy in all patients and decreased to half of the

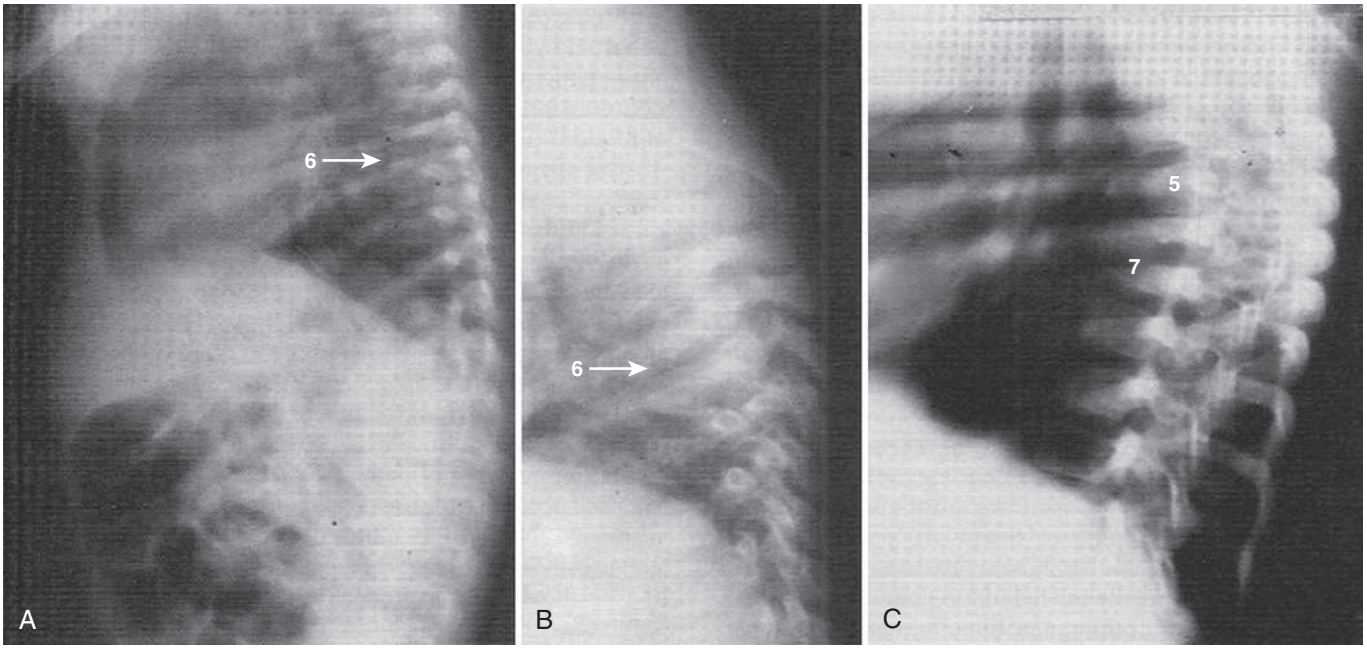

FIG. 87.5 This infant developed a vertebral osteomyelitis and life-threatening sepsis. Unlike the relatively benign disc space infection of childhood, this infection of infancy follows a much more destructive course. (A) At the time that the infant became septic, the T6 vertebral body could be clearly visualized (*arrow*). (B) Two months later, despite aggressive antibiotic treatment, there is gross destruction of the T6 vertebral body (*arrow*). (C) This lateral radiograph taken 2.5 years after the spine infection reveals that the patient has a kyphotic deformity from T5 to T7. This deformity behaves much like an anterior failure of formation of the T6 vertebral body. (From Eismont FJ, Bohlman HH, Soni PL, et al. Vertebral osteomyelitis in infants. *J Bone Joint Surg Br.* 1982;64[1]:32–35.)

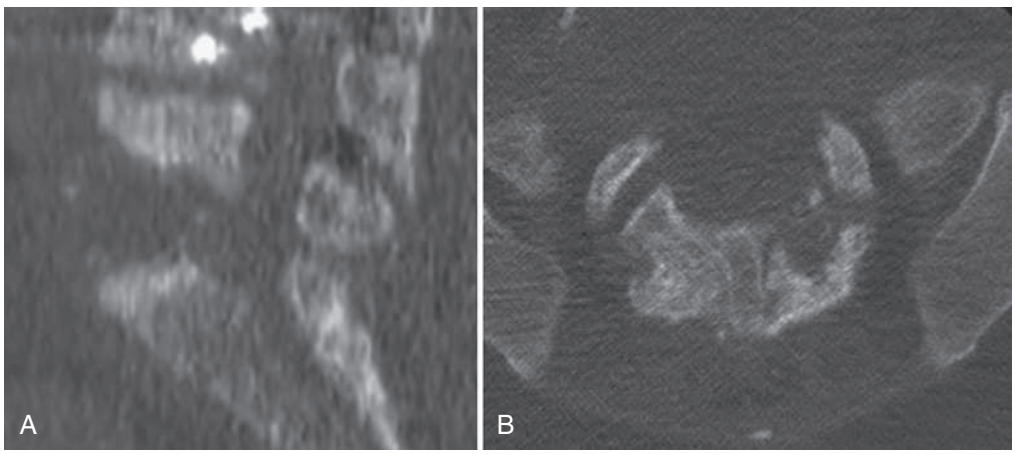

FIG. 87.6 Computed tomography scan with (A) sagittal and (B) axial images of the lumbar spine of an active intravenous drug abuser. Severe destruction of L5 can be seen. The patient presented with severe back pain, bilateral dorsiflexor weakness, and fever. The L5 vertebral body and the inferior portion of L4 have been destroyed by infection. Cultures revealed *Staphylococcus aureus*.

original value in the majority.[31] In another series of 30 cases, the sedimentation rate returned to normal after resolution of the infection.[25] However, the ESR remains elevated for more than 3 weeks after infection.[106] The CRP, in contrast, decreases more rapidly and returns to normal levels in 10 days. In cardiac patients, elevated preoperative CRP increases the risk of postoperative infectious complications.[107] Similar to the ESR, the CRP unfortunately suffers from low specificity because any infectious or inflammatory process will elevate these values.[108] After routine spinal surgery, the CRP returns to normal in 5 to 14 days, whereas the ESR takes 21 to 42 days to return to normal.[109] Thus, an abnormal increase in CRP 1 to 2 weeks after spinal surgery may represent onset of postoperative infection. In all cases, a blood culture should be obtained because it remains a convenient, readily accessible means of identifying an organism. Blood cultures may only be positive in about 30% of cases.[91] In most cases, the identification of the offending organism correlates well with biopsy results.

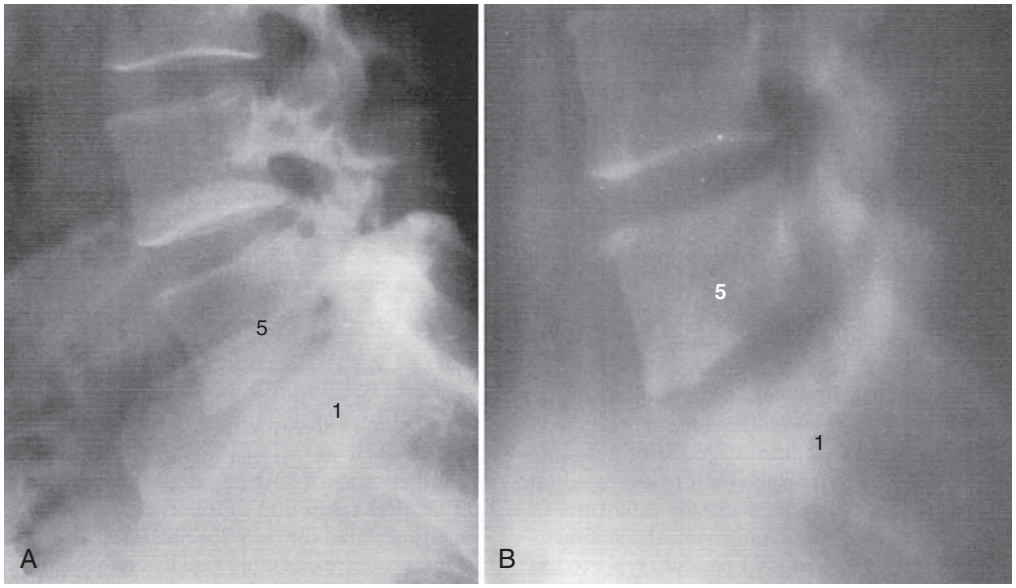

FIG. 87.7 This patient presented with an idiopathic disc space infection at L5–S1 with an associated vertebral osteomyelitis. His main complaint was low back pain. (A) This lateral radiograph demonstrates marked narrowing of the disc space at L5–S1; however, nothing is seen on this radiograph that would clearly demonstrate this to be a spine infection. (B) This lateral tomogram better demonstrates the destruction of the endplates at L5–S1 and the rarefaction of the adjacent bone. The only diagnosis consistent with these findings is a disc space infection with associated vertebral osteomyelitis.

In a study of 29 cases of pyogenic spondylitis, O'Daly and colleagues[110] found a 100% correlation between blood cultures and vertebral cultures when both were positive. In patients who are medically stable, antibiotics should be helpful until a biopsy can be obtained since the yield decreases from 80% to 48% in patients receiving antibiotic treatment.[111]

Imaging Studies

The findings on plain radiographs are characteristic but do not appear for at least 2 to 4 weeks.[25,30,32,35,61,81] The earliest and most constant radiographic finding, narrowing of the disc space, is present in 74% of patients at presentation.[31] Other findings include endplate destruction, osteolysis, and vertebral collapse. Plain radiographs also provide valuable information regarding alignment and mechanical stability.[112] Tomograms show abnormalities earlier than plain radiographs (Fig. 87.7) and may show local osteopenia of the endplates at 10 to 14 days, but tomography has largely been supplanted by computed tomography (CT).[35] Widening of the retropharyngeal space in the cervical spine, enlargement of the paravertebral shadow in the thoracic spine, or changes in the psoas shadow in the lumbar spine may indicate either abscess or granulation tissue surrounding the infection. After 3 to 6 weeks, destructive changes in the body can be noted, usually beginning as a lytic area in the anterior aspect of the body adjacent to the disc and diffusely in the endplate.

Reactive bone formation and sclerosis are present in 11% of patients on presentation; most patients will have sclerosis when the disease heals.[31] Depending on the virulence of the organism and the response to treatment, progressive bony destruction, collapse, and kyphosis may develop. The radiographic findings generally lag behind the clinical response by 1 to 2 months. With healing, new bone formation and hypertrophic changes at the vertebral margins eventually may produce spontaneous fusion. Fusion occurs in just over 50% of the cases[31,113] but may take up to 5 years.[114] If a solid fusion does not occur, a fibrous ankylosis may be achieved.[26,113]

Although the radiographic findings are characteristic, they are not specific; a definite diagnosis is possible only by biopsy.[113] An unusual radiographic finding that may help with the diagnosis is gas in the disc space; this may represent infection with a gas-forming organism (Fig. 87.8).[70] However, the most common cause of gas in the disc space in adults is due to degenerative disease.

An atypical presentation of vertebral osteomyelitis was reported by McHenry and colleagues.[89] They described a series of six patients with osteomyelitis in an osteoporotic vertebral compression fracture. The vertebral endplates were intact on the initial plain radiographs.[89] This presentation occurred in 13% of all hospitalized patients with vertebral osteomyelitis and 2.4% of inpatients with osteoporotic compression fractures at one institution over a 5-year period.[115] Chest radiographs may reveal atelectasis, pleural effusion, and soft tissue masses that may be confused with a tumor.[94]

Radionuclide studies are useful for early detection and localization of infection before plain films become positive.[26,28,32,95,105,116-118] Clinical studies have suggested that gallium scans become positive before technetium scans do,[116] which has been confirmed in experimental studies.[119] Technetium scans show increased uptake diffusely in the region of the infection, whereas gallium scans may show increased uptake in a butterfly area around the infected spine.[120] Gallium scanning has been found to have a sensitivity of 89%, a specificity

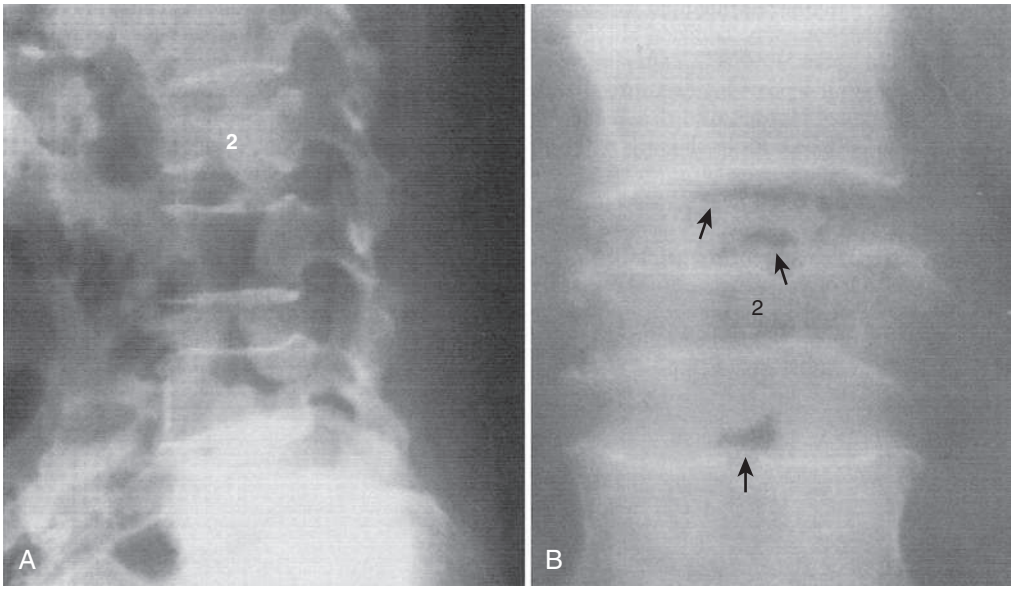

FIG. 87.8 This patient presented with a significant paraparesis and associated sepsis. (A) This lateral radiograph demonstrates marked diminution in the height of the L2 vertebral body. It is surprising that the disc heights at L1–L2 and L2–L3 appear to be relatively normal. (B) Tomograms of the lumbar spine reveal gas shadows (*arrows*) within the disc spaces at L1–L2 and L2–L3. At the time of surgical debridement, *Escherichia coli* was cultured.

of 85%, and an accuracy of 86% in the diagnosis of disc space infections.[116] In a separate study,[117] technetium scans were found to have a sensitivity of 90%, a specificity of 78%, and an accuracy of 86%. The accuracy of combined technetium and gallium scans was 94%.[117] These two scans combined are currently our preferred nuclear medicine studies.

In experimental disc space infection, bone scans were positive in 23% at 3 to 5 days, in 29% at 6 to 8 days, and in 71% at 13 to 15 days.[121] The probability of technetium bone scans becoming abnormal increases with the duration of symptoms, to almost 100%, but false-negative scans have been reported in young children and in the elderly. This has been postulated to be the result of regional ischemia.[73]

The major mechanism of gallium localization is thought to be neutrophil labeling followed by migration to the inflammatory focus. False-negative gallium scans have been reported in leukopenic patients.[118] Both technetium and gallium scans may be negative with occult infection by low-virulence organisms.[73] Two cases have been reported in which the technetium scan was negative but the gallium scan was positive; the authors postulated that this represented pyogenic discitis without vertebral osteomyelitis.[122] Technetium scans remain positive for a long time after resolution of the disease, whereas gallium scans become normal during healing and, therefore, may be useful in following the response to treatment.[123]

Indium-111-labeled leukocyte imaging has been found to be helpful in the evaluation of sepsis in the appendicular skeleton.[124] Unfortunately, it is not sensitive in the spine.[125–127] This may be related to the fact that most cases of vertebral osteomyelitis are chronic by the time the patients are studied, and the inflammatory response may have fewer leukocytes. The overall sensitivity of indium scanning for infections of the spine is 17%, the specificity is 100%, and the accuracy is only 31%.[126] A correlation was found between prior antibiotic therapy and false-negative indium scans and photon-deficient indium uptake.[126] Photon-deficient lesions may be detected by indium-111-labeled leukocyte imaging in many other conditions, including previous surgery, radiation therapy, or metastatic disease.[128] Palestro and colleagues[129] reported that the specificity was 52% and the sensitivity was 54% when decreased activity was the criteria for osteomyelitis with indium-111 scanning. Single-photon emission computed tomography (SPECT) is a sensitive bone scintigraphic modality for early detection of spondylitis. It is more sensitive than planar scintigraphy and has the advantage of increased contrast resolution and the capability of three-dimensional localization.[130] Scintigraphy with technetium and gallium are now often performed with SPECT. Love and colleagues[131] compared three-phase bone technetium SPECT with gallium SPECT and MRI in 11 patients with spinal infections. Gallium SPECT and MRI were comparable in accuracy and superior to technetium SPECT. Thus, gallium SPECT may be useful in patients in whom MRI is contraindicated or in cases in which the diagnosis is uncertain. A positive technetium SPECT in the setting of a negative gallium scan points toward noninfectious causes of back pain such as degenerative disease or pseudarthrosis.[132]

CT may show cystic changes in the bone as well as soft tissue masses, gas in the soft tissues or within the bone and disc, and, later, lytic destruction of the body.[133–135] The prevertebral soft tissue involvement seen on CT usually completely surrounds the spine anteriorly, and the destruction of the vertebra is generally an osteolytic process around the disc space (see Fig. 87.6). This is in contrast to neoplasms, which are characterized by no or only partial paravertebral soft tissue

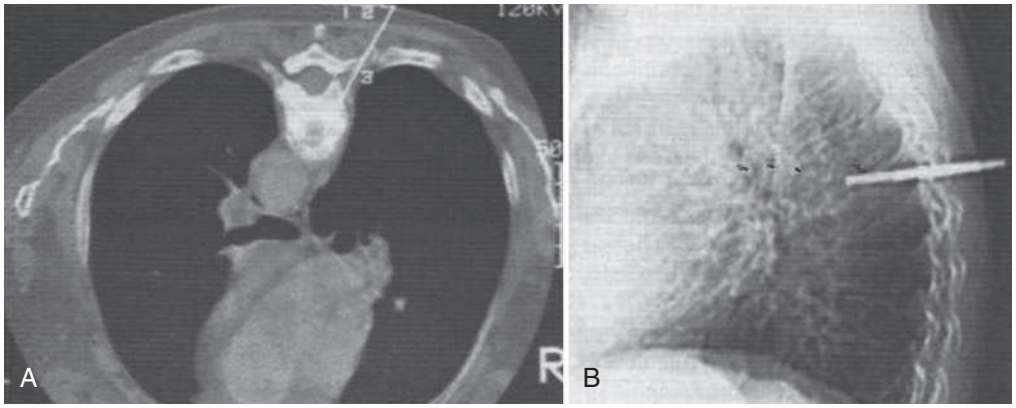

FIG. 87.9 Craig needle biopsy in the thoracic spine. (A) The course of the needle is determined by the measurements obtained on the scout computed tomography (CT) scan. The distance from midline and the angle from the vertical position can be accurately determined. (B) The lateral scout film from the CT scan should be used to determine the exact level to be sampled.

swelling and by changes that may be osteoblastic and more likely to involve the posterior elements than in infection.[136]

CT is valuable in differentiating pyogenic spondylitis from a tuberculous or fungal infection; in the latter, the soft tissue components tend to be more prominent.[137] The finding of disc hypodensity on CT is relatively specific for infection in the lumbar spine but is less useful in the thoracic and cervical region.[135] A relatively unique feature of tuberculous infection is vertebral fragmentation and paraspinal calcifications.[138,139] The destruction tends to extend into the pedicle, which is uncommon in pyogenic infections. CT with contrast medium is helpful to delineate the boundary between abscesses and swollen paravertebral muscles.[133–135] CT after intrathecal administration of a water-soluble, nonionic contrast agent provides exquisite detail of the spinal canal.[137] CT-guided biopsies of the spine have been shown to be safe and can be done at all levels of the spine (Fig. 87.9).[133,140–142] Myelography and postmyelography CT are indicated in cases of neurologic deficit and radicular pain to rule out epidural and subdural abscesses and are always used when an MRI scan is contraindicated. Cerebrospinal fluid (CSF) should also be examined to rule out meningitis whenever the myelogram is done with suspicion of a spine infection.[88]

The imaging modality of choice for the evaluation of spine infections is MRI. MRI permits early diagnosis of infection and recognition of paravertebral or intraspinal abscesses without the risk associated with myelography.[143,144] In a prospective study of 37 patients suspected clinically of having vertebral osteomyelitis, MRI was found to be at least as accurate and as sensitive as gallium and bone scanning combined: MRI had a sensitivity of 96%, a specificity of 93%, and an accuracy of 94%.[117] MRI has the advantage of providing more anatomic information than radionuclide studies and is capable of differentiating degenerative and neoplastic disease from vertebral osteomyelitis.[145] The changes on MRI occur at about the same time as the changes on gallium scans.[117]

Disadvantages of MRI are that it is more sensitive to motion degradation, and there are problems with patient positioning and claustrophobia. MRI has a limited field of view, whereas radionuclide scans can image the entire skeleton. MRI may be falsely negative in cases of epidural abscess without involvement of the adjacent bone because the signal intensity of the inflammatory exudate is similar to that of CSF.[117,146]

The MRI changes in vertebral osteomyelitis are characteristic (Fig. 87.10). On T1-weighted sequences, there is a confluent decreased signal intensity of the vertebral bodies and adjacent disc, making the margin between the two structures indistinct. On T2-weighted sequences, the signal intensity of the vertebral bodies and the involved disc is higher than normal, and there is generally an absence of the intranuclear cleft normally seen within the adult disc.[117,143] The extent of the infection is best seen, however, using gadolinium contrast enhancement. The disc and the involved portions of the vertebral bodies reveal a marked increased signal intensity that delineates the margins of the infection (see Fig. 87.10C).[147] The typical T1 changes in the vertebral body and endplates and the T2 changes in the disc space were seen in 95% of the 37 cases of vertebral osteomyelitis described by Dagirmanjian and colleagues.[148] Only 56% of their cases had typical T2 vertebral body changes. Isointense or decreased signal in the vertebral body on T2-weighted images is consistent with infection if the other typical findings are present. In a more recent study by Ledermann and colleagues,[149] 46 patients with culture or histologic-positive spinal infections were systematically evaluated with gadolinium-enhanced MRI. The most sensitive MRI criterion was the presence of paraspinal or epidural inflammation (97.7% sensitivity), followed by disc enhancement (95.4% sensitivity). Hyperintensity or fluid-equivalent disc signal intensity on T2-weighted MRI was 93.2% sensitive, erosion or destruction of at least one vertebral endplate was 84.1% sensitive, and effacement of the nuclear cleft was 83.3% sensitive. When the infection is confined to a single vertebral body, spread of infection occurs in a subligamentous path.[150] Interestingly, the spread of infection tends to be more commonly in a cephalad direction, affecting the superior disc space more commonly than the inferior disc space. The cause of the signal intensity changes seen in vertebral osteomyelitis is uncertain but is thought to parallel the pathogenesis of the disease. The earliest changes are thought to be related to ischemia and the increased water content of the inflammatory

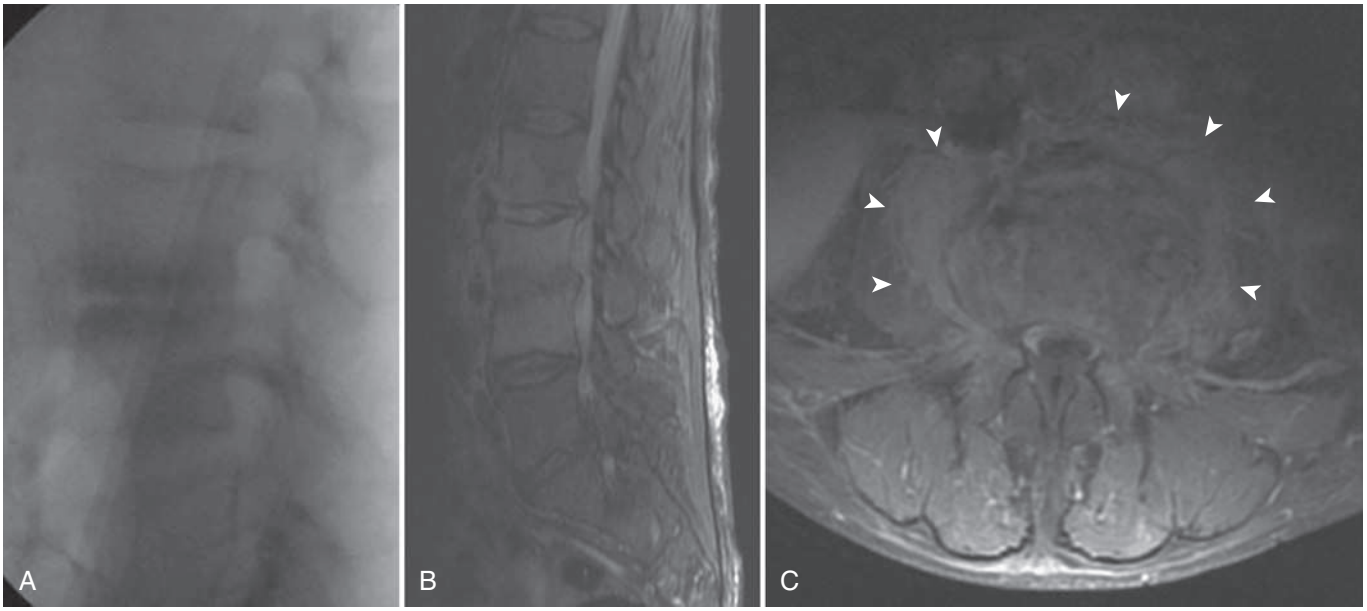

FIG. 87.10 (A) Preoperative imaging studies show L3–L4 disc height loss and irregular endplate sclerosis on lateral radiographs. (B) Contrast-enhanced magnetic resonance image shows involvement of the L2–L3 disc space along with increased signal of the L3 and L4 vertebral bodies. (C) Axial image shows enhancement of the anterior soft tissues (*arrowheads*).

process. As the infection crosses the endplate, a confluent signal intensity occurs on MRI. The normal finding of an intranuclear cleft within adult discs is thought to be related to fibrous tissue within the nucleus pulposus. This cleft is lost at the time of inflammatory involvement of the disc.[117]

In an elegant study comparing MRI findings of pyogenic vertebral osteomyelitis with tuberculous osteomyelitis, Chang and colleagues[151] identified five key distinguishing features that help to differentiate between the two disease entities. A retrospective study of 33 patients with confirmed tuberculous spondylitis were compared with 33 randomly selected patients with known pyogenic osteomyelitis. The key distinguishing features were (1) degree of bone destruction; (2) degree of disc preservation; (3) paraspinal abscess appearance; (4) abscess with postcontrast rim enhancement; and (5) postcontrast enhancement pattern of the vertebral body. As expected, the degree of vertebral body and disc destruction were the two most distinguishing differences found. Most patients in the tuberculous (TB) group (82%) had near-complete destruction of at least one vertebral body, whereas less than one-third (30%) in the pyogenic group had severe vertebral body destruction. Conversely, the disc was preserved in more than one-half (57%) of the TB group, whereas only 3% of the pyogenic group had a preserved disc space. Thus, the credo that TB spondylitis "skips the disc space" is relatively well supported. However, a more accurate distinguishing feature would be better stated that pyogenic vertebral osteomyelitis differs from TB spondylitis by severe disc space destruction with relative preservation of the vertebral body.

Chang and colleagues went on to further show that there were marked differences in the imaging pattern of the vertebral body itself.[151] In the TB group, the enhancement pattern of the vertebral body was always focal and heterogeneous, with rim-enhancing abscesses. In contrast, the enhancement pattern of the vertebral body in the pyogenic group was nearly always (94%) diffuse and homogeneous. A discrete rim enhancement intraosseous abscess was never observed in the pyogenic group. The paraspinal soft tissue imaging patterns provide further distinguishing features. In the TB group, the paraspinal soft tissues revealed well-defined rim-enhancing lesions. In contrast, the pyogenic infections tended to show more diffuse, ill-defined areas of enhancement.

In a comparison of MRI, bone scans, and plain radiographic evaluations in an animal model of disc space infection, MRI was found to have a sensitivity of 93%, a specificity of 97%, and an accuracy of 95%, corresponding well to results of clinical studies in humans.[117,121] The findings are time related. In one study, scans of rabbits made 3 to 5 days after injection of bacteria all showed a decreased signal from the nucleus pulposus on both T1-weighted and short T1-inversion recovery (STIR) sequences. Scans at 6 to 8 days also showed increased signal from the adjacent endplates on the STIR sequence and blurring of the disc margins on the T1 image. Scans at 13 to 18 days showed more florid endplate changes, and in several scans at 21 days there was increased signal from the vertebral endplates and the disc on STIR sequences.[121] The MRI findings slowly return to normal after successful treatment of vertebral osteomyelitis.[117] Gallium scans revert to normal much more rapidly and are better indications of appropriate therapy. Post and colleagues[147] noted that abnormal gadolinium enhancement of the disc, vertebral bodies, and paraspinal soft tissues progressively decreases with successful treatment of the infection. Gillams and colleagues[152,153] described some patients who were improving clinically and had stable or increasing enhancement patterns and concluded that such findings should not be interpreted as treatment failure.

Unfortunately, even MRI may be negative in surgically documented occult infections by low-virulence organisms.[73] Despite the accuracy of MRI, an absolute diagnosis must be based on bacteriologic or microscopic examination of the tissue.[29,154,155] The only situation in which the diagnosis can be made without a tissue biopsy is when a positive blood culture is obtained from a patient with signs and symptoms of spondylitis. Blood cultures are positive in 24% to 59% of patients with pyogenic spine infections.[24,28] Urine cultures are less reliable because patients with vertebral osteomyelitis may have a coexistent urinary tract infection with a different organism.[24,26]

Finally, a transesophageal echocardiogram should be considered to rule out bacterial endocarditis.[156]

Biopsy

Needle biopsy of the spine was first reported by Ball in 1934. In 1956, Craig described a set of instruments designed to increase the percentage of successful closed-needle biopsies, especially in sclerotic or softened bone, discs, or fibrous tissue.[157] Needle biopsies have been shown to be safe in the cervical and thoracic spine as well as in the lumbar spine.[158,159] A definite diagnosis is possible by closed-needle biopsy in 68% to 86% of cases.[31,35,142,159,160] CT-guided closed biopsy of the spine should provide a margin of safety and allow biopsy of the area most likely to yield the diagnosis. In a series of 22 patients with a mass or destructive lesion who underwent this procedure, 17 biopsies provided a definite diagnosis; only one was false negative and in four cases the specimens were insufficient. All areas of the spine were sampled, including one lesion at C2. The patient with the C2 lesion had a transient increase in quadriparesis but returned to baseline, and no other complications were reported.[140]

Closed biopsies of the spine are often false negative in patients who are being treated with antibiotics at the time of the biopsy. If a biopsy is nondiagnostic, it would be reasonable to observe the patient off the antibiotic regimen and repeat the biopsy if the clinical situation allows such a delay. If the second closed biopsy is also nondiagnostic, an open biopsy should be considered. This will provide larger tissue samples and selection of grossly pathologic tissue and should have a lower false-negative rate. In their review of the literature, Sapico and Montgomerie[31] found that 30% of needle biopsy specimens and aspirates were sterile, compared with only 14% of surgical specimens. The technique of transpedicular biopsy allows for larger bony samples to be obtained. The transpedicular approach is safely performed with either fluoroscopy or CT. For general biopsies, including tumor, the accuracy rate is over 92%.[161–163] In the setting of infection, this technique yields better results than traditional needle biopsy. Hadjipavlou and colleagues[164] examined 28 patients with suspected spinal infections diagnosed by a combination of laboratory test, MRI, and scintigraphy. Positive cultures were obtained in 71% of the biopsies.[164]

The differential diagnosis of pyogenic vertebral osteomyelitis includes tuberculosis, fungal infections, metastatic carcinoma, multiple myeloma, localized Scheuermann disease, trauma, degenerative disease, epidural abscess, and fractures associated with osteoporosis.[17,31,89,165] Less common disorders in the differential diagnosis are leukemia, perinephric abscess, neuropathic spinal arthropathy, and sarcoidosis, as well as erosive arthritides in rare cases of facet joint involvement.[30,82,100,166–168] With such a wide variety of diseases that can present with signs and symptoms similar to those of vertebral osteomyelitis, diagnostic acuity is important. As Kulowski said in 1936, "Knowledge of the disease is the primary factor in the diagnosis."[29]

Management

Before the advent of antibiotic therapy, treatment of pyogenic vertebral osteomyelitis involved drainage of abscesses, rest on a frame or plaster bed, and attention to nutrition and general hygiene. The mortality rate with this approach was between 25% and 70%.[29,57] The use of antibiotics has drastically changed the prognosis with this disease, but attention to good general medical care is still a vital part of the treatment. Associated conditions that compromise wound healing or immune response should be managed aggressively. Attention to proper nutrition and the reversal of metabolic deficits and hypoxia are essential. Diabetes and other systemic illnesses should be brought under control.[98] Any underlying focus of infection in the urinary tract, lungs, skin, or elsewhere must be treated concurrently with the spine infection.[169]

The goals of treatment are to establish tissue and bacteriologic diagnoses, prevent or reverse neurologic deficits, relieve pain, establish spinal stability, correct symptomatic spinal deformity, eradicate the infection, and prevent relapses. Biopsy, by either a closed or an open method, is mandatory in any case of spine infection before the institution of antibiotic therapy. The only exceptions to this rule are straightforward cases of pediatric discitis and cases with positive blood cultures in association with strong clinical evidence of spine infection.

Changes in patterns of pathogenic organisms and antimicrobial agents necessitate an accurate bacteriologic diagnosis. If possible, treatment should be withheld until an organism is identified in case a second biopsy is necessary. However, patients who are systemically toxic should be treated with maximal doses of broad-spectrum antibiotics as soon as the biopsy has been completed. Most patients with vertebral osteomyelitis are not septic and will not be harmed by a delay in treatment for several days. Conversely, if the biopsy is nondiagnostic and antibiotic therapy has been started, a second biopsy may not yield the organism. Patients with clinical evidence of vertebral osteomyelitis but negative cultures from open biopsy should be treated with a full course of broad-spectrum antibiotics. When possible, the choice of antibiotics should be based on the culture and sensitivity test results so that more specific and less toxic agents can be used.

Daly and colleagues[170,171] have demonstrated that antibiotic penetration of osteomyelitic bone parallels serum concentrations for all classes of antibiotics. The penetration of antibiotics into inflammatory exudates and the intervertebral disc is less certain.[172–177] Vancomycin, gentamicin, tobramycin, clindamycin, and teicoplanin all penetrate the nucleus pulposus

reasonably well.[172,178] The data regarding cephalosporins are inconclusive, but if penetration does occur, it appears to be at a relatively low level.[173,176,177] The penetration of cephalosporins into inflammatory exudates appears to be inversely proportional to the degree of serum protein binding.[174] Riley and colleagues[179] have shown that the penetration and distribution of antibiotics into the nucleus pulposus is significantly influenced by the charge of the antibiotic, with positively charged molecules penetrating the best.

The route of administration of the antibiotics and the duration of therapy are somewhat empiric because little research has been done to clarify these topics. At present, it is recommended that parenteral antibiotic therapy be used in maximal dosage for 6 weeks and followed with an oral course of antibiotics until resolution of the disease. It may be reasonable to switch from parenteral to oral therapy at 4 weeks.[26] Parenteral therapy for less than 4 weeks results in a higher rate of failure.[31] Oral ciprofloxacin therapy has been used successfully in the management of patients with chronic osteomyelitis of the tibia or femur.[180] It is possible that ciprofloxacin and other new agents for oral use may supplant parenteral treatment of vertebral osteomyelitis in the future, but general use of these agents should await evidence of their effectiveness.

The ESR has been found to be a reasonable guide to the response to therapy[17,25,26,28,31,104,105] and can be expected to decrease to one-half to two-thirds of pretherapy levels by the completion of successful treatment.[31] If the sedimentation rate does not decrease with treatment, consideration should be given to a repeat biopsy. CRP is a more useful laboratory test to follow resolution of the infection, as described earlier. However, it is still unclear at what point to discontinue antibiotics on the basis of CRP levels. Further studies are necessary to correlate CRP levels with the duration of antibiotic treatment. Currently, at least 6 weeks of parenteral antibiotics is used empirically. Antibiotic administration must be carefully monitored to avoid toxicity, especially in diabetics and others who might have impaired renal function.[54] Risk factors for failure of conservative treatment include ESR greater than 55 mm/h and CRP greater than 2.75 μg/mL after 4 weeks of IV antibiotic therapy.[181,182]

Patients should be immobilized for pain control and prevention of deformity or neurologic deterioration. The length of time that a patient should rest, the type of orthosis, and the duration of its use all depend on the location of the infection in the spine, the degree of bone destruction and deformity, and the response to treatment. In rare cases, thoracic and thoracolumbar lesions may require bed rest on a RotoRest or similar device if there is undue pain. Rigid bracing with a thoracolumbosacral orthosis (TLSO) suffices in most cases to allow mobilization of the patient. Thoracic and thoracolumbar lesions are more likely to cause deformity and, if neurologic deficits occur, the prognosis is worse with these lesions than with lumbar spine involvement.[26,98]

Cervical and cervicothoracic lesions may be immobilized with a halo device if there is significant instability or deformity. In most cases, external bracing is sufficient and is always better tolerated by the patient. Upper thoracic lesions are best immobilized in a TLSO device with a chin piece; lower thoracic and lumbar lesions should be immobilized in a TLSO device without a chin piece. Frederickson and colleagues[26] found that immobilization was most important in those patients with destruction of greater than 50% of a vertebra and recommended immobilization for the first 3 months. In 5 of their 17 cases, significant deformity developed in the first 6 to 8 weeks, all at the thoracolumbar junction or above. Those patients with the greatest deformity had 50% or more vertebral body destruction at presentation.[116] Most authors recommend bracing for at least 3 to 4 months. Garcia and Grantham[35] recommended that the duration of immobilization should be individualized and based on the response to treatment.

Surgical Treatment

Surgery is indicated in the following circumstances: (1) to obtain a bacteriologic diagnosis when closed biopsy is negative or deemed unsafe; (2) when a clinically significant abscess is present (spiking temperatures and septic course); (3) in cases refractory to prolonged nonoperative treatment, in which the ESR and/or CRP remain high or pain persists; (4) in cases with spinal cord compression causing a neurologic deficit; and (5) in cases with significant deformity or with significant vertebral body destruction, especially in the cervical spine.[98,183,184] Upper cervical osteomyelitis is rare but generally requires fusion because of the associated instability.[86]

In cases of lumbar lesions with root deficits, the final outcome is satisfactory with or without surgical treatment, but patients with spinal cord compression have a better prognosis with surgery.[98] Surgery should be carried out as soon as possible in these cases, but when doubt exists regarding the chances of a reversible spinal cord lesion, decompression should be carried out because recovery has been noted in patients with paralysis who underwent decompression as late as 5 months after the onset of weakness.[98]

In most cases, the spine should be approached anteriorly because this allows direct access to the infected tissues and adequate debridement. Anterior exposure allows stabilization of the spine by bone grafting, which promotes rapid healing without collapse and assists rehabilitation (Fig. 87.11).[98,185–189] Laminectomy without anterior debridement and reconstruction is contraindicated in most cases because it may lead to neurologic deterioration and increased instability.[98,186,190] The situation is similar to that in acute trauma.[191] Laminectomy may be performed in the lumbar spine below the level of the conus provided that there is no psoas abscess or extensive anterior destruction of the bodies that would require debridement.

Anterior approaches to the spine have been described elsewhere[187,192] and are reviewed in Chapters 17, 18, and 19. For lesions in the thoracic or thoracolumbar spine, the transthoracic approach has the advantage of better exposure, allowing more extensive debridement and better decompression of the cord and more effective bone grafting.[185,189,193,194] The disadvantage is the potential increased morbidity after a thoracotomy in the presence of a purulent infection. After debridement of the infected focus, anterior strut grafting can be performed during the same procedure. The graft should extend from healthy bone above to healthy bone below.[185,189,193,194] Autogenous bone

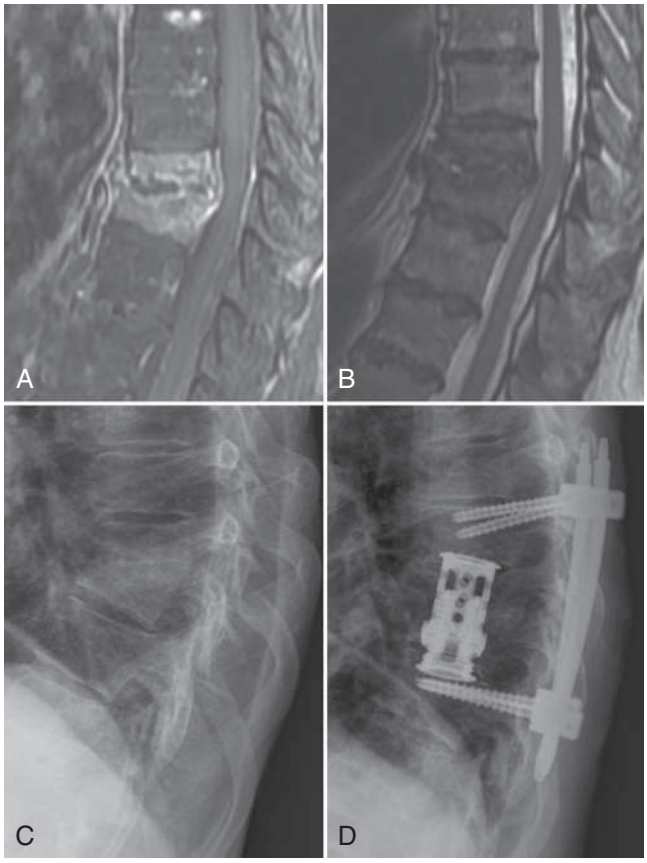

FIG. 87.11 T8–T9 discitis with osteomyelitis. Magnetic resonance imaging showing enhancement with (A) gadolinium and (B) corresponding T2-weighted image showing bony destruction. (C) Preoperative lateral radiograph shows focal kyphosis, which is treated with anterior mini-open direct lateral thoracotomy with T8 and T9 corpectomies and strut fusion with a titanium expandable cage (D). Posterior stabilization was achieved by percutaneous pedicle screw fixation at the same stage.

grafting after vertebral body resection in the presence of active infection was first reported by Wiltberger in 1952 and has since been demonstrated to be safe and effective regardless of the causative organism.[32,195] Grafting with iliac crest is generally better than grafting with rib.[185,188,196] If a good-quality rib is excised in the process of a transthoracic approach, however, it is often adequate as long as a large segment does not need to be spanned and there is no significant kyphotic deformity.[196] Revascularization of a cortical graft may not be complete even after 1 year.[197] Vascularized rib grafts have been used with good success for the stabilization of kyphosis.[198] Louw has reported successful fusions in 95% of cases at 6 months and 100% at 1 year when vascularized rib grafts were used for TB kyphosis.[199] Fibular grafts have been shown to be effective for reconstruction of multiple-level anterior decompressions of the cervical spine[200]; however, the large amount of cortical bone in fibular grafts makes them less ideal in the presence of infection. In cases with significant kyphotic deformity, anterior reconstruction with autogenous bone grafts after debridement should be carried out as a first stage.[185,189,196] Posterior stabilization and fusion can be performed in a second-stage procedure if necessary (see Fig. 87.11D).[185,186,196,197,201] Posterior instrumentation has been shown to be safe and effective after anterior debridement and fusion.[24,202] The use of titanium mesh cages may provide better anterior column support because their structural integrity is not affected by degradative enzymes present in an infected environment.[203] The addition of posterior instrumentation provides even better deformity correction and faster rates of fusion.[203] The addition of posterior instrumentation does not appear to increase the risk of infection.[181,204] The anterior and posterior surgeries can be performed on the same day with good results. Safran and colleagues[205] reported on 10 consecutive patients with lumbar osteomyelitis treated with same-day anterior decompression and strut fusion with posterior instrumented fusion. All 10 patients achieved solid fusion with eradication of infection. Single-stage anterior and posterior surgery has been shown to be safe and effective using titanium implants. Interestingly, bacteria have a lower propensity to adhere to titanium compared with stainless steel.[206–210] Kuklo and colleagues[211] retrospectively reviewed 21 consecutive patients with pyogenic vertebral osteomyelitis treated with anterior and posterior surgery on a single day with titanium mesh cages. Most patients (16 of 21) had a significant reduction of pain. Radiographically, they averaged 12 degrees of improvement in segmental kyphosis (preoperatively 11.5 degrees to 0.8 degrees postoperatively) with an average of 2.2-mm cage settling (range, 0–5 mm) on latest follow-up. There were no instrumentation failures, signs of chronic infection, or rejection, but two patients required a second surgery during the same admission for persistent wound drainage at the posterior wound. Both patients were successfully treated with irrigation and debridement. These findings are supported by previous studies showing the safety and efficacy of single-stage surgical debridement and reconstruction.[205,212,213]

In the past, cervical spine vertebral osteomyelitis was managed effectively without bone grafting by drainage, antibiotics, and skull traction for 6 to 12 weeks.[41] Prolonged hospitalization can be avoided by debridement, bone grafting, halo immobilization, and outpatient antibiotics. Posterior stabilization performed as a second stage may be reasonable in order to avoid a halo. Today, most cervical spine infections refractory to nonoperative treatment are treated with anterior plate fixation at the time of debridement and strut grafting.[214]

When vertebral osteomyelitis occurs in a patient who has undergone a surgical procedure on the spine or sustained a penetrating trauma of the spine, a fistula should be suspected. Depending on the level of the spine infection, the appropriate imaging study (barium swallow or gastrointestinal series) or endoscopic examination should be ordered to rule out a fistula. If a fistula is identified, it must be repaired along with treatment of the spine infection (Fig. 87.12).

Costotransversectomy or the slightly more extensive lateral rachiotomy described by Capener is recommended when a spine biopsy or minimal decompression with limited grafting is necessary or when gross purulence is expected.[215] This approach is being used more frequently with the advent of improved spinal reconstruction devices, such as expandable cages. Lu and colleagues[216] reported on 36 patients with known vertebral osteomyelitis treated with anterior debridement and reconstruction with an expandable titanium cage. In four of

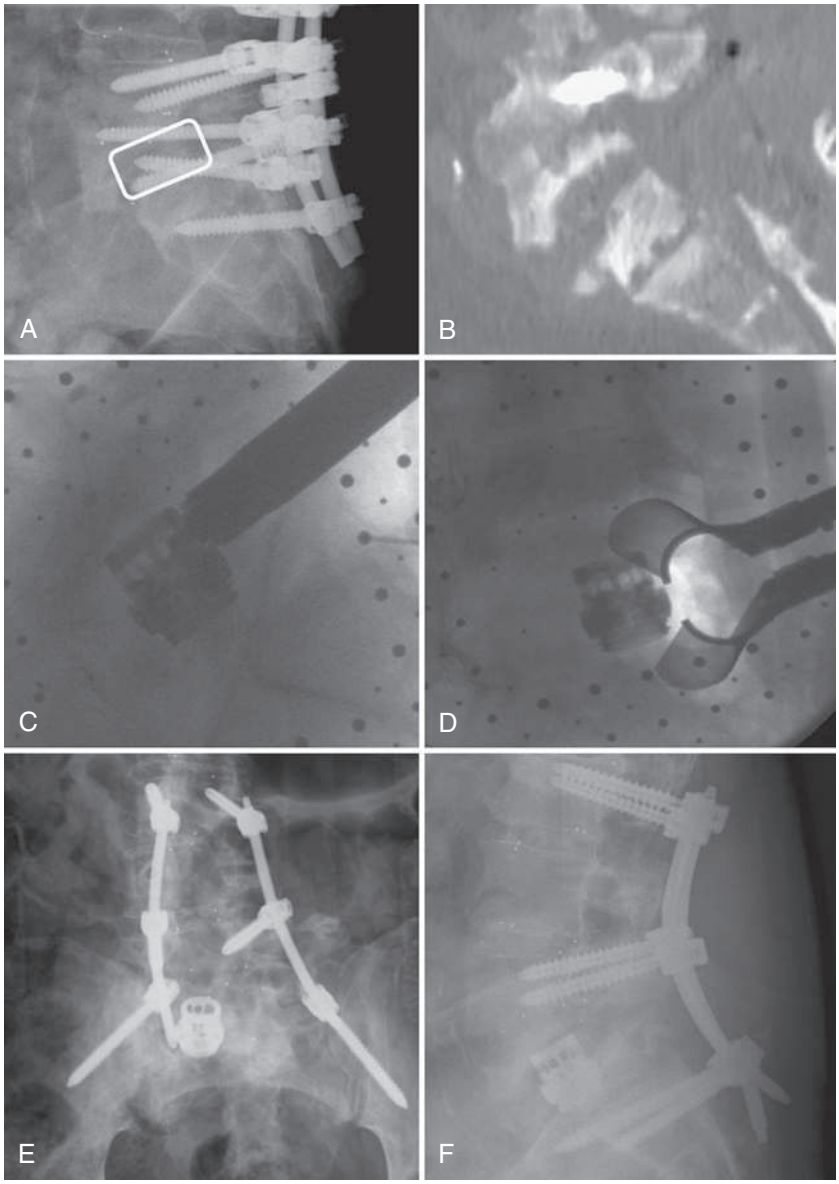

FIG. 87.12 (A) Mini-open posterior transpedicular corpectomy and reconstruction of L5 vertebral osteomyelitis. Preoperative radiograph of a 57-year-old man with a history of multiple previous operations and progressively worsening back pain showing destruction of the L5 vertebral body. The white square outlines the expected location of L5. (B) Sagittal computed tomography image shows complete destruction of L5 and partial destruction of L4 and S1. A posterior, mini-open corpectomy was performed through a paramedian approach with insertion of an expandable titanium cage. (C) Anteroposterior view of the retractor system used. (D) Removal of instrumentation was achieved through separate mini-open approaches using tubular retractors. (E, F) Posterior stabilization was achieved with reinsertion of pedicle screws into L2 and L4 with insertion of iliac screws through the mini-open, paramedian exposure.

those cases, a transpedicular approach was used to perform debridement anteriorly, followed by insertion of an expandable cage from the same posterior exposure. All four patients had an excellent clinical result. The transpedicular approach has several advantages. First, the entire surgery can be completed in a single stage. In the treatment of burst fractures, single-stage surgery leads to shortened total operative time and decreased total blood loss.[217] Mochida and colleagues[218] described the treatment of osteoporotic compression fractures through a transpedicular approach. This strategy is better described in the treatment of metastatic spinal tumors.[219] Senel and colleagues[220] described good results with transpedicular tumor resection in seven patients with spinal metastases from breast, prostate, and thyroid cancer. Similarly, Bilsky and colleagues[221] described 25 patients who underwent posterior-only transpedicular procedures when comorbidities precluded an anterior approach or when the tumor was likely inaccessible entirely from an anterior approach. More recently, this technique has been used by Lee and colleagues[222] for the correction of late traumatic thoracic and thoracolumbar kyphotic spinal deformities in 28 patients. In light of the advantages of single-stage surgery, it appears that anterior-only single-stage surgery may be less advantageous. In the study by Lu and colleagues,[223] there was a difference in terms of postoperative pain among

various procedures. Only 60% of the patients who underwent an anterior-only approach reported being pain free as compared with 81% of patients who had anteroposterior surgery and 100% of the patients who had a transpedicular approach. Furthermore, one of two recurrent infections at the site of previous debridement occurred in the anterior-only patient.[216] Historically, much concern for the fate of the hardware has prompted removal of the retained instrumentation once a fusion is obtained. However, in our experience, the need for instrumentation removal due to recurrent infection at the original site of infection is uncommon. Routine removal of retained spinal instrumentation placed for vertebral osteomyelitis is not recommended.

Recent advances in minimally invasive spine (MIS) techniques offer alternative methods of surgical treatment. Staatz and colleagues[223] reported on 21 patients treated with catheters inserted into abscess cavities adjacent to the vertebral body via CT guidance. Two patients went on to surgery; however, the remainder were successfully treated with catheter drainage and parenteral antibiotics. Percutaneous suction-irrigation systems combined with posterior external fixation have also been shown as effective minimally invasive treatment.[224] However, the use of external fixators in the spine has not gained wide acceptance. Percutaneous debridement of the infected disc, such as via automated percutaneous lumbar discectomy[225] or endoscopic discectomy,[226–228] holds promise as a means of hastening antibiotic treatment when infection is identified before significant bony collapse, abscess formation, and deformity develops. Such techniques would be used when antibiotic treatment alone is likely to be insufficient but the infection is not severe enough to warrant major spinal surgery. Korovessis and colleagues[229] showed in a small number of patients that anterior debridement and reconstruction with titanium mesh cages followed by posterior MIS screw fixation led to decreased blood loss and shortened operative time. In a series of 24 consecutive patients, the last 8 cases were treated with posterior fixation and intertransverse fusion using bilateral paramedian intermuscular approaches. Intraoperative blood loss for their initial open posterior surgeries was 540 mL (range, 350–750 mL). With the MIS technique, blood loss averaged only 70 mL (range, 50–100 mL). This difference was statistically significantly (P <.001).

The combined use of expandable titanium cages and a minimally invasive posterior transpedicular approach provides another method of surgical treatment. Kim and colleagues[230] have described a unilateral paramedian (Wiltse-type) approach to expose the posterior aspect of the involved vertebral body. A subtotal vertebrectomy can then be performed using the transpedicular technique, followed by insertion of an expandable cage that can be placed in a smaller collapsed form and thereafter expanded to the proper size in situ (see Fig. 87.12). Similarly, the use of MIS direct lateral interbody fusion/extreme lateral interbody fusion (DLIF/XLIF) techniques shows promise for the treatment of frail patients with vertebral osteomyelitis (Fig. 87.13).[230a]

The recent advent and commercialization of bone morphogenetic proteins (BMPs) provides another adjunctive treatment. In both human and animal studies of infected long bone defects, the use of BMP led to improved bone healing in the presence of active infection.[231,232] Several studies in humans show similar efficacy in the treatment of vertebral osteomyelitis. Garfin and colleagues[233] reported on 14 patients treated by anterior reconstruction using structural allograft or titanium cages filled with BMP-2. Despite the presence of active infection, all 14 patients went on to solid fusion and eradication of infection. In 8 of the 14 cases, treatment was successful even when the anterior and posterior surgeries were performed on the same day. Similar results have been reported by other groups. O'Shaughnessy and colleagues[234] reported on the successful treatment of 20 patients with at least 2-year follow-up. Aryan and colleagues[235] showed successful treatment in 15 patients. On the basis of the mechanism of action and histologic studies of BMP in animal models, it is hypothesized that BMP increases vascular ingrowth and recruitment of immunologic cells to the site of infection.[233] BMP has not been proven to be safe or effective in large-scale studies of infection, and its use in this setting would be considered to be a physician-directed (off-label) use by the US Food and Drug Administration.

Prognosis

Relapse of infection is uncommon if antibiotics are administered for more than 28 days.[31,98] Nonoperative treatment has a higher failure rate in patients with an impaired immune system.[24] The mortality rate is less than 5% to 16% depending on the average age and comorbidities of patients in the series. Death is much more likely in the elderly and in those with an underlying disease.[24,31,35,98] In one series, *S. aureus* infection was associated with a higher mortality rate than infection with other pathogens.[24]

Factors that have been found to predispose a patient to paralysis include increased age, a more cephalic level of infection, and a history of diabetes mellitus or rheumatoid arthritis.[98] In one series, a neurologic deficit occurred in 45% of the 44 patients who had an impaired immune system, whereas only 19% of the remaining 67 patients developed a deficit.[24] Less than 7% to 15% of patients overall have residual neurologic deficits.[24,31] Diabetics are more likely to have permanent neurologic deficits, and patients with thoracic involvement are the least likely to recover.[31,98] Eismont and colleagues[98] described the results of operation in 14 patients with spinal cord paralysis. Three of the seven patients who underwent a laminectomy deteriorated, and four remained unchanged. In contrast, half of the patients treated by an anterior procedure recovered normal or nearly normal function, and no patient was made worse by the procedure. The patients with root lesions alone had an excellent outcome with or without operation.

In selected patients who require surgical treatment for pyogenic osteomyelitis, the prognosis is very good after the anterior debridement and primary bone grafting in conjunction with a full course of antibiotics. In a series of 21 patients, 6 of whom had neurologic deficits, there were no deaths and no relapses and all of the patients with neurologic deficit recovered. All but one of the patients who underwent fusion had a solid fusion, and one of the two patients who did not

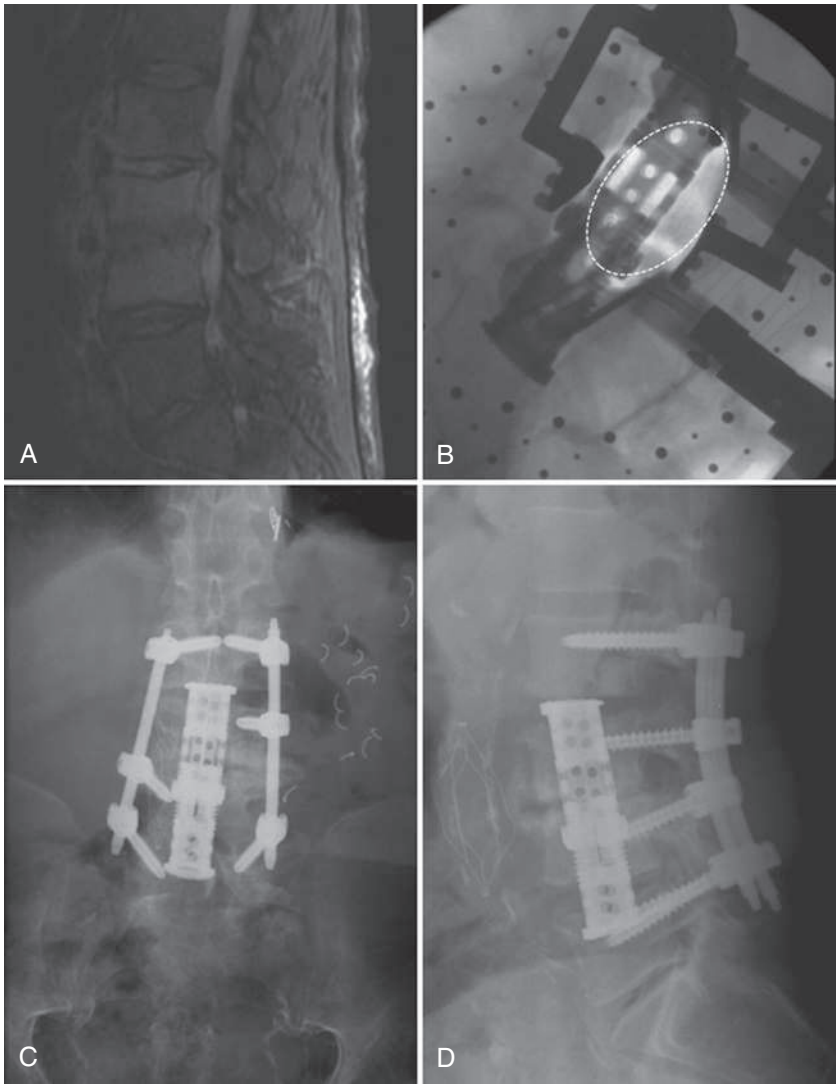

FIG. 87.13 Mini-open direct lateral lumbar corpectomy and reconstruction with expandable cages. A 67-year-old man presented with an infected pacemaker, sepsis, and severe intractable low back pain. (A) Gadolinium-enhanced magnetic resonance imaging shows disc space destruction and increased signal intensity at L3 and L4. (B) Direct lateral, mini-open, transpsoas exposure for L3 and L4 corpectomies, with insertion of expandable titanium cage filled with bone morphogenetic protein 2. (C) Anteroposterior and (D) lateral radiographs following posterior percutaneous pedicle screw fixation.

have a graft had spontaneous fusion. The mean increase in kyphosis was 3 degrees.[183]

Garcia and Grantham[35] found that spontaneous interbody fusion was the rule, which occurred in less than 1 year in most patients and in 2 years in almost all other cases. Some studies have found that the chance of spontaneous fusion in patients treated nonoperatively is 50% or less.[26,31,113] Fortunately, those who do not develop a bony union achieve a fibrous ankylosis, which is generally painless.[26,35,113,114] Occasionally, a patient complains of persistent back pain from localized degenerative changes at the site of previous infection.[26,35,113]

The more cephalad the level of infection, the higher the rate of spontaneous fusion; almost all cases of cervical infection will fuse spontaneously.[17,41] In one series, 6 of 6 cervical lesions went on to solid interbody fusion compared with 22 of 29 thoracic lesions and 5 of 21 lumbar lesions.[17] One of the patients with cervical infection and one with thoracic involvement had undergone posterior fusion. Fifteen of the patients with thoracic disease underwent costotransversectomy, and five patients with lumbar involvement had anterior debridement without fusion.[17]

Although deformities are much less common with pyogenic infection than with tuberculosis infection, they still may occur.[26,236] Deformities have been reported to occur in the cervical spine[236] but are more common in the thoracic and thoracolumbar areas and in those cases with involvement of more than 50% of one or more vertebral bodies.[26] Interestingly, IV drug abusers have an excellent prognosis. Ninety-two percent responded to parenteral antibiotic therapy for 4 weeks or more, and relapses responded to a second course. In 67 cases reported in the literature, there were no deaths or permanent neurologic sequelae.[42]

Overall, the long-term outcome of patients with vertebral osteomyelitis is relatively poor compared with the normal

population. O'Daly and colleagues assessed the long-term functional outcome of patients with pyogenic spinal infection using the Oswestry Disability Index (ODI) and the Short-Form 36 questionnaire (SF-36) survey to measure health-related quality of life (HRQOL).[110] Twenty-nine patients with a median follow-up of 61 months (range, 37–104 months) were examined. IV drug use was not reported in the study population. Eight patients (28%) underwent operative treatment and 21 (72%) were managed nonoperatively with antibiotics alone. "Recovery" was classified as survival and disappearance of all signs and symptoms of active infection, with no residual disability. "Adverse outcome" was classified as survival and disappearance of all signs and symptoms of infection but persistence of clinically significant residual disability or pain, or death caused by or associated with persistent infection at any time before follow-up. Nineteen patients (66%) had an "adverse outcome" as defined by this study. As expected, there were marked differences in SF-36 scores between these patients and the normative population. However, the "recovery" group patients had SF-36 physical function scores and ODI scores that were comparable with the normative values. There was no correlation between SF-36 bodily pain and general health measures and the ODI. Forty-eight percent of patients reported being pain free. Due to the small number of patients, no statistically significant difference was found between patients who underwent surgery compared with patients treated nonoperatively. Delay in diagnosis (>8 weeks) and neurologic deficit at diagnosis were independent risk factors for an "adverse outcome." Advanced age was a risk factor for acute death, and previous surgery at the site of initial infection was a risk factor for recurrent infection.

Woertgen and colleagues[237] compared the outcome of operative and nonoperative treatment using the SF-36. The authors retrospectively investigated 62 patients suffering from pyogenic spinal infections: 28 patients (45%) underwent nonoperative treatment and 34 (55%) underwent surgery. As seen in the study by O'Daly and colleagues,[110] most patients continued to suffer some sort of pain and various SF-36 measures did not reach normative levels. Despite different indications, the surgically treated patients experienced a slightly better HRQOL, self-reported satisfaction levels, and better clinical outcomes than patients treated nonoperatively. These results support the current recommendations that surgery should be pursued in those patients with progressive neurologic deficits, in those with obvious spinal instability, and in cases in which medical therapy has failed.

Epidural Abscess

Epidemiology

An epidural abscess is a bacterial infection of the spine that results in the accumulation of purulent fluid or infected granulation tissue in the epidural space. Most cases occur in adults (mean age, 57 years; range, 2–81 years).[238] Occurrence in children younger than age 12 years is rare.[239] The male/female ratio is approximately 1:1.[238] The incidence of the disease is 0.2 to 1.2 per 10,000 hospital admissions per year with an incidence of 1.8 per 100,000 population annually.[240,241] At the University of Miami/Jackson Memorial Hospital Medical Center, 137 spine infections were treated by the orthopaedic service over an 8-year period; of these, epidural abscess occurred in 10 (7.3%).[146] Approximately 50% of patients are initially misdiagnosed (range, 11%–75%).[242,243]

Danner and Hartman[238] noted an increased frequency at their hospital between 1971 and 1982. This increase was disproportionate to the small increase in admissions and laminectomies performed at that hospital. The authors' proposed explanations were an increased use of medical instrumentation, an increase in frequency of IV drug abuse, and an aging population.[238] Other investigators have also documented an increasing incidence in the condition.[244,245]

Etiology

Spinal epidural abscess occurs from a collection of purulent material between the dura and the osseous-ligamentous structures of the spine and was first described by Morgagni in 1761.[246] The primary source of infection can be identified in approximately 60% of the cases.[238] Infection may occur by hematogenous spread from a remote focus of infection,[238,240,247–250] by spread from a contiguous focus of vertebral osteomyelitis or a disc space infection,[146,238,240,249,251] or from direct inoculation at the time of operation, epidural steroid injection, lumbar puncture, or epidural catheterization.[44,238,240,249,252–254] In 136 cases compiled from five series in the literature, skin and soft tissue infections were thought to be the source in 21%, bone or joint infections in 13% (up to 28% if vertebral osteomyelitis is included), spine surgery or other procedures in 10%, upper respiratory tract infection in 6%, abdominal sources in 4%, urinary tract infection in 2%, and IV drug abuse in 4%.[3,238,240,248,250] The incidence of epidural abscess after catheter insertion is about 0.001%.[255] Although this risk is low, the increased use of epidural analgesia as a method of postoperative pain control is increasing.

Factors that may be associated with a higher incidence of infection include diabetes mellitus, human immunodeficiency virus (HIV) infection, IV drug abuse, prior back trauma, renal failure, liver disease, alcoholism, and pregnancy.[55,146,238,240,251] Between 12% and 30% of patients reported an episode of trauma preceding the infection.[238,240,251] A review of 75 patients from Baltimore revealed an increase in the incidence of epidural abscess over the prior 10-year period.[256] This increase may be due in part to better diagnostic techniques, particularly with gadolinium-enhanced MRI. This study population may be at higher risk of this disease. In this series of 75 patients, 33% had a history of IV drug abuse.

Bacteriology

In 1948, Heusner reported on 20 patients with an epidural abscess; *S. aureus* was the pathogen in all of the cases in which the organism was known.[249] In more recent series, *S. aureus* accounts for approximately 60% of cases in which the organism is known.[238,240,250] From the results in 166 patients from

five series, *S. aureus* accounted for 62%, aerobic streptococci for 8%, *Staphylococcus epidermidis* for 2%, aerobic gram-negative rods for 18%, anaerobes for 2%, and other bacteria for 1%; 6% of the organisms were unidentified.[238,240,248–250] Gram-negative organisms have been reported with increasing frequency.[240,247,250] One study found that IV drug abusers were frequently infected with gram-negative organisms[250]; in another series, 12 of 18 IV drug abusers were infected with *S. aureus* and only one with *Pseudomonas*.[39] A meta-analysis of 915 patients by Reihsaus and colleagues[257] showed that *S. aureus* accounted for 73%, other staphylococcal species 9.3%, aerobic streptococci for 7.7%, Enterobacteriaceae (mainly *E. coli*) 4.9%, *Pseudomonas* species 4.9%, mixed bacterial infections 3.6%, and fungi 1.7%.

Pathogenesis/Pathology

The epidural space is filled with fat and loose areolar tissue containing numerous veins.[258] The size and shape of this space is determined by the variations in size of the spinal cord. In the cervical region, this is a potential space with almost no fat between bone and dura. The epidural space exists only dorsal to the origin of the spinal nerves. Ventrally, the dura is closely applied to the canal from C1 to S2. Posteriorly, the space begins to appear at C7 and gradually deepens along the thoracic vertebrae to a depth of 0.5 to 0.75 cm between T4 and T8. The space tapers again and becomes shallow between T11 and L2 and attains its greatest depths below L2. Below S2, the epidural space surrounds the dura on all sides.[259] The epidural space communicates with the retroperitoneal and posterior mediastinal spaces through the intervertebral foramina.[260] As would be expected by this description of the anatomy, most epidural abscesses are in the thoracic and lumbar spine and are generally posterior.[238,240,248–250,261–263]

In several series, the thoracic spine was involved in 51% of cases, the lumbar spine in 35%, and the cervical spine in 14%.[238,240,249,250,261,262] The abscess was anterior in 21% and posterior in 79% of the 133 patients from four series in which the location was recorded.[238,240,248,249] An abscess is more likely to be located anteriorly if the infection is in the lumbar spine and if it is secondary to vertebral osteomyelitis.[238,248] Because there is no anatomic boundary within the space, the infection may extend the entire length of the canal but generally covers only three or four segments.[146,238,239,249,250,262]

The pathogenesis of the neurologic manifestations is related either to direct compression from epidural pus or granulation tissue or to disruption of the intrinsic circulation of the cord.[240,249,251,258] A microangiographic study in a rabbit model demonstrated that the initial neurologic deficit is related to compression rather than to ischemia. The spinal arteries and epidural venous plexus remained patent in cases of mild to moderate spinal cord compression. The vessels became occluded only with extreme spinal cord compression.[264] On the basis of postmortem examinations, Russell and colleagues[263] identified thrombosis and thrombophlebitis of the veins of the cord and epidural space without involvement of the arteriolar supply. However, others have found thrombosis of the arteriolar supply and veins.[240]

Several authors have identified a correlation between the duration of infection and the gross appearance at operation or postmortem examination. Corrandini and colleagues described an early presuppurative phase in which the inflammatory lesion was characterized by an epidural mass of swollen, red, friable fat without any gross pus.[265] In patients who have had symptoms for less than 2 weeks, gross pus with varying amounts of red granulation tissue has been identified.[238,240,251,263,265] Above and below the level of the pus, the epidural fat may undergo reactive changes and appear swollen and necrotic.[251] In patients with symptoms of longer duration, granulation tissue is often identified on the dura. Small beads of pus embedded in the granulation tissue are frequently observed.[238,240,263,265] In delayed cases with symptoms for 150 days or longer, grayish-white granulation tissue or maturing fibrous tissue has been found.[263] Some authors have thought that it is not always possible to predict whether pus or granulation tissue is likely to be found at operation.[248–250] Hancock described patients in whom granulation tissue was found 1 day after the onset of symptoms and other patients who had had symptoms for up to 4 weeks and had no granulation tissue at operation.[248] Subdural extension of infection is possible but uncommon.[88,240] With spinal cord involvement, there may be evidence of vessel thrombosis, inflammatory response of glial cells, and myelomalacia with liquefaction and vacuolization of the white matter.[251,258]

Clinical Presentation

Patients with an epidural abscess have a highly variable presentation, which causes initial misdiagnosis in approximately 50% of cases.[238] The difficulty in making the correct diagnosis frequently leads to significant delays between presentation and definitive treatment.[238,240,248-250,258,261,262,266,267] Patients who present acutely and who have had symptoms for less than 2 to 3 weeks generally have a better-defined syndrome than do patients with chronic disease. The differentiation between acute and chronic disease is somewhat arbitrary and probably relates to the virulence of the organism, the resistance of the host, and the type of treatment received before definitive diagnosis. Most patients with an acute epidural abscess present with fever, back pain, and spine tenderness. These signs and symptoms may be lacking in patients with chronic disease.[146,248,249,251,261–263] The most common presenting symptoms are spinal pain (89%), neurologic deficit (80%), and fever/chill (67%). Local tenderness (48%) and paresthesia (28%) are less common.[242] Patients with a history of IV drug use, diabetes, or multiple medical problems are particularly susceptible.[256]

Without treatment, the disease frequently progresses through four stages. The patients complain of local spine pain initially, followed by radicular pain and weakness and, finally, by paralysis. Heusner is frequently given credit for defining these stages of progression; however, Browder described the same syndrome in 1937, and a number of other authors reiterated the pattern before Heusner's report in 1948.[249,251,265,267,268] The transition from one stage to another is highly variable, and weakness or paralysis may not develop for many months

or may occur suddenly and unpredictably in a matter of hours.[146,238,262] Neurologic symptoms occur with motor weakness in 30% of cases, and 19% of cases involve paralysis.[269] The location of the pain depends on the site of disease; therefore, pain is more common in the thoracic than in the lumbar or cervical spine.

If the abscess penetrates the dura, a subdural abscess or meningitis may result.[88,240] Many patients with an epidural abscess have nuchal rigidity; this sign is not helpful in differentiating an epidural abscess from meningitis.[240] Fraser and colleagues[88] suggested that a patient with a subdural abscess presents exactly like one with an epidural abscess, except that often there is no spinal percussion tenderness. Butler and colleagues[270] reviewed 16 patients with subdural abscesses described in the literature and found that only four had spinal tenderness. Unfortunately, this feature is not pathognomonic because not all patients with an epidural abscess have spine tenderness.[248,261]

Heusner thought that it was possible to differentiate patients with acute hematogenous epidural abscess from those whose abscess developed secondary to vertebral osteomyelitis: the latter patients had a predictable delay between the phases of spine pain and radicular pain followed by rapid progression of the illness.[249]

Diagnostic Evaluation

Patients with an acute epidural abscess generally have more systemic illness than those with vertebral osteomyelitis. Despite this, the initial diagnosis is incorrect in most cases.[242] The leukocyte count and the ESR are generally increased. In a meta-analysis of 915 patients, the ESR was 77 mm/h (range, 1–150 mm/h) and the mean leukocyte count was 15,700/μL (range, 1500–42,000/μL).[257] Patients with chronic disease usually have less systemic illness and display leukocyte counts that are often normal.[240]

CRP is a sensitive marker for infection. In a study of 26 patients with epidural abscesses treated without surgery, the initiation of antibiotic therapy led to a rapid drop in CRP within 5 to 10 days.[271] CRP values returned to normal at 25.5 days, on average. The definitive diagnosis is based on identification of the organism. Pus from the abscess is positive in approximately 90% of the cases, blood cultures are positive in 60%, and cultures of spinal fluid yield the organism in approximately 17%.[238,240,248–250]

Imaging Studies

Plain radiographs are frequently normal unless vertebral osteomyelitis or disc space infection is present and enough time has elapsed for the radiograph to become positive.[39,263] Radionuclide studies are often helpful but nonspecific and may be falsely negative.[39] The gallium scan may be slightly more sensitive than the technetium scan.[39]

In the past, myelography was the standard imaging tool for the diagnosis of an epidural abscess, but now it is used only if the patient is unable to undergo MRI or if spinal fluid is necessary for diagnostic testing. The puncture should be performed at a level remote from the expected area of infection. It may be necessary to perform injections at two sites in order to demonstrate both the cranial and caudal extents of compression. The findings are those of an extradural mass, and generally there is a high-grade or complete block. The lateral myelogram will demonstrate whether the abscess is anterior or posterior.[240,250,263] In one series, myelography was accurate to within one vertebral level in both the cephalic and caudal extents of the abscess in 10 of 12 cases compared with findings at operation.[146]

The needle should be inserted slowly and, if pus is encountered, a specimen should be taken for culture without entering the thecal sac. Myelography can then be performed at a different level. At the time of myelography, CSF should be studied for cell total and differential counts, glucose, protein, and culture and sensitivities. The CSF findings generally reflect a parameningeal infection with markedly increased protein content and no bacteria unless there is an associated subdural abscess or meningitis.[240,250,263] If a CT scan can be done expeditiously after the myelogram is performed, the degree of neural compression will be defined more accurately.

Plain CT scans may be helpful if they demonstrate an extradural mass.[39] Plain CT has a high false-negative rate, and in one study it was diagnostic in only four of nine cases.[238] The CT scan may demonstrate hypodense tissue in the epidural space.[252] If gas-forming organisms are present, gas may be seen within the epidural space.[272] When positive, CT could be useful to guide epidural puncture for isolation of the organism.[273] Contrast-enhanced CT has been found to be helpful by some authors.[273–276] Positive findings include the loss of physiologic epidural fat and fixation of contrast at the level of the dura surrounded by an area of higher density between the bone and the dura.[273] One major limitation of CT without a preceding myelogram is that the area of interest may be missed unless a large number of cuts are taken.

MRI has proved extremely useful and is the imaging study of choice.[146,274,277,278] It is noninvasive and safe and is able to visualize the degree of cord compression and extent of abscess in all directions. In addition, it has the capability of diagnosing disc space infection or vertebral osteomyelitis. Areas of infection have characteristically high signal intensity on T2-weighted images (Fig. 87.14). One potential disadvantage of MRI is that the CSF also has high signal intensity on T2-weighted images; therefore, there is little contrast between the CSF and the epidural abscess. This has led to false-negative MRI results, especially with long abscesses that do not have a discrete abnormality.[148] MRI may also be falsely negative in patients with concomitant epidural abscess and meningitis because the signal changes in the abscess may not be distinct from those in the infected CSF.[144]

The sensitivity of MRI at detecting an epidural abscess is increased by administration of gadolinium.[147,256,279] The pus in the epidural space will enhance with gadolinium, whereas the CSF will have a low signal intensity on the T1-weighted sequence. Patients who have abundant epidural lipomatous tissue may have false-negative scans because fat has a bright signal on T1-weighted images before administration of gadolinium and the contrast enhancement of the epidural pus may

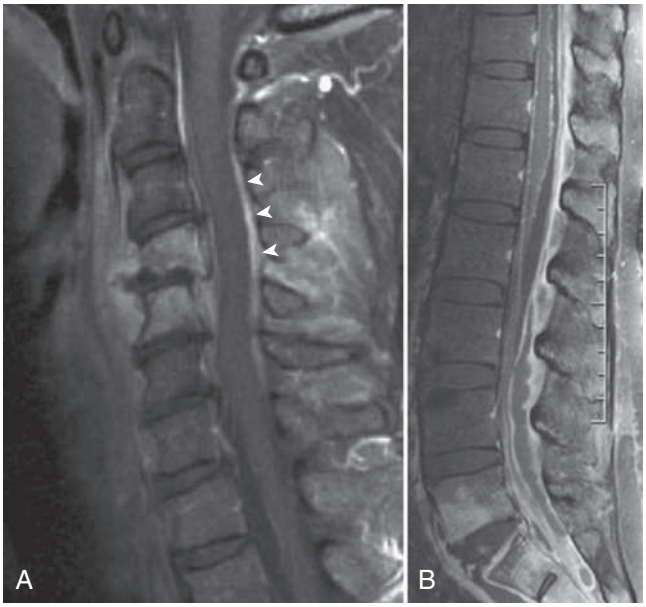

FIG. 87.14 Use of gadolinium-enhanced magnetic resonance imaging to detect epidural abscess. (A) Posterior epidural abscess in the cervical spine (*arrowheads*). (B) Multiloculated epidural abscess spanning entire lumbar spine.

be obscured.[279] The epidural venous plexus normally enhances with gadolinium administration and may be mistaken for an epidural abscess.[279] The plexus is characteristically more prominent in the cervical spine, and it should be symmetrical and extend into the neural foramina. The presence of concurrent noncontiguous spinal epidural abscess lesions, or skip lesions, should be conserved. Patients with a delay in diagnosis greater than 7 days, a concomitant area of infection outside of the spine or paraspinous region, and ESR greater than 95 mm/h have greater risk of a skip lesion. The predictive value was 73% for patients with all three characteristics, 13% with two, 2% with one, and 0% with zero.[280]

Myelography followed by CT should be performed in patients with negative MRI scans if they are suspected clinically to have an epidural abscess.[144] Injection of contrast via a lateral C1–C2 approach has been advocated as a means of avoiding the abscess pocket.[256] A repeat MRI with gadolinium enhancement may also detect an infection missed on the first study because there is a short time delay between the onset of clinical symptoms and the MRI appearance of an abnormality on MRI.[152,279]

Two other conditions to consider in the differential diagnosis of an epidural abscess are epidural metastasis and subdural abscess. It is much more critical to make the appropriate diagnosis in the case of epidural metastasis because the treatment of the two disorders is distinctly different. Subdural abscesses are uncommon. A review of the literature in 1988 revealed only 16 reported cases.[270] Myelography will reveal an intradural extramedullary filling defect, usually with a complete spinal block, and may demonstrate defects at several levels.[88,270,281,282] CT with intrathecal contrast provides better definition of the process than does myelography alone.[39,282] The definitive diagnosis is based on identification of the organism. Pus from the abscess is positive in approximately 90% of the cases, blood cultures are positive in 60%, and cultures of spinal fluid yield the organism in approximately 17%.[238,250]

Management

An epidural abscess accompanied by a neurologic deficit is a medical and surgical emergency. The goals of treatment are eradication of infection, preservation or improvement of the neurologic status, relief of pain, and preservation of spinal stability. The standard approach to an epidural abscess in the early part of the 20th century was immediate laminectomy for spinal decompression. In 1941, Browder and Meyers[258] suggested that chemotherapy might be a helpful adjunct to surgery. Heusner[249] found survival rates of 63% in patients managed surgically without antibiotics and 90% in those who received antibiotics in addition. A review of the literature from 1970 to 1990[283] revealed 37 cases of epidural abscess that had been treated conservatively. Of these cases, 63% had a successful result; however, some of the patients had poor outcomes.[238,240,249,266,268] Nonoperative management of epidural abscesses is recommended only in selected cases: (1) poor surgical candidates, (2) abscess involves a considerable length of the vertebral canal, (3) no significant neurologic deficit, and (4) complete paralysis for more than 3 days.[284,285] Surgical decompression and debridement is strictly recommended when there is emerging or worsening neurologic deficit or sepsis. The following factors are reported to predict a failure of medical management alone: diabetes, CRP greater than 155 µg/mL, WBC greater than $\times 10^9$/L and bacteremia.[286]

Nonoperative Treatment in the Neurologically Intact Patient

With increased use of MRI and a heightened awareness of this disorder, more patients are diagnosed early in the course of the disease. Recent reports show many patients present with no neurologic deficits. In this subset of patients, nonoperative treatment appears to be efficacious. In a retrospective review of 30 cases, Sorensen showed that all 8 patients without neurologic deficit were successfully treated with antibiotic therapy alone.[271] Liem and colleagues[287] reported on 21 patients with thoracic epidural abscesses. Three patients had no neurologic deficit. These patients were treated with antibiotics alone with good results. Mampalam and colleagues[285] showed good results in six patients without neurologic deficit treated with 4 to 6 weeks of IV antibiotics. The causative organism was identified by blood cultures. All patients became afebrile within 48 hours after initiation of antibiotic therapy. Most patients also noticed a marked diminution in pain. In most series, antibiotic therapy lasted at least 4 weeks and up to 12 weeks.

Siddiq and colleagues[288] compared the outcomes of patients treated with antibiotics alone (25 patients), antibiotics with percutaneous CT-guided drainage (7 patients), or surgery (28 patients). Nearly half of the nonsurgical group had neurologic deficits. Despite this, the overall treatment outcome was

comparable with the surgical group. The only predictor of outcome was neurologic abnormality at the time of hospital admission. This is consistent with previous findings, in which patients with little or no neurologic deficit had good overall results with nonoperative treatment.[283] To date, no randomized study directly comparing prophylactic surgery and medical therapy has been performed. However, it is clear that once neurologic deficits appear, surgical decompression and debridement must be timely. When surgery is performed within 24 hours after the onset of neurologic symptoms, overall good results can be obtained in 53% to 80% of cases.[256,287] If surgery is performed after 24 hours, the success rate is 10%.

Thus, nonoperative treatment should be pursued with extreme caution. If an epidural abscess is discovered before the onset of neurologic symptoms, the patient should be hospitalized for close clinical follow-up. Identification of the organism is a critical step in the treatment regimen. Often, this can be done through blood cultures. If the infection begins in the disc space or vertebral body, a percutaneous biopsy in that area can be performed along with drainage. Once cultures are obtained, IV antibiotics should be initiated promptly and serial physical examination and daily CRP values should be assessed.[289] The fever curve and CRP levels should trend downward within 24 to 48 hours. Pain may decrease to some extent. If the baseline leukocyte count was elevated, a downward trend will also be appreciated. In approximately 5 to 10 days, the CRP should be dramatically decreased and is often near normal ranges. Antibiotic therapy should be started immediately on the basis of the Gram stain results and the known bacteriologic basis of the disease. Gram-negative organisms should be suspected if there is a history of a spinal procedure or in IV drug abusers. *S. epidermidis* should also be considered after spinal procedures.[238] The definitive antibiotic therapy should be based on the culture and sensitivity results. Antibiotics should be given in maximal dosages for at least 2 weeks; most authors recommend 3 to 4 weeks of parenteral therapy.[238,240] Antibiotics must be administered parenterally for at least 6 to 8 weeks for coexistent vertebral osteomyelitis.[238,240]

If the patient remains neurologically intact and afebrile, outpatient treatment can be instituted in the reliable patient. Initially, weekly follow-up examinations and laboratory studies should be performed. Such outpatient therapy is reserved for patients who can reliably return to appointments and can readily respond to changes in their symptoms. In our institution, we typically treat with IV antibiotics for at least 6 weeks. Surgical treatment in this patient population is pursued for the following indications: (1) lack of response to medical treatment, (2) onset of systemic infection (sepsis), and/or (3) development of neurologic signs and symptoms. A lack of response to medical treatment often follows a relatively slow course. There is a lack of decline in the fever curve and CRP levels. Pain may persist or increase. Often, this is evident after 5 to 10 days of medical treatment.[289] When systemic infection (sepsis) or neurologic deficits emerge, surgical treatment becomes urgent because the time point when a neurologic injury becomes irreversible is unknown.[290]

Surgical Treatment

It is clear that, in a small proportion of patients, a rapid neurologic decline can occur despite the initiation of appropriate antibiotics.[283] This can be a devastating event; for this reason, surgical decompression and debridement remain the treatment of choice in nearly all patients.[291–293] Up to 75% of patients are reported to fail medical management alone.[294] The surgical approach depends on the location of the abscess. Because the abscess is posterior in most cases, laminectomy is generally the treatment of choice.[240,249] The facet joints should be left intact for spinal stability. Intraoperative ultrasonography after laminectomy allows localization of epidural masses and differentiation of them from the adjacent spinal cord.[144] When the abscess is secondary to vertebral osteomyelitis, it may be necessary to perform both anterior and posterior decompression. Instrumentation and fusion may be necessary in those cases in which spinal stability has been compromised by the decompression. Such extensive reconstruction can be staged at a time subsequent to an initial decompression and debridement in patients who have active comorbidities.

The wound may be closed over drains.[238,240,249] Garrido and Rosenwasser[295] recommended closure of the wound and continuous suction-irrigation for 5 days after decompressive laminectomy. Baker and colleagues[240] recommended open-wound treatment in cases with gross purulence followed by closure of the wound only when granulation tissue is identified. If the wound is left open, delayed closure may be carried out when the leukocyte count, sedimentation rate, and temperature return to normal and the wound shows good granulation tissue.[249] Closure with wound vacuum-assisted closure therapy (Kinetic Concepts Inc.) may be considered, although no series have been reported to our knowledge on the safety or efficacy of the technique.

In children, an extensive laminectomy is undesirable because of the risk of postoperative spinal deformity.[170,266] Hulme and Dott[266] suggested two limited procedures for children. They recommended first a laminoplasty type of en bloc removal of the lamina and ligaments with replacement after drainage. Alternatively, they advised exploration of the canal through a small fenestration made by removing the ligamentum flavum and portions of the adjacent lamina and insertion of thin rubber catheters. They thought that this technique was appropriate when gross purulence was encountered but recommended laminectomy if granulation tissue was found to be compressing the dura.[266] de Villiers and Cluver[260] reported on four children successfully managed by a modification of Hulme's second technique. A single-level laminectomy was performed, catheters were passed cranially and caudally, and the epidural space was irrigated with antibiotic solution. None of the children required reoperation, and no sinus tract developed with this technique.[260]

A variation of Hulme's technique was reported by Cardan and Nanulescu in 1987.[296] A 2.5-year-old boy with an extensive epidural abscess was treated by epidural lavage using Mancao needles. Three hundred milliliters of isotonic saline was flushed through the epidural space over a 30-minute period

while the patient was under general anesthesia. A multiple-hole catheter was then inserted from the sacral hiatus to the midthoracic spine, and a gentamicin isotonic saline solution was administered. The patient improved clinically and, at 18 months postoperatively, was neurologically intact without any sequelae.

A modification of this technique has been employed in adults with good initial outcome. Schultz and colleagues[297] reported on two patients with extensive epidural abscesses. Both patients had abscesses extending from the cervical to the lumbar spine. Rather than performing full-length laminectomies, limited approaches above and below the levels of involvement were used to pass Fogarty catheters through the areas of the abscesses. Once the catheters reached to the opposite opening, the balloon was inflated and carefully pulled back through the canal, effectively "milking" the purulent material out of the canal. Usually, two passes were required. Both patients had resolution of the infection. One patient had near full recovery of motor function; the other patient had moderate improvement of motor function. This technique is promising as an alternative to complete laminectomies, particularly when there is extensive involvement over many levels or when a minimally invasive approach is warranted due to a fragile medical condition of the patient.

Prognosis

The natural history of an untreated epidural abscess is relentless progression of symptoms and eventual paralysis and possibly death. Before the advent of antibiotics, the overall mortality rate was between 55% and 70%.[251,258,298] Mixter and Smithwick[298] reported on 10 cases; all 3 patients treated nonoperatively died. With surgery, the mortality rate decreased to between 30% and 57%[258,298]; 50% of the survivors were left with residual neurologic deficit.[258] From the data on 168 patients reported in six early series since the introduction of antibiotics, 38% made a complete recovery, 29% had residual weakness, 21% were paralyzed, and 12% died.[238,240,248,250,258,261,262] The data from five series published since 1990[244,245,299–302] indicated that 78% of patients undergoing surgery recover fully or with minimal weakness. The prognosis is similar for patients with acute or with chronic disease as long as they are managed appropriately.[240]

The prognosis for neurologic recovery depends on the duration and severity of the neurologic deficit.[238,249,250,261,262] Heusner found that most patients with paresis of less than 36 hours' duration had a complete recovery. No patient with complete paralysis for more than 36 to 48 hours recovers significant neurologic function.[249,261,303] Complete sensory loss is also a poor prognostic factor.[261] Patients who have an acute progressive syndrome with complete paraplegia occurring within the first 12 hours have a poor prognosis; it is postulated that these patients have spinal cord infarction rather than mechanical compression as the pathogenesis of the neurologic deficit.[39] Rigamonti and colleagues[256] reported more recently on 75 patients with spinal epidural abscesses. In patients with severe neurologic deficit, treatment after 24 hours had a 47% poor outcome, whereas those treated before 24 hours had a 10% poor outcome. Thus, they recommend early surgical intervention in patients with neurologic deficit.

Other associated conditions thought to be poor prognostic factors are diabetes, advanced age, female gender, HIV infection, and associated vertebral osteomyelitis.[39,55,249] Furthermore, patients with thoracic-level involvement and those with severe deficits preoperatively also have significantly worse outcomes.[304] The prognosis with subdural abscess is relatively similar—two-thirds of the patients in reported cases made a complete or good recovery after surgical treatment in association with antibiotic therapy.[281,305]

Granulomatous Infections

Granulomatous infections may be caused by fungi, certain bacteria, and spirochetes. If a granuloma is identified on the frozen section, appropriate studies should be initiated to assist an accurate diagnosis.[306] The most common granulomatous spine infection in the world is tuberculosis (TB). TB spondylitis will be described in detail; the fungal and other granulomatous infections will be briefly reviewed by outlining the differences between them and TB infection. Bacteria in the order Actinomycetales cause chronic infections. This order includes the following families of pathogens: Mycobacteriaceae (genus: *Mycobacterium*), Actinomycetaceae (genera: *Actinomyces, Arachnia*), and Nocardiaceae (genus: *Nocardia*).[307]

Tuberculosis

The incidence of TB spondylitis varies considerably throughout the world and is usually proportional to the quality of public health services available. It is extremely common in underdeveloped countries where malnutrition and overcrowding are major problems. In affluent countries, the incidence has decreased dramatically in the past 30 years, and it now is uncommon.[17] Bone and joint involvement develops in approximately 10% of patients with TB[308]; half of these affected patients have TB of the spine.[309,310] A neurologic deficit will develop in 10% to 47% of those with TB spondylitis.[5,201,310–319] In developing countries, the disease is still a significant source of morbidity and mortality and remains the most common cause of nontraumatic paraplegia.[320]

In North America, Europe, and Saudi Arabia, the disease primarily affects adults; in Asia and Africa, a large percentage of the patients are children.[312,313,318,321–327] These patterns are changing, and a decrease in the incidence of infection in infants and young children has been noted in Hong Kong.[324] The age incidence of paraplegia corresponds with the general age incidence of TB of the spine, except for the first decade, in which the incidence of paraplegia is significantly less.[315]

In the United States, it is estimated that 10% of all TB cases occurred in HIV-positive patients.[328] Although it can occur in patients with any range of CD4 count, disseminated and extrapulmonary disease is more common in patients with CD4 counts less than 200 cells/μL and is an acquired immunodeficiency syndrome (AIDS)-defining condition.[328] Weinstein and Eismont[55] showed that patients with HIV had a

higher rate of osseous spinal TB than the general public. Their data indicated that HIV-positive patients were 11 times more likely to be admitted for spinal TB than HIV-negative patients. HIV-positive patients represented 24% of the patients admitted with spinal TB. Among their patients with spinal TB, the average CD4 count was 75.7 cells/mm^3.[55]

Etiology

Spinal TB may occur from hematogenous spread from well-established foci outside the spine. The pulmonary and genitourinary systems are the most frequent sources, but spinal TB may also arise from other skeletal lesions.[81,312] At presentation, the primary focus of infection may be quiescent. Spinal involvement may develop from visceral lesions by direct extension.[81]

Bacteriology

Infection is most commonly caused by *Mycobacterium tuberculosis,* but any species of *Mycobacterium* may be responsible.[329]

Pathogenesis/Pathology

The pathogenesis of the early stages of spinal TB is similar to that of pyogenic infections of the spine and may result from hematogenous spread or from direct extension of disease.[81] One study has suggested that the venous or lymphatic routes may be more important than the arterial system for dissemination of this disease. Blacklock was unable to produce spinal disease by injection of mycobacteria into a vertebra or into the left ventricle of experimental animals.[330]

There are three major types of spinal involvement: paradiscal, central, and anterior.[331] In one series of 914 cases, the disease was paradiscal in 33%, central in 11.6%, and anterior in 2.1%; in 52.8%, the disease was too widespread at presentation for identification of the primary focus.[314] Atypical forms of spinal TB include those with neural arch involvement only and rare cases in which granulomas occur in the spinal canal without bony involvement.[314,332,333] A similar classification system along with specific MRI findings have recently been described by Moorthy and Prabhu.[334] The actual incidence of TB primarily involving the posterior elements is unknown but is probably between 2% and 10%.[332,333,335] MRI shows a homogeneous hyperintense T2-weighted signal in the posterior elements and associated paraspinal abscess.[334]

With paradiscal disease, the infection begins in the metaphyseal area and spreads under the anterior longitudinal ligament to involve the adjacent bodies. In contrast to pyogenic infections, the disc is relatively resistant to infection and may be preserved, even with extensive bone loss.[81] Disc space narrowing has been postulated to occur either as a result of extension of disease or from dehydration of the disc secondary to the altered functional capacities of the endplate. MRI shows low signal on T1-weighted images and high signal on T2-weighted images in the endplate, with disc space narrowing and large paraspinal and occasional epidural abscesses.[334]

In cases with primarily anterior involvement, the infection spreads beneath the anterior longitudinal ligament and may extend over several segments. The radiographic features include scalloped anterior erosion of several vertebral bodies. This pattern is said to result from aortic pulsations transmitted via a prevertebral abscess beneath the anterior longitudinal ligament.[336] However, similar changes have been seen in the cervical spine, and another hypothesis is that the scalloping may be due to changes in local vertebral body blood supply.[201] A combination of pressure and ischemia caused by this pus may produce anterior scalloping. MRI reveals subligamentous abscesses, preservation of disc space, and abnormal signal of multiple vertebral bodies.[334]

In cases classified as central involvement, the disease begins within the middle of the vertebral body and remains isolated to one vertebra. These lesions are frequently mistaken for a tumor. They tend to lead to vertebral collapse and therefore are the most likely type to produce significant spinal deformity.[331] Such pathologic fractures may mimic the more common osteoporotic compression fracture.[337] MRI in central lesions shows signal abnormality of the vertebral body with preservation of the disc space and may also mimic lymphoma or metastases.[334] The pathologic features of TB spondylitis may be altered by secondary pyogenic infection, which may occur through sinus tracts or after debridement procedures.[81]

The pathologic findings in TB spondylitis differ in several ways from those in pyogenic infections. The disc is relatively resistant to TB infection. The pathologic changes generally take longer to develop and are frequently associated with greater deformity. Large paraspinal abscesses are more common with TB infections.[25,30,81,319]

There are numerous mechanisms by which a neurologic deficit may develop in a patient with TB spondylitis. The focus of disease may be within the bone or, occasionally, within the spinal canal without osseous involvement.[322,332,333,338–341] Seddon recognized that neurologic deficits may occur either acutely or chronically.[2] He classified acute disease as "paraplegia of active disease" and recognized that this was due to either external pressure or invasion of the dura. Pressure on the spinal cord may arise from an epidural granuloma or abscess, from sequestered bone and disc, or from pathologic subluxation or dislocation of the vertebra. The paraplegia in chronic cases is related to pressure on the cord from epidural granulomas or fibrosis or from a ridge of bone anteriorly caused by a progressive kyphotic deformity. Several other authors have confirmed these pathogenetic mechanisms at operation or postmortem examination.[10,201,308,341–344]

An epidural granuloma is analogous to a pyogenic epidural abscess. Most frequently, the granuloma arises by spread from the adjacent bone. Because the primary bony lesion is anterior in the majority of cases, spinal cord compression occurs anteriorly. With posterior arch involvement, however, the cord may be compressed from behind.[333,335,345] Although isolated involvement of the neural arch is uncommon, posterior compression from arch involvement occurs in approximately 10% of cases associated with paralysis.[14]

Rarely, an epidural granuloma may occur directly by hematogenous seeding without any bony involvement.[48,273,322,332,333,340,341]

Other lesions that may cause a neurologic deficit without bony involvement are intradural tuberculomas and TB arachnoiditis.[322,338,340] Paraplegia from extraosseous disease occurs in no more than 5% of cases.[322] Transdural extension of TB inflammation was first described by Michod in 1871.[343] Since then, it has been described by other authors.[201,319,340,341,343] Presumably, transdural extension can occur regardless of whether or not the process originates within the bone. TB meningitis is characterized by a granulomatous reaction in the subarachnoid space.[346] Intradural extramedullary mycobacterial disease is the least common presentation of spinal TB. In 2005, Roca reviewed 22 cases in the literature over the past 25 years.[346] Only 3 (14%) were HIV positive and had CD4 counts of 137 to 228/μL.[346] Roca reported that the majority of patients (82%) with intradural extramedullary tuberculomas required operative intervention. At surgery, pathologic tissue revealed granulomatous reaction secondary to a persistent inflammatory reaction. Although organisms may be absent in the specimen, immunohistochemical staining reveals TB antigen (Fig. 87.15).

Clinical Presentation

The clinical presentation of TB spondylitis is variable and depends on many factors. In the classic presentation, the patient complains of spine pain and exhibits manifestations of chronic illness such as weight loss, malaise, and intermittent fever. The physical findings include local tenderness, muscle spasm, and restricted motion. The patient may also have a spinal deformity and neurologic deficit. The duration of symptoms before a definitive diagnosis is made varies from months to years; most cases are diagnosed in less than 2 years.[201] In affluent countries, presentation is generally early. In underdeveloped countries, the complications of neglected disease—such as paraplegia, kyphosis, and draining sinuses—may be the presenting complaints.[319,326,347]

The location of the pain corresponds to the site of the disease, which is most frequent in the thoracic region, less common in the lumbar region, and rare in the cervical spine and sacrum.[201,314,317] Patients may present with an abscess in any one of many locations, including the groin and buttocks.[331]

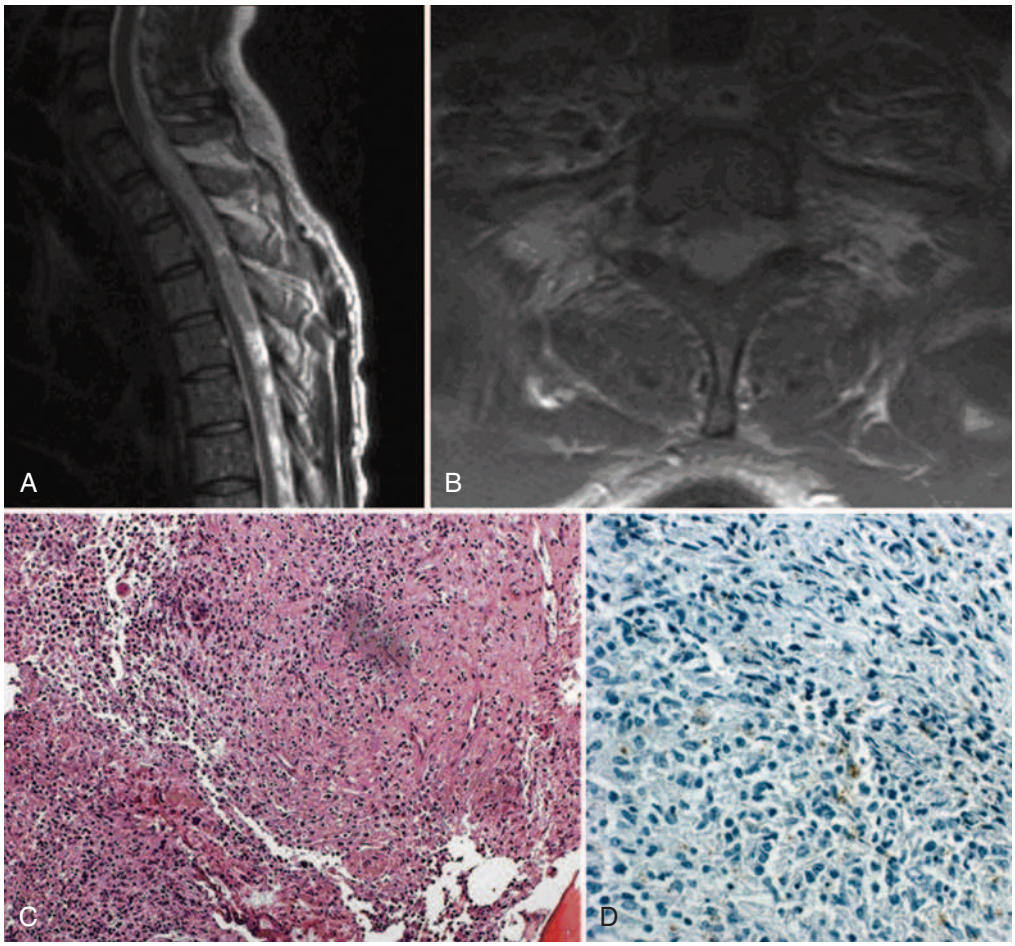

FIG. 87.15 (A) Sagittal T2-weighted magnetic resonance image (MRI) demonstrating a diffuse posterior mass displacing the spinal cord anteriorly. (B) Axial T2-weighted MRI demonstrating a diffuse posterior mass displacing the spinal cord anteriorly. (C) Hematoxylin and eosin–stained tissue of the pathologic specimen removed at surgery. This ×10 magnification view demonstrates a poorly formed granuloma. (D) Antituberculosis immunohistochemical stain at ×40 magnification. The immunohistochemical stain is directed against tuberculosis antigen and is brown in the pathologic specimen. This brown staining indicates the presence of tuberculosis antigen.

In 10% to 47% of patients, neurologic deficits develop during the course of their disease.[5,201,310–312,314–319] The incidence of paraplegia is higher with spondylitis in the thoracic and the cervical spine.[314,348] The most common complications occurring prior to diagnosis include abscesses (69%), neurologic deficits (40%), spinal instability (21%), and spinal deformity (16%).[349]

The manifestations of cervical spine involvement vary with the age of the patient. Children younger than age 10 years usually have extensive disease, with large abscesses and a relatively low (17%) incidence of paralysis. In older patients, the disease is more localized with less pus, but the incidence of paraplegia is 81%.[348] A distinct syndrome has been reported in heroin addicts with TB spondylitis. All five patients in one series had an acute toxic reaction with fever, back pain, weight loss, night sweats, and rapidly evolving neurologic deficits. All patients had disseminated TB with involvement of extravertebral sites.[350]

Diagnostic Evaluation

The sedimentation rate is generally increased with TB spondylitis, but this is nonspecific. The tuberculin purified protein derivative skin test is usually positive and indicates either past or present exposure to *Mycobacterium*.[322] Cultures of early morning urine samples may be helpful in cases of renal involvement, and sputum specimens and gastric washings may be positive with active pulmonary disease. These laboratory findings are helpful in the diagnosis, but an absolute diagnosis can be made only by biopsy of the spine lesion.[189] Aspiration of a subcutaneous abscess on occasion may reveal the organism and obviate the need for spine biopsy.

Isolation of *Mycobacterium* from clinical specimens takes 6 to 8 weeks, and the sensitivity of culture may be as low as 50%.[351] In the past, the most rapid method of detecting mycobacteria was the staining and smear microscopy of acid-fast bacilli. However, the acid-fast bacilli smear technique requires 5000 to 10,000 bacilli per milliliter of sputum for detection, with only 50% to 80% of specimens testing positive.[352] Polymerase chain reaction (PCR) has been used to rapidly identify the presence of mycobacteria in formaldehyde solution–fixed, paraffin-embedded tissue specimens.[353] Over the past several years, a number of commercially available molecular detection systems have been introduced. All of these systems use detection of *Mycobacterium* DNA or RNA, using the publication of the *M. tuberculosis* genome.[352] These extremely sensitive detection systems require great care in minimizing contaminants in the sample specimens and thus are relatively expensive. Molecular detection systems are also able to test for genes known to be associated with drug resistance, including rifampin, isoniazid, pyrazinamide, ethambutol, and streptomycin. The specificity of molecular detection techniques is approximately 98%, the sensitivity 85%, the positive predictive value 95%, and the negative predictive value 93%.[354]

The findings on plain radiographs of the spine will vary depending on the pathologic type and chronicity of the infection. The earliest finding may be bone rarefaction, regardless of type. With peridiscal involvement, disc space narrowing is followed by bone destruction, similar to pyogenic infections. With anterior multilevel spine involvement, the anterior aspect of several adjacent vertebrae may be eroded in a scalloped fashion. Central body involvement resembles a tumor, with central rarefaction and bone destruction followed by collapse. The initial radiographs often show far advanced bony changes in contrast to pyogenic infections, in which radiographs may be normal on first presentation. The central type is more common in the thoracic area, and the peridiscal variant is more common in the lumbar region. The central type causes greater and earlier bone collapse than the peridiscal type.[331] Although these radiographic changes are characteristic, a diagnosis based on radiologic changes alone is inadequate in 10% of cases.[355]

Chest radiographs are helpful in demonstrating pulmonary involvement and may show a paraspinal abscess. It is not possible to differentiate fibrosis and paravertebral edema from abscess formation on the basis of plain radiographs.[201] Occasionally, lumbar spine radiographs will demonstrate calcification in the psoas muscle in cases with a long-standing abscess.[201] Sclerotic reactive bone formation occurs with healing of TB infection but is seen much later and is less marked than with pyogenic infection.[93] Heroin addicts with Pott disease may have atypical radiographs. In one study, four of five patients had atypical radiographs, including two with an ivory vertebra.[350] Radionuclide scanning with technetium or gallium may help to define the extent of disease.[356] Gallium scanning has been recommended for diagnosing extrapulmonary TB and also to monitor the response to treatment.[356] Unfortunately, radionuclide scans are not sensitive for TB infection; technetium bone scans are negative in 35% of cases, and gallium scans are negative in 70%.[322] CT is useful to delineate soft tissue changes around the spine and in the canal but is not capable of differentiating an abscess from granulation tissue.

MRI is the imaging modality of choice because it demonstrates both bony and soft tissue involvement. The MRI findings in TB spondylitis may be indistinguishable from pyogenic infections, but there are some differences that are characteristic of TB and reflect the different pathologic types described earlier.[357] The intervertebral disc may have normal height and a normal signal on MRI, reflecting the resistance of the disc to TB infection (Fig. 87.16). Involvement of the anterior aspect of several contiguous vertebral bodies or involvement of posterior elements suggests a diagnosis of TB spondylitis. Paraspinal masses tend to be longer in TB spondylitis than in pyogenic infections and can be imaged well with plain or gadolinium-enhanced MRIs. Enhanced scans can distinguish abscesses from granulation tissue (Fig. 87.17). A mass with near-total enhancement is generally granulation tissue, whereas a mass with enhancement only at the periphery is generally an abscess.[358] As the infection resolves, the T1-weighted images of the vertebral body characteristically have progressively greater signal intensity.[115] Even the MRI findings are not completely characteristic; thus, a biopsy is necessary in all cases. Central body TB closely resembles a neoplasm[357,359]; an epidural TB granuloma without osseous involvement cannot be differentiated from an epidural neoplastic metastatic lesion. The distinction between

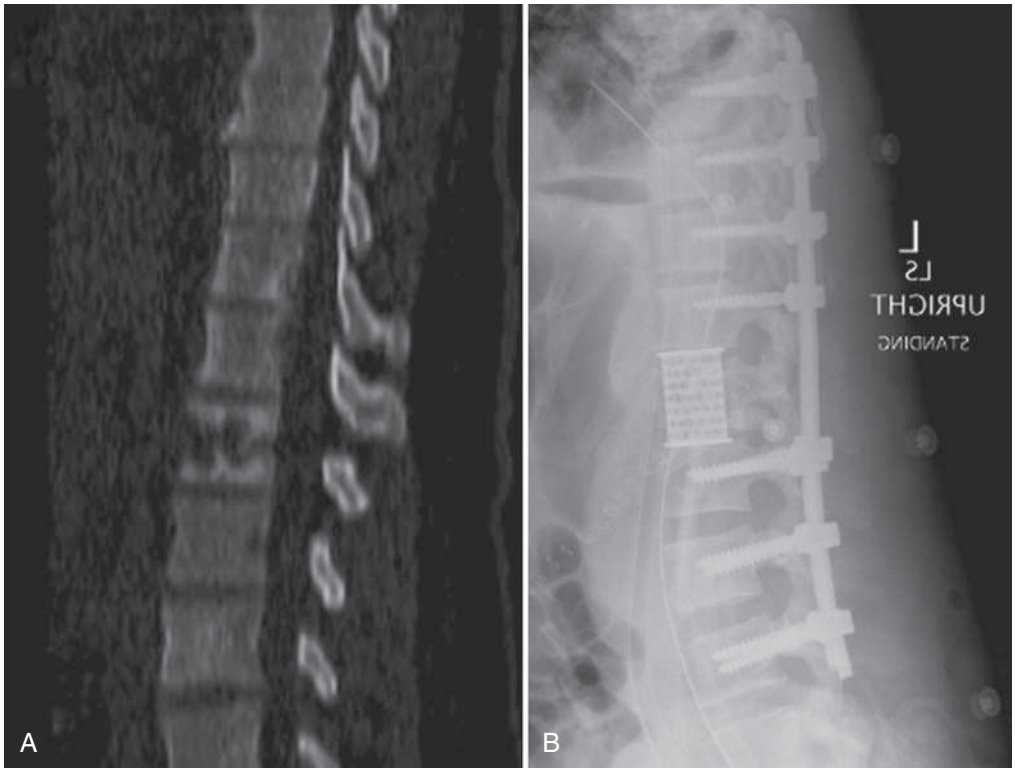

FIG. 87.16 Tuberculous vertebral osteomyelitis. In contrast to pyogenic infections, the disc tends to be spared relative to the vertebral body. (A) Computed tomography scan showing tuberculous infection of the vertebral body and relative preservation of the disc spaces above and below. (B) Radiograph of anterior corpectomy and strut fusion with posterior instrumented fusion.

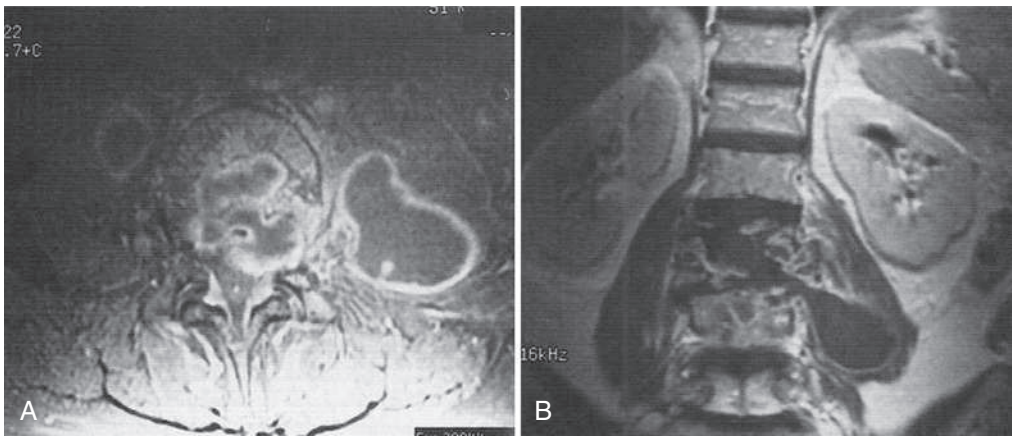

FIG. 87.17 (A) Axial and (B) coronal images of an abscess in the left psoas muscle in association with L3 and L4 tuberculous vertebral osteomyelitis. The periphery of the abscess enhances after administration of gadolinium, suggesting that the mass is an abscess rather than granulation tissue. The psoas abscess was found to be a sterile loculation of pus.

these conditions can be made only at operation.[332] Two MRI findings shown to significantly identify TB versus pyogenic infection are the presence of abscesses with thin and smooth walls (75% with TB vs. 0% in pyogenic spondylitis; $P < .001$) and well-defined paraspinal soft tissue (66.7% in TB vs. 11.1% in pyogenic spondylitis; $P = .007$).[360]

The differential diagnosis should include other bacterial and fungal infections as well as sarcoidosis and neuropathic spine disease. Sarcoidosis rarely involves the spine but may produce paraspinal masses and circumscribed lytic spine lesions with or without a sclerotic rim. Purely sclerotic lesions occur less frequently.[82] Neuropathic disease of the spine is usually limited to one to three contiguous vertebrae and is characterized by marked reactive sclerosis or destruction. Sclerosis associated with neuropathic disease of the spine parallels the base of the vertebral body and commonly involves the posterior arch. It is associated with paraspinal debris but not masses.[82]

Management

The goals of management are to eradicate the infection and to prevent or treat neurologic deficits and spinal deformity. The modern era in the treatment of spinal TB began in 1943 with the discovery of streptomycin by Waxmin. The first major description on the use of streptomycin in TB bone and joint lesions was published by Bosworth and colleagues[361] in 1950. The drug had a tremendous influence on the mortality rate from TB. Between the 5 years before streptomycin was used and the 5 years after its introduction, the mortality rate at Sea View Hospital in New York decreased by 72.5%.[275] Kondo and Yamada[362] reported a decrease in the mortality rate from 42.9% to 9.3% with the addition of streptomycin to the regimen for patients treated nonoperatively. In patients undergoing Albee fusion, the mortality rate was 32% without streptomycin and none with streptomycin. In patients undergoing focal debridement, the mortality rate decreased from 71.4% without streptomycin to 2.1% with streptomycin.[362]

In 1952, Bosworth and associates published a preliminary report showing encouraging results with the use of isoniazid.[363] These drugs and others eliminated the risk of dissemination of disease and the development of chronic sinuses after surgical debridement and allowed radical procedures to be performed in relative safety.[9,364] Both drugs were found to be effective without surgery when the patients were kept immobilized in the hospital for long periods.[365]

In Nigeria, a shortage of medical beds and poor medical facilities forced Konstam and Konstam[12,13] to use chemotherapy on an ambulatory basis. Although many patients in their study were lost to follow-up, 96% of those returning were thought to be healed and free of disease. Spinal deformity was found to be a problem with this form of treatment; only 75% developed a bony fusion, 49% had between 0 and 10 degrees of increased kyphosis, and 18% had 30 degrees or more of kyphosis.[12] Other authors found reasonably good results with chemotherapy alone.[9,312,366]

Hodgson and Stock[9,10] had excellent results with their procedure of radical debridement and anterior strut graft fusion in association with chemotherapy (the Hong Kong operation). In 1963, the Medical Research Council Committee for Research on Tuberculosis in the Tropics began to investigate these widely divergent forms of treatment. A subcommittee was established that later became known as the Working Party on Tuberculosis of the Spine. This group initiated a number of large-scale controlled, prospective trials of treatment methods. The design of each study was based on the available resources in areas where TB was endemic. The first studies, carried out in Korea and Rhodesia, established that chemotherapy is highly effective in ambulatory patients.[325,347,367] These investigations showed that there was no advantage to an initial period of bed rest in the hospital,[325] application of a plaster of Paris jacket,[367] or addition of streptomycin to the chemotherapy regimen.[325,347,367] These results were maintained after 5 years[368] and 10 years[369] of follow-up. Other studies comparing the effectiveness of debridement with that of more radical resection and bone grafting were carried out at three different centers. In Hong Kong, where the radical procedure was popularized, resection and fusion were found to have advantages in terms of less deformity and earlier bony fusion.[370] Patients with extensive disease and neurologic deficit were excluded from that study. In two concurrent studies in Africa, in which patients with more severe disease were included, there was no significant difference between the two surgical approaches.[326] Most of the patients in the three centers were doing well by the 3-year follow-up, and these results were maintained with up to 5 years of follow-up.[327] No changes were found at 10 years in the Hong Kong series.[371] The Medical Research Council then set out to determine whether short courses of chemotherapy would be as effective as the standard 18-month regimen (used in all previous studies). In Hong Kong, patients underwent the radical operation and either a 6- or 9-month chemotherapy regimen of isoniazid and rifampin supplemented with streptomycin for 6 months. The 6- and 9-month courses were equally effective and at least as successful as the standard 18-month regimen when assessed at 3 years.[372] In South India, ambulatory chemotherapy alone with 6- or 9-month regimens was compared with radical surgery plus 6 months of chemotherapy.[373] Of the patients treated by the 9-month regimen, 97% achieved a favorable status at 3 years compared with 93% for the patients in the 6-month ambulatory group. Surprisingly, only 85% of the patients in the surgical series achieved a favorable status. The conclusion of the Medical Research Council was that the treatment of choice for spinal TB in developing countries is ambulatory chemotherapy with 6- or 9-month regimens of isoniazid and rifampin. Surgery should be considered only for biopsy or the management of myelopathy, abscesses, and sinuses. Even in technically advanced countries, they advised against surgery in all cases. When surgery is felt to be necessary, the Hong Kong operation was recommended.[371,372] Although the results of the studies in Hong Kong and Africa on radical debridement and fusion versus debridement alone were at variance, the overall conclusion was that the Hong Kong operation allows anterior bony fusion to occur earlier and in a higher percentage of patients. Kyphotic deformity was less common and not progressive in those patients undergoing the more radical procedure.[371] Other independent studies have demonstrated the effectiveness of debridement and fusion and support the recommendation of the Medical Research Council.[185,189,374–377] The group in Hong Kong has written extensively on this approach and is responsible for its popularity.[9,10,188,319,323,348,378] Another advantage of anterior decompression and fusion compared with nonoperative treatment that has been demonstrated by a number of authors is the higher recovery rate in patients with neurologic deficit.[201,316,318,322]

Refinements in antituberculosis chemotherapy have permitted a more selective approach to the surgical management of spinal TB. Many mild cases respond well to standard chemotherapy without the need for surgery.[378a] Rather than operate in every case, Tuli described a "middle-path" regimen of operating only when medical management failed.[14,309] The first line of treatment was drug therapy; operation was considered for the following: decompression in patients with neurologic deficit who failed to respond to conservative therapy, posterior spinal lesions, failure of response after 3 to

6 months of nonoperative treatment, doubtful diagnosis, instability after healing, or recurrence of disease or of neurologic complications. In cases without neurologic involvement, healing occurred in 94% with antibiotics alone. In 200 cases with neurologic involvement, 38% of the patients recovered with drugs alone; of those patients requiring operation, 69% recovered completely. The overall success rate in patients with neurologic complications treated by this regimen was 78.5%.[14]

The indications for operation outlined by Tuli are similar to our current recommendations, except that patients with a neurologic deficit would be operated on urgently rather than after a delay to see if drug therapy alone would be effective. In general, the indications for operation are the same as with pyogenic infection. Lifeso and colleagues[322] think that patients with mild neurologic deficits should not undergo operation because medical therapy alone with close observation is safe. Two of their 23 patients became worse with conservative treatment; both recovered completely after anterior decompression and fusion. They also thought that patients with slight kyphosis could be treated with medical therapy alone because the increase in kyphosis and in the number of affected vertebral bodies reported in children was not found in adults treated medically.[322]

When an operation is indicated, it is easier to do it early because abscesses tend to dissect along tissue planes. If operation is delayed, fibrosis makes the procedure technically much more difficult. Hodgson and Stock[188] found a direct correlation between the duration of neurologic symptoms before the operation and the time for recovery from paraplegia. Others have confirmed this finding.[316] Operation also is advised in late-onset paralysis associated with cord compression by a hard bony ridge in association with kyphosis. Hsu and colleagues[342] think that, in patients with mild or moderate paraplegia, stabilization alone may be indicated, with decompression reserved for those patients with severe paralysis.

Regardless of whether an operation is performed or not, chemotherapy is an integral part of the management of spinal TB. The only cases in which chemotherapy is not indicated are those in which late-onset paraplegia from progressive deformity has occurred in a patient with healed inactive disease. Drug therapy is usually started preoperatively but may be started after operation if a biopsy is necessary. The first line of drugs currently in use include isoniazid (INH), rifampin (RMP), pyrazinamide (PZA), streptomycin (STM), and ethambutol (EMB). A number of second-line agents that occasionally are used in special circumstances include ethionamide, cycloserine, kanamycin, capreomycin, prothionamide, and para-aminosalicylic acid.[379] The choice of agents, dosages, and duration of therapy should be directed by an infectious disease expert.

Multiple drugs are used because of the potential for resistance to a single agent. Selection of rational combinations of drugs is based on the mechanism of action and toxicity of the agents.[379] The organisms may be in several different environments and therefore not accessible to all agents. They may reside in the extracellular space, either in the hyperoxic neutral environment of the pulmonary cavity or in the hypoxic acidic environment of caseous material in the spine. They also may exist in the highly suppressive acidic environment inside the activated macrophage. INH and RMP are bactericidal against both intracellular and extracellular organisms.[380] RMP may have an advantage against bacilli with low metabolic activity, as are present in caseous material. PZA is bactericidal only in an acidic environment and therefore is effective against intracellular organisms or within caseous lesions. Conversely, STM is active only in the extracellular space and therefore is often used to complement PZA. EMB is bacteriostatic against both intracellular and extracellular organisms and often is used in multiple-drug regimens in place of the once-popular para-aminosalicylic acid. All of these agents have the potential for significant toxicity. Hepatitis may be caused by both INH and RMP and is four times more common in patients receiving both agents than in those receiving INH alone. INH can also cause dose-dependent peripheral neuritis. The major toxicity of STM is nerve VIII damage; that of EMB is optic neuritis.

Antimicrobial resistance may occur from the multiplication of resistant mutants under the selective pressure of single-drug therapy. Resistance developing during the course of treatment in a patient with an initially drug-sensitive infection is termed "secondary resistance." "Primary resistance," defined as infection with drug-resistant organisms in a previously untreated patient, may be transmitted to other patients. The prevalence of primary resistance rose from less than 3% in the United States during the 1970s to approximately 9% by 1986.[381] Resistance is much more common in certain urban areas and in patients who are homeless, drug abusers, or infected with HIV. The patterns of drug resistance are variable throughout the world, reemphasizing the need for close follow-up during treatment.[12,188,322,372] Resistance is generally not a problem with multiple-drug regimens as long as the patient is in compliance.

A 6-month, three-drug regimen including INH, RMP, and PZA is used for most cases of drug-sensitive infection in Western nations. Atypical mycobacterial species are often resistant to standard drug regimens.[329] Because spinal TB carries a significant risk, maximal chemotherapy should be used. In a study of lumbar and lumbosacral spine involvement, triple antibiotic therapy with INH, EMB, and RMP yielded excellent results.[382] All patients healed the original site of infection with little change in spinal alignment. At 36 months' follow-up, the kyphosis angle improved slightly by 2.2 degrees and the Cobb angle increased slightly by 5.4 degrees.[382] Spontaneous bony union occurred in 87.5% of patients. Purtuiset and colleagues[383] reported on their experience of 103 cases of spinal TB occurring in a developed country. Most of their patients (74%) were treated with medical therapy alone and the remainder with surgery. Overall, there were two TB-related deaths. Their mean duration of medical treatment was 14 months. These results are similar to those observed in less developed countries, such as India.[384]

Surgical Treatment

An operation may be performed to drain abscesses, to debride sequestered bone and disc, to decompress the spinal cord, or to stabilize the spine for the prevention or correction

of deformity. In 1779, Pott described the drainage of a TB abscess: "The remedy for this most dreadful disease consists merely in procuring a large discharge of matter, by suppuration from underneath the membrana adiposa on each side of the curvature, and in maintaining such discharge until the patient shall have perfectly recovered the use of his legs."[1] His statement was rather optimistic—many patients did not recover neurologic function after this procedure, and many others died of secondary pyogenic infection. In general, abscess drainage is indicated only if the patient is septic from the abscess or has a neurologic deficit from an epidural abscess or when the abscess is extremely extensive. After drainage of an abscess, the tissues may be closed in layers or the wound may be packed open. Paravertebral abscesses in the thoracic spine can be drained effectively by a costotransversectomy.[215] Large psoas abscesses may be drained by a retroperitoneal approach.[385]

Simple debridement of the spine without fusion is advocated by some surgeons.[326,362] However, most authors agree with the conclusions of the Medical Research Council that the Hong Kong procedure of anterior radical debridement and strut graft fusion is superior.[10,185,188,189,201,319,375–377,386] Surgery performed when the disease is active is safer, and the response is faster and better than that performed in patients with healed disease.[342]

In the Hong Kong procedure, the spine is approached anteriorly so that the affected area may be dealt with most directly. The sequestered bone and caseous material must be debrided back to bleeding bone above and below and back to the posterior longitudinal ligament. The decompression should go back to the dura in cases of neurologic deficit when spinal cord decompression is necessary.[327] The angular deformity is corrected by insertion of a strut graft. The anterior approach produces statistically better kyphosis correction and less correction loss, but it has been reported to be clinically insignificant.[387] Autogenous bone grafting at the time of the primary debridement is reliable in both adults and children.[10,185,188,189,194,201,316,319,323,371,375,377,388–390] The incidence of fusion with a bone graft is 97% at 10 years compared with 90% with debridement alone. Medical management with chemotherapy alone may yield a solid fusion in 65% to 79% of cases.[11,12,113]

The choice of graft material is based on considerations of graft incorporation and structural support. The grafts used most frequently are iliac crest and ribs. Fibular grafts provide good structural support, but the large amount of cortical bone is undesirable in cases of infection. In addition, long segments of fibula are likely to fracture. In a study of 4-cm-long canine fibular grafts, the grafts were markedly weakened between 6 weeks and 6 months after implantation. The total incorporation may take several years; at 48 weeks, approximately 60% of the necrotic matrix had been remodeled. Despite that, the strength of the graft is nearly normal at 1 year.[197] Bradford and Daher[198] described the use of vascularized rib grafts for stabilization of kyphosis. Incorporation of the grafts occurred between 4 weeks and 16 weeks (mean, 8.5 weeks). They described three patients in whom the graft was placed 4 cm or more anterior to the apical vertebra for mechanical advantage; none of these grafts fractured.[198] High fusion rates have been reported when vascularized rib grafts are used in the treatment of TB kyphosis.[199]

Kemp and colleagues[185] found that rib grafting was inadequate in adults. They reported a 32% incidence of graft fracture and a mean increase in kyphosis of 20 degrees. Partial collapse occurred in some cases because the ribs penetrated the endplate. The overall fusion rate was 62% with rib grafts and 94.5% when autogenous, full-thickness iliac crest grafts were inserted as long as they crossed the coronal diameter of the vertebra.[185] Iliac crest may be preferable to rib, especially in patients with large defects.[185,188,196]

McCuen described the first case of TB spondylitis treated by laminectomy in 1882. In the early part of the twentieth century, it had become a common procedure for patients with Pott paraplegia. In 1935, Seddon condemned the procedure, claiming that "laminectomy is futile" because it removes the integrity of the posterior arch and may lead to instability and further neurologic damage.[190] The opinion that laminectomy is contraindicated is shared by many authors.[186,315,316,319,341,364,375,391] Patients actually may improve considerably immediately after laminectomy. As Bosworth and colleagues[361] noted, however, paraplegia inevitably recurs unless fusion is performed both anteriorly and posteriorly. They described 14 patients who had had laminectomies: all died except 4, who had "circumduction" fusions.[361] Currently, the only indication for laminectomy in the treatment of Pott paraplegia is atypical disease involving the neural arch and causing posterior spinal cord compression.[155,186,190,314,333] It is also reasonable in rare circumstances with posterior epidural tuberculoma without bony involvement.[332]

Debridement, decompression, and fusion in the thoracic spine may be performed through a transthoracic approach, through a costotransversectomy, or by an extrapleural anterolateral approach. The last has the theoretical benefit of avoiding the TB empyema.[375] However, no studies have demonstrated any actual advantage of an extrapleural approach over a standard thoracotomy. Kirkaldy-Willis and Thomas[189] demonstrated that the transthoracic approach is more successful than lateral rachiotomy (modified costotransversectomy). The fusion rate was 95% in the former and 78% in the latter; the mortality was 3% and 8%, respectively.[189] They recommended thoracotomy in cases of early TB, with lateral rachiotomy reserved for late-onset paraplegia associated with a large kyphotic deformity requiring lateral exposure of the dura.[189] Kemp and colleagues[185] support this concept.

With TB, the periosteum is generally thicker and frequently adherent to the pleura. Therefore, it is often necessary to dissect in a subperiosteal plane for exposure. If a lung abscess is found at the time of thoracotomy, the abscess may be debrided by scooping out the necrotic material. Yau and Hodgson[392] rarely found an air leak in this situation and had good success by insufflating the cavity with streptomycin and suturing the visceral pleura. Because of the potential for wound dehiscence in these patients, who are frequently immunocompromised and have poor wound-healing potential, the wounds should be closed in layers with interrupted nonabsorbable sutures. In patients with lesions involving

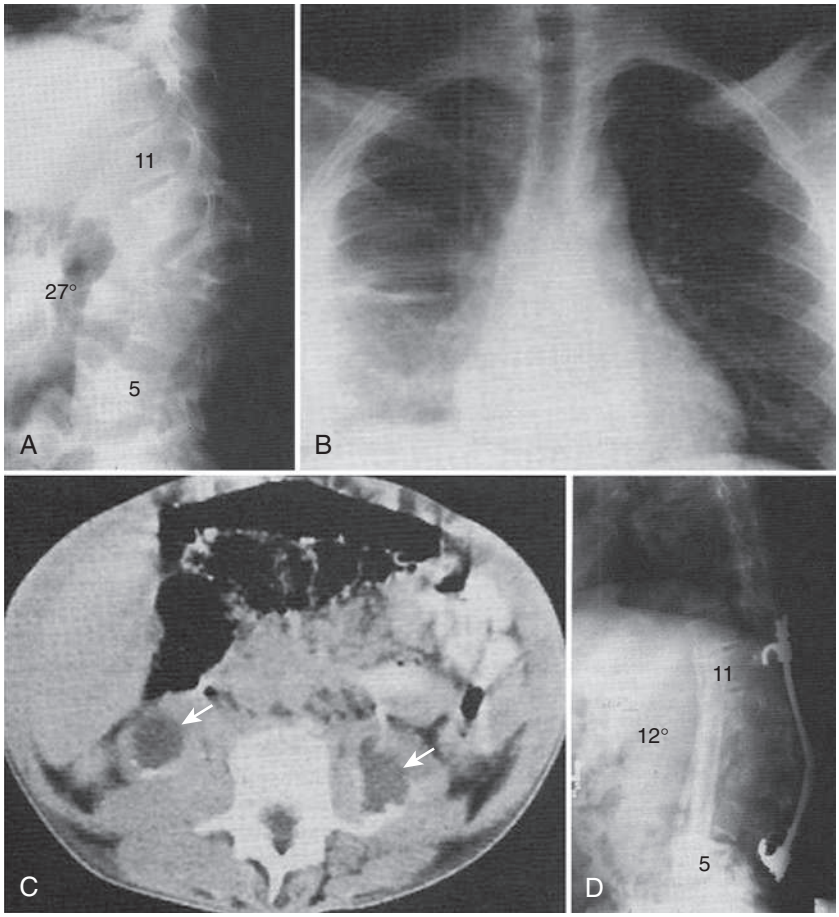

FIG. 87.18 This patient presented with intermittent fevers and spine deformity. He complained only of relatively minor spine pain. He was neurologically intact. Tuberculosis was suspected and confirmed by culture. (A) This lateral radiograph shows a 27-degree kyphosis from the inferior portion of T12 to the superior endplate of L5. The intervening vertebrae are grossly destroyed. (B) An anteroposterior chest radiograph reveals chronic changes in the right lung and an effusion, which are also consistent with tuberculosis. (C) Computed tomography (CT) scan of the lumbar spine reveals bilateral psoas abscesses (*arrows*). There is also a significant paraspinal mass, which is most likely granulation tissue. This was later verified at surgery. (D) This postoperative lateral radiograph reveals that the kyphosis at the thoracolumbar spine has been reduced to 12 degrees. The intervening neural elements have been decompressed with complete corpectomies from T12 through L4. The patient's fibula was used for an autogenous bone graft and supplemented with autogenous cancellous iliac bone graft. The patient remained neurologically intact. At the time of surgery, gross purulence was found, which corresponded with the psoas abscesses identified on the CT scan.

more than two vertebral bodies, a period of bed rest followed by external support in a TLSO is recommended until the fusion becomes consolidated if instrumentation is not used.[196]

Posterior fusion alone, without instrumentation, does not control progressive kyphosis,[393] but it may be performed in addition to anterior strut grafting for added stability (Fig. 87.18).[196,201] If a laminectomy is performed for posterior neural compression, a fusion should also be performed if any of the facets are removed.[186] Progressive kyphosis may occur in the immature spine in spite of a solid anterior fusion. Some authors recommend that a posterior fusion should be performed in addition to an anterior fusion in order to eliminate the risk of increasing deformity.[186,366] Fountain and colleagues[386] found that progressive kyphosis developed in only 3 of 31 children with solid anterior fusions. They recommended performing a supplementary posterior fusion only if progressive deformity is noted.

Anterior grafts may not provide stable fixation, especially in cases in which the graft spans more than two disc spaces.[196] To prevent loss of correction, some authors recommend a two-stage procedure with an instrumented posterior fusion followed by anterior debridement and fusion.[358,394,395] Moon and colleagues[394] reported on 39 adults undergoing the two-stage procedure in the same operative setting or in a delayed fashion. The infection was cured in all cases, and they achieved excellent deformity correction without a prior anterior release. The loss of correction did not exceed 3 degrees. Similarly good results have been reported by other groups from various countries, such as Taiwan, South Africa, India, Kuwait, and Turkey.[396–400]

Güven and colleagues[401] recommend a single-stage posterior approach without any anterior procedure in cases without paralysis, multisegmental involvement, or large abscesses. They reported on 10 patients who underwent the procedure.

All patients had resolution of the infection and the mean loss of correction was only 3.4 degrees. Mehta and Bhojraj[402] have proposed a reasonable classification system for surgical treatment of patients with thoracic spine infection. They propose four treatment groups on the basis of the location of the infection. Group A patients, who had paradiscal or central involvement with no deformity, were treated with transthoracic debridement and strut fusion with no further instrumentation. Group B patients, who had paradiscal or central involvement along with deformity, were treated with transthoracic debridement and strut fusion with posterior instrumentation. Group C patients were similar to group A patients but were too ill to tolerate a transthoracic approach. These patients were treated via a posterior transpedicular decompression and posterior instrumentation. Group D patients, who had only posterior element involvement but no deformity were treated with posterior decompression alone with no fusion or instrumentation. With these treatment guidelines, all their patients did well.[402]

Oga and colleagues[403] studied the risk of using spinal instrumentation despite active TB infection. All 11 of their patients had resolution of the infection and none developed a kyphotic deformity after operation. They also evaluated the adherence properties of *Mycobacterium tuberculosis* and *S. epidermidis* to stainless steel. The *Staphylococcus* heavily colonized the rods and was covered with a thick biofilm, whereas only a few biofilm-covered colonies of *M. tuberculosis* were seen. These findings have prompted the use of anterior instrumentation at the time of initial anterior debridement. Three recent reports reveal that this single-stage technique is efficacious. Benli and colleagues[404] reported on 63 patients from Turkey with involvement of the thoracic and lumbar spines. All patients underwent anterior debridement and decompression with autogenous iliac crest strut grafting. In the same setting, a lateral plate was applied. Kyphosis was corrected by 89% and maintained at an average follow-up of 51 months. Of the patients who had neurologic deficit, 80% had full recovery and 16% had partial recovery. No recurrence of infection was found. Govender reported on 41 patients from South Africa.[405] In these patients, the anterior strut was fresh-frozen allograft. Compared with autogenous rib graft, the fusion rate was slower with allograft. Fusion and remodeling was seen in 33 of 41 patients and partial remodeling with fusion in 8 patients at a mean follow-up of 6.4 years. There were no cases of fracture or late sepsis. Yilmaz and colleagues[406] reported on 22 patients from Turkey with similar results.

The incidence of cord compression with cervical TB spondylitis is more than 40% overall and much higher in adults[348]; therefore, an infection in this region requires aggressive treatment. Hsu and Leong[348] reported excellent results from using the Hong Kong procedure via a Southwick-Robinson approach in conjunction with medical management. With C1–C2 involvement, drainage may be performed by the transoral route with or without a supplementary posterior occiput-to-C2 fusion.[378] Isolated involvement of the arch of the atlas has been treated successfully in one case by chemotherapy, needle aspiration of an abscess, and halo-brace immobilization.[407] Lesions at the craniocervical junction are rare, occurring in only 0.3% to 1% of patients with TB spondylitis.[408] Behari and colleagues[408] reported on 25 patients treated variably for craniocervical infection. They classified patients as grade I, defined by neck pain only and no pyramidal signs; grade II, defined by a neurologic status of independent but with minor disability; grade III, defined by partial disability requiring assistance with activities of daily living; and grade IV, defined by severe disability, including respiratory compromise. Grade I and grade II patients were treated with brace immobilization and medical therapy. Grade III and grade IV patients underwent anterior decompression followed by posterior fusion. Significant improvements in all grades were seen with this strategy.

Lesions between C3 and C7 may be approached through either the anterior triangle[187] or the posterior triangle. The latter may be preferable in some cases because pus often tracks and points in the posterior triangle, making dissection easier.[409] When cervical disease is complicated by kyphosis, staged procedures may be necessary. Strut grafting may be performed at the time of debridement if the deformity can be reduced. If the deformity is too great, traction may be necessary before final anterior grafting. Anterior reconstruction should be followed by posterior stabilization and fusion.[378] Laminectomies are contraindicated in the cervical spine because subluxation and further neurologic deficits may occur.[348]

Complications of surgical treatment are frequent. The operative risk is greatest in elderly patients with extensive disease. In one series, the operative mortality was 2.9% and an additional 1% of the patients died of the disease later.[10] Early complications include wound sepsis, pleural effusion, pulmonary embolism, CSF fistula into the pleural cavity, ileus, progressive neurologic deficit, damage to the ureter, loss of graft fixation or graft fracture, atelectasis, pneumonia, air leak, Horner syndrome, and injury to one of the great vessels.[194] When streptomycin is placed directly on exposed dura, convulsions may occur.[194] Late complications include graft resorption, graft fracture, nonunion, and progressive kyphosis.[185,196,410] Adrenal insufficiency may occur secondary to TB involvement of the adrenal glands. Adrenal suppression should be suspected, especially if calcification is noted on radiographic studies.[316]

Prognosis

With TB spondylitis, the prognosis depends on the age and general health of the patient, the severity and duration of the neurologic deficit, and the treatment selected.

Mortality

Before the advent of chemotherapy, the mortality rate in patients treated nonoperatively was 12% to 43%.[5,314,317,362] The rate in patients with a neurologic deficit was close to 60%.[315] In one study, the mortality rate was found to be linked directly to associated pulmonary involvement: 9.4% of the patients with spine infections and inactive pulmonary TB died in contrast to 51.3% of those who had active pulmonary disease or metastatic spread to other organs.[310] Attempted debridement

of the spine without antibiotic coverage was associated with a mortality rate as high as 71%.[362] With the chemotherapeutic regimens now available, the mortality rate should be less than 5% if the disease is diagnosed early, the patients comply with the regimen, and follow-up is close.[321,322] The mortality rate in patients treated with the Hong Kong procedure in addition to antibiotics is directly proportional to the severity of the neurologic deficit. In one study, among patients undergoing operation, the mortality rate was 2% in those with mild to moderate neurologic deficit, 6% in those with moderate neurologic deficit, and 11% in those with a severe deficit.[321]

Relapse

The relapse rate in patients treated with the antibiotics available between 1952 and 1962 was 21%.[312] With current medical regimens and close follow-up, the rate should approach zero.[322]

Kyphosis

Progressive kyphosis is a significant cosmetic deformity, but more important is the fact that it may cause a neurologic deficit or respiratory and cardiac failure due to restriction of pulmonary function (Fig. 87.19). Rajasekaran and Soundarapandian reported the results of a prospective controlled study performed in collaboration with the Medical Research Council.[196] The treatment groups included chemotherapy alone for either 6 or 9 months or radical surgery in combination with 6 months of chemotherapy. Ninety patients (98% of the study group) were followed for a minimum of 6 years. Those who underwent nonoperative treatment had a statistically significant higher rate of kyphotic deformity than those treated surgically. There was a direct correlation between the final angle of the deformity and the amount of initial loss of vertebral body. The angle increased severely in 10% of the surgical group and in 32% of the nonsurgical group. Severe deformity in the surgical group was related to graft failure.

To predict the angle of deformity expected, the researchers devised a formula[410]; $Y = a + bX$, in which Y is the final angle of the deformity, X is the amount of initial loss of vertebral body, and a and b are constants (5.5 and 30.5, respectively). With their formula, the final angle of the gibbus was predictable, with 90% accuracy in the patients treated nonsurgically.[410] If the predicted angle is excessive, early operation should be considered.

Rajasekaran and Soundarapandian[196] provided additional information on 81 patients treated by the Hong Kong operation and followed for a minimum of 8 years; 19% of these patients had an increase in the gibbus angle of up to 20 degrees, and in 22% it was more than 20 degrees. The major risk factor for increasing deformity was extensive involvement of the vertebral bodies, which resulted in a large defect after debridement and necessitated a graft spanning more than two disc spaces. Patients with lesions of the thoracic vertebrae and those with marked kyphosis preoperatively were also more likely to have progression. These authors concluded that when the length of the graft exceeds two disc spaces, surgical treatment should be augmented by prolonged bed rest, bracing, or posterior arthrodesis. Rib strut grafts were used in many of the patients with progressive deformities, and it was proposed that iliac crest graft may be preferable in patients with large defects.[196] Iliac crest grafts were used exclusively by Hodgson and Stock[188] and may explain the low incidence of progressive kyphosis in their series. Others also have recommended the use of iliac crest grafts rather than

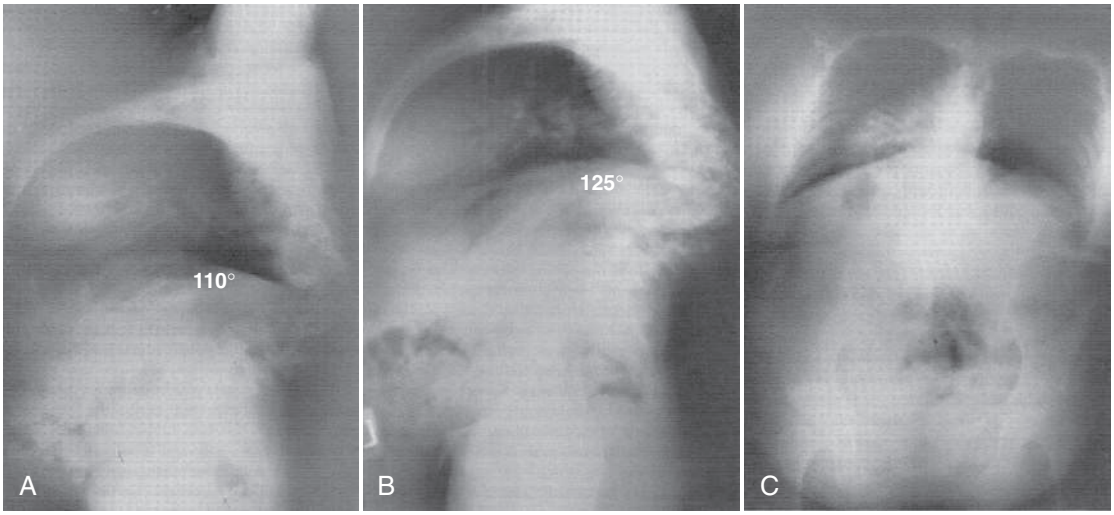

FIG. 87.19 This young adult patient was known to have had tuberculosis of the spine as a child. At this time, she presented with a history of spine pain that was relieved with bed rest and aggravated by increasing activities. (A) At the time of first presentation, the patient was seen to have a kyphosis of 110 degrees. It is apparent that she has had extreme shortening of the trunk due to the combination of kyphosis and vertebral body destruction. (B) Over a period of 5 years, it can be seen that the patient has had an increase in the kyphosis from 110 degrees to 125 degrees. At this point, she remained neurologically normal. (C) This anteroposterior radiograph of the thoracic and lumbar spine is consistent with the gross deformity seen on the lateral radiographs and obvious on clinical inspection. This is the type of deformity that is best prevented with surgical intervention.

rib struts.[185] In patients with small defects, however, the availability of rib graft and avoidance of additional donor site problems make rib grafts a more attractive alternative.

In addition to graft failure, children are at risk of progressive deformity after anterior debridement and fusion because of persistent growth posteriorly and growth retardation anteriorly. Close follow-up is necessary and a supplementary posterior fusion should be performed if progressive kyphosis occurs.[201,386] A study comparing the radiographs of 117 children operated on for spinal tuberculosis at the age of 2 to 6 years showed that anterior fusion alone leads to greater kyphotic angulation than a posterior fusion, a combined anterior and posterior fusion, or anterior debridement alone.[411]

Neurologic Deficit

Patients with neurologic deficit may improve spontaneously without surgery or chemotherapy[317,341] or with chemotherapy alone,[12,14,312] but in general the prognosis is improved with early surgery.[201,285,322] In one study, 94% of neurologically impaired patients recovered normal function after anterior decompression; only 79% totally recovered after nonoperative management.[322] When patients with a neurologic deficit were operated on only if they failed to respond to an initial course of antibiotics, the overall success rate was 78.5%.[14] As expected, patients with less severe neurologic deficit and those who were treated early after the development of neurologic signs had a better outcome.[14,308,311,319,321,412] In one study of 64 patients, only 48% of those with severe neurologic deficits recovered, whereas 83% of patients with moderate deficits recovered; only 4 of 10 patients with late-onset paraplegia had a satisfactory recovery.[321]

Patients with paraplegia of long duration should be treated aggressively. Hodgson and colleagues[319] found that the chances of complete recovery are good after surgical treatment, although it may take longer for them to recover. They documented recovery in a patient who had had a neurologic deficit for 5 years.[319] In patients with late-onset paraplegia, the response to operation is faster, better, and safer in patients who have active disease than in those with healed disease and a hard, bony ridge compressing the cord.[342] Overall, most patients with a neurologic deficit recover within 6 months, but those who have direct involvement of the meninges (pachymeningitis) may recover more slowly.[319] Govender and colleagues[308] found that patients who have an atrophic cord as seen on CT myelography preoperatively usually do poorly after decompression. Patients with cervical spine involvement are at high risk of neurologic deficit but do well after anterior debridement and fusion.[348]

The only indication for laminectomy is posterior cord involvement. In 19 patients with posterior element disease undergoing laminectomy, 16 had good results and 3 had fair results in one series. Six of 10 patients undergoing laminectomy for epidural tuberculomas without bony involvement had good results, 3 patients had fair results, and 1 had a poor result.[332] The overall prognosis with posterior spinal TB is better in those patients who have less severe neurologic deformity of shorter duration, slower progression, and are younger and in good general health.[335] In general, children have a better prognosis than adults.[185,201,318,319]

Fusion

Bosworth and colleagues[315] thought that a solid fusion was essential for permanent recovery from TB spondylitis. They described five patients who initially recovered but became paralyzed again with the development of pseudarthrosis. These patients recovered once again after repair of the pseudarthrosis.[315]

Spontaneous bony fusion occurred in 27% of patients treated with bed rest in a plaster shell, without surgery or chemotherapy.[314] With chemotherapy alone, spontaneous fusion occurred in 24% at 18 months and in 36% at 36 months.[366] In the prospective study by the Medical Research Council, the fusion rate in patients treated by the Hong Kong procedure was 28% by 6 months, 70% by 12 months, 85% by 18 months, and 92% at 5 years. The corresponding values for the patients undergoing debridement without fusion were 3%, 23%, 52%, and 84%, and the fusion rates in patients treated by ambulatory chemotherapy alone were 9%, 26%, 50%, and 85%, respectively.

Actinomycosis

Actinomyces israelii is an anaerobic, slowly growing, filamentous, gram-positive bacterium. *Actinomyces* was originally discovered in 1877 as a genus containing the causative agent of actinomycosis in cattle. Thereafter, in 1891, *A. israelii* was first isolated from a lung abscess by Wolff and Israel.[413] Since then, other *Actinomyces* species and related bacteria have been isolated and are believed to be involved in a wide variety of human infections, most commonly linked to *A. israelii*. A number of other species have also been involved in human infections. These include *Actinomyces meyeri, Actinomyces graevenitzii, Actinomyces turicensis, Actinomyces gerencseriae, Actinomyces odontolyticus, Actinomyces cardiffensis, Actinomyces radingae, Actinomyces naeslundii*, other *Actinomyces* species, and a closely related species, *Varibaculum cambriensis*.[413] It is postulated that the coexistence of other organisms may assist anaerobic growth by reducing the oxygen tension in the local environment.

The diseases it causes mimic those produced by fungi. The organism, an endogenous, oral saprophyte, requires trauma, surgery, or other infection to penetrate the mucosa. Once *Actinomyces* invades the tissue of a disrupted mucus membrane, it slowly expands and develops into an abscess. It is noted for causing chronic suppurative infections with external sinuses that discharge distinctive aggregates of organisms ("sulfur granules").[306,414] Infections involving *Actinomyces* frequently are polymicrobic, including *Fusobacterium, Bacteroides, Capnocytophaga, Eikenella, Staphylococcus, Streptococcus,* and *Enterococcus* species.[414]

The lesions are characterized by hard, fibrotic walls with granulation tissue surrounding loculations of pus. Sinus tracts extending to the skin or into other organs are commonly seen in more chronic infections.[414] Classic actinomycosis presents as an oral-cervicofacial lesion, known as "lumpy jaw" lesion,

which occurs in approximately 55% of actinomycosis cases.[415] Infection occurs at other sites and is manifest as thoracic (15%), abdominal and pelvic (20%), musculoskeletal (rare), and central nervous system (rare) disease.[82]

Several risk factors for the development of actinomycosis exist. It occurs more commonly in males, but there is no clear explanation for this. Other risk factors may include poor oral hygiene and the use of intrauterine devices. In addition, immunocompromise and other conditions such as diabetes, alcoholism, infections with immunosuppressive agents (e.g., HIV), and steroid use are thought to predispose individuals to the development of actinomycosis.[413,417]

Before 1950, vertebral actinomycosis was the most common form of osseous involvement. Vertebral involvement is usually secondary to an infection at an adjacent tissue. Hematogenous spread is less common for actinomycosis. Vertebral infection occurs by extension from retropharyngeal, mediastinal, or retroperitoneal soft tissue abscesses. Unlike *M. tuberculosis,* the organism has a predilection for the cervical and thoracic spine from retropharyngeal or pulmonary spread.[418,419]

Actinomycosis may be difficult to differentiate from mycobacterial and nocardial infections. Accurate diagnosis is essential because the treatment regimens differ markedly from these other organisms. The organism must be isolated from an anaerobic culture, which may take up to 21 days for positive culture growth. As in tuberculosis, the radiographs may demonstrate prominent paraspinal abscesses and involvement of several vertebral bodies. Distinctive features include simultaneous vertebral body and posterior element involvement, spread to adjacent ribs, periosteal new bone formation outlining the vertebra, and a mixture of lytic and sclerotic changes that may produce a honeycomb appearance of the bone.[82] The vertebral body collapse and disc space narrowing that are common in TB are uncommon in actinomycosis.[82]

Epidural abscesses may occur by extension from a vertebral source or through an intervertebral foramen from a cervical, pulmonary, or abdominal focus.[414] The dura generally resists penetration, but neurologic deficit may occur by epidural compression.[414] Before the introduction of penicillin, most cases of actinomycosis were fatal. The current treatment is still penicillin in large doses given over extended periods in association with abscess drainage and excision of sinus tracts when necessary.[414] Other first-line antibiotics that are effective are tetracycline, erythromycin, clindamycin, and the cephalosporins.[420,421] Long-term treatment for up to 6 months is common.[419] When response to penicillin is poor, the possible reasons include an undrained abscess, polymicrobial infection, and perhaps bacterial resistance. Overall, the treatment of actinomycosis infection results in good outcomes, even when there is extensive involvement. In a recent case report of a patient with severe mediastinal, paraspinal, and thoracic epidural involvement, limited debridement and laminectomy combined with antibiotics yielded excellent results.[422]

Nocardiosis

Nocardia asteroides is the most common human pathogen in this family of aerobic, weakly gram-positive bacteria. It is a natural soil saprophyte often found in decaying organic matter.[307] Infection most commonly occurs through the respiratory tract, although other modes of infection may occur. This infection is now seen most frequently in immunocompromised hosts. The predisposing factors are long-term corticosteroid use, chronic lung disease, hematologic malignancies, and organ transplant patients. Renal transplant patients are particularly susceptible, with a reported incidence as high as 5%.[423,424] Nocardiosis may initiate a chronic granulomatous response, but more frequently the histologic features are suppurative necrosis and abscess formation, typical of pyogenic infections.[414]

The most frequent primary site is the pulmonary system, but dissemination occurs frequently to the central nervous system, skin and subcutaneous tissues, eyes (especially the retina), kidneys, joints, and heart in up to 56% of cases.[425,426] Dissemination to the brain, meninges, and spinal cord occurs in 23%, but hematogenous involvement of the vertebrae is uncommon.[427] In a recent literature review and case report, Graat and colleagues[428] found only 11 cases of *Nocardia* spinal osteomyelitis reported in 40 years. Epidural spinal cord compression from vertebral osteomyelitis has been reported.[429,430]

Diagnosis of nocardiosis can be difficult because there are no pathognomonic signs or symptoms. Historically, phenotypic characteristics in conjunction with antibiotic susceptibility patterns have been used for diagnosis. These tests suffered from poor reliability. Current methods of identification rely on gene sequencing, particularly of the 16S rRNA gene, which has become the gold standard.[431] Rapidly growing bacteria in mixed cultures may obscure the growth of *Nocardia* species, and the laboratory should be alerted if *Nocardia* infection is suspected.

Sulfonamides, in conjunction with appropriate surgery, have been the mainstay of treatment since 1944. Many other antibiotics—including minocycline, trimethoprim-sulfamethoxazole, amikacin, imipenem, ceftriaxone, cefuroxime, and cefotaxime—have been used either alone or in combination. The most common first-line therapy is cotrimoxazole, with imipenem and amikacin as second-line therapies.[432,433] The optimal duration of therapy is uncertain but, because of the possibility of relapse, treatment is often continued for many months after apparent cure. A poor response to treatment may be related to the presence of a second pathogen.

Brucellosis

Human brucellosis remains an important public health problem in most developing countries, including those of the Mediterranean, Balkans, Middle East, Central Asia, and Central and South America. The occurrence is high when there is ineffective eradication of brucellosis in animals.[434–436] Brucellosis is caused by an aerobic, gram-negative coccobacillus commonly found in domestic animals and transmitted to humans by direct contact, by ingestion of contaminated products, and possibly, by inhalation of aerosols.[306,437,438] The disease affects approximately 500,000 persons per year worldwide. Its incidence is decreasing throughout the United States, primarily because of pasteurization of milk. In 1976,

$75.6 million were spent to maintain the brucellosis control program and the incidence in the United States is now less than 0.5 cases per 100,000 population.[439] The causative organisms include *Brucella abortus* (cattle), *Brucella melitensis* (goats), *Brucella suis* (swine), and *Brucella canis* (dogs).

Brucellosis mainly affects the musculoskeletal system, with the spine as the most common location.[440,441] The infection spreads via lymphatics and blood vessels and produces acute systemic infection, as well as chronic relapsing disease (undulant fever). Involvement in joints tends to occur during acute infections, whereas spinal manifestations tend to occur during chronic infections.[436,442,443]

The clinical presentation of patients with brucellosis varies widely. After an incubation period of days to several weeks, low-grade fever, weakness, headaches, lymphadenopathy, hepatosplenomegaly, and generalized musculoskeletal complaints may develop insidiously.[306,444] Approximately one-third of the patients have a more fulminant illness with acute onset of systemic toxicity.[445] Some infections are asymptomatic initially. After the initial illness, which may last for several days to weeks, relapses occur in about 5% of patients. Relapses seldom occur in patients who receive appropriate treatment and are often the result of focal suppurative complications, such as spondylitis.[445] The classic feature of an undulating fever is not present in most cases.[437,445] Late complications may affect almost any organ system and include septic arthritis, central nervous system involvement, osteomyelitis, and spine infection. The statistics on brucellosis vary widely depending on the source of the information. Between 11% and 80% of patients with brucellosis have bone and joint involvement and, of these, 6% to 54% have spinal column involvement,[438,444–447] most commonly in the lumbar spine.[306,437] Localized spine pain is the earliest sign of spondylitis.[437] Of those with spondylitis, between 10% and 43% have some degree of neurologic compromise,[438,444] and in 10% to 20%, a paraspinal abscess develops. This may occur with other system signs such as fever, hepatomegaly, and splenomegaly. Osteoarticular infections have a genetic predisposition and are associated with HLA-B39.[436,442,443]

In one series of 593 patients with brucellosis, neurologic deficits occurred in five of the patients with cervical spondylitis, two of the patients with thoracic involvement, and nine of the patients with lumbar disease. The patients with cervical and thoracic disease had significantly more paraspinal and epidural abscesses than the patients with lumbar infection. Patients with cervical spine involvement had a much worse prognosis than those with disease in other areas.[446]

Blood cultures are positive in less than half the cases overall but are positive in 70% of patients with acute *B. melitensis* infection.[437,438] An agglutination reaction with a *Brucella* antibody titer of 1:160 or greater is presumptive evidence of infection, but an increasing titer is a more helpful sign of active infection.[437,438] If *B. canis* infection is suspected, a specific agglutination test must be used because the standard test does not react with antibodies against *B. canis*. When blood cultures are combined with serologic tests, the diagnostic yield is high. Colmenero and colleagues[448] reported on 105 cases of brucellar spondylitis. In only five cases (4%) was a bone biopsy necessary for diagnosis. This is in contrast to pyogenic and TB spondylitis, for which bone biopsies were required in 50% and 75%, respectively, to confirm the diagnosis.

The characteristic radiologic features of brucellar spondylitis include predilection for the lower lumbar spine, intact vertebral architecture despite evidence of diffuse vertebral osteomyelitis, disc space involvement, minimal associated paraspinal soft tissue involvement, and absence of gibbus deformity.[438,449,450] The facet joints are often involved in brucellar infections, which can be readily seen on gadolinium-enhanced MRI.[451] Bone destruction is less severe than in TB spondylitis.[452] Bone scintigraphy is not helpful in differentiating brucellar from tubercular spondylitis. The MRI findings are similar in the two, except that tuberculosis often produces more severe changes with more deformity and abscess formation.[450]

The current World Health Organization treatment of choice for brucellosis is doxycycline at 200 mg/day and rifampin at 600 to 900 mg/day for at least 6 weeks.[445] A randomized, double-blind study comparing doxycycline plus rifampin with doxycycline plus streptomycin for 45 days showed that the latter was more effective for treatment of spondylitis.[453] Some authors recommend that treatment should be continued for at least 3 months in cases of spondylitis because high relapse rates have been reported with shorter courses.[438] After single-agent therapy with tetracycline, streptomycin, rifampin, or trimethoprim-sulfamethoxazole, the relapse rates are between 5% and 40%.[445] Response to treatment is monitored with repeated agglutination tests. Lifeso and colleagues[438] recommend continuing antibiotic therapy until the titer is 1:160 or less and there is clinical and radiographic evidence of resolution. Surgery is usually unnecessary.[438] However, Nas and colleagues[454] reported on 11 cases from Turkey: 8 patients required surgical decompression to alleviate neural compression.

Fungal Infections

Some fungi are normal commensals of the body and cause opportunistic infections (e.g., *Candida* and *Aspergillus*). Other fungi are endemic and are limited to specific geographic areas. The two most common endemic fungi that give rise to spinal infections are *Coccidioides immitis* and *Blastomyces dermatitidis*. The former is endemic to parts of the southwestern United States (especially the San Joaquin Valley in central California), Central America, and parts of South America.[306,455] The fungus exists in its mycelial phase in the soil of desert areas. Humans become infected most commonly by inhalation of the spores (conidia) or, less commonly, through abrasions of the skin. Person-to-person transmission is rare. *Blastomyces dermatitidis* is a dimorphic fungus endemic in the southeastern and south central states, especially those bordering the Mississippi and Ohio River basins, and in the Midwestern states that border the Great Lakes. Cases have also been reported in Central and South America, Africa, and the Middle East.[306] *B. dermatitidis* is considered to be an inhabitant of soil, and infection occurs by inhalation of conidia.

Cryptococcus, *Candida*, and *Aspergillus* are found worldwide. *Cryptococcus neoformans* is found in the soil and in pigeon feces. The disease is the fourth most common infection in HIV-infected patients and is found in 1% to 5% of organ transplant recipients. *Candida* species are part of the normal flora and are commonly found on the skin and in the gastrointestinal (GI) tract. These sites are believed to be the most likely ports of entry into the bloodstream. *Candida* species are also commonly found in sputum, the female genital tract, and the urine of patients with indwelling urinary catheters. Human-to-human transmission is possible, but most infections are endogenous.[456–458] *Aspergillus* species are ubiquitous saprophytic fungi that produce numerous small spores (2–4 μm in diameter). The small size of the spores allows for ready dispersion onto air currents from contaminated air-handling systems and deposition into human lung alveoli.[459] Spores are frequently found in water, soil, decaying vegetation, hay, and grains.

Fungal infections of the spine are uncommon. They frequently occur in immunosuppressed hosts with multiple medical problems. Often, there is a long delay in diagnosis, mainly because other medical conditions may mask the diagnosis and because fungal spondylitis characteristically runs an indolent course.[460] In one series of 11 cases, the source of infection was hematogenous seeding from septic episodes in five, postoperative osteomyelitis in three, local extension from an adjacent fungal infection in two, and direct traumatic implantation in one.[460] The incidence of fungal infections has risen markedly in recent years. Several factors have contributed to this increase. These include greater use of immunosuppressive drugs, prolonged use of broad-spectrum antibiotics, widespread use of indwelling catheters, and AIDS.

Because presenting features can be nonspecific, mycotic spine infections can be difficult to recognize in the early stages. In addition, diagnostic and susceptibility testing methods for fungi have not progressed as quickly as those for bacteria. As such, institution of appropriate treatment is often delayed, which can lead to poor patient outcome. Definitive diagnosis rests on the evaluation of a tissue specimen. Biopsies must be evaluated with fungal stains as well as cultures because the latter may be negative or take several weeks or months before identification is possible. Closed biopsy was reported to be positive in only 50% of cases, whereas open biopsy was positive in all cases in the series of Campbell and colleagues.[460]

Laboratory Studies

A rise in inflammatory markers—such as white cell count, ESRs, and CRP levels—can alert the physician to the possibility of a spinal infection. However, these are not specific for fungal infections. Antibody tests are seldom helpful in the diagnosis of spinal infections due to ubiquitous fungi such as *Candida* and *Aspergillus*. Because these are sometimes normal commensals, previous exposures can elicit antibody formation and reduce the sensitivity and specificity of these tests. Several tests are commercially available. The Platelia *Aspergillus* assay (Bio-Rad, Marnes-la-Coquette, France) is a commercial kit with relatively high sensitivity to *Aspergillus* galactomannan antigen.[461] This test is one of the most sensitive methods currently available for detection of this fungus. The Platelia *Aspergillus* assay, however, has a false-positive rate ranging from 1% to 18%.[462] Several commercial kits are also available for detection of *Candida* species antigens. These also have limitations in sensitivity or specificity, or both.[462] In general, repeated serum sampling can improve sensitivity for antigen detection tests.[463] Detection of cryptococcal capsular polysaccharide antigen by latex agglutination procedure is a rapid serodiagnostic test. Rheumatoid factor, however, can also cause agglutination, leading to a false-positive result. The PREMIER Cryptococcal antigen assay (Meridian Diagnostics) does not react with rheumatoid factor, gives fewer false-positive reactions, and is helpful in diagnosis of the disease.[464]

The detection of fungal nucleic acid via PCR holds promise as a diagnostic tool. So far, the technology has demonstrated high sensitivity and specificity for detecting isolates of *Candida* and *Aspergillus*.[465,466] The technology not only allows for the rapid identification and subtyping of fungi but it also enables monitoring of clinical progress.[467–470] Disadvantages include the inability to distinguish between normal colonization and active infection. A false-positive result can also be obtained from specimen contamination due to the high sensitivity of the PCR assay.[462]

Histology

Biopsy and histopathologic assessments are critical in the diagnosis of fungal infections. Accurate diagnosis is dependent on the skill of the pathologist and adequacy of organisms received in aspirates or tissue biopsies. Further identification can be aided by other methods, such as the carbohydrate-assimilation test for *Candida* and the phenol oxidase reaction for *Cryptococcus*. It is important that microscopic appearances are correlated with microbiology findings as well as other tests for specific host antibodies, fungal antigens, and fungal nucleic acids.

Imaging Studies

Radiographic findings in mycotic spinal infections resemble those of TB: relative sparing of the disc, anterior involvement of the vertebral body, and development of large abscesses (Fig. 87.20). There may be less frequent invasion of adjacent ribs or involvement of the posterior elements and formation of draining sinuses.[82,306] Certain patterns do occur more commonly with certain fungal infections. For instance, paravertebral soft tissue swelling with involvement of the posterior structures is more common in late *Coccidioides* infections (Fig. 87.21).[471] With *Blastomyces,* collapse and gibbus deformity tend to be seen more commonly.[82,306,472] In *Cryptococcus,* lytic lesions within vertebral bodies can resemble those in coccidioidomycosis or the cystic form of TB with discrete margins and surrounding abscess formation (Fig. 87.22). The infection may also appear as a permeative lesion of a single vertebra with collapse.[82] The degree of bone involvement is often advanced compared with a patient's symptoms.

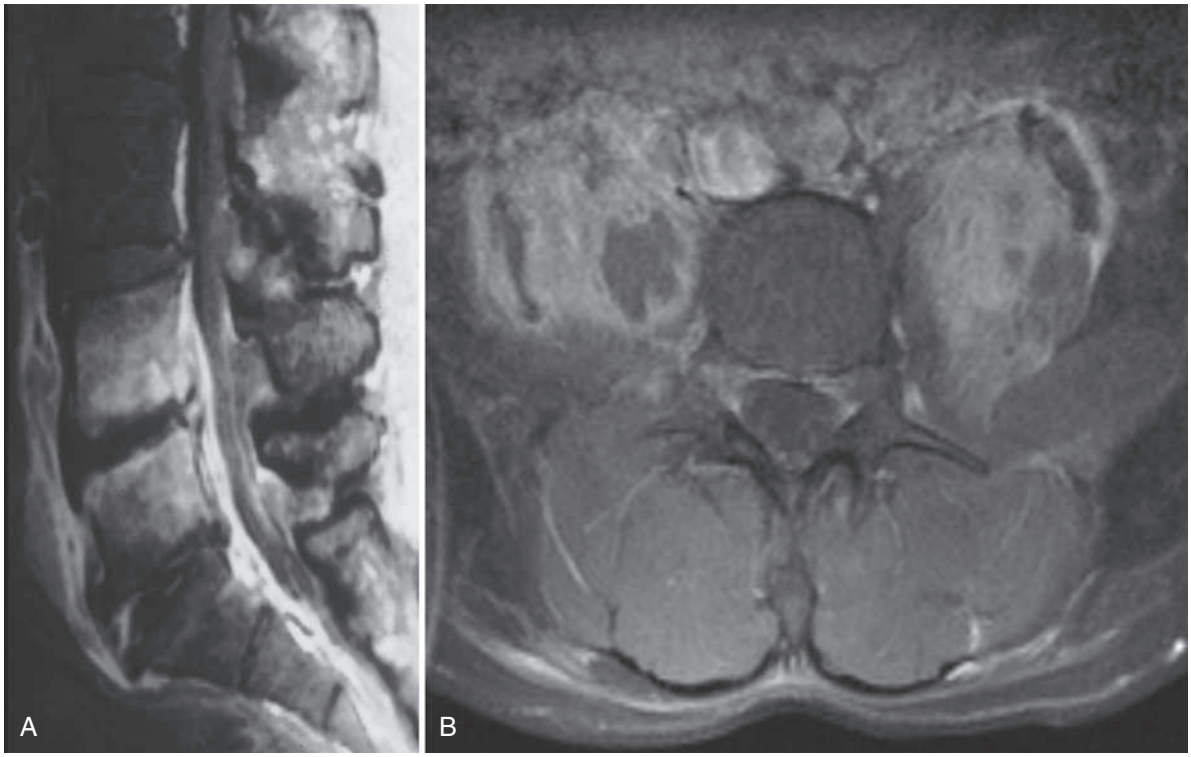

FIG. 87.20 (A) Sagittal and (B) axial gadolinium-enhanced magnetic resonance images of L4–L5 *Aspergillus* infection.

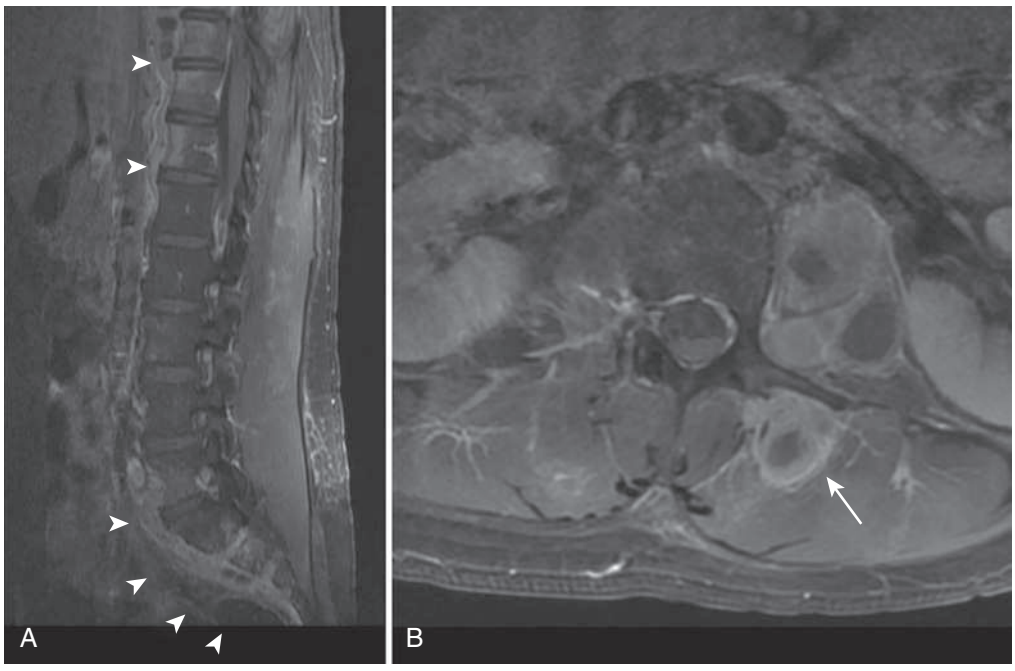

FIG. 87.21 (A) Sagittal and (B) axial gadolinium-enhanced magnetic resonance images showing diffuse, multifocal infection of the lower thoracic spine and sacral region (*arrowheads*) along with large paraspinal abscesses of *Coccidioides immitis* infection. The arrow shows extension into posterior compartment.

In fungal vertebral osteomyelitis, CT and MRI are effective in determining the extent of disease spread. In contrast to pyogenic vertebral osteomyelitis, fungal infections often spare the disc.[473] These changes, however, can be seen in other causes of nonpyogenic vertebral osteomyelitis, such as TB, and are not specific to fungal vertebral osteomyelitis. The CT appearance is often one with holes in the bone, punctuated with small irregular bone islands, contrasted with tumors where bone is completely gone over segments of the vertebra.

Scintigraphic studies can also be helpful in identifying regions of infection, but they cannot differentiate among the various causes of vertebral osteomyelitis. Radionuclide scans

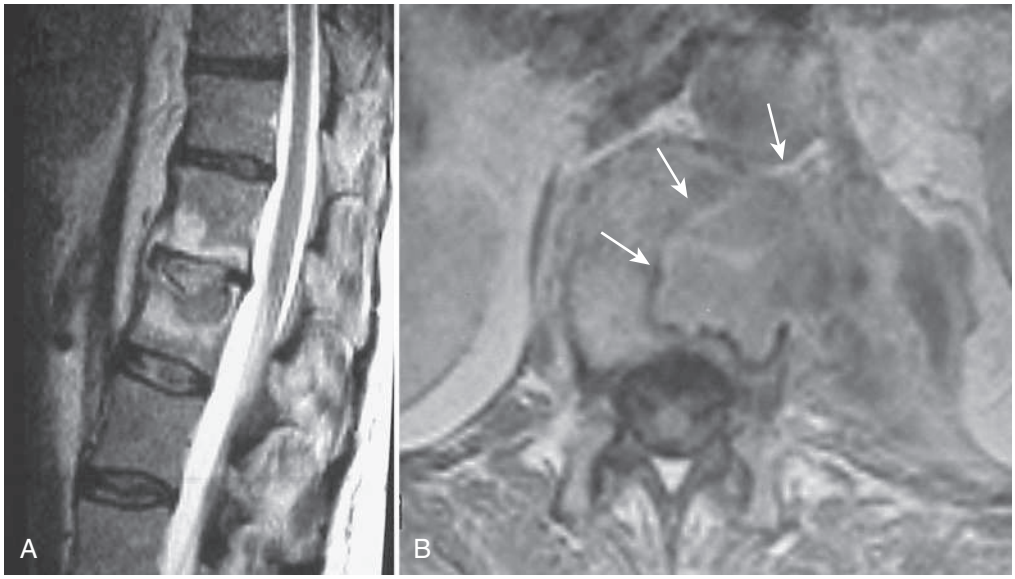

FIG. 87.22 (A) Sagittal and (B) axial gadolinium-enhanced magnetic resonance images of T12–L1 *Cryptococcus neoformans* infection. Vertebral body involvement shows discrete margins along with paraspinal abscess formation (*arrows*).

with technetium-99m compounds are frequently abnormal before changes are seen on plain radiographs and may be useful in the early stages of infection. Isotope uptake occurs in any bone-forming process and is nonspecific for infection. Indium-111-labeled white blood cells are more specific for infection and can be used to differentiate tumor from abscess. These tests are less important since the advent of MRI.

Treatment

The treatment of fungal infection involves correcting any underlying medical conditions that may compromise wound healing or immune defense capabilities. Antifungal agents are the mainstay of treatment, but surgery is often necessary in cases of abscess formation, spinal instability, developing neurologic deficits, or sepsis. The use of newer antifungal medications, including azoles, has improved patient survival rates.[474] The approach should be based on the pathologic features encountered, but in general anterior debridement and stabilization are preferred.[460] The prognosis for patients with fungal vertebral osteomyelitis depends on the organism and the host. As with bacterial infections, it appears that patients with diabetes mellitus or neurologic deficits have a poorer prognosis.[460]

Nonoperative Treatment

Historically, nonsurgical treatment has been met with varied success in the management of fungal spinal infections. Successfully treated patients experience resolution of spine pain and often fuse spontaneously. Nonoperative treatment includes the institution of antifungals, spinal immobilization (cast or bracing), and early ambulation. Consulting an infectious disease specialist is advised because treatment is often prolonged and antifungal agents may be toxic. It has been shown, however, in a rabbit model that both amphotericin B and the lipid formulations of amphotericin B have poor penetration into the intervertebral disc when given IV.[475]

Amphotericin B is a broad-spectrum antifungal that is often used as a first-line agent for fungal spinal infections.[476] It is also recommended in cases of *Blastomyces* that are nonresponsive to oral azoles. It must be administered intravenously, which can be inconvenient, and it possesses nephrotoxicity. The newer lipid formulations are significantly less toxic.

The azoles (e.g., itraconazole, ketoconazole, fluconazole, miconazole) are alternative agents for fungal osteomyelitis.[476–480] In the same rabbit model study discussed earlier, fluconazole had excellent penetration into the intervertebral disc.[475] On the basis of these data, fluconazole might be a better first-choice antifungal agent when a fungus is sensitive to both amphotericin B and fluconazole. The potential side effects of fluconazole are also significantly less than amphotericin B.[475] Itraconazole and ketoconazole are the first-line agents for spinal infections due to *Blastomyces*.[481] Echinocandin and caspofungin are newer promising drugs that are capable of providing higher availability at infected sites with better long-term tolerability.[482,483]

Surgical Treatment

Indications for surgical intervention include relief of spinal cord or nerve root compression, correction of instability and/or deformity, and management of overwhelming infection. Lack of identification of organisms on blood culture, serology, and needle aspirates may necessitate open surgical biopsy. Due to the relative scarcity of reported cases in the literature, the optimal method of surgical treatment is difficult to define. In general, it is accepted that infected tissue should be thoroughly debrided and existing or anticipated spinal instability addressed.

Posterior Decompression Without Fusion

This method of treatment may be advisable only in isolated posterior epidural collections without anterior vertebral element involvement. This is relatively uncommon. In general, when the pathology is located in the anterior vertebral elements, posterior decompression fails to address the problem and may further contribute to instability by removing uninvolved supporting tissue.

Posterior Decompression With Fusion and Instrumentation

Aggressive vertebrectomy via a posterior approach can be challenging and has the potential for anterior column instability. Debridement of the anterior vertebral elements may be accomplished posteriorly through variations of the extracavitary or costotraversectomy approaches. An important advantage of this approach is that it avoids entering the thoracic cavity. The disadvantages are the limited exposure and visualization of the anterior thecal sac.[460] There is also the risk of rupturing a mycotic aneurysm, with little or no ability to control it. Anterior graft placement can also be difficult. Additionally, there is the dilemma of placing instrumentation during the initial surgical debridement close to a contaminated wound. If there is adequate anterior column support, posterior instrumentation and autograft fusion will provide spinal stability and prevent sagittal plane deformity.

Anterior Decompression and Fusion With Posterior Stabilization

Successful vertebrectomy and fusion using anterior strut grafts and posterior instrumentation for fungal vertebral osteomyelitis has been described.[484,485] This can be performed under the same anesthetic, with little risk of infection from the fungal infection posteriorly. The anterior approach also provides the best opportunity of a thorough debridement. In most cases, posterior stabilization is required (Fig. 87.23). This type of treatment is highly successful in the treatment of pyogenic and mycobacterial spinal infections. The effectiveness for the treatment of fungal infections appears to be modest on the basis of the limited information available to date.

Percutaneous Techniques

Percutaneous suction/irrigation systems with adjunctive percutaneous external spinal fixation have been described for the treatment of bacterial vertebral osteomyelitis.[224] These procedures may be alternatives to open instrumentation for disease located between T3 and S1. At present, there are no published cases of fungal spinal infections treated in this manner. Percutaneous techniques in fungal spinal infections have been limited to tissue sampling and for performing therapeutic aspiration.[486,487]

Coccidioidomycosis

Coccidioides immitis infection was first described in 1892 by an Argentinian medical student, Alejandro Posadas.[488] The disease, often referred to as "valley fever," is localized to geographic regions with arid soil due to high temperatures and low humidity.[489] *C. immitis* is endemic in parts of the southwestern United States (especially the San Joaquin Valley in central California), Central America, and parts of South America.[306,455] Disease prevalence is increasing with the rise in tourism to those countries. The fungus exists in its mycelial phase in the soil of desert areas. The saprophytic cycle includes the formation of spores that become airborne. Humans become infected most commonly by inhalation of the spores or, less commonly, through abrasions of the skin. The spores swell and become spherules, which reproduce by the formation of internal spores known as "endospores." When the spherule ruptures, endospores are released and each may develop into a new spherule, completing the parasitic cycle. The saprophytic cycle can begin again only when the spores are returned to the soil. The disease is not contagious because person-to-person transmission can occur only in rare circumstances when the fungus reverts from its tissue phase to its airborne form in contaminated secretions.[490]

The primary focus of disease is the lung, but infection may become disseminated in 0.5% of the cases; osseous manifestations occur in 10% to 50% of those with disseminated disease.[491] Histologically, coccidioidomycosis causes a granulomatous tissue reaction resembling TB. Extrapulmonary disease is uncommon if the infection has been quiescent in the year after the initial pulmonary infection, unless the host is immunocompromised.[490] Bone lesions are multifocal in 40% of cases overall and in most cases of vertebral involvement. The bones most commonly involved are the skull, metacarpals, metatarsals, spine, and tibia. Spine infection occurs in 10% to 60% of patients with osseous involvement.[82]

Serum immunoglobulin M precipitins can be detected by a variety of methods. These antibodies occur in 75% of cases 1 to 3 weeks after onset of symptoms of primary infection, and they disappear within 4 months. Skin tests with coccidioidal antigens are positive within 3 weeks after the onset of symptoms. Anergy is common in disseminated coccidioidomycosis; therefore, skin testing is unreliable in systemic disease. A negative skin test in a patient with a primary infection suggests that dissemination will occur.[490] An increased complement-fixing antibody titer indicates disseminated disease. Sixty-one percent of patients with disseminated disease have titers of at least 1:32, and 41% have titers of at least 1:64. In contrast, 95% of patients without disseminated disease have titers below 1:32, and 99% have titers below 1:64.[490]

Spine lesions are frequently multiple (Fig. 87.24) and generally lytic.[82,306,492] Filipinos, African Americans, pregnant women in their third trimester, young children, and elderly individuals are at higher risk of developing disseminated disease.[493] The entire vertebra including the arch is often involved, but the disc is usually spared. Paraspinal masses are frequent, and contiguous rib involvement may be seen.[492] Vertebral collapse occurs late.[492] MRI of coccidioidal spondylitis is nonspecific. Infection may involve a single level, multiple levels, the surrounding soft tissues, and the disc space.[494] The disc may become narrowed; however, the extent of disc space

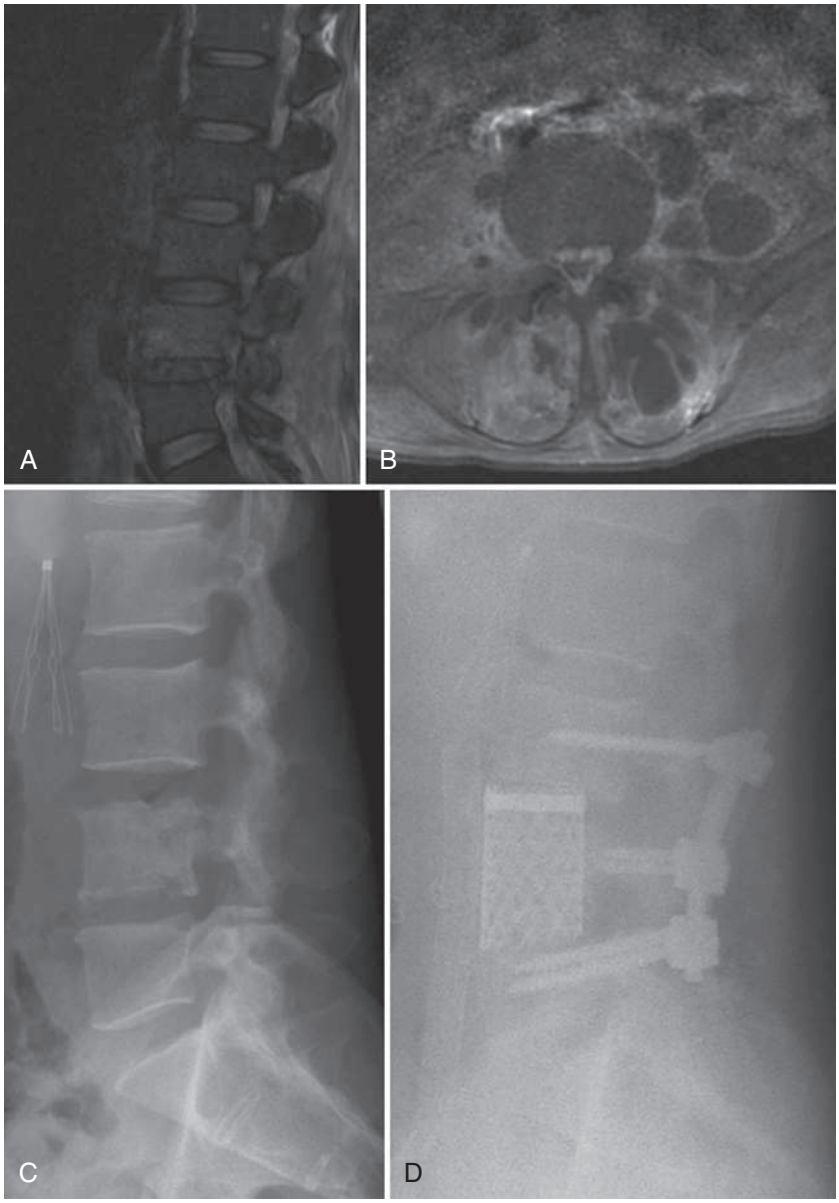

FIG. 87.23 (A) Sagittal and (B) axial gadolinium-enhanced magnetic resonance images of L4 fungal infection showing relative sparing of the disc space along with large multiloculated abscesses in both the anterior psoas compartment and posterior spinous erectae compartment. (C) Plain radiograph shows bony changes of the L4 vertebral body. (D) Surgical treatment included staged debridement of the posterior paraspinal abscesses followed by debridement of the left psoas abscesses, L4 corpectomy, and strut grafting with posterior instrumented fusion.

changes is disproportionately less than the extensive vertebral body and adjacent soft tissue involvement.

Although most patients with primary, localized infection recover without therapy, a small subgroup of patients (<0.5% of cases) will develop severe primary infection with dissemination, which will often involve the spine. Coccidioidomycosis of the spine is a highly aggressive disease that, if not managed appropriately, can lead to significant morbidity and mortality. Treatment regimens limited to systemic antifungal therapy alone, percutaneous drainage of lesions, or limited open debridement have led to poor outcomes with chronic recurrence of disease.[495] The standard treatment of coccidioidomycosis has been a total dose of 1 to 2.5 g of amphotericin B intravenously. Alternative agents include miconazole, an azole available for IV therapy, or the oral azole ketoconazole. The oral triazole drugs, itraconazole and fluconazole, are under evaluation in clinical trials.[490] Itraconazole is now available in both parenteral and oral formulations.[496–499] Reliable absorption of the itraconazole oral solution has been demonstrated in patients with HIV infection, neutropenic patients with hematologic malignancies, bone marrow transplantation patients, and neutropenic children. In clinical trials, the oral form of itraconazole is more effective than the oral forms of fluconazole and amphotericin B.[479,480] In chronic granulomatous disease of childhood, itraconazole is effective as a prophylactic treatment against recurrent fungal infections.[500]

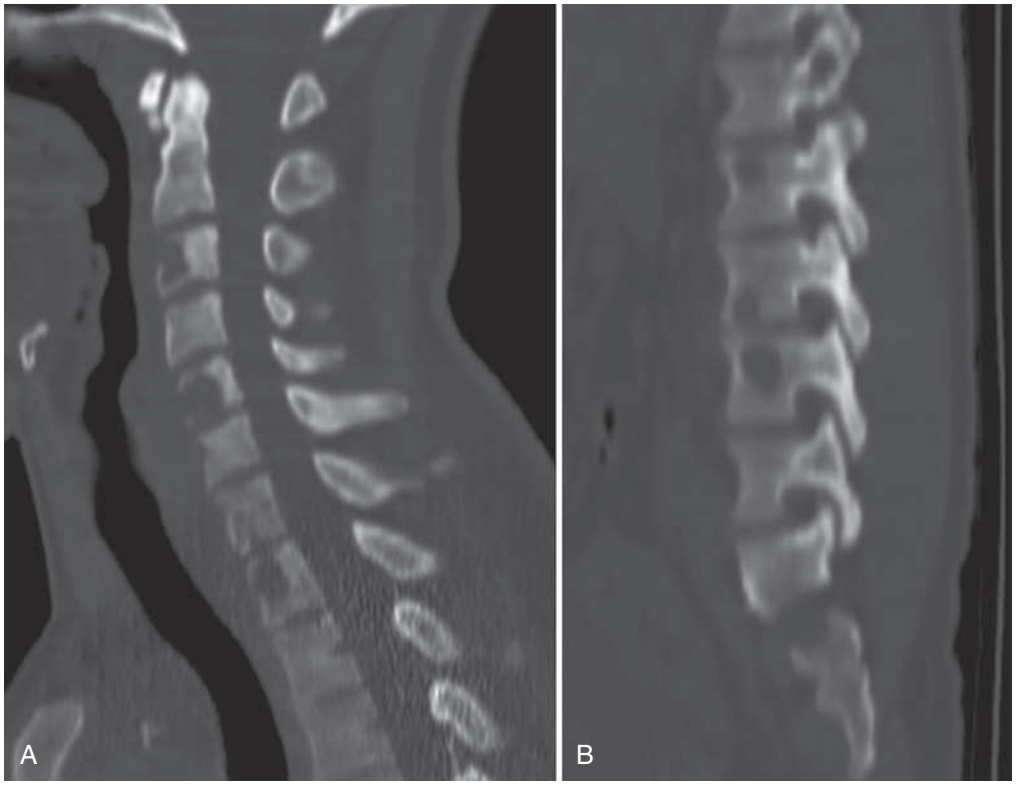

FIG. 87.24 Computed tomography (CT) scan of a 35-year-old man with fevers, weight loss, neck pain, and low back pain. (A) Sagittal CT of the cervical spine shows lytic lesions within C3, C5, and T1. (B) Similar lytic lesions are present in L1–L3. There is no disc involvement. Surgical specimens revealed coccidioidomycosis infection.

However, its prophylactic effect in neutropenic patients due to hematologic malignancy was not shown.[501] Relapse rates are high and azole therapy should probably be continued for 6 months after the disease is inactive.[490]

The response to treatment may be followed by measuring complement-fixing antibody titers. The treatment program should be reassessed if the titers are increasing.[490] The indications for surgery are the same as in other spine infections.[455] In established spinal disease, surgery is often required to eradicate infection.[502] The local use of antifungal agents may be added by depositing amphotericin B with bone cement or calcium sulfate cements.[495]

Blastomycosis

Blastomyces dermatitidis is a dimorphic fungus endemic in areas bordering the Mississippi and Ohio Rivers, the Great Lakes, and the St. Lawrence River.[503] Cases have also been reported in Central and South America, Africa, and the Middle East.[82,306] The organism exists in warm, moist soil rich in organic debris.

Primary infection in humans occurs by inhalation of conidia, which then converts to the yeast phase at body temperature. Infection occurs by inhalation of the conidia, a product from the hyphae in the mycelia form, which, in turn, causes pneumonia.[504] The inflammatory response resembles coccidioidomycosis, with clusters of neutrophils and noncaseating granulomas. The incubation period for acute pulmonary infection is 30 to 45 days. The symptoms are nonspecific, and acute infection may go unrecognized. Dissemination by hematogenous spread occurs frequently. Direct invasion from adjacent tissues is also common. The skin is the most common extrapulmonary site, being affected in 40% to 80% of the patients. Skeletal blastomycosis is seen in 10% to 50% of cases; the long bones, vertebrae, and ribs are the most common sites of osseous involvement.[82]

The radiographic findings in vertebral blastomycosis resemble those in TB: disc space narrowing, anterior involvement of the vertebral body, and development of large abscesses. Collapse and gibbus deformity are more common with blastomycosis than with the other fungal diseases.[82,472] The thoracic and lumbar regions are more commonly involved than the cervical spine.[505] Unlike the situation in TB, lesions frequently invade adjacent ribs, cause draining sinuses, and involve the posterior elements.[82,306,472]

Unfortunately, serum complement-fixation tests are not sensitive or specific. An immunodiffusion test is more sensitive and more specific and is more likely to be positive in patients with disseminated disease. A radioimmunoassay and an enzyme immunoassay are available and are quite sensitive but lack specificity. An enzyme-linked immunosorbent assay is commercially available and is often used for initial screening.

Before the availability of effective antimicrobial therapy, the mortality rate exceeded 60%.[506] The drug of choice for mild to moderate disease is itraconazole, an oral broad-spectrum antifungal, which has a 90% to 95% cure rate in such cases.[504] In severe cases, the drug of choice is amphotericin B, which

can be converted to an oral azole such as itraconazole, ketoconazole, fluconazole, and miconazole.[507] Itraconazole has less toxicity and is at least as effective as ketoconazole. Some authors consider itraconazole to be the oral azole of choice.[506] Fluconazole has been compared to ketoconazole with comparable cure rates, but with less toxicity.[504] Miconazole is only moderately active and must be administered intravenously; thus, it has been widely used. Ketoconazole cannot be used in patients with central nervous system blastomycosis because it does not cross the blood-brain barrier.[506] Chemotherapy should be continued for 6 months, although the optimal duration of treatment has not been determined. A reasonable regimen is amphotericin B given intravenously for 4 weeks, followed by 6 months of itraconazole.[508] The role of surgery in blastomycosis is the same as in other spine infections. Successful anterior instrumentation at the time of initial debridement and strut grafting has been reported.[507]

Cryptococcosis

Cryptococcus neoformans, a yeastlike fungus, is surrounded by a thick, gelatinous capsule. It is found throughout the world, most commonly in pigeon feces and soil.[509] The disease is more common in males, whites, and immunocompromised hosts. Cryptococcosis is the fourth most common life-threatening infection in patients with AIDS. In the parts of Africa where there is a high HIV seroprevalence, *Cryptococcus neoformans* is the leading cause of adult meningitis, and infection accounts for a high proportion of deaths in HIV-infected cohorts.[510–513] Infection is acquired by inhalation after the organism is aerosolized. There are no known instances of direct human-to-human or animal-to-human transmission.[306,509] The inflammatory response is variable and generally made up of chronic inflammatory cells, but neutrophils may predominate. The cellular reaction usually is minimal, and there is little suppuration and necrosis.[306] The exudate in cryptococcal lesions is quite mucoid, giving the granuloma a gelatinous appearance so that it may be mistaken for a myxomatous tumor.[306] Well-formed granulomas are uncommon.[509]

Cryptococcosis may be localized to the lung or generalized. Central nervous system involvement is common in the disseminated form. Osseous involvement occurs in approximately 5% to 10% of patients and resembles cold abscesses, similar to TB.[509] Unlike the findings in other fungal infections, sinus tracts and abscess formation are rare.[82] Radiographically, the lesions resemble those of coccidioidomycosis. Lucent lesions of the vertebral bodies and posterior elements are sharply defined but lack reactive sclerosis or periosteal new bone formation.[82] The disc spaces are frequently spared, but involvement of the posterior elements is common.[82]

A latex agglutination procedure for the detection of cryptococcal polysaccharide capsular antigen is available. Both serum and CSF should be tested. The tests detect antigen in 90% of patients with cryptococcal meningitis, but antigen is much less sensitive in patients without central nervous system involvement.[509] Rheumatoid factor also causes agglutination in this procedure, necessitating a test for rheumatoid factor as a control on all samples.[509] Definitive diagnosis is made by culture of the organism.

The current recommended medical treatment of cryptococcosis is a combination of amphotericin B (0.3 mg/kg/day, intravenously) and flucytosine (37.5 mg/kg every 6 hours by mouth) for 6 weeks. The dose of flucytosine can be adjusted on the basis of serum levels to reduce the risk of drug accumulation. Alternatively, amphotericin B alone in doses of 0.5 to 0.7 mg/kg/day for at least 10 weeks can be given. Flucytosine is limited by the development of drug resistance when used alone. Ketoconazole and itraconazole both penetrate CSF poorly and therefore cannot be used in cases of central nervous system involvement. Of the patients initially cured of the disease, 20% to 25% have a relapse. Patients who also have AIDS are rarely cured of the cryptococcal infection; the goal of treatment in these patients is suppression of disease.[509] Recently, Bicanic and colleagues[514] performed a randomized control trial of higher-dose amphotericin B in HIV-infected patients. Higher-dose amphotericin B at 1 mg/kg/day with flucytosine showed improved fungicidal activity with 2-week and 10-week mortality rates of 6% and 24%, respectively. Surgical treatment with decompression and strut grafting in cases of neurologic compression progresses to successful fusion in most cases.[471]

Candidiasis

Ten species of *Candida* are regarded as pathogens for humans. *Candida* organisms are small, thin-walled yeast cells that reproduce by budding. The organisms are normal commensals of humans and are found throughout the gastrointestinal tract, in sputum, in the female genital tract, on diseased skin, and in the urine of patients with indwelling catheters. Human-to-human transmission is possible, but most infections are endogenous.[515] For *Candida* organisms to become pathogenic, the host must be immunocompromised. *Candida* may gain access to the vascular system of susceptible patients via IV lines or monitoring devices and the implantation of prosthetic materials. IV drug abusers are also at risk.[515–517] Although there are 10 species of *Candida* that are pathogenic to humans, 62% of cases of vertebral osteomyelitis are caused by *Candida albicans,* 19% by *Candida tropicalis,* and 14% by *Candida glabrata* (formerly called *Torulopsis glabrata*).[518] Infection caused by *C. glabrata,* however, is becoming more common. This may be secondary to the general trend of increasing *Candida* infections and widespread use of azole antifungals.[519]

The initial cellular reaction is by polymorphonuclear leukocytes. Chronic inflammatory cells appear early, causing a granulomatous response. In severely immunocompromised patients, the reaction may be minimal.[515] Spinal involvement (Fig. 87.25) is rare. Overall, *Candida* is responsible for approximately 0.7% to 2.7% of cases of spinal infections.[56,458,520] The lower thoracic or lumbar spine is most frequently involved (95% of patients) with only a few reported cases occurring at a higher spinal level and one published case involving the sacrum.[518,521] At presentation, 83% of patients complain of back pain of more than 1 month's duration. Only 32% of cases have fever. Most of these patients had complex multisystem

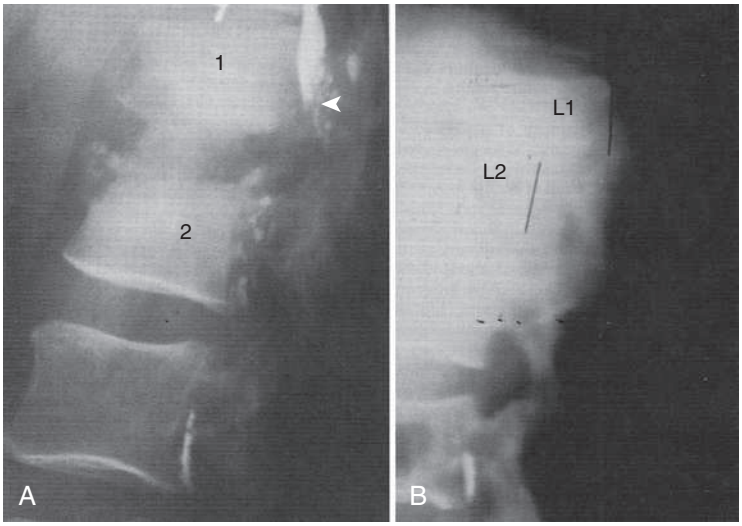

FIG. 87.25 This patient, who had been chronically ill, developed a *Candida* disc space infection at the L1–L2 interspace. (A) This lateral radiograph reveals erosion of the endplates at the inferior portion of L1 and superior portion of L2 vertebral bodies, which is consistent with a standard disc space infection and adjacent vertebral osteomyelitis. This cannot be differentiated from a standard pyogenic disc space infection. (B) The patient was inappropriately treated with a wide laminectomy posteriorly and subsequently developed retrolisthesis of L1 on L2. The paraparesis never improved. He subsequently died of a gastrointestinal hemorrhage while still under treatment for this spinal condition. (From Eismont FJ, Bohlman HH, Soni PL, et al. Pyogenic and fungal vertebral osteomyelitis with paralysis. *J Bone Joint Surg Am.* 1983;65[1]:19–29.)

medical problems, and the disease occurred after prolonged hospitalization.[516]

The treatment of choice is amphotericin B; a total dose of 1 to 1.2 g may be adequate. Flucytosine and ketoconazole are alternative agents in selected patients, but comparative studies with amphotericin B have not been done.[516] Patients who have persistent back pain should undergo another biopsy to confirm resolution of the disease. Most cases reported in the literature of candidal spinal osteomyelitis have undergone surgery combined with medical therapy with good results.[522–524] When making treatment choices for treating patients with *Candida* intervertebral disc space infection, it is important to understand that, in a rabbit model, both amphotericin B and its lipid complex formulation have poor penetration into the disc and fluconazole has excellent penetration.[475]

Aspergillosis

Aspergillus is a mold found throughout the world. There are more than 350 known species of *Aspergillus*. The organism is pathogenic only in immunocompromised hosts.[353,484,525] The one report of aspergillosis occurring in a previously healthy young man without immunocompromise is an enigma.[526] The most frequently isolated species in humans are *Aspergillus fumigatus* and *Aspergillus flavus*. Patients with AIDS and chronic granulomatous disease, those on long-term antibiotics, and IV drug abusers are especially at risk of developing the disseminated form.[527,528] Infection occurs by inhalation of small spores (conidia). Vascular invasion is common in immunosuppressed patients and leads to necrosis of tissues with abundant hyphae from proliferation of the organism. In patients with chronic granulomatous disease, vascular invasion is uncommon and hyphae are sparse.[525]

Osseous involvement may occur by direct extension from the lung or by hematogenous spread.[253,525] It has also been reported as a complication after lumbar discectomy.[525] Spine involvement with *Aspergillus* is uncommon, with only 45 cases in the literature to date.[529–532] The lumbar region is the main area (63%) of osseous involvement followed by the tibia, ribs, wrist, sternum, pelvis, and knee.[533] Advances in imaging and a greater awareness of the severity of this disease have led to a higher rate of diagnosis. *Aspergillus* vertebral osteomyelitis shares several features in common with other causes of pyogenic vertebral osteomyelitis. These include bimodal age distribution, male preponderance, predominance of lumbar involvement, and back pain.[31,530,534] Back pain has been reported almost consistently as the initial complaint with this infection.

The radiographic findings are similar to those in TB of the spine. Disc space narrowing, involvement of adjacent vertebrae, and the presence of paraspinal abscesses are characteristic.[82] Dense new bone formation with small lytic lesions without sequestration may be seen.[253] Clinically, sinus tract formation is characteristic. The incidence of epidural abscess formation in association with neurologic deficits is quite high.[253] The diagnosis is made by microscopic examination of tissue and by culture. *Aspergillus* may be isolated in culture due to contamination or colonization; thus, the culture results must be correlated with the clinical situation.

The drug of choice for the treatment of aspergillosis is amphotericin B, although the response may be poor in markedly immunosuppressed patients.[525] Itraconazole has been effective in some of the more indolent cases of aspergillosis.[525,535] The prognosis of patients with *Aspergillus* spondylitis is guarded. Surgery has been used in the past in almost all cases. In 10 cases in adults reported in the literature, all were

treated by posterior decompression and antifungal therapy; four recovered and two died. The four patients with epidural abscess and paraplegia did not improve, and one died. Of five children with aspergillosis but without paraplegia, four died.[253] There have been several reports of successful treatment with antifungal agents alone, without surgery.[253,532] If surgery is thought to be indicated, the principles of treatment outlined for TB should be followed.[484,536] Posterior segmental instrumentation and fusion may be necessary in some cases of spinal instability.[484] With surgical treatment, including posterior instrumentation, the overall recovery rate is 68%.[530]

Syphilitic Disorders of the Spine

The spirochete *Treponema pallidum,* the organism responsible for syphilis, causes two types of spine lesions. The incidence of syphilis has decreased significantly with the advent of penicillin, but another rise has been observed with the appearance of AIDS.[537] The central nervous system is most commonly involved in tertiary syphilis. Tabes dorsalis is the most well-known spinal form of neurosyphilis. Other spinal manifestations include meningomyelitis, pachymeningitis, spastic paraparesis, and myotrophy.[538,539] Establishing the diagnosis is based on a positive antitreponemal antibody test such as the Venereal Disease Research Laboratory (VDRL) test, *Treponema pallidum* hemagglutination antibody (TPH), and fluorescent treponemal antibody (FTA) tests. The VDRL test of the CSF is highly specific for active neurosyphilis but suffers from a relatively low sensitivity of 27%.[540]

Charcot spine is the most common lesion and tends to occur in the thoracolumbar or lumbar spine.[82,541] It may be detected coincidentally or may produce low back pain or root involvement if destruction and hypertrophic changes are severe. The pathophysiology of the lesion is a manifestation of posterior column involvement of the spinal cord and not a primary lesion of the bone itself. It is related to defective protective sensation. The treatment should be bracing to limit excessive movement and to prevent further injury. The role of fusion is undetermined.

Infection of the spine causes syphilitic granulomas due to the local reaction of the tissues to the organism and its products. Granulomas are destructive and usually symptomatic, causing collapse and neurologic deficits. When infection occurs in the spinal cord, termed *syphilitic meningomyelitis,* MRI reveals diffuse spinal cord swelling that mimics transverse myelitis, sarcoidosis, tumor, demyelinating disease, or spinal cord ischemia.[542] The involvement of the dorsal column is characteristic in neurosyphilis, whereas in spinal cord infarction the anterior cord is affected when the anterior spinal artery of Adamkiewicz is occluded.[543] Syphilis is the "great imitator" and must be differentiated from a host of other disorders, including TB of the spine. It is difficult to distinguish the clinical features of spinal disease from coincident neuropathy that is frequently present, and biopsy is necessary for the diagnosis.[541]

The combination of penicillin and prednisolone is the treatment of choice for syphilitic myelitis. The use of prednisolone is to reduce spinal cord edema or ischemia.[539] Ceftriaxone and doxycycline can be used in patients who are allergic to penicillin. For neurosyphilis, 2.4 million units of procaine penicillin daily with probenecid 500 mg four times a day or IV benzyl penicillin 12 to 24 million units daily can achieve treponemicidal levels in the CSF. A 10-day course is adequate for early syphilis, but late-stage disease should be treated for 21 to 28 days.[544]

PEARLS

1. For every spine biopsy, send tissue for appropriate cultures and pathologic study. Uncommon infections, such as TB and fungal infections, will often be identified first by microscopic evaluation.
2. Delay antibiotic treatment for a suspected spine infection in an adult until culture results are positive except in cases in which there are clinically significant signs of systemic infection (sepsis) or undue risk of neurologic deterioration.
3. Antibiotics with a positive charge—such as vancomycin, aminoglycosides, and clindamycin—penetrate into the nucleus pulposus better than negatively charged antibiotics, such as penicillin, oxacillin, and cephalosporins.
4. Surgery for disc space infection with associated osteomyelitis at spinal cord level is usually best done anteriorly and should include a fusion.
5. A high index of suspicion for a spinal infection should be maintained for patients presenting with worsening nonmechanical back pain (e.g., worse at night, not relieved with rest) in immunocompromised patients, such as transplant patients, AIDS, intravenous drug abusers, and frail patients with significant malnutrition.

PITFALLS

1. In adult patients with discitis and associated vertebral osteomyelitis, laminectomy alone is associated with a high rate of clinical deterioration.
2. For an established disc space infection at L4–L5, the blood vessels are usually adherent to the spine, which can make surgical treatment challenging due to risk of blood vessel injury.
3. The granulation tissue associated with discitis and vertebral osteomyelitis often resembles an abscess on MRI.
4. Although more than 50% of spine infections are due to *Staphylococcus,* many are due to uncommon organisms.
5. Relapse often occurs when the course of antibiotics is discontinued before 6 weeks and/or the sedimentation rate and C-reactive protein levels are abnormal.

KEY POINTS

1. *Diagnosis:* Nonspecific complaints, such as back pain without fever or constitutional symptoms, often lead to delayed diagnosis of spinal infection. A high index of suspicion should be maintained for patients at risk for spinal infection, including diabetics, frail and elderly patients with malnutrition, IV drug abusers, immunocompromised patients, and patients with travel history to endemic areas. MRI together with biopsy remains the most reliable method of accurate diagnosis and treatment.
2. *Initial treatment:* Identification of the offending organism, together with antibiotic sensitivity profiles, provides a means of successful nonoperative treatment in patients without undue instability or neurologic compromise. The CRP profiles are useful to monitor the activity of most infections and can guide duration of antibiotic therapy, especially pyogenic infections.

Serial MRI is not recommended because improvements in the appearance on MRI tend to lag significantly behind clinical improvement.

3. *Surgical treatment:* Surgical treatment is indicated when there is clinically significant instability (such as worsening deformity), neurologic deterioration (due to epidural abscess or bony nerve compression), or severe infection (such as sepsis or persistent infection after trial of nonoperative treatment). When infection affects the anterior column, marked with bony destruction and deformity, circumferential reconstruction with anterior support and posterior instrumented fusion remains the standard of care. Single-stage anteroposterior reconstruction is viable when sufficient debridement and stabilization can be achieved.
4. *Postoperative management:* Appropriate antibiotic therapy is required after surgical treatment. Selective antibiotics based on biopsy results should be used according to the specific disease entity. For most pyogenic infections, 4 to 6 weeks of antibiotics are recommended, whereas fungal, granulomatous, and especially mycobacterial infections require longer periods of postoperative antibiotic treatment.

CHAPTER 88

Metabolic Bone Disorders of the Spine

SECTION XII

Joseph M. Lane
Matthew R. Cohn
Tyler Kreitz
Mark F. Kurd

Metabolic bone diseases are a group of disorders that occur as a result of changes in osteoblast and osteoclast function. Because the spine represents a significant portion of the skeletal bone mass, contains the largest quantity of metabolically active (cancellous) bone, and loads this bone in compression during upright posture, metabolic bone diseases often affect the spine primarily.

Bone fulfills its role as a metabolically active homeostatic organ. As in all bones, the component cells of the spine are physiologically active and responsive to numerous metabolic and mechanical stimuli. The bony skeleton actively performs three main roles: (1) a biochemical role of mineral balance (through storage and release of Ca^{2+}, Mg^{2+}, HPO_4^{2-}, and H^+); (2) a structural role, responding to the skeletal demands for remodeling and repair; and (3) protection of the spinal cord.

Metabolic bone diseases result when bone constituents (cells and matrices) behave abnormally, when the stimuli to which bone responds are inappropriately interpreted, or when systemic processes disturb the bone's environment, leading to impairment of either its biochemical or structural tasks.

Accordingly, this chapter begins with an understanding of the normal bone physiology: the characteristic interplay of cells, ions, and proteins and the role of bone in maintaining skeletal and mineral homeostasis. Next, abnormal metabolic bone pathology and pathophysiology are considered. Finally, for the two most common metabolic bone diseases of the spine—osteoporosis and Paget disease—the epidemiology, clinical manifestations, and prevention and treatment strategies are discussed.

Cellular Biology

Bone Cells

Four families of cells combine to create bone tissue that is biomechanically functional and structurally sound. These include the osteoprogenitor cell from the mesenchymal stem cell lineage; its derivative, the osteoblast; the incorporated mature form, the osteocyte; and, finally, the osteoclast. Together, these cells produce new osseous tissue. This tissue is maintained through resorption and remodeling. In short, the cells determine mechanical stability and mineral homeostasis. Healthy bone metabolism results from equilibrating these competing forces. Therefore, some forms of metabolic bone disease can be viewed as the pathologic imbalance—in number, power, or degree of differentiation—of bone-forming and bone-resorbing cells.[1,2]

The osteoprogenitor cells are components of the bone marrow stromal system, approximating the surfaces of bone (periosteum and endosteum) and the adjacent bone marrow environment.[3] These potentially mitotic cells, under appropriate stimulation and conditions, give rise to either the bone-forming osteoblast or the cartilage-producing chondroblast. The natural history of these osteoprogenitor cells and the precise signals for their differentiation and modulation are not yet fully elucidated.

Osteoblasts sit on the metabolically active surface of bone in an adherent row, where they synthesize and release unmineralized bone matrix called osteoid.[4–7] They subsequently participate in the mineralization of the osteoid by releasing packets of ions and by synthesizing regulatory and crystal-nucleating noncollagenous proteins. These cells are characterized by high levels of alkaline phosphatase, the ability to manufacture type I collagen and osteocalcin, and the presence of numerous receptor sites for parathyroid hormone (PTH), estrogen, vitamin D, and other growth factors and extracellular matrix proteins. Osteoblasts are also thought to govern the actions of osteoclasts (described later), thus regulating and coupling bone formation and bone resorption.

The osteocyte, the terminal cell of the osteogenic cell line, is derived from osteoblasts.[4,5] As the osteoblast synthesizes bone matrix, it becomes embedded within its mineralized product. Once embedded, the cell is termed an *osteocyte* and the space in which it sits is termed a *lacuna.* Despite being surrounded by bone matrix, the osteocyte communicates with other cells via slender cell processes that it extends for some distance into canaliculi in the surrounding matrix. The surface area covered by the canaliculi is greater than the surface area of osteoblasts; the total volume is comparable to the brain.[8] Thus, osteocytes are not completely isolated in their lacunae from other cells but appear to communicate with one another and with surface

cells via these cell-to-cell junctions. In this way, osteocytes maintain the matrix that envelops them, regulate local ionic concentrations, and govern the degree of mineralization. In addition, they monitor the local mechanical load and signal changes in the matrix, translating these forces into biologic activity. One crucial mechanism through which the osteocytes regulate bone formation is by the secretion of the glycoprotein sclerostin.[9,10] Sclerostin reduces osteoblast proliferation and the formation of bone by inhibiting the canonical Wnt/β-catenin signaling pathway.[11] Antibodies that bind sclerostin increase bone mineral density (BMD) and show promise in treating osteoporosis.[12] Romosozumab, an anti-sclerostin antibody, has shown efficacy in increasing BMD and reducing risk of vertebral fractures.[12,13]

Osteoclasts resorb bone.[14,15] Unlike the mesenchymally derived osteoblast lineage, osteoclasts arise from hematopoietic progenitor cells of the monocyte line. These large multinucleated cells are found on the resorbing surfaces of bone, where they bind to a bone-specific integrin and form an isolated macrocavity. At this attachment cavity site, an acidic microenvironment causes the dissolution of the hydroxyapatite mineral and releases acidic proteases that degrade the organic collagen matrix. The resultant resorption cavity is called a *Howship lacuna*. Thus, by remodeling formed bone and delivering calcium into the circulation, the osteoclasts participate in both the mechanical and biochemical roles of bone tissue. The coordinated activity of osteoclast resorption and osteoblast bone formation is most prominent during periods of growth, fracture repair, and periosteal bone widening.

Neighboring osteoblasts and osteocytes influence osteoclast differentiation as well as osteoclast activity. Osteoclast precursors are stimulated to differentiate by osteoblast lineage cells and bone marrow stromal cells that express receptor activator of nuclear factor-κβ ligand (RANKL), also known as osteoprotegerin-ligand (OPGL), and macrophage colony-stimulating factor (M-CSF). M-CSF primarily induces osteoclast progenitor cell replication, whereas RANKL promotes differentiation.[11] Osteoclasts are devoid of PTH receptors, even though they functionally respond to this hormone. On stimulation by PTH, osteoblasts produce RANKL, leading to differentiation and activation of mature osteoclasts. Osteoprotegerin (OPG, also known as osteoclastogenesis inhibitory factor [OCIF]) is a soluble decoy receptor for RANKL that blocks this pathway. RANKL, reeptor activator of NF-κβ (RANK) and OPG are the key regulators for the development and activation of mature osteoclasts (Fig. 88.1). Agents that inhibit RANKL via OPG or anti-RANKL antibodies can be used for the treatment of osteopenic disorders such as osteoporosis as well as bone loss associated with bone metastases.[16–19]

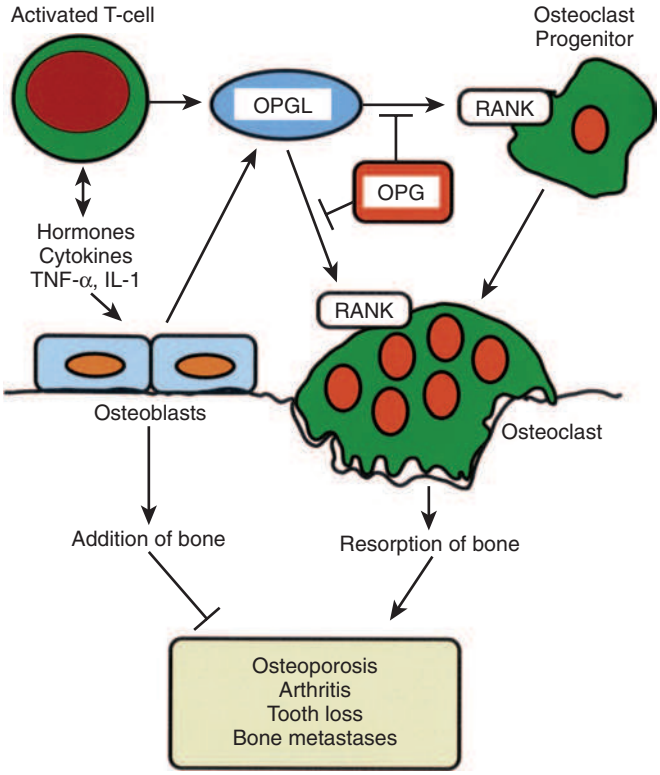

FIG. 88.1 The relationship between RANKL (also known as OPGL), RANK, and the decoy receptor OPG in bone formation and bone resorption. Activated T cells lead to expression of RANKL on osteoblasts by two pathways: (1) They produce cytokines that lead to RANKL expression and (2) they directly express and produce RANKL. OPG, the decoy receptor for RANKL, blocks both of these pathways. RANKL induces osteoclast formation and activation, thereby increasing bone resorption. Inhibition of RANKL via OPG may prove useful in the pharmacologic treatment of osteopenic disorders, including osteoporosis and Paget disease. IL-1, interleukin-1; OPG, osteoprotegerin; OPGL, osteoprotegerin ligand; RANKL, receptor activator of nuclear factor-κβ ligand; TNF-α, tumor necrosis factor-α. (From Theill LE, Boyle WJ, Penninger JM. RANK-L and RANK: T cells, bone loss, and mammalian evolution. *Annu Rev Immunol.* 2002;20:795–823.)

Bone Matrix

In addition to the cellular component, two matrices—an organic matrix and an inorganic matrix—constitute the remainder of bone tissue (Fig. 88.2). Whereas the inorganic matrix consists of bone mineral, the organic matrix consists of collagenous fibers embedded in a ground substance.

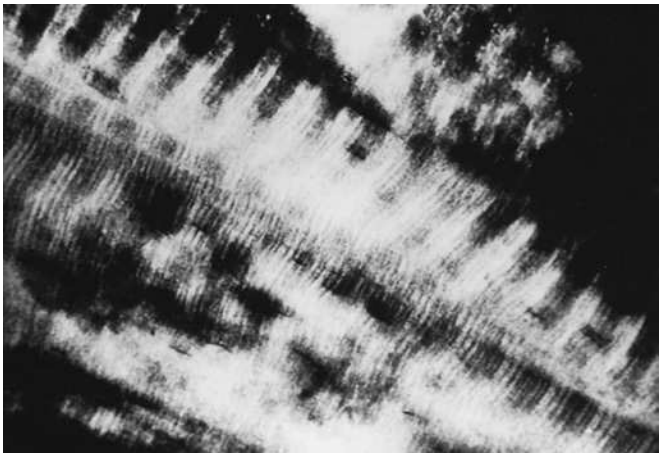

FIG. 88.2 Collagen-mineral relationship. The hydroxyapatite forms in the hole zone between collagen molecules. (From Anatomy II. Orthop. Science. Park Ridge, IL: American Academy of Orthopaedic Surgeons; 1986.)

Bone Mineral

The inorganic matrix represents two-thirds of the dry weight of bone and primarily consists of calcium phosphate,[16] which exists in three forms: (1) crystalline hydroxyapatite [$Ca_{10}(PO_4)_6(OH)_2$], the most abundant; (2) octacalcium phosphate [$Ca_8H_2(PO_4)_6 \cdot 5H_2O$)], a rarer form; and (3) brushite [$CaHPO_4 \cdot 2H_2O$]. The hydroxyapatite forms platelike crystals 40 nm in length and 3 nm in thickness. Occasional contaminants, including carbonate substituted for a phosphate or a fluoride for a hydroxy group (as well as the potential inclusion of lead or arsenic), disrupt the purity of the crystals. These contaminants alter the physical properties of the matrix and may also affect the biologic characteristics. The mineral crystal closely associates with the organic matrix, initially deposited in the hole zones of the collagen fibril. Later, it surrounds itself with ground substance (proteoglycan), as well as with water and other ions.

The initial formation of hydroxyapatite is under the control of osteoblasts, which contain abundant alkaline phosphatase. This enzyme catalyzes reactions that, among others, release phosphate from pyrophosphate. The conversion of pyrophosphate has two effects: (1) it increases the local concentration of phosphate to a level that permits calcium and phosphate to precipitate; and (2) it destroys pyrophosphate, an inhibitor of calcification. Vitamin D and adequate calcium are critical for mineral deposition.

Collagen

Concentrations of calcium and phosphate alone do not dictate mineral deposition. An organic matrix, consisting of collagenous fibers embedded in ground substance, assists with and regulates mineralization.[20] The organic matrix of bone is primarily composed of proteins, approximately 95% of which is collagen in adult humans. Collagen, a rigid macromolecule, employs tropocollagen as its basic structural unit. Tropocollagen, in turn, is composed of three polypeptide chains, each comprising approximately 1000 amino acids.[21] In bone collagen (type I), two of these chains share an identical amino acid sequence; a third chain (α_2) has a similar, but not identical, sequence. All three chains contain unusually high concentrations of glycine, proline, alanine, hydroxyproline, and hydroxylysine and are wound into right-handed helices.

Type I collagen synthesis occurs in osteoblasts. It is formed as a precursor "procollagen" molecule in the cytoplasm and then extruded from the osteoblast after cleavage of signal sequences. Numerous additional modifications are subsequently made to the secreted procollagen molecule. Notably, extensive nonhelical regions are removed from both its amino and carboxy terminals, and key proline and lysine residues are hydroxylated by an iron-containing enzyme. (The iron in this hydroxylase functions only in the ferrous state; therefore, ascorbic acid, functioning as a reducing agent, is necessary.) The hydroxylation of proline and lysine occurs after these amino acids are incorporated into the chain; therefore, free hydroxyproline in the serum signifies lysis of collagen or its precursors. Accordingly, measurements of urinary hydroxyapatite excretion provide a qualitative measure of bone turnover. The hydroxylation of proline and lysine assists cross-linking, which, in turn, lowers the solubility of collagen and increases its tensile strength. Collagen is one of the strongest components of bone; the tensile strength of bone collagen exceeds the compressive strength of the bone mineral by 2000 N/cm^2. Pyridinoline, deoxypyridinoline, C-telopeptides, and N-telopeptides are cross-link breakdown products that all provide better markers of bone resorption than hydroxyproline.[22,23] They are elevated in high-turnover osteoporosis and Paget disease, and they decline rapidly with successful antiresorptive therapy (discussed later). Adequate nutrition and vitamin C (ascorbic acid) are required for collagen maintenance.

Type I collagen is found not only in the bones of the spine but also in the intervertebral discs, where it coexists with type II collagen. These homologous molecules differ only in the chains that compose their triple helices. Within the disc, each type of collagen maintains a separate anatomic domain: type I collagen is more abundant in the anulus fibrosus, whereas type II predominates in the nucleus pulposus.[24]

Collagen derives its mechanical strength from covalent collagen cross-links between helical and nonhelical domains of neighboring collagen molecules. Cross-links between collagen molecules are formed by one of two mechanisms: (1) enzymatic cross-linking, which occurs via lysine hydroxylase and lysyl oxidase; and (2) nonenzymatic cross-linking, which occurs via glycation or oxidation. The latter mechanism occurs when states of hyperglycemia, oxidative stress, or aging induce spontaneous formation of advanced glycation end products (AGEs) within collagen fibers. These AGEs undergo nonenzymatic cross-linking within collagen matrix and undermine bone quality. This mechanism is believed to contribute to elevated fracture risk in patients with diabetes and advanced age. In addition, AGE-related collagen cross-links have been shown to be a significant risk factor for vertebral fracture in clinical samples[25,26] and suppression of bone turnover by bisphosphonates leads to continued addition of nonenzymatic cross-links. Long-term bisphosphonate users may have less plasticity and reduced toughness in certain regions of bone, which may contribute to the occurrence of atypical femoral fractures in this population.[27]

Ground Substance

Proteoglycans form the ground substance of bone. A proteoglycan monomer is composed of two kinds of glycosaminoglycans—keratin sulfate and chondroitin sulfate—joined to a core protein. Keratin and chondroitin sulfate form through the polymerization of disaccharide units, one sugar of which is always a hexosamine possessing an anionic group. This negatively charged group binds water, expanding the tissue volume and imparting resilience to the ground substance. In addition, the presence of water in the ground substance allows for the diffusion of metabolites in the organic matrix. Thus, the proteoglycans in bone exert regulatory and structural forces. When the bone mineralizes, the water content is reduced, leading to denser, more compact tissue. The intervertebral discs also contain

proteoglycans, which comprise 30% to 60% of the dry weight of the nucleus pulposus. With age, proteoglycan concentration (and, consequently, water concentration) declines. However, even with decreased proteoglycan concentration, osmotic forces allow the proteoglycans to remain somewhat hydrated.[28]

Osteocalcin is a bone-specific protein that, like type I collagen, is synthesized by osteoblasts.[29] Osteocalcin comprises only 2% of the organic matrix by weight. Vitamin D enhances the synthesis of osteocalcin but is not an absolute requirement for synthesis. Osteocalcin prefers to bind to calcium within hydroxyapatite. The precise function of this prevalent osseous protein is currently being explored, although its levels are correlated with bone mineral content. Possible roles include the attraction of osteoclasts to sites of bone resorption, regulation of the rate of mineral turnover, and determination of the morphology of the mineral crystal. Osteocalcin also functions as a bone-derived hormone that exerts systemic effects. These actions include stimulation of insulin secretion by the pancreatic beta cells, promotion of insulin receptor sensitivity, and stimulation of testosterone production in the Leydig cells of the testes.[30] Through a feed-forward loop, insulin also stimulates secretion of osteocalcin by osteoblasts, which, in turn, increases insulin release. Osteocalcin production is halted by the hormone leptin. Through this interplay with osteocalcin, insulin, and leptin, bone remodeling is linked to energy metabolism and may be involved in the development of osteoporosis in patients with inflammatory bowel disease.[31]

Osteonectin, a 32-kd phosphoprotein secreted by osteoblasts, is the second most prevalent protein in bone. It binds to both collagen and hydroxyapatite[32] as well as to carbohydrate moieties. Putative roles for osteonectin include calcium phosphate nucleation and stabilization of the newly formed crystal.

Bone morphogenetic protein (BMP), as the name implies, induces osteoprogenitor cells to form bone.[25,33] A small protein, BMP accounts for only 0.1% of the total bone protein mass in cortical bone, and even less in the spine. More than 15 BMPs exist, some of which are related to the transforming growth factors. Experimentally, BMP implanted in ectopic sites (in the absence of bone collagen) induces perivascular mesenchymal cells to become bone-forming osteoprogenitor cells. The absence of BMPs (or the inhibition of their activity) may contribute to the pathogenesis of diseases of decreased bone mass or impaired bone remodeling or repair. The genes for the expression of BMPs have been cloned,[33,34] and the protein has proven to possess a pharmacologic role in repairing bone and inducing spinal arthrodesis.[35] Recombinant human bone morphogenetic protein-2 has been used clinically as a bone graft substitute in anterior interbody lumbar fusion, posterolateral lumbar fusion, posterior lumbar interbody fusion, and anterior cervical discectomy and fusion. However, early industry-sponsored reports may have overestimated the decreased need for revision surgery with recombinant human bone morphogenetic protein-2 use and underestimated serious adverse events such as osteolysis, subsidence, graft migration, cyst formation, wound problems, and others.[36]

Skeletal Homeostasis

Bone growth occurs during all phases of life.[4,5] Functionally, this growth can be divided into two processes: modeling and remodeling. The deposition of new bone in regions not first cleared by resorption or the resorption of old bone without deposition of new tissue is termed *modeling*. Modeling results in changes to the external shape, mass, or volume of existing bone. Alternatively, remodeling retains approximately the external form of bones. During remodeling, bone replaces itself by balancing synthesis in some places with lysis in others. This balanced turnover releases ions into the circulation and prevents accumulation of aged or fatigued bone.

In the remodeling cycle, osteoclasts work as much as four times faster than osteoblasts. Although the clastic phase in the typical remodeling unit requires approximately 20 days, the blastic phase requires 80 days. After this period elapses, the tissue is restored, notably with younger, newly mineralized bone. The preferential remodeling of older tissue leads to an overall younger skeleton, one better suited to constant mechanical demands.

Remodeling, a process that ordinarily prevents structural collapse by repairing old or damaged regions in bone, can be responsible for eroding the bones' mechanical integrity. This may result in any of several ways. First, the remodeling can occur too frequently, magnifying what would ordinarily be an inconsequential net loss. Second, the remodeling can be poorly focused, inappropriately replacing young, healthy bone instead of weaker, older tissue. Finally, the remodeling can be unbalanced if the formation cycle does not fully replace the bone lost during resorption. After the age of 40 years, the remodeled bone unit rarely fully reconstitutes itself. High turnover states lead to net bone loss, and the younger matrix has a lower modulus until the crystals can fully mature.

Mineral Homeostasis

Calcium

Bone exchanges calcium, magnesium, and phosphate and participates in acid–base balance. Of all of these, calcium homeostasis is the most important to both the skeletal and metabolic functions of bone.[37–40] Calcium fulfills its skeletal role in the hydroxyapatite mineral crystal, where it provides mechanical strength. It serves its metabolic function as a free divalent cation. These functions include transducing hormonal signals within the cytoplasm ("second messenger" function), coupling neural excitation with muscular contraction, and effecting homeostasis by interacting with both vascular smooth muscle and platelets.

Body stores of calcium in the typical, 70-kg male total approximately 1300 g, more than 98% of which resides in the teeth and bones. The remainder is divided between the cytoplasmic and extracellular fluids. The normal serum calcium concentration centers around 9 mg/dL and is found in three states: (1) free (ionized and diffusible); (2) complexed to citrate and other anions (i.e., nonionized but diffusible); and

(3) bound to proteins (i.e., neither ionized nor diffusible). Only the free ion (normally about 45% of the total) possesses physiologic activity. At normal body pH, albumin and other anionic proteins bind 50% of the total body calcium. The proportion of protein-bound calcium increases with alkalinity. Accordingly, as the pH rises, the individual becomes effectively hypocalcemic, even though the total amount of calcium, and, importantly, the amount typically reported by standard laboratory tests, remains within normal range. Conversely, in states of liver and kidney failure, when albumin is either not synthesized or lost in the urine, even though the absolute levels of total serum calcium may be depressed, the effective physiologic calcium concentration may be near normal. Calcium-anion complexes account for the remaining 5% of serum calcium. Abnormal levels of these anions may also cause a physiologic calcium disturbance, one not necessarily obvious from the serum calcium concentration. Thus, unless ionic calcium is directly measured, attention should be directed at albumin levels and pH state before inferring functional calcium levels from the total serum measurement.

Maintenance of calcium concentration is the responsibility of three organ systems: the gut, to absorb calcium; the bone, to store it; and the kidney, to excrete it. Each of these systems can alter the magnitude of the calcium contribution in response to a number of regulatory substances.

The gut (duodenum and jejunum, specifically) absorbs calcium from the diet, ingested primarily from dairy products. Despite the critical need for calcium absorption, the gut performs this duty with surprising inefficiency: of the recommended daily allowance of 800 mg, only half will ever cross the luminal border; of that fraction, more than half will be returned to the lumen with the secretion of intestinal fluids.[41] Thus, less than one-fourth of the daily intake (or only about 150 mg) enters the system.

Active absorption in the duodenum takes place by means of a protein-dependent transport system[32] that is activated by 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]. In the jejunum, passive diffusion accounts for the remainder of the calcium absorbed. Clearly, the jejunal phase depends more on concentration gradients and intestinal transit times. In addition, dietary composition affects absorption: diets high in fiber and oxalate (both found in green vegetables) allow for less calcium absorption. In times of increased calcium demand—such as the growth years, or during pregnancy—the duodenal fractional absorption can be augmented by increased carrier protein synthesis, which is, in turn, stimulated by the active vitamin D metabolite (discussed later). The efficiency of calcium absorption decreases with aging and is adversely affected with bariatric surgery.[40]

The bone stores calcium. The bone tissue constantly exchanges calcium with the plasma, even when intake matches excretion. This daily 400-mg exchange results from the nearly balanced remodeling activity of osteoclasts and osteoblasts as well as the movement of ions between intracellular and extracellular compartments at the osteocyte plasma membrane.

The kidneys are the prime organs of calcium excretion. The glomerular load of calcium is almost 10,000 mg. Most of it is resorbed proximally, following sodium-driven bulk flow. Some calcium remains in the lumen until the distal nephron, where it can be selectively resorbed by calcium-specific transport processes. It follows not only the dictates of calcium-regulating agents but also the demands of salt and water balance and acid-base control. For example, when volume depletion demands increased sodium resorption, proportionally more calcium will be retained proximally, regardless of the serum levels. Diet can also affect renal calcium handling, with both high-protein and high-carbohydrate loads increasing urine calcium excretion. Under normal conditions, the kidneys resorb 98% of the filtered load, with excretion commensurate with intake or resorption from bone. One deleterious consequence of the renal response to high calcium is the formation of stones. Although there is no precise threshold at which stones will form (because other factors, such as urinary flow rate, influence the process) the risk of stone formation increases with hypercalciuria. Most diuretics (with the exception of the thiazides) induce renal calcium loss. Patients with low calcium levels should be evaluated for excessive calcium excretion.

Phosphate

The second important ion in bone metabolism is phosphate.[42] Like calcium, phosphate serves multiple functions throughout the body. As a component of adenosine triphosphate, phosphate participates in the interconversion of the energy of metabolism; as a constituent of nucleotides, phosphate partakes in the transmission and expression of genetic information; and in 2,3-diphosphoglycerate, it regulates the oxygen affinity of hemoglobin.

Phosphate is found in two forms: $H_2PO_4^-$ and PO_4^{3-}. The ratio of this dissociation, like that of any acid, depends on the pKa of the system, a constant, and the local pH, which can vary. In the extracellular fluid, where the pH is 7.4, the ratio of $H_2PO_4^-$ to PO_4^{3-} is about 4:1, whereas in the slightly less alkaline cytosol, the ratio is closer to 2.5:1. Unlike calcium, which is physiologically sensed as the free ion, phosphate is internally measured as a sum of both forms. Phosphate's role outside of bone is also less dependent on concentration; therefore, alterations in its level cause few immediate effects. Nevertheless, the quantity of phosphate, normally about 4 mg/dL, is regulated.

Similarly to calcium, serum phosphorus concentration is determined by the degree of intestinal phosphate absorption in the gut, storage of phosphate in bone, and phosphate excretion by the kidney. Regulatory mechanisms for calcium and phosphate are intertwined, as PTH and vitamin D are key regulators. However, fibroblast growth factor-23 (FGF-23) is also critical for phosphate control and is secreted by osteoblasts and osteocytes.[43] The body stores of phosphate sum to 700 g, about half that of calcium. As with calcium, the majority of phosphate (perhaps 85% of the total) resides in bone. The typical dietary intake is about 1000 mg/day, of which about two-thirds is absorbed. The presence of substances in the gut that can bind phosphate, such as aluminum salts, largely determines the amount of phosphate absorbed. Under normal circumstances, the amount absorbed increases linearly with intake. As with calcium, the kidney is responsible

for maintaining phosphate balance,[45] and it does so by a similar mechanism: proximal sodium bulk-driven flow and distal control. When phosphate intake is high, the kidney excretes increasing amounts by spilling the excess phosphate into the urine. When serum phosphate concentrations are low, the kidney can avidly conserve phosphate by implementing vitamin D–mediated changes in calcium concentration. In addition to calcium balance, dietary load, volume status, and acid–base balance also affect renal phosphate handling

Regulators of Bone and Mineral Metabolism

Parathyroid Hormone

PTH is an 84-amino-acid polypeptide secreted by the chief cells of the parathyroid glands in response to low serum calcium.[46] Its physiologic role is to restore a normal calcium concentration by stimulating all three organs of calcium homeostasis. The kidney and the bone are affected directly,[47] whereas the intestine is affected only indirectly, by means of the synthesis of the active vitamin D metabolite $1,25(OH)_2D_3$.

PTH promotes calcium conservation in the kidney.[48] There, increased serum calcium is achieved through a twofold mechanism; both steps depend on stimulation of adenylate cyclase, the enzyme that forms cyclic adenosine monophosphate. First, PTH increases calcium resorption in the distal nephron. It also promotes the loss of phosphate. This phosphaturic effect prevents the recently resorbed calcium from being deposited into the bone hydroxyapatite or into ectopic calcium-phosphate deposits. Moreover, the excretion of phosphate lowers the levels of circulating calcium-anion complexes, causing more of the serum calcium to remain in the physiologically useful free form.

In the kidney, PTH further promotes elevation of calcium level by stimulating additional synthesis of 1α-hydroxylase, a key enzyme in the formation of $1,25(OH)_2$ vitamin D, which, in turn, enhances calcium absorption in the digestive system. In this manner, PTH indirectly affects gut handling of calcium as well.

In the bone, PTH affects calcium metabolism by increasing the surface resorption of the mineral by osteoclasts, by promoting ion flux by osteocytes, and by decreasing their bone synthetic activity through the inhibition of calcium "consumption" by osteoblasts. PTH increases the number of resorptive surfaces in bone and, within them, the density of osteoclasts. However, the effects of intermittent and continuous PTH stimulations on bone differ. Low-dose, intermittent PTH stimulation exerts anabolic properties, which is believed to be through direct effects on osteoblasts and inhibition of sclerostin—a promoter of bone resorption.[43,49] Conversely, continuous PTH stimulation of osteoblasts causes expression of RANKL. Osteoclasts respond to RANKL by resorbing bone and release of calcium and phosphate into the systemic circulation. The most commonly used laboratory test to measure PTH clinically is intact PTH, which detects levels of both the 84-amino-acid polypeptide and the C-terminal PTH fragments.[28]

Vitamin D

Unlike the polypeptide hormone PTH, vitamin D is a steroid.[47] As such, it defies rapid proteolytic inactivation and thus functions best as a longer-acting regulator of calcium homeostasis. The principal effect of this hormone is to increase intestinal absorption of calcium from the diet, a process that is usually only 25% efficient. Secondarily, it complements PTH in the promotion of calcium resorption from the bone, again by promoting transport across cell membranes (in this case, bone cells rather than intestinal cells).

Cholecalciferol (inactive vitamin D_3) forms in the skin from the ultraviolet light activation of 7-dehydrocholesterol, an intermediate of cholesterol synthesis.[50] 7-Dehydrocholesterol can degrade and re-form cholecalciferol; therefore, once formed, cholecalciferol is removed from the local environment by a transport protein, thus favoring further formation. As little as 15 minutes of sunlight exposure allows the synthesis of a fair-skinned individual's vitamin D_3 requirement. The total need for sunlight increases with melanin concentration. In the absence of sun exposure, cod liver oil and enriched milk and cereals can provide usable precursors of the hormone.

In the liver, vitamin D_3 undergoes 25-hydroxylation,[51] forming the prehormone 25-hydroxyvitamin D [25(OH)D]. Subsequent 1-hydroxylation to the active form, $1,25(OH)_2D_3$, takes place in the kidney and is promoted by PTH. In the presence of low PTH or FGF-23, an alternative hydroxylation occurs at the 24 position, yielding $24,25(OH)_2\ D_3$, an inactive form of the hormone. Unlike PTH, which is functionally regulated at the level of secretion (calcium levels do not cause minute-to-minute changes in messenger RNA activity but rather control the release of PTH), vitamin D is regulated at the level of biosynthesis. The 1-hydroxylation reaction is the rate-limiting step and is regulated by feedback inhibition as well as by PTH levels.

Active vitamin D, also known as *calcitriol,* promotes increased transport across cell borders. As a steroid maturation hormone, vitamin D works by crossing the cell membrane and subsequently entering the nucleus. There, it binds to DNA via the vitamin D receptor to promote DNA translation, thus increasing the synthesis of the target proteins. Vitamin D receptor is most highly expressed in the intestinal enterocytes, osteoblasts, and renal distal tubules, where it mediates expression of calcium-transport proteins.[52] In the gut, $1,25(OH)_2D_3$ causes increased calcium and phosphate absorption. In the bone, $1,25(OH)_2D_3$ complements the action of PTH by increasing calcium transport across bone cell membranes, thus assisting with the mobilization of calcium from the bone and into the circulation. As such, it functions as an agent of bone resorption. It can indirectly assist with bone formation as well because the tasks of mineral homeostasis and skeletal homeostasis are not always at odds with each other. Vitamin D also functions as a maturation hormone by increasing the villous membrane of the gut and augmenting PTH recruitment of macrophage stem cells, the bone-resorbing osteoclast precursors. Accordingly, vitamin D, which promotes the uptake of dietary calcium, typically also serves as an agent of bone maintenance. In addition, vitamin D has been associated

with decreased cancer rates, improved muscle function, and a more normal immune system.[53]

Fibroblast Growth Factor-23 (FGF-23)

The major sources of fibroblast growth factor-23 (FGF-23) in the body are osteocytes and osteoblasts. This protein is a potent regulator of serum phosphate and contributes to vitamin D and PTH homeostasis.[54] After FGF-23 is released into the systemic circulation, it acts synergistically with PTH in promoting renal phosphate excretion.[55] This is done by suppressing expression of the sodium phosphate cotransporter in the proximal tubule.[44] However, unlike PTH, FGF-23 inhibits conversion of 25-(OH)D to the active form, 1,25-$(OH)_2D$[56] and promotes its conversion to the inactive form.[54] The net result is a decrease in serum phosphate. Primary elevation of FGF-23 leads to conditions characterized by hypophosphatemia, decreased $1,25(OH)_2D$, and rickets/osteomalacia. These include autosomal-dominant hypophosphatemic rickets, tumor-induced osteomalacia, and X-linked hypophosphatemic rickets.[57] This interplay between FGF-23, PTH, and vitamin D in controlling calcium and phosphate handling is often described as the bone-parathyroid-kidney axis.

Calcitonin

Calcitonin is a 32-amino-acid polypeptide secreted by the parafollicular cells in the thyroid in response to increased serum calcium concentration. Calcitonin lowers serum calcium levels by its actions in the bone and the kidney. Still, its precise physiologic role awaits determination.[58,59]

In the bone, calcitonin rapidly inhibits osteoclastic action at pharmacologic doses. Direct calcitonin-binding sites are present on osteoclasts. Calcitonin decreases the number and activity of osteoclasts. Specifically, it decreases the adherence of osteoclasts to bone resorptive surfaces and diminishes their activity once they adhere. Calcitonin also affects osteocytes, causing decreased calcium ion flux across their cell membranes. In the kidney, calcitonin blocks the reuptake from the glomerular fluid of calcium and phosphate, as well as that of other ions, notably sodium (which influences calcium uptake by the passive mechanisms described earlier). Calcitonin may also influence calcium handling in the gut and, at pharmacologic doses, may alter other intestinal processes (such as water balance).[60]

High levels of calcitonin may cause transient hypocalcemia without causing any residual skeletal effects. In patients with medullary carcinoma of the thyroid (a malignancy of the parafollicular cells), calcitonin levels are several orders of magnitude higher than in healthy patients. Nevertheless, such patients demonstrate neither long-term derangements of calcium metabolism nor loss of skeletal integrity. Furthermore, patients who have had a complete thyroidectomy, and are thus completely calcitonin deficient, show no persistent hypercalcemia. Both examples bolster the hypothesis of a small physiologic role for calcitonin.

Despite a perhaps minor physiologic role, calcitonin is important medically. First, in patients with medullary carcinoma of the thyroid, measurement of serum calcitonin level provides an assessment of tumor burden. Calcitonin levels can be measured as a screening test in those patients at risk for medullary carcinoma, namely, relatives of patients with multiple endocrine neoplasia type II. Finally, calcitonin (most often as a salmon-derived analog) is also used as a drug to inhibit osteoclasts, as in Paget disease and osteoporosis, or to quell the hypercalcemia accompanying a variety of malignancies. In addition, it has analgesic properties that enhance its therapeutic use.

Osteoporosis

Osteoporosis is a metabolic bone disease characterized by low bone mass and microarchitectural deterioration of bone tissue, leading to increased bone fragility and a consequent increase in fracture risk. In the United States, osteoporosis affects an estimated 10 million adults. An additional 43 million are estimated to have low bone mass, placing them at increased risk for osteoporosis.[61] It is the most prevalent metabolic bone disease, affecting 10.3% of those over the age of 50.[61] The direct medical costs of osteoporosis are substantial, accounting for an estimated 17 to 20 billion dollars in 2005, expected to increase 50% by 2025.[62] Among the elderly, especially postmenopausal women, osteoporosis is a major cause of pathologic fractures, specifically fractures of the hip, spine, pelvis, proximal humerus, and wrist.[63] In 2005, osteoporosis accounted for approximately 2 million fractures, 27% of those occurring in the vertebrae. The number of fractures is estimated to grow to over 3 million annually by 2025.[62]

Like all metabolic bone diseases, osteoporosis is not limited to the spine. While 27% of postmenopausal women will develop a vertebral compression fracture, an additional 15% will experience a hip fracture.[64] In the elderly, hip fractures, most caused by osteoporosis, result in death, disability, and dependency: the in-hospital mortality rate in patients with hip fractures exceeds 5%[65]; up to 50% require long-term nursing home care, and more than half do not regain their prefracture level of mobility in the first postoperative year.[66,67]

Among the vertebral fractures, two-thirds are clinically silent; however, these patients have lower quality-of-life function.[68] Of women with scoliosis older than 65 years of age, 75% have at least one osteopenic wedge fracture. Although primary osteoporosis is a common cause of osteopenia in the elderly, it is only one of many possible causes. Medicare patients with vertebral compression fractures have a mortality rate approximately twice that of age-matched controls.[69]

Generally, osteoporosis is classified as either primary or secondary. Primary osteoporosis is further subdivided on the basis of its pathogenesis. Type I, or postmenopausal osteoporosis, is related to the abrupt decline of estrogen levels that occurs in menopausal women. Type II osteoporosis, known as senile or age-related osteoporosis, is due to the progressive decrease of BMD that occurs with aging.

Several risk factors for osteoporosis have been identified. Nonmodifiable risk factors include age greater than 50 years, female sex, family history of fragility fractures, and white or

Asian ethnicity.[70–72] A typical patient is a slim, white, postmenopausal woman of northwestern European descent.[50] She may have a history of premature menopause, cigarette or excessive alcohol use,[37] an eating disorder (e.g., anorexia nervosa), a sedentary lifestyle, use of anticonvulsants,[52] or lifelong low calcium intake.

Secondary osteoporosis results from any medical condition or medication that contributes to accelerated bone loss. A secondary cause of osteoporosis is found in about 30% of postmenopausal women, 40% to 50% of premenopausal women, and 50% to 55% of men. The most common causes are glucocorticoid use, hypogonadism, alcohol abuse, and malnutrition.[73] Corticosteroid-induced osteoporosis is the most common cause of drug-related osteoporosis and is associated with a high fracture rate. Corticosteroid therapy causes bone loss and fractures because it suppresses bone formation and inhibits intestinal calcium absorption, which leads to secondary hyperparathyroidism and increased osteoclastic bone resorption.[74] Less common causes include hematologic and neoplastic diseases, such as multiple myeloma and lymphoma; inflammatory diseases, such as inflammatory bowel disease and rheumatoid arthritis; endocrine conditions, including hyperthyroidism and adrenal insufficiency; human immunodeficiency virus (HIV); renal osteodystrophy; and nutritional deficiencies resulting from bariatric surgery or celiac disease, among others.[73] Endogenous hyperthyroidism increases cortical bone loss and may accelerate skeletal deterioration.[75] Inflammatory bowel disease (i.e., Crohn disease or ulcerative colitis) can cause osteoporosis both from the disease itself and its treatment. Autoimmune disorders and malignancies that destroy localized regions of bone, resulting in isolated areas of low BMD, include rheumatoid arthritis, periodontal disease, myeloma bone disease, and osteolytic bone metastases. These are associated with overexpression of RANKL at the site of pathology. In addition, osteomalacia (vitamin D deficiency) may mask itself as osteoporosis. The distinction is important because antiresorptive medications for osteoporosis are not appropriate choices to treat osteomalacia. Many secondary causes of osteoporosis are treatable and may necessitate a different management course than primary osteoporosis.

Pathology

Osteoporosis is defined as low bone strength. The two components of bone strength are bone mass and bone quality. Osteoporosis results from decreased overall bone mass with normal bone mineralization. Cortical and cancellous bone differ in their microarchitecture but maintain the same molecular composition. In addition, inadequate mineralization, poor-quality collagen, and microfractures all result in diminished bone quality.[76] Bone is remodeled throughout our lives in response to stress, up to 10% of bone mass may be remodeling at any one time. Peak bone mass is attained in the mid-30s for both sexes. Gender, nutrition, race, exercise habits, and overall health all influence bone mass. Peak bone mass is higher in men than in women and higher in African Americans than in whites.[77] After the fourth decade, both men and women lose bone mass from the skeleton (Fig. 88.3). Two phases of this loss have been identified: slow and accelerated. The slow phase, related to a bone remodeling imbalance with less bone formation than resorption, leads to trabecular thinning and subsequently destruction of connections between trabeculae. It results in an annual basal slow-phase rate of bone loss of 0.3% to 0.5%.[78] The accelerated phase that occurs with estrogen deficiency—a phenomenon found exclusively in women—is responsible for cortical bone mass loss of 2% to 3% per year. This loss is in addition to the slow-phase losses, which continue during the accelerated phase. The accelerated phase begins after surgical or natural menopause and lasts for approximately 5 years.[78] Thereafter, bone loss continues at the basal slow-phase rate.

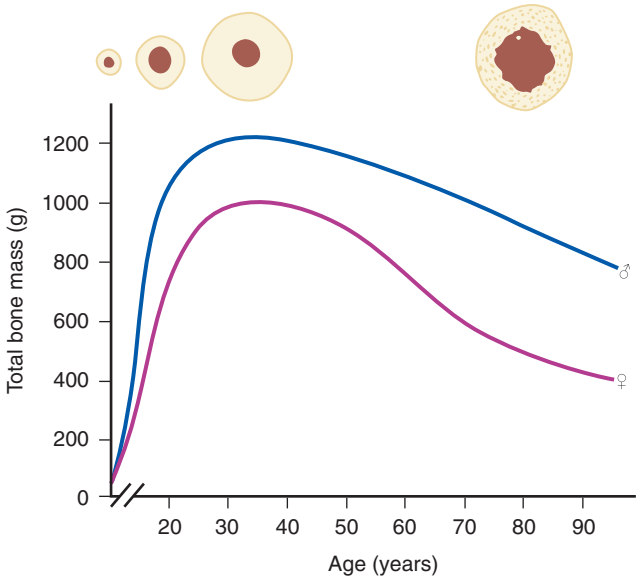

FIG. 88.3 Bone mass as a function of age in men *(blue)* and women *(purple)*. The images above the graph depict a cross-section of bone as maturation occurs over time. Mass is accumulated until peak bone mass is reached and then decreases and becomes more porous in advanced age. (From American Academy of Orthopaedic Surgeons, Park Ridge, IL: 1986.)

Multiple studies have shown the importance of estrogen deficiency in the causation of the accelerated phase.[79,80] Estrogen is thought to play a critical role in maintaining bone mass in adult women by suppressing cancellous bone remodeling and maintaining remodeling balance between osteoblastic and osteoclastic activity. At the molecular level, RANKL expression by bone marrow stromal cells and lymphocytes increases during the acute phase of estrogen deficiency.[81] In addition, estrogen stimulates production of OPG in premenopausal women, which binds RANKL and prevents bone resorption. As estrogen decreases in menopause, the net result of both of these mechanisms is enhanced osteoclast activity and bone loss.[82] Estrogen is also implicated in calcium metabolism through its effects on the kidney and intestine.[83] Others contend that estrogen antagonizes PTH activity[84] or stimulates calcitonin release. Decreased calcitonin levels have been found in oophorectomized and postmenopausal patients. Estrogen likely acts on a multitude of pathways affecting bone metabolism. The administration of estrogen to women during this period of rapid bone loss can decrease the loss in all bones, especially

TABLE 88.1 Type I vs. Type II Osteoporosis

	Type I	Type II
Female/male ratio	6:1	2:1
Calcium deficiency	No	Yes
Estrogen deficiency	Yes	No
Bone loss	Disproportionate loss of trabecular bone	Proportionate loss of both cortical and trabecular bone

From Riggs BL, Melton LJ 3rd. Evidence for two distinct syndromes of involutional osteoporosis. *Am J Med.* 1983;75:899.

those rich in trabecular bone (e.g., the vertebral bodies, the pelvis and other flat bones, in the ends of long bones).[85]

Riggs and Melton[78] have subclassified primary osteoporosis on the basis of patterns of bone loss and fracture (Table 88.1). Type I osteoporosis primarily affects trabecular bone sites and is characterized by fractures of the vertebral bodies and wrist. In patients with type I osteoporosis, the rate of trabecular bone loss is three times above normal, but the rate of cortical bone loss is only slightly above normal. In contrast, type II osteoporosis occurs in both men and women aged 75 years and older and involves areas of predominantly cortical bone. Clinically, fractures of the hip, pelvis, proximal humerus, and proximal tibia are seen. The causes of senile osteoporosis are the aging process itself and chronic calcium deficiency. Senile osteoporosis may also involve decreased vitamin D and increased PTH activity or impaired bone formation. Osteoporosis in women between the ages of 66 and 74 years may represent a combination of these two syndromes.

Metabolic remodeling occurs on the surface of bones and affects primarily trabecular bone. Due to their shape and trabecular pattern, vertebral bodies are preferentially resorbed in times of bone mass loss.[86] Osteoporosis is thus characterized by trabeculae of decreased size and number. Work by Dempster and colleagues[87] has demonstrated that osteoporosis involves a thinning of the cortex and a change in the shape of the trabecular bone from plates to narrow bars. The trabecular bone contains areas in which osteoclasts create a loss of connectivity, leading to a significant and localized weakening of the bone.[87,88] Vertebral body density declines before a similar loss is detected in cortical areas.

The body accommodates bone loss by redistribution. As people grow older, the diameter of the long bones gradually increases in both women and in men. Concurrently, the medullary diameter also increases, leading to a net thinning of the cortical bone. A 10% shift of bone mass outward from the epicenter through an enlargement of the bone diameter will compensate for a 30% decrease in the bone mass against applied bending and torque stresses but not against axial loading. This differential resorption explains the timing and patterns of the fracture syndromes seen in osteoporosis.[66] The incidence of vertebral compression fractures rises immediately after menopause, whereas the hip (with its higher proportion of cortical bone) fractures later in life, when cortical bone loss accumulates over the next 1 to 2 decades. The distal forearm, like the spine, has high trabecular content; thus, the incidence of Colles fractures also increases in menopause.

Deficiencies in dietary calcium cause decreased peak bone mass.[89] White women, on average, have less bone than either white men or African Americans of either sex.[90] Thus, the risk of clinically significant osteoporosis depends on hereditary factors, gender, race, and nutrition, which all contribute to peak bone mass, and aging, which causes progressive bone loss. Although the formation of good bone in sufficient quantity in young adulthood is clearly important, the aging process remains the most important cause of involutional osteoporosis.

Aging leads to bone loss independent of menopause, but the rapid decline of skeletal mass after estrogen deficiency implies that this hormone prevents the dissolution of the skeleton.[91] Nonetheless, its precise mechanism is unclear. Some investigators believe that the action is mediated by estrogen receptors on osteoblasts.[92] Others contend that estrogen antagonizes PTH activity[93] or stimulates endogenous calcitonin release. Decreased calcitonin levels have been found in oophorectomized and postmenopausal patients, and increased calcitonin levels are noted after estrogen administration. Regardless of the mechanism, estrogen deficiency leads to bone loss and plays a major role in the pathogenesis of type I osteoporosis.

The age-related ("slow-phase") bone loss is not affected by estrogen; rather, it likely represents impaired vitamin D metabolism. As an individual ages, the kidney gradually loses its ability to hydroxylate vitamin D into its active form, $1,25(OH)_2D$.[94] This active vitamin D is necessary to transport calcium in the gut; therefore, decreased hydroxylation, often coupled with poor dietary intake, leads to lowered serum calcium levels and, in turn, to elevated secretion of PTH. In addition to secondary hyperparathyroidism, elderly people are also more likely to take medications (e.g., diuretics) that further contribute to calcium losses. Furthermore, there is some evidence that the mechanism in remodeling that couples the actions of osteoclasts and osteoblasts functions suboptimally in old age: after the fourth decade, at a given site of remodeling, less bone is laid down than is resorbed.[90] Accordingly, normal bone turnover in the elderly leads to calcium depletion as well.

Clinical Course

End-stage osteoporosis culminates in fracture.[37,38,95] Still, for most of its course, osteoporosis is a silently progressive disease. Patients typically present to the physician late in the course, following one of three general scenarios. In the first of these, the patient presents with an acute painful fracture, usually of the spine (Fig. 88.4), but possibly of the rib, wrist, or hip. In the spine, normal activity (even minimal activity) may exceed the depleted bones' stress tolerance and result in fracture. The acute fracture can be severely painful, with the pain remaining over the affected area or radiating across the thorax. The pain from a vertebral fracture does not radiate down the legs. Symptoms such as leg pain suggest involvement of the spinal cord and obligate the physician to search for another or concomitant process to explain the pain. Osteoporosis, even if established in such a case, is probably not the only disease present. The acute pain usually abates when the fracture heals.

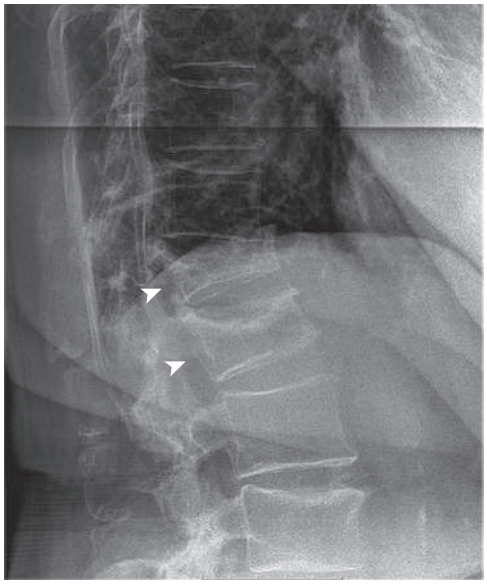

FIG. 88.4 Lateral radiograph of the lumbar spine showing vertebral compression fractures at L1 and L2 levels (*arrowheads*).

Nonetheless, the patient rarely returns to prefracture status. At a minimum, there may be point tenderness over the fracture site. The patient may note constant abdominal pain, often brought about by the constraining forces on the viscera in the now smaller abdominal cavity. Other patients complain of generalized backache. The backache may be due to changing muscular demands brought on by altered spinal curvature. Furthermore, some patients fear reinjury and strictly limit their activities. Others develop chronic pain syndromes, dysthymic states, or even overt clinical depression. Osteoporosis, therefore, often has a profound effect beyond the acute fracture episode. The incidence of vertebral compression fractures (highly trabecular bone) rises after menopause, whereas hip fractures occur 1 to 2 decades after menopause from progressive loss of cortical bone. Evidence suggests that these patients have a 15% increase in 5-year mortality risk.[96]

Not every patient has an acute episode. In an alternate scenario, an asymptomatic thoracic wedge or lumbar compression fracture of the spine may be noted on a radiographic examination performed for an unrelated purpose. These compression fractures may present subacutely, with twinge pain noted on minimal strain or exercise over a period of time, or the patient may even have no complaints at all. The macroscopic fracture observed on radiography, then, represents integration over time of a series of small, individually insignificant microfractures.

In the thoracic spine, both asymptomatic and painful fractures have a predilection for the anterior aspect of the bone. Progressive fracture thus leads to progressive shortening of the anterior height of the vertebral body relative to the posterior. The resultant shape of the body suggests the name of this process: wedge fracture. The wedge shape of the body, when summed over two or more vertebrae, causes dorsal kyphosis. In the lumbar region, the fractures are usually distributed equally throughout the vertebral body. No wedge is formed in this situation, and the process is thus termed *compression* or *collapse fracture*. The combined effects of compression and wedge fractures lead to an unfortunate, but common, skeletal deformity: lost height coupled with excessive dorsal kyphosis. A vertebral body deformation due to an osteoporotic fracture can be difficult to determine.

Finally, generalized osteopenia without fracture may be noted on plain radiographs. This is not a different disease but, rather, an earlier phase of the same process that leads to fracture and deformity. These patients suffer from bone loss but have not yet crossed the critical point of stress tolerance.

TABLE 88.2 Definition of Osteoporosis Based on Total Hip Bone Mass Density

Group	T Score
Normal	≥–1.0 SD
Osteopenia (low bone mass)	Between –1.0 and –2.5 SD
Osteoporosis	≤–2.5 SD
Severe osteoporosis	≤ –2.5 SD and fragility fracture

SD, standard deviation.

Diagnosis

Though osteoporosis is characterized by low bone mass as well as poor bone quality, which includes microarchitectural deterioration, the only readily available test for osteoporosis focuses on the bone mass. BMD measured via dual-energy x-ray absorptiometry (DEXA) remains the clinical standard for diagnosing osteoporosis. The World Health Organization (WHO) defines osteoporosis by the T score, or number of standard deviations (SD) below peak bone mass of healthy adults (Table 88.2). A T score within 1 SD (T score ≥–1) of the mean is considered normal bone density. A T score between 1 and 2.5 SDs below the mean (T score <–1 but –2.5) is defined as osteopenia. Osteoporosis is diagnosed with a T score greater than 2.5 SDs below the mean (T score <–2.5). Concomitant fragility fracture denotes severe osteoporosis.[97]

DEXA also provides a Z score, a value for BMD relative to those of the same age, sex, and ethnicity. The Z score cannot be used to diagnose osteoporosis but is useful for screening for secondary causes of osteoporosis. Patients with a Z score 1.5 SDs below the mean for their age, sex, and ethnicity (Z < –1.5) should be evaluated for secondary causes of osteoporosis.[98] In addition, the Z score less than 1.5 is an indicator of osteoporosis in patients under the age of 40 years old.[99] DEXA is a fast and noninvasive means to determine BMD. It is produced by penetration of a low-energy and high-energy x-ray beam aimed at the posteroanterior spine and hip.

Wrist BMD is measured if the spine/hip measurement cannot be determined, if the patient is obese, or if the patient has hyperparathyroidism.[100] The spine is a useful site for BMD measurement because it predicts the risk of any fracture as well as or better than hip BMD in the perimenopausal population in which hip fracture risk is low. With advancing age, however,

spine measurements are confounded by osteoarthritis and soft tissue calcification to a greater degree than the hip.[101,102] For this reason, the hip is the preferred site, especially in women older than 60 years. Based on the WHO diagnostic threshold, 15% to 20% of postmenopausal women can be identified as having osteoporosis when measurements using DEXA are made at the spine or hip.[95] The US Preventive Services Task Force recommends that all women aged 65 years should receive a DEXA scan. They conclude that there is insufficient evidence to suggest screening in men,[103] but the National Osteoporosis Foundation recommends DEXA screening in men aged 70 years or those older than 50 years with risk factors.[104]

The Fracture Risk Assessment Tool (FRAX) provides physicians a means to determine 10-year fracture risk in at-risk populations. The FRAX model was developed by the WHO by studying population-based cohorts around the world. This was created to broaden the evaluation beyond bone density alone. Factors evaluated by FRAX include age, sex, height and weight, previous fracture, parent with fractured hip, smoking and alcohol use, glucocorticoid use, rheumatoid arthritis, secondary osteoporosis, and BMD at the femoral neck. An individual with a 20% chance of a long bone fracture or a 3% chance of a hip fracture within 10 years is deemed of sufficient risk to warrant antiosteoporotic drug intervention.

While BMD is an indispensable tool in evaluating for osteoporosis, the National Bone Health Alliance issued a statement that osteoporosis may be diagnosed clinically based on the presence of hip fracture; osteopenia-associated vertebral, proximal humerus, pelvis, or low-trauma distal forearm fracture; or FRAX scores with more than 3% (hip) or 20% (major) 10-year fracture risk.[63]

The trabecular bone score is a newly developed tool that estimates trabecular microarchitecture using gray-level texture measurements of DEXA images. The diagnostic utility of this tool is under continuing investigation, but reports show that low lumbar spine trabecular bone score is associated with both history of fracture and incidence of new fracture. This tool has shown greatest utility in patients who are close to an intervention threshold based on BMD. Notably, it is unclear at this time whether trabecular bone score continues to reflect fracture risk once osteoporosis treatment is initiated.[105]

Evaluation for Osteoporosis

Once diagnosed with osteoporosis, a complete medical history should be obtained with particular attention to the risk factors for osteoporosis. These include age of 65 years or older, a history of vertebral fracture or any fracture during childhood, a family history of hip fracture, low body weight (body mass index [BMI] <21 or weight <127 pounds), cigarette smoking, and use of corticosteroids for more than 3 months.[106] Assessment of fall risk in the elderly should also be performed by evaluating orthostatic hypotension, cognitive impairment, sedating medications, and loss of vision/hearing. Physical examination for vertebral injuries should be included as up to two-thirds of osteoporotic compression fractures are asymptomatic.[107] Examination includes height, excessive deformity, and tenderness over the spinous process.

Laboratory Investigations for Osteoporosis

Generally, laboratory investigations other than bone mass density measurement are not required for the diagnosis of osteoporosis. Some routine tests, however, should be performed to obtain baseline values as part of the initial workup. These include complete blood count with differential, urinalysis, and blood chemistry profiles with serum calcium and phosphate. Although vitamin D deficiency is common among the elderly, with a prevalence of approximately 50%, many patients are asymptomatic. In addition, serum calcium and phosphate levels in this group of patients may not necessarily be abnormal. All older individuals, therefore, should be tested for vitamin D deficiency by measuring levels of 25(OH)D. If low, adequate vitamin D supplementation is encouraged. Performance speed and proximal muscle strength were markedly improved when 25(OH)D levels increased from 4 to 16 ng/mL and continued to improve as the levels increased to more than 40 ng/mL.[108]

Notably, blacks consistently have lower levels of 25(OH)D than whites, and are frequently labeled as having vitamin D deficiency. However, this population also has significantly lower levels of vitamin D–binding protein due to high prevalence of a common genetic variant. The low level of vitamin D–binding protein results in levels of bioactive 25(OH)D that are equivalent to those in whites. Indeed, black patients with measured 25(OH)D levels below the threshold used to diagnose vitamin D deficiency do not typically have the associated clinical manifestations. Therefore, low vitamin D levels in this population should be interpreted with caution and future workups may incorporate vitamin D–binding protein levels as well.[109]

Some special laboratory tests are available to measure the balance between bone resorption and bone formation from serum and urine samples. These assays are called *biochemical bone markers*. Biochemical bone markers can be classified into two groups: bone formation and bone resorption markers (Table 88.3). Although BMD is a critical measurement used

TABLE 88.3 Biochemical Markers of Bone Turnover

Bone Formation Markers	Bone Resorption Markers
Serum	***Serum***
• Bone-specific alkaline phosphatase • Osteocalcin • Carboxyterminal propeptide of type I collagen • Aminoterminal propeptide of type I collagen	• Tartrate-resistant acid phosphatase • NTXs • CTXs
	Urine
	• Free and total pyridinolines • Free and total deoxypyridinolines • NTXs • CTXs

CTX, C-telopeptide of collagen cross-link; NTX, N-telopeptide of collagen cross-link.

to evaluate patients for osteoporosis, it represents a static parameter that provides no information regarding the rate of bone turnover in a given patient. Biochemical bone markers are generally noninvasive, widely available, quickly performed, and relatively inexpensive. Unlike DEXAs, they can be used repeatedly over short intervals to assess the dynamic process of bone turnover. In principle, they can be used (along with BMD) to predict future risk of fracture.

Biochemical Markers of Bone Turnover

During bone formation, osteoblasts produce type I collagen, which is their major synthetic product. Carboxy-terminal propeptide and amino-terminal propeptide of type I collagen, known as *PICP* and *PINP*, respectively, are cleaved from the newly formed collagen molecule and therefore can be used as the indices to indicate type I collagen biosynthesis. Osteoblasts also secrete a variety of noncollagenous proteins, two of which are used clinically as markers of osteoblast activity: bone-specific alkaline phosphatase and osteocalcin. It is these non-collagenous products that are most useful as markers for bone formation. Although alkaline phosphatase is derived from several tissues, the two most common sources are from liver and bone. Utilization of tissue-specific monoclonal antibodies enables differentiation between liver and bone isoform; however, the bone isoform has 10% to 20% cross-reactivity with the liver isoform.[110]

During osteoclast-mediated bone resorption, the collagen structure within bone is degraded. This collagen degradation product is used as an indicator for bone resorption. In general, collagen molecules in bone matrix are staggered to form collagen fibrils by covalent cross-links.[111] These cross-links consist of pyridinolines (Pyds) and deoxypyridinolines (Dpds). Pyd and Dpd cross-links occur at two intermolecular sites in the collagen molecule: amino-terminal-telopeptide (NTX) and carboxy-terminal-telopeptide (CTX). As part of this degradation process, cross-linked collagen peptides from both the NTX and CTX are released and achieve measurable concentrations in both serum and urine. Therefore, when osteoclasts resorb bone, they release a variety of collagen breakdown products into the circulation that are further metabolized by the liver and kidney. These include free Pyds, free Dpds, NTX, and CTX.

Despite the popularity of urine NTX, there are limitations to its use as a dynamic measure of bone resorption. As with other urine biochemical bone markers, NTX must be normalized for creatinine clearance. The urine assay loses reliability with impaired renal function, and the serum markers are then preferred. Biochemical bone markers are also subject to technical and biologic variability. Unlike BMD measurements for osteopenia and osteoporosis, there are currently no accepted criteria for what constitutes a high turnover rate.

The use of bone biochemical markers to determine therapy effectiveness is their best established clinical use. Several studies indicate that, within 4 to 6 weeks, there is significant reduction in biochemical markers of bone resorption after initiation of antiresorptive therapy.[112–114] Lack of marker reduction may indicate noncompliance or the need to change the dosage or the therapeutic agent. Serial BMD tests should be at least 12 (and possibly 24) months apart; therefore, more frequent measurements of biochemical markers offer a significant advantage.

Evaluation for Secondary Osteoporosis

When secondary osteoporosis is suspected on the basis of clinical findings or because the patient is relatively young and presented with a fragility fracture, specific tests should be considered to evaluate contributing causes that may require additional medical attention. These include basic laboratory investigation of a complete blood count with differential, erythrocyte sedimentation rate, serum calcium and phosphate levels, liver function tests, thyroid-stimulating hormone level, testosterone level in men, and a serum protein electrophoresis if myeloma is considered (Table 88.4). When abnormalities are detected, the patient should be referred to a specialist for further evaluation and specific treatment (see Table 88.4).

TABLE 88.4 Laboratory Investigations for Secondary Osteoporosis

Medical Diseases	Diagnostic Study
Endocrine	
Hyperparathyroidism	Serum calcium, serum phosphate, parathyroid hormone level
Hyperthyroidism	TSH, T3, free T4
Hypogonadism	LH, FSH, estrogen, testosterone (men)
Diabetes	Blood glucose
Gastrointestinal Disorders	
Crohn disease, ulcerative colitis	CBC, ESR, CRP, serum albumin, colonoscopy
Liver Disease	
Primary biliary cirrhosis, chronic active hepatitis	Liver function test, antimitochondrial antibody, antibody for hepatitis A, B, and C
Bone Marrow Disorders	
Multiple myeloma, leukemia, lymphoma	CBC with differential, serum calcium, serum protein electrophoresis
Collagen Vascular Disease	
Osteogenesis imperfecta, Ehlers-Danlos syndrome, Marfan syndrome	Genetic testing for collagen defects
Inflammatory Disease	
Rheumatoid arthritis	CBC, ESR, CRP, rheumatoid factor
Other	
Renal failure	BUN, creatinine
Osteomalacia	Serum 25-hydroxy-vitamin D, parathyroid hormone level

BUN, blood urea nitrogen; CBC, complete blood count; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TSH, thyroid-stimulating hormone.
Data from Unnanuntana A, Gladnick BP, Lane JM: Osteoporosis and the aging spine: diagnosis and treatment. In: Yue JJ, Guyer RD, Hochschuler SH, et al., eds. *The Comprehensive Treatment of the Aging Spine: Minimally Invasive and Advanced Techniques.* Philadelphia: Elsevier; 2011.

Prevention and Treatment

Osteoporosis is a silent disease with a multitude of causes and risk factors. Patients may not present until they experience a fall and painful fracture; even those patients may not present with fracture pain, which often abates without intervention. First and foremost, treatment aims at prevention of osteoporosis and associated morbidity. Building strong bones begins in childhood and adolescence. Up to 90% of peak bone mass occurs at age 18 years in girls and 20 years in boys and may continue to climb until age 30 years. At this point, peak bone mass is achieved.[115] Adequate peak bone mass is achieved through proper nutrition, including calcium and vitamin D, exercise, and avoidance of smoking and alcohol abuse. Inadequate calcium intake during adolescence can account for a 10% reduction in peak bone mass.[115] Smoking one pack per day throughout adult life is associated with a 5% to 10% reduction in bone density,[116] and cigarette smoking is also associated with accelerated metabolism of estrogen.[117] It is recommended that clinicians strongly encourage smoking cessation when initiating osteoporosis treatment.

Nutrition, Calcium, and Vitamin D Supplementation

First-line treatment of osteoporosis includes adequate dietary intake of calories, protein, calcium, and vitamin D. Calcium and vitamin D supplementation is the cornerstone of all treatment modalities for osteoporosis. Literature has clearly shown that adequate calcium and vitamin D intake reduces the risk of fractures.[118] Adequate calcium and vitamin D intake reduces fracture risk.[118] A diet balanced with fruit, vegetables, and low-fat dairy can provide the majority of calcium needs. The National Osteoporotic Foundation (NOF) and Institute of Medicine recommend that men age 50 to 70 years consume 1000 mg per day of calcium and that women age 51 years and older and men age 71 years and older consume 1200 mg per day.[119–122] To maximize the absorption of calcium across the small bowels, no more than 500 to 600 mg of elemental calcium should be taken at any given time.[123] A patient's PTH level is used to adjust the dose of calcium to the individual patient. Generally, a PTH greater than 50 pg/mL indicates inadequate calcium, while a PTH less than 25 pg/mL suggests oversupplementation of calcium. Among all calcium formulations, calcium citrate is the preferred form because it can be readily absorbed in patients taking proton pump inhibitors or H_2 blockers, and it does not lead to kidney stone formation.[124]

The current recommended dosages of vitamin D_3 from the Institute of Medicine are 600 to 800 IU per day,[120] whereas the NOF recommends 800 to 1000 international units (IU) of vitamin D per day for adults aged 50 years and older.[119] However, many experts consider these recommendations to be too low and suggest that the minimum adult intake should be 1000 to 2000 IU/day.[125] The appropriate amount of vitamin D intake should be evaluated by monitoring 25(OH)D level and serum PTH. Experts suggest that 25(OH)D concentration be maintained at a minimum of 50 nmol or 20 ng/mL.[126] The upper limit of safety is estimated to be 125 nmol/L. Toxicity is rare even if a dosage of 10,000 IU/day is given for up to 5 months.[126,127]

Protein is also a significant contributor to bone health. A randomized prospective study that studied hip fractures in 82 elderly women demonstrated that those who took protein supplementation in addition to calcium and vitamin D supplements had an attenuation of the loss of bone at 1 year compared with those who received nonprotein supplements.[128] However, high dietary protein and sodium increase urinary calcium excretion and have also been shown to decrease the calcium available to the skeleton.[129]

Exercise

Those diagnosed with osteoporosis are recommended to engage in exercise 3 to 5 times per week for at least 45 minutes.[119] Regular physical activity reduces the risk for osteoporosis and osteoporotic fractures.[130,131] Weight-bearing exercise has beneficial effects on BMD, including that of the spine in both premenopausal and postmenopausal women.[130,132-135] In one study, young women (aged 20 to 35 years) were randomized into groups of exercise and calcium supplementation for 2 years and bone density at various sites was evaluated. The group randomized to the aerobics and weight-training program had a 2.5% increase in their spine density compared with the calcium and stretching program.[136] Muscle mass is significantly correlated to bone mass,[40] suggesting that increased skeletal loading leads to increased bone mass. As little as 1 hour of exercise two or three times per week can increase vertebral bone mass in postmenopausal women, whereas inactivity results in continued bone loss and increased risk for hip fracture.[137]

Immobilization results in decreased bone mass through increased activation at remodeling sites and decreased osteoblast stimulation.[138] Bone loss with complete immobilization can reach 40% in 1 year but can be prevented with upright positioning and daily postural shifting for 30 minutes.[139] Permanent bone loss can be prevented by instituting exercise within the first months of immobilization.[138] Therefore, although the gains in bone mass with exercise may be small, the decline in bone mass and subsequent increased fracture risk with inactivity can be substantial and irreversible.

Regular physical activity also improves muscle strength and balance, thus reducing the risk of falls.[140-143] Recommended exercises include resistance training, walking/jogging, Tai Chi, yoga, and Pilates. These programs significantly improve balance,[144] mitigate the fear of falling, and reduce falls in the elderly by more than 47%.[140]

Conservative management of osteoporotic patients should include an exercise program to minimize the effects of a more sedentary lifestyle common in the elderly. The prescribing physician should tailor the exercise regimen to the patient's overall fitness, most specifically cardiac tolerance. Accordingly, exercises that deliver high impact for a given aerobic effort, such as walking, are preferable to those that have less effect, such as swimming. Nevertheless, general muscle-strengthening therapy prevents falls.

A comprehensive general rehabilitation program that stresses spine extension and abdominal-strengthening exercises without flexion, as well as impact-loading activities such as walking, should be part of the treatment plan for every osteoporotic patient. Persistent participation in the exercise program is important because the benefits of exercise are quickly lost with cessation of the exercise regimen.[134]

Pharmacologic Treatment

Current pharmacotherapies aim to improve BMD and halt osteoporosis progression.

The NOF recommends pharmacologic treatment in postmenopausal women and men aged 50 years or older who have a hip or vertebral fracture, T score of –2.5 with secondary causes ruled out, or a T score between –1.0 and –2.5 with 10-year hip fracture risk of at least 3% or 10-year risk of osteoporotic fracture of 20%.[119] Current US Food and Drug Administration (FDA)-approved pharmacotherapies for osteoporosis include bisphosphonates, estrogen agonists, calcitonin, PTH, and the RANKL inhibitor denosumab. According to the American Association of Clinical Endocrinology, the bisphosphonates—alendronate, risedronate, and zoledronic acid—and denosumab are first-line therapies. Second-line agents include ibandronate and raloxifene. Calcitonin is a last-line agent and teriparatide is reserved for high fracture risk patients in whom bisphosphonates have failed or anabolic agents are indicated.[145] Before beginning pharmacologic treatment, all patients should take calcium and vitamin D supplements and participate in an exercise regimen.

Estrogen

Hormone replacement therapy, including estrogen, was once considered first-line treatment for osteoporosis. Postmenopausal osteoporosis results from loss of estrogen; its replacement has been shown to increase bone mass and reduce the risk of vertebral and hip fractures by 30% to 40%.[146] Hormone replacement therapy is no longer considered first-line therapy for osteoporosis because of its association with breast cancer, myocardial infarction, stroke, and venous thromboembolism.[146] Rather, it is used for management of postmenopausal symptoms in a tapered fashion.[146]

Selective Estrogen Receptor Modulators (SERMs)

Selective estrogen receptor modulators (SERMs) were developed for their beneficial effects of estrogen while limiting the adverse side effects described earlier. Raloxifene (Evista) is FDA approved for both the prevention of breast cancer, decreasing the risk by 70%, and for osteoporosis through its effects on bone estrogen receptors.[147] Raloxifene has been shown to reduce the risk of vertebral fracture but has no significant effect on nonvertebral fractures.[148] Its beneficial effects must be weighed with increased risk of venous thromboembolism and exacerbation of postmenopausal symptoms.[148,149] In 2013, the FDA approved the use of bazedoxifene combined with conjugated estrogens for the treatment of osteoporosis and vasomotor menopausal symptoms. This combination has increased BMD of the spine and hip significantly greater than raloxifene alone.[150] The benefit of SERMs should be weighed against their potential harmful side effects before initiation of treatment.

Bisphosphonates

Bisphosphonates are the most commonly used antiresorptive agents in the treatment of osteoporosis and are available in both oral and intravenous forms. Several bisphosphonates have been approved by the FDA for the treatment and prevention of osteoporosis: alendronate (Fosamax), risedronate (Actonel), ibandronate (Boniva), and zoledronic acid (Reclast). Bisphosphonates exist as nitrogen-containing and non-nitrogen-containing forms. Nitrogen-containing bisphosphonates inhibit osteoclast GTPase synthesis via farnesyl pyrophosphate synthase enzyme, inactivating these cells. Non-nitrogen-containing bisphosphonates form an ATP analog, preventing DNA synthesis and ultimately osteoclast apoptosis.[151] These drugs differ in their potency, administration, and dosing schedules. All bisphosphonates bind to bone and reside within the bone mineral for periods of up to 60 years. Alendronate and risedronate are given orally, zoledronic acid intravenously, and ibandronate is available in both oral and intravenous formulations. Bone turnover rate significantly slows within 6 weeks in those taking oral formulations and within 3 days with intravenous formulations.

Several clinical trials have shown that oral bisphosphonates —alendronate (Fosamax), risedronate (Actonel, Atelvia), and ibandronate (Boniva)—reduce the risk of osteoporotic fractures of the spine by 70% and hip up to 50% over 1 to 3 years after previous fracture.[152–154] Intravenous zoledronic acid is the most potent bisphosphonate available, increasing BMD of the spine by 4.3% to 5.1% and BMD of the hip by 3.1% to 3.5% compared with placebo. It also reduced the incidence of vertebral fractures by 70%, hip fractures by 41%, and nonvertebral fractures by 25% over 3 years.[152] It reduces cardiac mortality by more than 20% when given within 3 months of hip fracture without affecting fracture healing.[155]

The most common side effects of bisphosphonates include difficulty swallowing and dyspepsia from mucosal irritation. All bisphosphonates can affect renal function and are contraindicated in patients with a glomerular filtration rate less than 30 mL/min.[119] Acute renal failure requiring dialysis has been reported with zoledronic acid use; therefore, the FDA recommends serum creatinine testing before administration.[156] Long-term use of bisphosphonates beyond 5 years is associated with osteonecrosis of the jaw (ONJ), although this is more common with high doses used to treat bone cancers.[157] ONJ is characterized by exposed bone in the musculofascial region that fails to heal after 8 weeks. Prolonged use of bisphosphonates can lead to adynamic fragile bone, resulting in atypical fractures of the femur. Atypical subtrochanteric and femoral shaft fractures appear radiographically as a transverse pattern with beaking of the cortex and occur with minimal trauma. Any patient presenting with groin pain should be evaluated with radiographs of both hips and potentially MRI or bone

scan if suspicion persists. The absolute risk of atypical subtrochanteric or femoral shaft fracture after 5 years of bisphosphonate use is 0.13% during the subsequent year and 0.22% within 2 years.[158] The American Association of Clinical Endocrinology recommends a drug holiday after 4 to 5 years of bisphosphonate therapy in mild osteoporosis.[145] While effective, the use of bisphosphonates requires the prescribing physician to be vigilant for the potentially severe side effects.

Calcitonin

Calcitonin (Fortical, Miacalcin) works by inhibiting osteoclastic bone resorption. Evidence suggests a reduction of vertebral fractures with modest effect on BMD.[159,160] Calcitonin may offer an analgesic effect in vertebral fractures, thought to be mediated by increased beta endorphins.[161] A postmarketing analysis by the FDA revealed increased risk of malignancy, 4.1% versus 2.9% in placebo groups, although a causal relationship has not been identified.[70] It is available as injection or nasal spray and is indicated only in postmenopausal women with reduced BMD in whom other agents have failed.

Anabolic Agents

Teriparatide (Forteo), recombinant human parathyroid hormone (1–34), is the only anabolic agent available for the treatment of osteoporosis. It is indicated for postmenopausal women or hypogonadal men who are at high risk for fracture and intolerant to or failed other treatment options. It is contraindicated in patients with hypercalcemia, renal impairment, pregnancy, breastfeeding, skeletal malignancy, Paget disease, or elevated alkaline phosphatase.[162] When given continuously, it results in increased bone turnover and net bone loss; however, when given intermittently, it leads to an anabolic phase and increased bone mass. It has been shown to increase bone mass up to 13% over 2 years[163] with reduction of vertebral and nonvertebral fractures by 65% and 53%, respectively.[164] Evidence suggests benefits of teriparatide on fracture healing through accelerated callus formation and proliferation of osteoprogenitor cells. Studies have shown promotion of healing in atypical subtrochanteric fractures associated with bisphosphonate use[165] as well as treatment of ONJ.[166] Prolonged exposure to high doses of teriparatide in rodents has been associated with increased risk of osteosarcoma.[167] Patients should be monitored using serum calcium, PTH levels, and 25(OH) vitamin D levels and treatment discontinued after 2 years.

Denosumab

Denosumab (Prolia) is approved for the treatment of men and postmenopausal women with osteoporosis at high risk for fracture. It is a human monoclonal antibody that acts as a RANKL inhibitor, dosed every 6 months by subcutaneous injection. Over 3 years, denosumab reduces the risk of vertebral fractures by 68%, hip fractures by 40%, and nonvertebral fractures by 20%.[168] Denosumab is associated with hypocalcemia, skin rash, and, less commonly, ONJ and atypical femur fractures. It does not bind to bone and is not measurable within the body after 2 months.

Pharmacologic Agents and Spinal Fusion

The effect of bisphosphonates on spinal fusion rates in animal models has provided inconsistent results. Several studies have shown no effect on fusion rates in porcine and rabbit models receiving alendronate postoperatively.[169–172] Others have shown increased size of fusion mass, new bone formation, and improved adherence at the screw-bone interface in rat models.[172,173] Nagahama et al.[174] performed a prospective randomized controlled trial in humans with osteoporosis undergoing lumbar interbody fusion. They demonstrated greater 1-year fusion rates (95%) in those receiving alendronate compared to control groups receiving vitamin D (65%). They also demonstrated decreased rates of cage subsidence, pseudarthrosis, and adjacent-level compression fractures in those taking alendronate.[174] Intermittent administration of teriparatide in both rat and rabbit models significantly enhanced spinal fusion rates and increased the fusion mass.[175,176] Clinically, in randomized trials, PTH enhanced distal radius fracture and pelvic fracture fusion rates over controls. A recent series of randomized blinded trials of PTH, risedronate, and controls were tested in 1-level and 2-level spine fusions by Ohtori and his colleagues.[177] PTH decreased fusion failure by 50% and pedicle screw pullout by 50%. Risedronate, a bisphosphonate, was undistinguished from controls. Presently, the use of calcium and vitamin D supplements, bisphosphonates, teriparatide, and anabolic agents appears to enhance spinal fusion rates in the perioperative period.[178]

Strategies for Treatment of the Osteoporosis Spine Patient

Patients considered for spine surgery with a diagnosis of osteopenia or osteoporosis should optimize nutrition status with adequate protein intake, calcium, and vitamin D supplementation. If a patient is under consideration and has significant osteoporosis, consider presurgical treatment with an anabolic agent to increase trabecular bone for 3 to 6 months. At surgery, in line with Ohtori data, place on anabolic PTH until fusion is united, usually for 1 to 2 years. If there is prior bisphosphonate exposure and low bone turnover (NTX <20), pretreat with PTH until NTX is over 20 and then continue for 2 years postoperatively. If the patient has osteopenia, hold bisphosphonate until fusion takes, then start bisphosphonate.

Spinal cord injury (SCI) results in unique and significant loss of BMD in its distribution, rate, and mechanism. In patients with complete SCI, sublesional BMD loss may approach 1% per week during the initial postinjury period. This rate is significantly higher than disuse osteopenia seen in nonparalytic conditions, such as bed rest. Proposed mechanisms include loss of sensory and sympathetic osteoanabolic innervation and catabolic effects of muscle atrophy. The rate of sublesional fracture in complete SCI patients is 1% for the first year and then 4.6% for each additional year.[179] Given the accelerated bone loss in these patients, an aggressive approach

is recommended, including optimizing calcium and vitamin D intake, the use of antiosteoclastic medications such as bisphosphonates, teriparatide, or denosumab, correction of hypogonadal states, and weight-bearing movements, such as gait training.

Future Directions

Current pharmacologic agents for the treatment of osteoporosis have unique mechanisms, benefits, and side effects. These factors must be considered for each patient given each individual's diagnosis and associated risk factors. Current developmental treatments focus on monoclonal antibodies targeting specific metabolites and enzymes involved in bone homeostasis. Research in rare genetic diseases—sclerosteosis and Van Buchem disease—has led to the discovery of the protein sclerostin. This protein inhibits the Wnt signaling pathway and formation of new bone. Current trials using rosozumab and blosozumab, monoclonal antibodies against sclerostin, demonstrate superiority to placebo.[12,181] Emerging pharmacologic agents should aim to reduce resorptive activity while promoting bone formation in a way that maintains the structural integrity of the bone and limits side effects of the drugs.

Strontium ranelate is an agent that has both antiresorptive and anabolic action. Treatment of postmenopausal osteoporotic women with strontium ranelate has been shown to decrease fracture risk and increase bone mineral density.[182,183] The long-term effects, however, remain unknown. The development of new formulations of teriparatide (noninjectable forms) or development of alternative PTH analogs that possess longer half-life, leading to less frequent dosing, are also under investigation.[184,185]

Paget Disease of Bone (Osteitis Deformans)

Paget disease of the bone is the second most prevalent metabolic bone disease. The overall incidence of Paget disease is decreasing, however.[186,187] The pelvis is the most frequently affected site, but the disease in the pelvis is most often asymptomatic. When Paget disease is clinically apparent, spinal complaints, notably pain, are the most common.[188] Paget disease primarily affects older individuals; in the United States, it occurs in 2% to 3% of people older than the age of 60 years.[189] Paget disease affects men and women equally and has a distinctive geographic distribution. It is found more commonly in the United Kingdom, North America, Australia, New Zealand, France, and Germany. It is rarely encountered in Scandinavia, China, Japan, India, Africa, or the Middle East.[103,190]

Pathology

Paget disease is a focal disorder of accelerated skeletal remodeling that usually involves a single bone (monostotic) or several bones (polyostotic) and rarely affects numerous bones. Initially, there is an increase in the rate of bone resorption at areas of bone remodeling (Fig. 88.5). Pagetic osteoclasts are abnormal in several ways: they are greater in size and number and highly multinucleate, with up to 100 nuclei.[191,192] In response to this increased resorptive activity, additional osteoblasts are recruited to remodeling sites, with increased production of qualitatively poor new bone matrix that is deposited in a disorganized woven pattern. The result is increased bone formation and a disruption of the normally organized lamellar collagen architecture.[191] Over time, this woven bone is incompletely replaced by more organized bone, as is the case with a fracture callus.

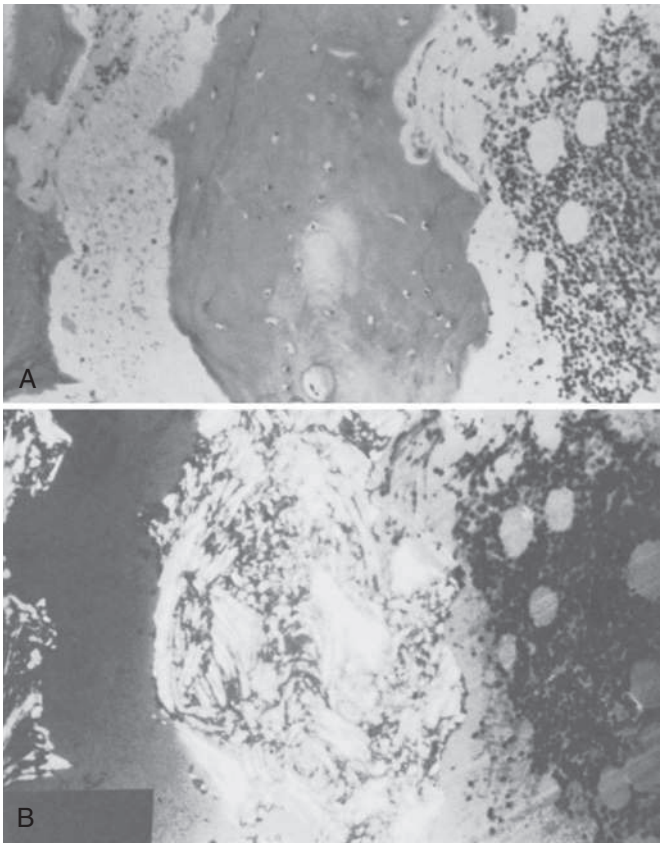

FIG. 88.5 Histologic appearance of Paget disease. (A) Mosaic pattern. (B) Polarized view of disorganized collagen. (From Disorders of Bone 20. Orthop. Science. Park Ridge, IL: American Academy of Orthopaedic Surgeons; 1986.)

The etiology of Paget disease remains unknown. Evidence exists for both viral and hereditary causes. Genetic factors seem to play a role, as evidenced by the epidemiology of British migrants being affected more frequently. Familial clusters of Paget disease have been documented.[193,194] A positive family history has been reported in up to 40% of patients.[189] A first-degree relative has 7 times greater risk of developing Paget disease.[194] Genetic studies have identified several possible loci for Paget disease.[195–197] Sequestosome 1 (*SQSTM1*) is the best studied and encodes for a scaffold protein (p62) in the nuclear factor κ1 (NF κ1) signaling pathway.[198] The common area of interruption is the region encoding the binding site for ubiquitin. The loss of the ubiquitin site leads to dysregulation of the protein, which is thought to lead to activation of the RANKL pathway and subsequent increased osteoclast activity.[45] There is currently a large clinical trial

investigating if zolendronate may prevent or delay the onset of Paget disease in patients with *SQSTM1* gene mutations.[199]

Environmental factors also may play a role in Paget disease. Initial enthusiasm for a viral etiology was stimulated by the nuclear and cytoplasmic inclusion bodies, similar to paramyxovirus nucleocapsids, detected in affected osteoclasts by numerous methods in several studies.[200–203] Several syncytial viruses and canine distemper virus have also been postulated to play a role in the etiology of Paget disease.[200,201] A characteristic feature of these viruses is their ability to persist at low levels and invade the host immune system.

Despite decades of research, a pure viral cause for Paget disease has not been proven. No virus has ever been cultured from pagetic cells. Polymerase chain reaction studies have had mixed results attempting to isolate measles virus and canine distemper virus from blood and osteoblasts of patients with the disease.[204,205] Also, unlike the distinctive geographic distribution of paget disease, measles has a similar incidence worldwide and occurs in young patients, whereas Paget disease generally occurs in the elderly.[206] Furthermore, similar viral nuclear inclusion bodies have been identified in other skeletal disorders; thus, the virus may be a nonetiologic cotraveler in an osteoclast altered by some other mechanism.

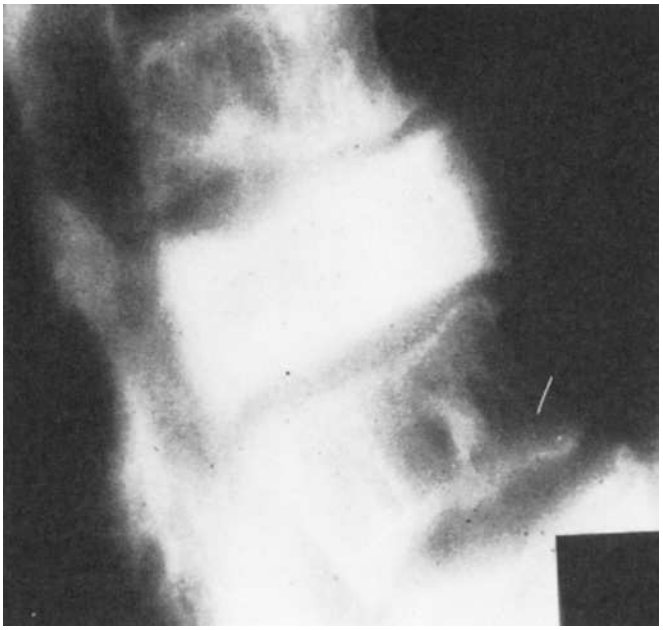

FIG. 88.6 Spinal involvement in Paget disease. The vertebral body is squared and enlarged.

Clinical Course

Most patients with Paget disease are asymptomatic. In fact, 22% of patients diagnosed with Paget disease are asymptomatic. The disease is often detected when the patient has a radiograph taken or serum alkaline phosphatase measured for an unrelated reason. In the majority of patients with Paget disease, one or several bones are involved. In decreasing order, the most commonly involved bones include the pelvis, lumbar spine, femur, thoracic spine, skull, tibia, humerus, and cervical spine; however, any bone may be affected. The lumbar, thoracic, and cervical vertebrae are affected in 58%, 45%, and 14% of patients, respectively.[204,207]

Clinical manifestations, when present, cover a wide spectrum. In order of decreasing frequency, symptomatic individuals may present with pain, bone deformity, deafness, and pathologic fractures.[208] Patients who are symptomatic most often present with back pain,[209] although other areas, especially the hip, can be involved. The skull can be implicated in the disease, and when it is the woven bone, expansion can encroach on the cranial nerves, most typically the eighth nerve. Both the acoustic and the vestibular branches can be affected; thus, the initial presentation of Paget disease might be decreased hearing or difficulty with gait or balance.[210]

In the spine, the pain is infrequently due to primary pagetic involvement alone but rather represents related secondary changes (Fig. 88.6).[211] These include osteoarthritis of the spinal facets; encroachment on the spinal cord; or, in the case of intense pain, pathologic fracture. When the spinal column is involved, most often it is the thoracolumbar regions that are affected, but cervical disease may also contribute.[212] Involvement of the spinal cord may be secondary to a mechanical or vascular complication. Of the mechanical causes, vertebral collapse, osteophytic overgrowth, or bony volume expansion in the osteosclerotic phase (discussed later) can all impinge on neural elements.[213] The spinal cord's vascular supply can likewise be disrupted by bone compression of afferent arteries, leading to neural ischemia. In addition, Paget disease causes a reactive vasodilation near diseased areas. This may lead to shunting of blood and ischemia of the deprived areas. In the spine, increased blood flow around pagetic lesions may result in a diversion of blood destined for the cord, causing the so-called arterial steal phenomenon and leading to neurologic signs. In summary, spinal Paget disease can cause not only bone pain and arthritis or pathologic fractures but also, through its effect on nerves, headaches, hearing or vision loss, cerebellar deficits, and even fecal and urinary incontinence.

A hallmark of Paget disease is skeletal deformity, which may be manifest as an increase in bone size or an abnormality in bone shape. Bone is resorbed and replaced rapidly in Paget disease, and the replacement bone is necessarily less organized and weaker. In weight-bearing bones, this can cause skeletal deformities.[214] Although this problem is more common in the femur and tibia, it can occur in the spine, leading to significant kyphotic changes.

Paget disease can also cause high-output cardiac failure. This rare occurrence is not due to increased blood flow within the pagetic bone but rather to reactive vasodilatation of the tissue adjacent to the involved bone. This increased vascular flow explains the skin warmth felt over the involved bone and, as discussed earlier, may cause ischemia in regions where the blood normally flows.

The most serious clinical complication of Paget disease heralded by the acute onset of pain or sharp increase in the intensity of chronic pain is osteosarcoma or other types of sarcoma. Although the incidence of osteosarcoma is less than 1% of patients with Paget disease, it is 1000 times higher than in the general population for this age group.[215] Moreover, the

tumors that do form are particularly aggressive. Fortunately, sarcomatous degeneration is especially infrequent in spinal Paget disease. An unusual form of tumorous degeneration in Paget disease is the giant cell tumor. The lesion is frequently multifocal and has a unique association with individuals from Avellino, Italy.[216] The tumor frequently involves the spine and leads to paraplegia unless treated. It responds to dexamethasone therapy, which can be augmented by selective radiation.

Other clinical manifestations of Paget disease may be related to the phase of the patient's disease. During the early osteolytic phase, for example, the patient may suffer the consequences of bone loss, such as a pathologic fracture, whereas in the late sclerotic phase, arthritic complaints predominate. Furthermore, Paget disease may advance geographically within a bone or may progress from a monostotic disease to one involving many bones. Therefore, a mixed picture may be observed, with lysis in some areas and sclerosis in others.

Diagnosis

Radiographic Assessment

Paget disease is nearly always diagnosed radiographically. Although the osteoclastic lesion is readily apparent on histologic section, because the radiologic presentation is classic and generally unambiguous, there is rarely a need to progress beyond radiographs. Paget disease occurs in three phases, each of which has a distinct appearance on radiographs. In the earliest phase of the disease (lytic phase) when osteoclast resorption predominates, a well-demarcated, circular region of decreased bone density may be seen in the affected bone. This lesion has been termed *osteoporosis circumscripta.* Later, in the lytic-blastic phase, when osteoblasts begin to replace resorbed bone, radiographs demonstrate both osteolytic and sclerotic changes in the same bone. In the spine, this mixed picture is seen with expanded, radiodense regions in the periphery of the vertebral bodies (cortical thickening) and heightened radiolucency centrally. In the final phase of the disease, when osteoblastic bone formation outpaces osteolysis and primarily sclerotic changes are seen on radiographs, the affected bones appear dense, enlarged, and often deformed. The differentials for osteoblastic vertebrae include lymphoma, Paget disease, and osteoblastic metastases. Only Paget disease increases the size of the vertebrae.

Biochemical Markers

The increase in bone resorption and bone formation is reflected in an increase in biochemical markers of bone turnover. Bone resorption releases fragments of the collagen matrix, as evidenced by an elevated urinary excretion of hydroxyproline and hydroxylysine. Although these provide reasonably accurate measures of bone collagen resorption, more specific tests are used routinely. Serum total alkaline phosphatase is a bone formation marker; its elevation in Paget disease is the most common index of disease activity. A measure of bone-specific alkaline phosphatase may be preferred in a subset of patients with hepatic disease or monostotic involvement, in which 15% of patients have a normal alkaline phosphatase level[207] but appears to offer no advantage in the average patient.[217] In all patients, however, changes in total serum alkaline phosphatase activity are adequate to monitor changes in overall disease activity. Urinary and serum markers of bone resorption—including deoxypyridinoline, N-telopeptide, and C-telopeptide—provide more immediate measures of response to therapy than bone formation markers.

Biopsy

Although radiographic and biochemical indices are usually diagnostic, if uncertainty remains, a bone biopsy can definitively diagnose the disease. However, early Paget disease cannot always be distinguished with sufficient confidence from a metastatic tumor in the spine (a frequent site of metastasis). In such a case, a biopsy of the lesion (not of the iliac crest, the typical location of biopsy in metabolic bone disease) may be performed.

Treatment

Calcium and Vitamin D

Calcium and vitamin D deficiency should be corrected before the use of any bisphosphonates or treatments for Paget disease. Hypocalcemia is a significant risk, especially with the use of any of the intravenous bisphosphonates.[218]

Bisphosphonates

The emergence of newer, more potent bisphosphonates has resulted in a major change in the treatment of Paget disease over the past several years. Bisphosphonates, which inhibit osteoclast-mediated bone resorption and induce osteoclast apoptosis,[219] are the mainstay of drug treatment for Paget disease. Studies have demonstrated that bisphosphonates are effective in reducing bone turnover,[220–222] decreasing pain,[220,222] and promoting healing of osteolytic lesions.[223] On the other hand, studies have yet to demonstrate the long-term efficacy of bisphosphonates to prevent complications of the disease. There is debate as to whether to treat only symptomatic patients or to treat all patients with the goal of normalizing bone turnover markers. While there is some evidence from a large randomized clinical trial that there is no difference in outcomes between the two approaches, other studies have shown that treating to normalization of bone turnover markers leads to healing of lytic radiologic lesions, pain relief, and improved quality of life.[220,223–225] Availability of more potent bisphosphonates in recent years also supports an early intervention approach. In order of decreasing potency, the FDA-approved bisphosphonates for the treatment of Paget disease are zoledronic acid, risedronate, alendronate, pamidronate, tiludronate, and etidronate. Zoledronic acid was recently shown to be more efficacious than risedronate in controlling pain, decreasing bone turnover markers, and maintenance of suppression after treatment.[220]

Calcitonin

Calcitonin, the first widely used therapy for Paget disease, also inhibits osteoclastic bone resorption.[226] In addition, calcitonin has analgesic properties that can benefit patients with significant pain. Salmon calcitonin is available in injectable and nasal-spray forms, but only the injectable form is FDA approved for the treatment of Paget disease. Compared with bisphosphonates, calcitonin is less powerful and does not suppress the disease activity for as long after cessation. Calcitonin use today is largely limited to those patients who are unable to tolerate bisphosphonates.[227]

Surgery

Finally, some patients with Paget disease benefit from surgery. Although operative intervention cannot cure the basic lesion of the disease, surgery may relieve symptoms caused by secondary changes, including fractures, bone deformities, arthritis, and spinal stenosis. Before surgery, pretreatment with a potent oral bisphosphonate (or pamidronate infusion if time is limited) quiets the operative field, helps prevent postoperative hypercalcemia, and fosters better healing and hemostasis.

Summary

Metabolic bone diseases are a group of disorders that occur as a result of changes in osteoblast and osteoclast function. The osteoblast and osteoclast play a major role in maintaining the structure and material properties of bone, controlling the synthesis of bony matrix, and regulating mineral metabolism and the mineralization process. Thus, an alteration of these cells' function results in a variety of clinical disorders. An understanding of the pathogenesis of such diseases and an attempt to define the cause of a patient's acute problem is the key for treatment. This requires a thorough medical history, physical examination, imaging studies, and appropriate laboratory investigations. In general, appropriate care includes adequate replacement of calcium, vitamin D, and initiation of antiosteoporotic agents, including bisphosphonates for high-turnover state and teriparatide for low-turnover state. Anabolic agents are the preferred drugs in the setting of operative spinal fusion for osteoporotic patients. Orthopaedic surgeons should be aware of these biologic and biochemical disorders and familiar with their clinical presentation.

PEARLS

1. An approach combining assessment of BMD, bone turnover rate, and tissue properties may allow improved prediction of fracture risk.
2. Osteoporosis has been divided into high-turnover and low-turnover osteoporosis. Antiresorptive agents, such as bisphosphonates, have been developed to address the high-turnover state, while an anabolic agent, PTH, provides active building of bone mass and treats the low-turnover state. Clinical trials suggest that the anti-sclerostin antibody romosozumab has significant potential to increase BMD and reduce risk of vertebral and nonvertebral fractures.
3. In the setting of spinal fusion and fracture healing, an anabolic agent may be advantageous in the early phases to enhance appropriate biologic healing responses.
4. The treatment of metabolic bone diseases of the spine, including osteoporosis and Paget disease, requires a multidisciplinary approach. An understanding of the pathogenesis of such diseases and an attempt to define the cause of a patient's acute problem is the key for treatment.

PITFALLS

1. Failure to recognize metabolic bone disease preoperatively in patients may lead to inferior postsurgical outcomes.
2. BMD and bone quality are the major determinants of bone strength. An alteration in either BMD or bone quality results in osteoporotic vertebral compression fractures.
3. Prolonged treatment with bisphosphonates may result in oversuppression of bone turnover, leading to adynamic, fragile bone.
4. Bisphosphonates should be discontinued following spinal fusion or acute vertebral fracture in order to reduce the possible adverse effects to the early biologic processes of fracture healing.
5. Teriparatide is contraindicated in Paget disease, unexplained elevations of alkaline phosphatase, history of skeletal irradiation, and children with open physes.

KEY POINTS

1. Metabolic bone diseases are a group of disorders that occur as a result of changes in osteoblast and osteoclast function. Among all disorders of the spine, osteoporosis is the most common metabolic bone disease affecting the spine.
2. BMD and bone quality are the major predictors for osteoporotic vertebral compression fractures. An approach combining assessment of BMD, bone turnover rate, and tissue properties may allow improved prediction of fracture risk.
3. Osteoporosis has been divided into high-turnover and low-turnover osteoporosis. Antiresorptive agents, such as bisphosphonates, have been developed to address the high-turnover state, while an anabolic agent, PTH, provides active building of bone mass and treats the low-turnover state.
4. In the setting of spinal fusion and fracture healing, clinicians should discontinue bisphosphonates at the time of surgery. An anabolic agent, such as teriparatide, may be advantageous in the early steps to enhance appropriate biologic healing responses.
5. The treatment of metabolic bone diseases of the spine, including osteoporosis and Paget disease, requires a multidisciplinary approach. An understanding of the pathogenesis of such diseases and an attempt to define the cause of a patient's acute problem are the keys for treatment.

1. Ohtori S, Inoue G, Orita S, et al. Comparison of teriparatide and bisphosphonate treatment to reduce pedicle screw loosening after lumbar spinal fusion surgery in postmenopausal women with osteoporosis from a bone quality perspective. *Spine*. 2013;38(8):487-492.
This prospective study evaluates the efficacy of teriparatide and risedronate in preventing pedicle screw loosening after lumbar

posterolateral fusion in female patients with osteoporosis. It concludes that teriparatide (daily subcutaneous injection of 20 μg) significantly reduces the incidence of pedicle screw loosening compared with risedronate and the control group. Use of risedronate was not associated with decreased loosening compared with controls. The authors recommend administration of teriparatide to improve the quality of lumbar spine bone marrow and pedicle cortex.

2. McClung MR, Grauer A, Boonen S, et al. Romosozumab in postmenopausal women with low bone mineral density. *N Engl J Med*. 2014;370(5):412-420.
This randomized controlled trial assesses the safety and efficacy of romosozumab, a monoclonal antibody that increases bone formation by binding sclerostin. Results indicate that romosozumab significantly increases bone mineral density in the lumbar spine. An 11.3% increase in bone mineral density was observed with the 210-mg dose at 12-month follow-up. Adverse events were limited to mild injection-site reactions. It concludes that romosozumab is a robust stimulator of bone formation in postmenopausal women with osteoporosis.

3. Cosman F, Crittenden DB, Adachi JD, et al. Romosozumab treatment in postmenopausal women with osteoporosis. *N Engl J Med*. 2016;375(16):1532-1543.
This large, randomized controlled trial evaluates the rates of new vertebral and nonvertebral fractures in patients treated with romosozumab versus placebo. Patients on romosozumab had a 73% lower risk of vertebral fractures and a 36% lower risk of nonvertebral fractures compared with those on placebo.

4. Kanis JA. FRAX and the assessment of fracture probability in men and women from the UK. *Osteoporos Int*. 2008;19:385-397.
This study reports the use of an assessment tool to determine the absolute risk of a hip fracture or osteoporotic fracture within the next 10 years on the basis of the patient information, including BMD, body mass index, a prior history of fracture, a parental history of hip fracture, use of oral glucocorticoids, rheumatoid arthritis and other secondary causes of osteoporosis, current smoking, and alcohol intake.

5. Vieth R. Why the optimal requirement for Vitamin D3 is probably much higher than what is officially recommended for adults. *J Steroid Biochem Mol Biol*. 2004;89-90:573-579.
This review article provides a concise summary of the current evidence from animal studies, epidemiologic studies, and randomized, controlled clinical trials of fracture prevention using vitamin D. It concludes that the optimal 25(OH)D concentration in osteoporotic patients should exceed 70 nmol/L, which requires an average vitamin D intake of 800 to 1000 IU per day. The author further suggests that optimal vitamin D levels for other aspects of human health are probably higher still.

6. Lyles KW, Colon-Emeric CS, Magaziner JS, et al. Zoledronic acid and clinical fractures and mortality after hip fracture. *N Engl J Med*. 2007;357:1799-1809.
This randomized controlled trial found that the administration of zoledronic acid after a hip fracture decreased fracture risk and mortality rate compared with placebo.

7. Huang RC, Khan SN, Sandhu HS, et al. Alendronate inhibits spine fusion in a rat model. *Spine*. 2005;30:2516-2522.
This study investigates the effects of alendronate on posterolateral lumbar fusion in a rat model. The investigators concluded that alendronate inhibits spine fusion in rats. The fusion masses in rats treated with alendronate were radiographically larger and denser than those in control animals despite lower fusion rates. Alendronate was also shown to inhibit bone graft resorption and incorporation. The authors recommend that patients undergoing spine arthrodesis should not take alendronate until fusion is achieved.

8. O'Loughlin PF, Cunningham ME, Bukata SV, et al. Parathyroid hormone (1-34) augments spinal fusion, fusion mass volume, and fusion mass quality in a rabbit spinal fusion model. *Spine*. 2009;34:121-130.
The aim of this study was to assess whether intermittent parathyroid hormone (PTH) would improve spinal fusion outcomes in the Boden rabbit posterolateral spinal fusion model. The investigators found that PTH increased posterolateral fusion success in rabbits. Fusion bone mass and histologic determinants were also improved with PTH treatment. The authors conclude that PTH has promise for use as an adjunctive agent to improve spinal fusion in clinical medicine.

89 CHAPTER Osteoporosis: Surgical Strategies

Frank M. Phillips
Mark F. Kurd
Gregory D. Schroeder
Tyler Kreitz

Osteoporosis is a metabolic bone disease characterized by low bone mass, microarchitectural deterioration, and skeletal fragility resulting in an increased risk of fracture. Osteoporosis and low bone mass affects more than 50 million adults in the United States; with a prevalence of 10.3%, it is the most common metabolic bone disease in those over 50 years of age.[1,2] Among the elderly, especially postmenopausal women, osteoporosis is a major cause of pathologic fractures predominantly of the hip, spine, and wrist. In 2005, osteoporosis accounted for approximately 2 million fractures and approximately 27% occurred in the spine. This number is expected to continue to grow to over 3 million total fractures annually by 2025.[2] Fragility fractures are most common in postmenopausal women with approximately half of all postmenopausal women experiencing an osteoporosis-related fracture. While these fractures are common, up to two-thirds of osteoporotic vertebral fractures are undiagnosed, despite the fact that these injuries have been clearly shown to lead to a decrease in the patient's quality of life[3] and a mortality rate twice that of age-matched controls. The survival rates following a fracture diagnosis were 53.9%, 30.9%, and 10.5% at 3, 5, and 7 years, respectively.[4]

The World Health Organization defines osteoporosis as having bone mineral density (BMD) more than 2.5 standard deviations below that of the average peak bone mass as measured by dual-energy x-ray absorptiometry.[5] Type I osteoporosis results from loss of estrogen and occurs abruptly in women at the time of menopause. Immediately after menopause, women may lose up to 2% to 3% of their trabecular bone mass per year for approximately 5 years, resulting in an increased risk of vertebral and distal radius fractures. Type II, or senile osteoporosis, is an age-related process occurring in both men and women. It affects predominantly cortical bone, resulting in a 0.3% to 0.5% rate of annual bone loss, and increased risk of hip and spine fracture.

With an aging population that desires to remain active, a spine surgeon must be knowledgeable of the strategies for treating the sequelae of osteoporosis of the spine. This includes managing painful osteoporotic fractures and the late sequelae, such as kyphotic deformities. Additionally, spine surgeons must understand the effect of low BMD on spine reconstructive procedures. Recognizing osteoporosis prior to surgical intervention is critical so that osteoporotic patients undergoing spine surgery can be appropriately treated and optimized from a medical perspective.

Osteoporotic Vertebral Compression Fractures

Osteoporotic vertebral compression fractures (VCFs) are a major cause of morbidity in the elderly. These injuries may lead to chronic pain from a nonunion, a significant deformity that results in sagittal imbalance and even depression. Fractures are often painful in the acute setting, but they also may result in chronic pain from a pseudarthrosis or altered kinematics with progressive deformity leading to sagittal imbalance. A kyphotic deformity from a thoracolumbar compression fracture shifts the center of gravity anteriorly, resulting in an increased bending moment about the apex. This deformity creates an environment favorable to additional fractures, which can lead to a progressive deformity.[6] The risk of a new vertebral fracture within 1 year of a VCF is 5 to 25 times above baseline risk.[4,7] Therefore, treatment strategies for osteoporotic vertebral fractures should not only focus on pain management but also on overall bone health to prevent subsequent fractures. Additionally, if a significant deformity is present, correcting sagittal alignment can lead to improved health-related quality-of-life (HRQOL) metrics.

Nonsurgical Treatment

Conventional management of osteoporotic VCFs includes pain management, activity modification, physical therapy, and bracing.[8] Acute pain management using antiinflammatory medications and narcotics should be limited to the short term, as these medications increase risk of confusion, falls, and gastrointestinal complications in the elderly. Physical therapy and an exercise regimen focused on axial muscle strengthening may improve deformity and prevent further injury.[9] Early mobilization is preferred to bed rest as immobilization results in disuse osteopenia, muscle atrophy, and

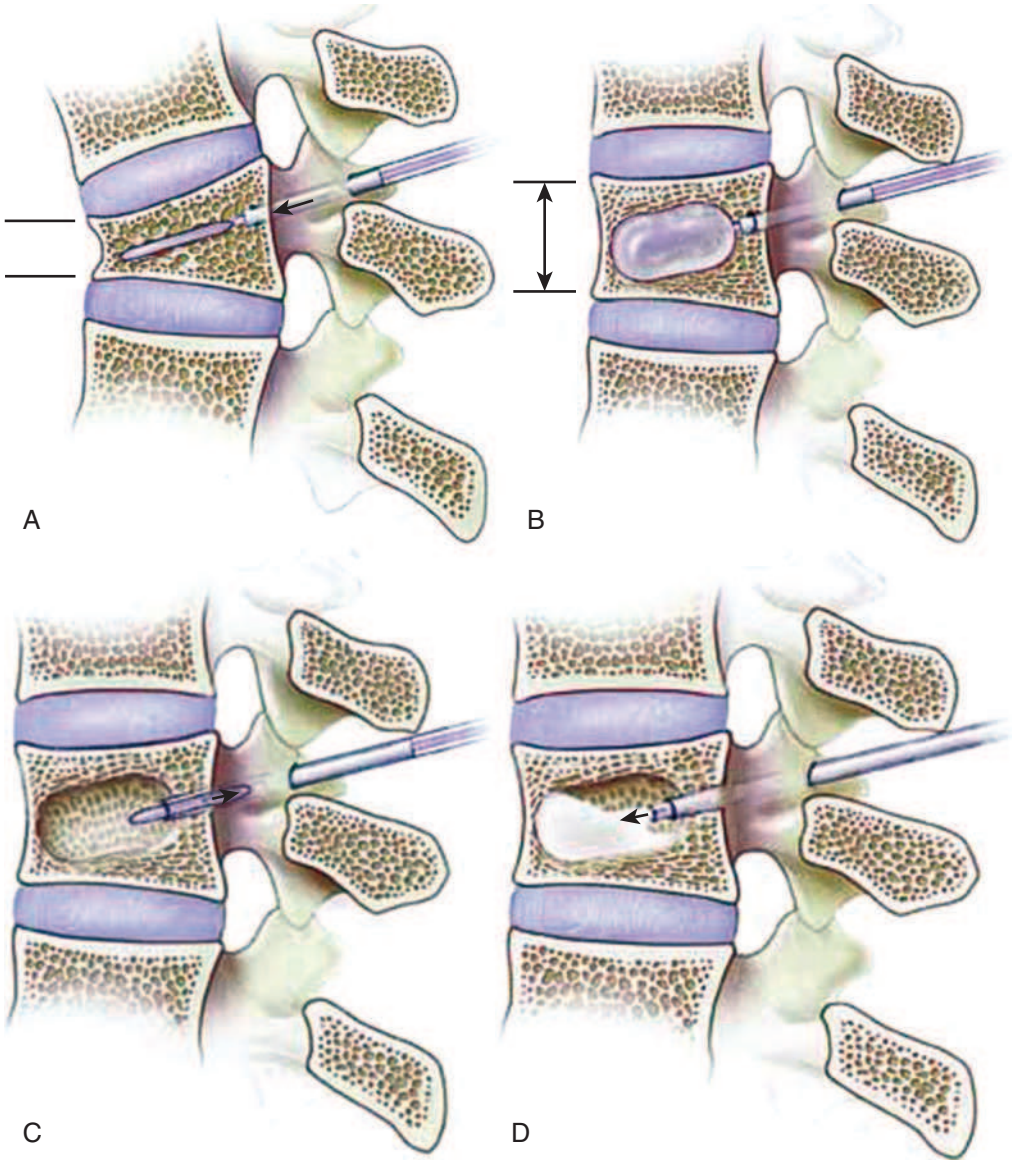

FIG. 89.1 (A) During kyphoplasty, the fractured vertebral body is percutaneously cannulated with an inflatable bone tamp. (B) The tamp is inflated, which elevates the vertebral body endplates and restores vertebral body height. (C) The tamp is withdrawn, leaving a cavity to be filled with bone void filler. (D) Bone void filler is placed into the vertebral body under low pressure.

deconditioning. Bracing may improve pain and posture but is expensive, often not tolerated in the elderly due to poor fit and compliance, and may result in further restriction in severely debilitated patients.[8] Appropriate nonoperative management involves pain control, prevention of secondary complications, maintenance of endurance, and optimized medical management of osteoporosis, as discussed in Chapter 88.

Cement Augmentation: Vertebroplasty and Kyphoplasty

Orthopaedic fracture care emphasizes restoring anatomy, correcting deformity, and preserving function. Cement augmentations in the form of vertebroplasty and kyphoplasty have been used as minimally invasive procedures to address pain and deformity in osteoporotic spine fractures. Both involve percutaneous fluoroscopic or computed tomography (CT)-guided injection of polymethylmethacrylate (PMMA) into a fractured vertebral body. Vertebroplasty involves percutaneous cement injection into a fractured vertebral body without any attempt at reduction. Kyphoplasty involves the percutaneous insertion of an inflatable bone tamp into a fractured vertebral body. Inflation of the tamp elevates the endplate and restores the vertebral body height while creating a cavity to be filled with PMMA (Fig. 89.1). Indications for cement augmentation in VCFs include painful osteoporotic VCFs refractory to nonsurgical management, patients requiring hospitalization for pain or medical complications secondary to VCFs,[10] and VCFs with progressive kyphotic deformity.[11] Suggested mechanisms for pain improvement with cement augmentation include fracture immobilization, cortical support by cement, and thermal deafferentation of the vertebra by

PMMA polymerization.[12] In 2009, the American Academy of Orthopaedic Surgeons recommended strongly against the use of vertebroplasty in osteoporotic VCFs and gave kyphoplasty a weak recommendation for use in pain relief in osteoporotic VCFs.[13] Their recommendations were based primarily on two randomized control trials (RCTs) comparing vertebroplasty and kyphoplasty to sham procedures.[14,15] Buchbinder et al. performed a multicenter double-blinded RCT evaluating overall pain in patients undergoing vertebroplasty versus a sham procedure. They found no difference in pain improvement between vertebroplasty and the sham procedure group at all intervals during the 6-month follow-up.[14] Kallmes et al.[15] performed a multicenter RCT assigning patients with osteoporotic compression fractures to either a vertebroplasty or a simulated procedure. They found improvements in pain and pain-related outcomes in patients treated with vertebroplasty that were similar to improvements in the simulated procedure group. These studies, however, had significant methodological flaws, including inconsistent inclusion criteria, inability to determine that radiographically identified fractures were the source of the patient's pain, validity of sham procedure in control groups, and inability to complete enrollment targets at busy centers, suggesting that those patients in most pain with acute fractures may have been unwilling to undergo randomization.[16]

Since that time, there have been numerous RCTs and meta-analyses published regarding the efficacy of cement augmentation for VCFs.[17–29] Wardlaw et al.[17] performed a large multicenter RCT comparing outcomes of kyphoplasty versus nonsurgical care in patients with one to three acute VCFs. They demonstrated significant improvement in the Short-Form 36 questionnaire physical component summary at 1 month in the kyphoplasty group, 7.2 points, compared to the nonsurgical care group, 2 points ($P < .0001$), with no difference in frequency of adverse events. This suggested that kyphoplasty is an effective and safe procedure in the management of acute VCFs. Anderson et al.[26] performed a meta-analysis of six RCTs evaluating pain, function, and HRQOL outcomes of vertebroplasty compared to conservative management in VCFs in both short-term (<12 weeks) and long-term (6–12 months) follow-up. They demonstrated superior pain relief, functional recovery, and greater HRQOL in vertebroplasty compared to conservative management or sham procedure at both early and late time points.[26] More recently, Li et al.[27] performed a meta-analysis of 8 RCTs comparing vertebroplasty to conservative management or sham procedure with regard to pain relief, function, and quality of life. The results of their analysis demonstrated improved pain relief, especially with fracture age less than 3 months, greater spine function, and quality of life at early, middle, and late time points in those treated with cement augmentation compared to control. Conversely, Buchbinder et al.[28] published a Cochrane Review evaluating outcomes and complications of vertebroplasty compared to sham procedure (two trials), conservative or usual care (six trials), and vertebroplasty versus kyphoplasty (three trials). The results of their review demonstrated no difference in pain, disability, or quality of life at any time point between those treated with vertebroplasty compared to sham procedure. Compared to nonoperative care, vertebroplasty resulted in improved pain outcomes at all time points.

Given the conflicting results in the literature, it is likely that there is a select group of patients who will benefit from cement augmentation for acute painful VCFs; however, the ideal indications are still unclear.

Vertebroplasty Versus Kyphoplasty

Although similar to vertebroplasty, kyphoplasty allows for improvement in vertebral body height and kyphotic deformity in addition to cement augmentation. Han et al.[30] performed a meta-analysis of RCTs and nonrandomized trials comparing vertebroplasty to kyphoplasty. Their results demonstrated greater improvement in pain with vertebroplasty in the first 7 days, greater improvement with kyphoplasty at 3 months, and no difference in long-term pain relief or functional outcomes between the two techniques.[30] Papanastassiou et al.[31] performed a systematic review of nonrandomized trials and RCTs comparing efficacy and safety of vertebroplasty, kyphoplasty, and nonsurgical management (NSM). Superior pain reduction was seen in vertebroplasty (–4.55/10; $P < .01$) and kyphoplasty (–5.07/10 points; $P < .01$) compared to NSM (–2.17/10). Subsequent fracture rate was greater in the NSM group (22%) compared to both vertebroplasty and kyphoplasty (11%). Comparison of cement augmentation techniques demonstrated greater kyphosis correction (4.8 vs. 1.7 degrees; $P < .01$; Fig. 89.2) and quality-of-life improvement ($P = .04$) with a lower rate of cement extravasation ($P = .01$) in kyphoplasty compared to vertebroplasty. This review suggests superior outcomes with cement augmentation techniques and a preference for kyphoplasty in reduction of kyphotic deformity and disability. Omidi-Kashani et al.[11] showed improvement in baseline visual analog scale and the Short-Form 36 questionnaire with both vertebroplasty and kyphoplasty but demonstrated no difference between the two in single-level osteoporotic VCFs. There was a 3.1-degree improvement in focal kyphosis associated with kyphoplasty, although the clinical significance of this improvement is unknown. More recently, Gu et al.[32] performed a systematic review and meta-analysis of RCTs and nonrandomized studies comparing vertebroplasty to kyphoplasty. They demonstrated no difference between the two methods of cement augmentation with regard to pain and disability outcomes in the short and long term. Significant heterogeneity exists in the literature comparing outcomes of kyphoplasty to vertebroplasty in the treatment of VCFs, though kyphoplasty may be preferable in the setting of significant kyphotic collapse.

Indications and Contraindications

Cement augmentation has historically been used for many vertebral disorders, including the treatment of acute painful VCF, pain due to vertebral metastasis and myeloma, vertebral hemangiomas, and Kummell disease, which is avascular necrosis of the vertebrae after VCF. Recent clinical evidence supports its use in the management of acute pain associated with VCFs that have failed to improve with nonsurgical

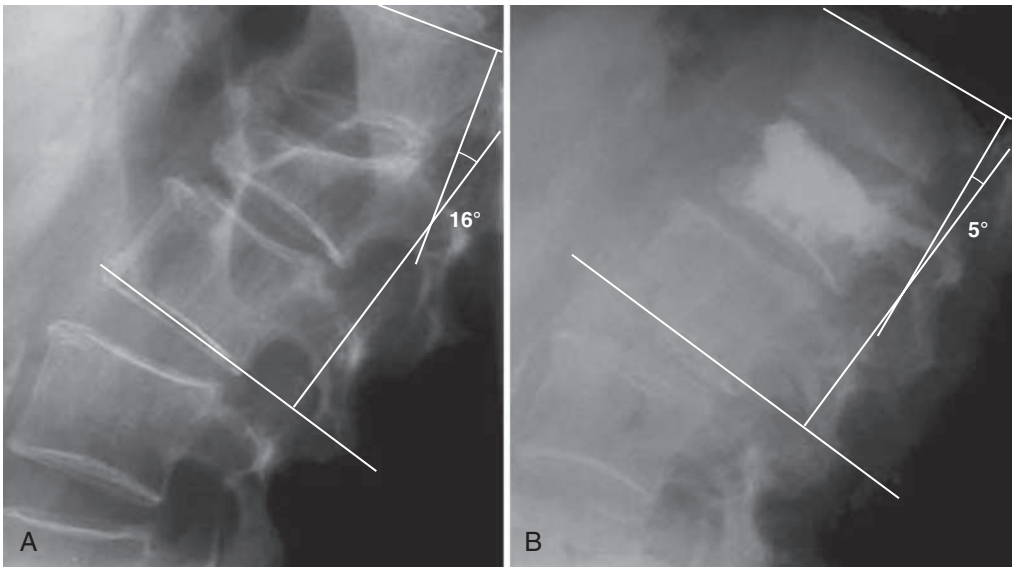

FIG. 89.2 A 73-year-old woman with an L1 vertebral compression fracture was treated with kyphoplasty 6 weeks after the injury occurred. The focal kyphosis was corrected from (A) 16 degrees to (B) 5 degrees.

management and patients requiring hospitalization for pain or medical complications secondary to VCFs.[10] In addition to pain relief, kyphoplasty may also aid in reduction of fractured vertebrae and improvement of sagittal alignment with kyphotic deformity.[11] Contraindications include subacute or chronic injuries, neurologic compromise, radicular symptoms, loss of integrity of the posterior vertebral cortex, and osteomyelitis. Considerations include bleeding disorders and cardiopulmonary compromise that may preclude safe performance of the procedure. When considering cement augmentation as treatment for a painful VCF, a clinician must ensure that the fracture is the source of the patient's back pain. This requires careful correlation of the patient's history and clinical examination with radiographic documentation of an acute VCF.[33] Magnetic resonance imaging (MRI) may be useful in detecting vertebral edema, suggesting an acute fracture as well as ruling out infection or tumor as potential causes of fracture. Acute VCFs will show bony edema characterized by increased signal on T2-weighted MRI and short tau inversion recovery imaging sequences and decreased signal on T1-weighted MRI. Subacute and chronic fractures will not show increased signal on T2-weighted and short tau inversion recovery MRI images.

Techniques

Vertebroplasty

Vertebroplasty is performed on an outpatient basis with the use of mild sedation and local anesthesia. The patient is positioned prone with the spine extended by chest and pelvic bolsters. Under fluoroscopic or CT guidance, an 11- to 13-gauge needle is advanced toward the center of the affected vertebral body using a transpedicular or peripedicular approach. If concern exists for metastatic or metabolic disease, a biopsy may be obtained before cement injection. PMMA cement is mixed with barium for fluoroscopic opacification. Antibiotics may also be added to the cement mixture if concern exists for infection, such as when operating on immunocompromised patients. Once reaching appropriate consistency, 2 to 10 mL of cement is injected into the vertebral body under live fluoroscopy until complete opacification or evidence of extravasation occurs. The patient is maintained in the prone position until the cement has cured. Patients rest supine under observation for at least 4 hours before discharge.

Kyphoplasty

Kyphoplasty is similar to vertebroplasty, but it also involves reconstitution of lost vertebral height using 1 or 2 inflatable bone tamps in addition to cement augmentation. When inflated, the percutaneous bone tamp elevates the depressed vertebral body endplate(s), thereby restoring vertebral body height and pushing remaining trabecular bone to the periphery, creating a cavity within the vertebral body that is then filled with bone cement. The patient is positioned prone on a radiolucent table. As with vertebroplasty, percutaneous needle placement into the affected vertebrae is performed under fluoroscopic or CT guidance using a transpedicular or peripedicular technique. Once accurate placement within the vertebrae is confirmed, a working channel is created within the vertebrae. The balloon tamp is inserted into the canal and inflated within the vertebrae. The balloon tamp is expanded using visual (fluoroscopy), volume, and pressure (digital manometer) controls. The inflation continues until (1) adequate fracture reduction is achieved, (2) the maximal balloon pressure is reached, or (3) cortical wall contact occurs. The balloon is then deflated and removed. Prepared thickened cement is injected through the cannula into the expanded void within the vertebrae under low pressure. The cement volume should approximate that of the intravertebral cavity. The patient is maintained in the prone position until the cement has solidified.

Complications

There is a low incidence of clinically significant complications reported for vertebral cement augmentation. Most complications result from cement extravasation, embolization, and adjacent vertebral fractures. Asymptomatic cement extravasation has been observed clinically in up to 72% of patients[22] and by postprocedure CT in 88% of patients undergoing vertebroplasty. The most common site of leakage is the endplate or disc (45%), paravertebral (35%), epidural (20%), and prevertebral (18%).[34] Leakage has been correlated with lower-viscosity cement, greater injected volume, and more severe fracture.[35] One meta-analysis demonstrated no difference in the rates of cement extravasation and subsequent fracture between vertebroplasty and kyphoplasty.[30] Two systematic reviews demonstrated reduced rate of cement extravasation[31,32] and reduced rate of subsequent fracture in kyphoplasty compared to vertebroplasty.[32] The cavity created during kyphoplasty allows for use of low-pressure, high-viscosity PMMA, resulting in controlled filling and possibly reduced rate of cement extravasation. Accounts of neurologic dysfunction from cement extravasation have been reported in the literature. The majority of dysfunction resolves with prompt surgical intervention, although permanent dysfunction has been reported.[36] Asymptomatic venous extravasation of cement toward the lungs has been reported in 2.9% of patients.[37] A systematic review reported the incidence of cement pulmonary embolism from 2% to 26%, with severity ranging from asymptomatic embolus to transient hemodynamic instability and death.[38] Bone marrow fat embolus may also occur with vertebroplasty.

There is concern that the increased stiffness of vertebrae after cement augmentation may result in increased load across adjacent vertebrae and increased risk of adjacent-level VCF. However, the meta-analysis by Anderson at al. demonstrated roughly a 20% risk of new fracture within 12 months of index VCF treated with either vertebroplasty or conservative management.[26] Zhang et al. reported a similar rate, 21%, of new VCF after vertebroplasty and correlated low BMD, low body mass index, and intradiscal cement leakage as significant risk factors for a subsequent fracture.[39] An RCT comparing outcomes and complications of vertebroplasty to kyphoplasty demonstrated no difference in rate of new fracture between the treatment groups at 12 and 24 months of follow-up.[40]

Novel Implants

Tutton et al.[41] have recently published initial outcomes of the Kiva Safety and Effectiveness Trial. The Kiva system involves deployment of small-coiled implants with a single transpedicular approach allowing for directed and controlled insertion of PMMA into the fractured vertebrae. They demonstrated noninferiority of the Kiva system compared to balloon kyphoplasty for pain reduction and functional outcomes at 12 months in patients with VCFs. This multicenter industry-sponsored trial randomized 300 patients with one or two VCFs to receive Kiva system or balloon kyphoplasty. They demonstrated a similar improvement in the mean visual analog pain scale (70.8 vs. 71.8) and in the Oswestry Disability Index (38.1 vs. 42.2) in patients undergoing either Kiva or kyphoplasty, respectively. Additionally, they demonstrated no difference in adverse device-related events or adjacent-level fracture rate at 12 months between the two groups (20.9% vs. 22.3%, respectively). Benefits of the Kiva group included use of approximately 50% less PMMA cement with more direct injection and significant reduction of cement extravasation in the Kiva group, 16.9%, compared to kyphoplasty, 25.8%.[41]

Instrumentation of the Osteoporotic Spine

As the population ages, there will be greater demand for spine procedures in patients with significant comorbidities, including osteoporosis. In those aged 50 years or older who required spine surgery, the reported incidence of osteoporosis was 14.5% and 51.3% for men and women, respectively.[42] Osteoporosis of the spine places patients at elevated risk of pathologic fracture, progressive deformity, and spinal stenosis. Loss of microarchitectural integrity makes successful instrumentation of osteoporotic bone a challenge. Selection of spinal instrumentation must take into account the fragility of osteoporotic bone, the stability of the spine, and the likely failure mechanisms of applied instrumentation.

Early postoperative complications (<3 months) in patients older than 65 years with poor bone quality include instrumentation failure, pedicle fracture, and VCFs. Late complications (>3 months) include pseudarthrosis, graft subsidence, proximal junctional kyphosis, and progressive deformity.[43] Optimal screw orientation, multiple points of fixation, combined anterior and posterior procedures, cement augmentation, and the use of novel implants are all proposed strategies for reducing the risk of complications.

Regardless of the increased risk due to medical comorbidities and instrumentation failure, evidence suggests considerable benefit for spinal fusion in this patient population.[44–47] One retrospective study demonstrated a successful fusion rate of 93% and no correlation between BMD and fusion and complication rates in adults undergoing spinal fusion for deformity correction, suggesting that a high frequency of successful outcomes can be achieved in this population.[45] Kim et al.[46] retrospectively reviewed 40 patients with low BMD who underwent lumbar fusion for degenerative kyphosis. They demonstrated good correction of deformity and no association between low BMD and rate of pseudarthrosis or adjacent-level vertebral fractures. Rather, they demonstrated correlation between postoperative spinopelvic parameters and sagittal decompensation, suggesting that correction of sagittal balance in this population can result in successful outcome. Recent analysis of the Spine Patient Outcomes Research Trial data compared outcomes of patients older than 80 years to those younger than 80 years who underwent surgical treatment of lumbar stenosis and degenerative spondylolisthesis.[47] Those patients older than 80 years had greater baseline prevalence of medical comorbidities, including osteoporosis. Those in the octogenarian cohort treated surgically had significant improvement in all primary outcome measures compared to those treated nonsurgically without an increase in

complication or mortality rates compared to younger patients. Clinical outcomes suggest substantial benefit of spine surgery in older patients with lower BMD. The preoperative workup for these patients should include evaluation for the severity of osteoporosis as well as optimized medical and pharmacologic management, as described previously.

Posterior Spinal Instrumentation

Posterior instrumentation may be used to stabilize the spine after decompression of neural elements in combination with anterior procedures for increased stability and enhanced fusion or primarily for deformity correction. Pedicle screws, sublaminar wires, and hooks may be used in conjunction with rods or plates to achieve posterior spinal fusion. Failure of posterior thoracolumbar instrumentation has been shown to correlate with BMD.[48] Instrumentation failure may occur at physiologic loads in the osteoporotic spine, resulting in failure of fusion and recurrence of deformity. Modes of failure of all devices most commonly occur at the implant-bone interface through implant pullout or cutout. Therefore, recognition of poor purchase and optimization of bone implant fixation at the time of insertion is of paramount importance for successful outcome.[49,50]

Strategies for improved purchase and reduced risk of screw cutout include increased length and diameter of screws, optimal screw trajectory, cement augmentation, expandable pedicle screws, and hybrid constructs. Previous studies focused on improving fixation through increased screw length and diameter, though these techniques were limited by risk of anterior cortical breach and pedicle fracture. Newer techniques advocate optimal screw trajectory, cement augmentation, and screw design to improve bone purchase.

Optimal screw trajectory can improve fixation at the bone-implant interface by capturing robust subchondral bone, resulting in enhanced stability in the osteoporotic spine. In the sagittal plane, screw threads engaging subchondral bone may provide superior fixation over thread engagement of cancellous bone centrally within the vertebrae. Biomechanical analysis has demonstrated that pedicle screws oriented cephalad 23 degrees to the vertebral endplate resulted in a 100% increase in pullout strength compared to standard anatomic placement.[51] In the axial plane, medialization of the screw vector and triangulation of bilateral screws have been demonstrated to increase pullout strength by 121%.[52] A bilateral triangulated pedicle effectively holds all of the bone between the screws rather than just the bone within the threads of each screw. Bony anatomy limits triangulation of pedicle screws; lower lumbar levels allow for more medialization, whereas upper lumbar and thoracic pedicles allow for less. In the thoracic spine, maximal insertional torque and implant fixation may be better achieved through straightforward orientation of pedicle screws rather than anatomic orientation.[53] The technique of screw "hubbing" has been used in the thoracic spine in an attempt to provide a load-sharing effect by providing additional aperture purchase of the dorsal lamina with the screw head. Biomechanical analysis has demonstrated decreased pullout strength of thoracic pedicle screws that are "hubbed" with this technique compared to standard anatomic insertion. In addition, this technique may predispose to iatrogenic fracture of the lamina[54] and is therefore not recommended.

Subchondral purchase strategies may also be used in instrumentation of the sacrum. Sacral screws should be directed toward the promontory for tricortical bone purchase. Sacral screws inserted in this manner have been shown to have twice the insertional torque as bicortical screws.[55] Divergent screws placed in the sagittal plane may also increase pullout strength and by improving load-bearing capacity in the sacrum.[50]

Pretapped pedicle screws provide several advantages in the osteoporotic spine by providing tactile feedback, improved screw orientation, and maximizing diameter. Tapping insertion torque has been shown to directly predict pullout strength; therefore, tactile feedback can be used to optimize bone purchase and screw size.[49] Using this technique, care should be taken to not aggressively tap or oversize the screw, which would result in pedicle fracture. Biomechanical analysis demonstrates that undertapping pedicle screws by 1 mm increases maximal insertional torque by 47% compared to undertapping by 0.5 mm.[56] Undertapping improves pullout strength by compacting preserved cancellous bone between screw threads.

Pedicle screw augmentation with PMMA bone cement is used to enhance the strength of the bone-implant interface.[57–59] Cement augmentation may lead to higher fusion rates and decreased loss of deformity correction in patients with osteoporosis undergoing posterior instrumentation. In a retrospective analysis of patients undergoing posterior spinal fusion for pseudarthrosis after VCF, those with cement augmentation of pedicle screws demonstrated higher fusion rate (94.1% vs. 76.1%) and decreased correction loss (3 vs. 7.2 degrees) compared to nonaugmented screws with at least 2 years' follow-up.[59] Cement augmentation may be combined with other strategies. Biomechanical analysis demonstrates that pretapping cement-augmented screws improves fixation strength by 54% compared to cement augmentation alone.[51] Risks of this technique include cement extravasation outside the vertebra, spinal canal, or neural foramen. This risk may be reduced by screw design, with fenestrated screws reducing extravasation.[57] Non-PMMA augments, such as calcium phosphate, may also be used to enhance the implant-bone interface.[60]

Expandable pedicle screws have been designed to enhance bone purchase and spinal fixation. In these screws, the distal two-thirds of the screw is split lengthwise by two perpendicular slots to form four anterior fins when expanded. An expansion peg is threaded into the inner core of the pedicle screw, resulting in fin expansion. Biomechanical studies demonstrate superior fixation with expandable pedicle screws compared to standard screws with a twofold increase in pullout strength. Cement augmentation of expandable screws resulted in a 250% increase in pullout strength.[61,62] Wu et al.[63] demonstrated a decreased rate of screw loosening and greater fusion rates at 24 months postoperatively in osteoporotic patients undergoing lumbar spine fusion with expandable compared to conventional pedicle screw fixation. The use of expandable

pedicle screws is recommended for use in the osteoporotic spine and may be combined with other strategies for improved bone purchase.

Increasing the number of fixation points to the spine improves stability of the construct by distributing deforming forces and reducing risk of segmental or junctional failure. The levels of the construct should address the underlying pathology and maintain sagittal alignment while avoiding termination at transition zones and at the apex of deformity. Risk of kyphotic collapse of the instrumented osteoporotic spine can be limited by fixation at three levels above and below the apex of kyphosis.[50] Hybrid constructs using pedicle screws with sublaminar wires or hooks may provide additional stability and reduce the risk of failure in osteoporotic bone.[64] Evidence suggests increased risk of proximal junctional kyphosis with larger deformity correction in patients older than 60 years[65] (Fig. 89.3). Accepting incomplete correction of sagittal balance in this population may be needed in order to improve successful fusion rates and reduced complications caused by proximal junctional kyphosis. The extent of deformity correction needs to be determined based on an individual patient's comorbidities and degree of disability. Extension of the instrumentation construct to the pelvis may also reduce the risk of instrumentation failure in this population.[66] The advantages of additional points of fixation must be weighed against the risks and morbidity associated with the additional-level surgery and potential long-term consequences of a longer fusion construct.

As described previously, failure of posterior instrumentation in the osteoporotic spine typically occurs through loss of fixation by screw toggling, loosening, and eventually pulling out. This may result in a relatively large void around the loose screw that can preclude reusing the same pedicle for revision screw fixation. If revision instrumentation is required, all previously mentioned strategies for enhancing posterior fixation should be considered. In addition, consideration should be given to including anterior column structural support and fusion as part of the revision strategy. Anterior column support will increase load sharing and reduce flexion-bending moments on the posterior instrumentation (Fig. 89.4).

Interbody Fusion

Interbody fusion techniques are often used in this population for the treatment of degenerative spondylolisthesis, deformity, and discogenic back pain. Interbody fusion may be performed through an anterior, lateral, posterior, or transforaminal approach. It typically involves the use of bone graft with or without cage support, and is often used in combination with pedicle screw or plate fixation. With this technique, the bone graft or cage is placed under compression and acts as a load-sharing construct with adjacent vertebral endplates. Solid fusion and successful clinical outcomes may be reliably achieved with interbody techniques in the osteoporotic spine.[67,68]

Failure of interbody fusion techniques in osteoporotic bone most commonly occurs as a result of graft subsidence into weakened cancellous bone of adjacent vertebrae, adjacent vertebral fracture, or screw loosening as described previously. Interbody graft and cage subsidence results from poor structural support by weakened adjacent vertebral endplates, graft pistoning, and modulus mismatch. Subsidence may result in recurrent deformity and stenosis. Maintaining the integrity of adjacent vertebral endplates during preparation for graft insertion may reduce the risk of graft subsidence. Oh et al.[68] demonstrated a correlation between cage subsidence and BMD in patients undergoing posterior lumbar interbody fusion. All patients, including those with cage subsidence, demonstrated improvement in clinical outcomes compared to preoperative scores, without deterioration in those with subsidence in the postoperative period. Their data suggests that, although subsidence may occur, posterior lumbar interbody fusion may be used to treat lumbar degenerative disease in osteoporotic patients with good outcome.

Larger-diameter struts and cages should be used preferentially in osteoporotic patients, as smaller implants tend to cut into and piston against weakened adjacent endplates. Avoiding stiff, high-modulus implants may also reduce the risk of subsidence.[69] Autologous corticocancellous grafts with wide and uniform surfaces may best accomplish this goal. Finally, low BMD is also a risk factor for adjacent vertebral fracture after interbody fusion requiring revision fusion surgery.[70,71] Supplementation with previously described techniques to improve screw fixation are recommended to reduce the risk of graft subsidence and adjacent vertebrae fracture in this patient population.

Considerations in the Cervical Spine

Decompression and fusion of the cervical spine is frequently performed to address pathologic degenerative changes in the elderly and is performed through an anterior, posterior, or combined approach. As with posterior instrumentation in the lumbar and thoracic spine, biomechanical analysis has demonstrated a linear relationship between decreased BMD and a decreased plate/screw cutout strength in the anterior cervical spine.[72] Increasing anterior screw length, diameter, and bicortical fixation are strategies that may be used to achieve superior bony purchase and limit excessive implant-vertebral motion in anterior cervical constructs. Cement augmentation may also be used to improve pullout strength and fatigue resistance.[73]

Graft subsidence into adjacent vertebral endplates may also occur when used after anterior discectomy or corpectomy. This risk is accentuated with multilevel anterior cervical plating and corpectomy as a result of increased construct stiffness and excessive graft extension load. When using multilevel anterior instrumentation in osteoporotic bone, the points of fixation should be maximized and strong consideration given to combined posterior stabilization to augment strength of the construct.[74] As with interbody fusion of the lumbar spine, care should be taken to maintain the viability of the adjacent vertebral endplate to reduce the risk of graft subsidence.

Novel techniques may provide adequate construct stability in osteoporotic bone while avoiding a combined approach. Anterior transpedicular screw fixation allows for improved

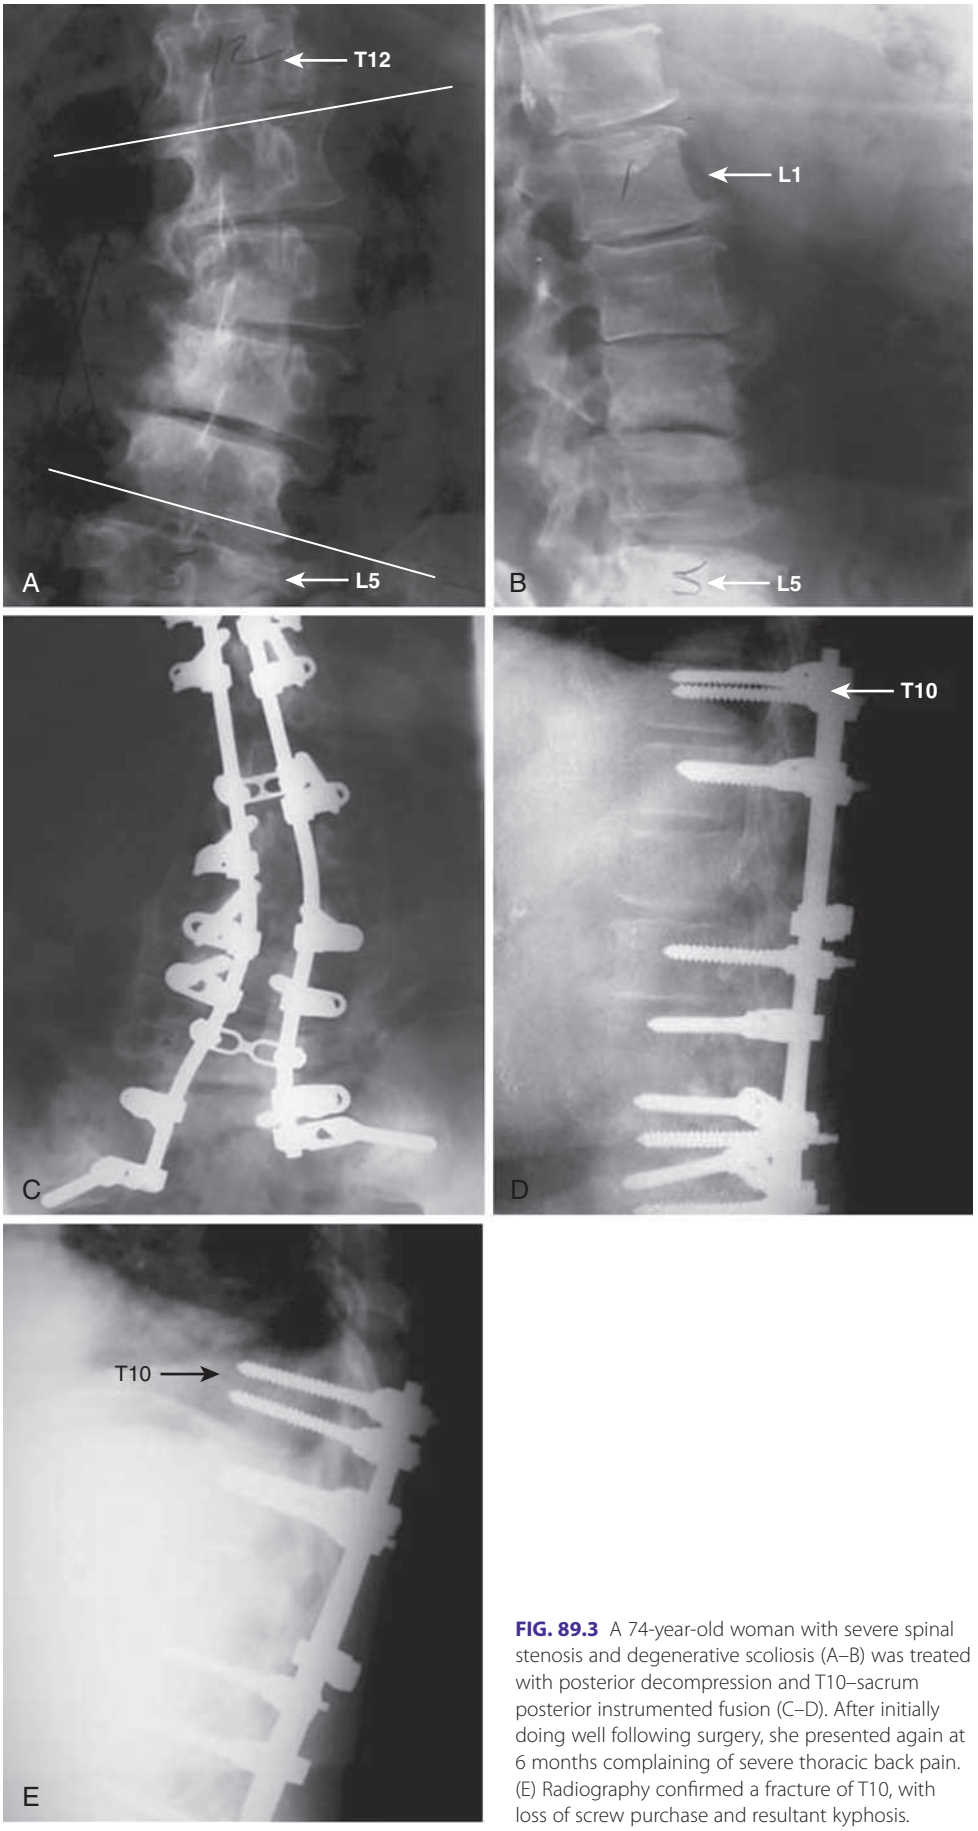

FIG. 89.3 A 74-year-old woman with severe spinal stenosis and degenerative scoliosis (A–B) was treated with posterior decompression and T10–sacrum posterior instrumented fusion (C–D). After initially doing well following surgery, she presented again at 6 months complaining of severe thoracic back pain. (E) Radiography confirmed a fracture of T10, with loss of screw purchase and resultant kyphosis.

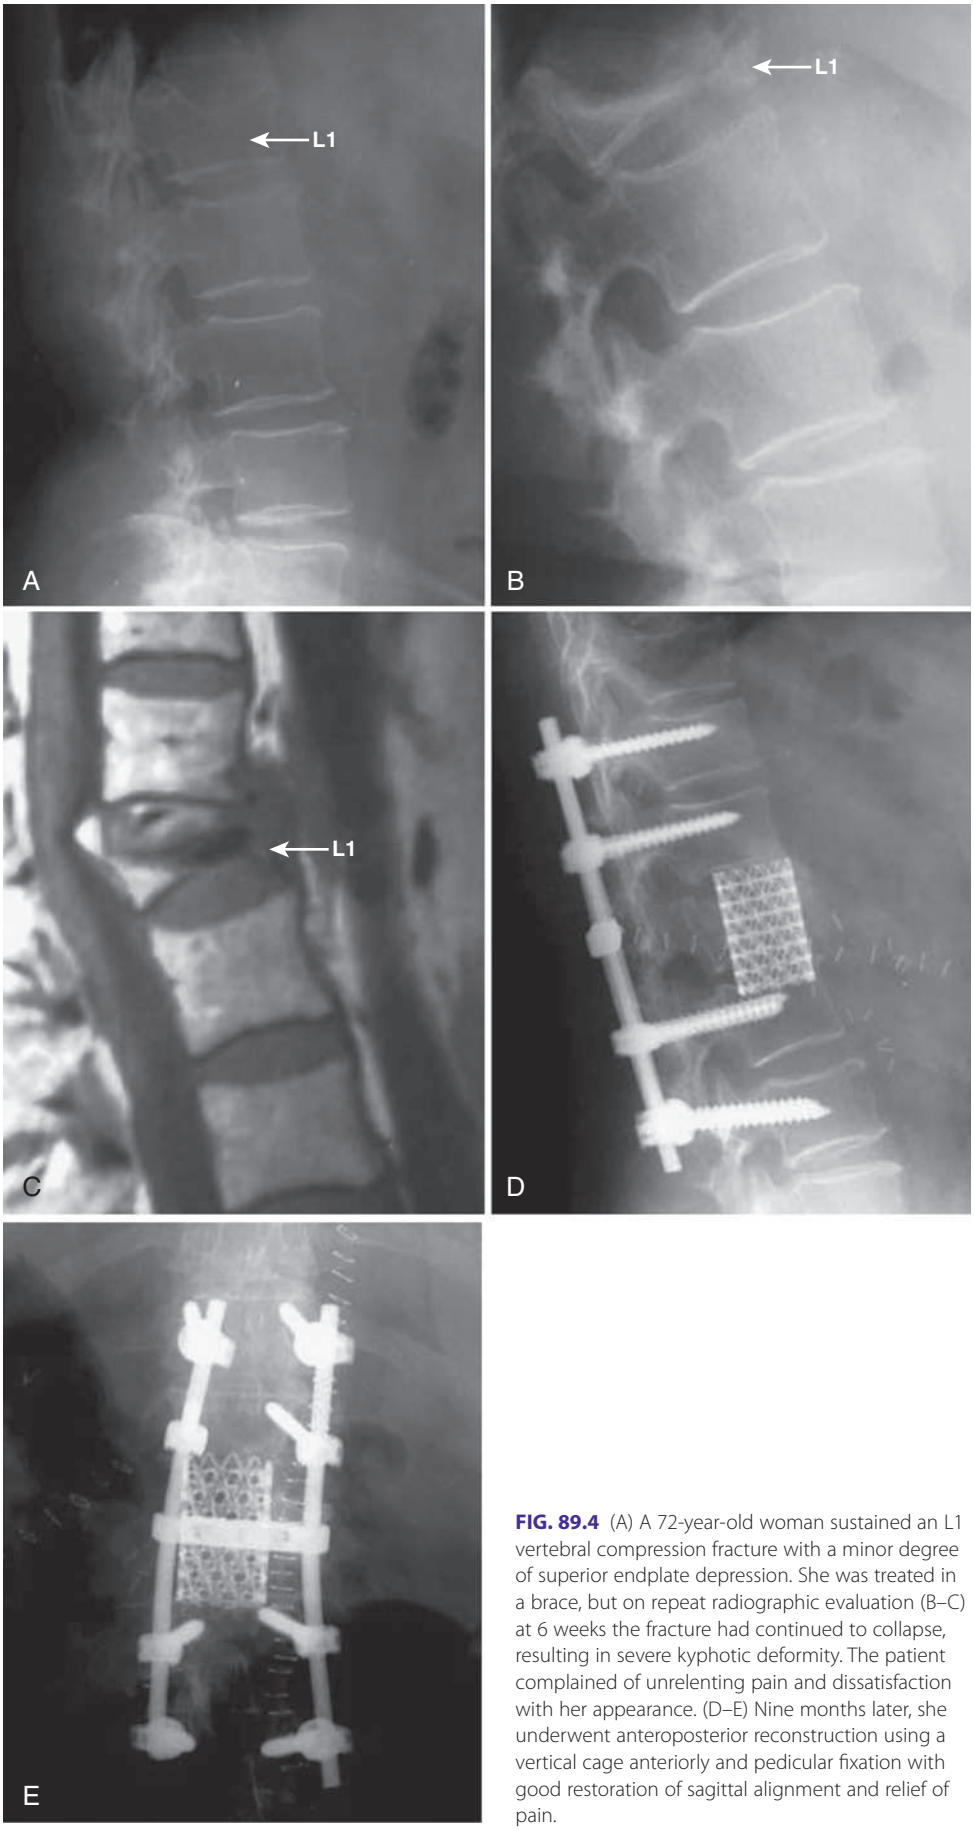

FIG. 89.4 (A) A 72-year-old woman sustained an L1 vertebral compression fracture with a minor degree of superior endplate depression. She was treated in a brace, but on repeat radiographic evaluation (B–C) at 6 weeks the fracture had continued to collapse, resulting in severe kyphotic deformity. The patient complained of unrelenting pain and dissatisfaction with her appearance. (D–E) Nine months later, she underwent anteroposterior reconstruction using a vertical cage anteriorly and pedicular fixation with good restoration of sagittal alignment and relief of pain.

fixation in patients undergoing multilevel anterior cervical spine discectomy or corpectomy through an anterior-only approach.[75] This technique involves use of fluoroscopic-guided wires for placement of anterior pedicle screws. Biomechanical analysis demonstrates smaller reduction in peak pullout force with anterior transpedicular screw (24%) compared to control (48%).[76]

Summary

With an aging population, the spine surgeon must appreciate the effects of osteoporosis on the spine. Osteoporotic VCFs may be associated with significant morbidity. The spine surgeon should be knowledgeable regarding the indications for vertebral augmentation for reduction of pain and improved sagittal balance. Reconstructive surgery in the osteoporotic spine may offer substantial benefit for patients but requires specific consideration of approach, implant use and design, augmentation, and length of construct in order to maximize the likelihood of fusion and reduce the potential of construct failure.

PEARLS

1. The spine surgeon may be required to treat direct sequelae of osteoporosis in the form of painful spinal fractures or resultant deformity or to consider osteoporosis as it relates to spinal reconstructive surgery in the older patient.
2. Osteoporotic VCFs and resultant spinal kyphosis are a leading cause of disability and morbidity in the elderly.
3. Treatment of osteoporotic vertebral fractures with vertebroplasty or kyphoplasty, although controversial, likely results in pain relief in a select patient population with acute fracture.
4. When neurogenic symptoms can be isolated to a particular level or nerve root, limited decompression in elderly osteoporotic patients is favored.
5. Surgical strategies that include improving screw purchase in bone and combining anterior and posterior stabilization should be considered to reduce the likelihood of instrumentation failure in the osteoporotic spine.
6. Consider improving pedicle screw fixation in the osteoporotic spine by increasing screw diameter, achieving bicortical fixation (at the sacrum), obtaining multiple points of fixation, use of expandable pedicle screws, hybrid constructs, and augmenting screw fixation with bone cement.

PITFALLS

1. Consider the patient's nutritional status and medical comorbidities before embarking on large spinal reconstructive surgeries in elderly patients.
2. Patients undergoing vertebroplasty or kyphoplasty for acute painful VCFs should be carefully selected while weighing the risks and benefits of these procedures versus conservative management.
3. Instrumented fusion should extend beyond the apex of any deformity to reduce risks of implant failure or progressive deformity adjacent to the fusion construct.
4. Avoid stand-alone interbody implants with modulus mismatch with bone in the osteoporotic spine.
5. Avoid excessive correction of rigid deformity that would place extreme forces on instrumentation.
6. Combined anterior/posterior circumferential fusion constructs should be considered for patients with osteoporotic bone.

KEY POINTS

1. When performing reconstructive spinal surgery in the elderly patient, the surgeon must consider the fragility of osteoporotic bone, the stability of the spine, and the potential failure mechanisms of any applied instrumentation.
2. Selective decompression and fusion should be performed based on the patient's symptoms and with consideration of potential for construct failure.
3. Increasing pedicle screw length and/or diameter can be the first-line in improving pedicle screw construct rigidity.
4. A twofold to threefold increase in screw pullout can be achieved with the use of PMMA injected into the vertebral body around the screws.
5. Combined anterior/posterior procedures may reduce the risk of instrumentation failure in patients with osteoporotic bone. This benefit must be weighed against the morbidity associated with additional surgery.

Intradural Tumors

The era of spinal tumor surgery began in London in 1887 when the influential surgeon Dr. Victor Horsley removed a thoracic intradural extramedullary tumor from a 42-year-old British Army General at the urging of the neurologist Dr. William Gowers.[1] The patient presented with a 4-year history of progressive symptoms that had culminated in urinary incontinence, spasticity, and paraplegia. Dr. Gowers diagnosed the lesion as a thoracic compressive lesion on the basis of a history and clinical examination and proposed surgery. After a thoracic laminectomy and removal of a compressive fibromyxoma, the patient made a remarkable recovery, regained the ability to walk, returned to work, and lived 20 additional years without recurrence. As a result, Dr. Horsley became a proponent of surgery as a viable treatment option for spinal tumors.

The next advancement in spinal tumor surgery was the first successful intramedullary spinal cord tumor removal in 1907 by Dr. Anton von Eiselsberg in Austria. However, the first published report of a successful intramedullary tumor removal is credited to Dr. Charles Elsberg in 1911 at the New York Neurological Institute.[2,3] Soon thereafter, in 1916, Elsberg published his influential book *Diagnosis and Treatment of Surgical Diseases of the Spinal Cord and Its Membranes*. He later published the first large series of intradural spinal cord tumor resections in 1925.[4] In his early writings, Elsberg advocated a two-stage surgery for intramedullary tumors: a laminectomy and myelotomy followed 1 week later by removal of the tumor that had delivered through the myelotomy. However, as his experience grew, he transitioned into performing single-stage operations for intramedullary tumor removal. For these significant early contributions, he is remembered as an important figure in spinal cord surgery.

Over the ensuing decades, the widespread practice of intraspinal tumor surgery was hindered by difficulty with tumor localization, infections, neurologic morbidity, and poor outcomes. Throughout the mid-20th century, intradural—especially intramedullary—tumors were treated with decompressive laminectomy, biopsy, and palliative radiation.[5] In the 1960s, technological advances—such as loupe magnification, widespread use of myelography, and bipolar cautery—began making good outcomes after surgery feasible and there was a renewed interest in aggressive surgical management.[6] Even in the past 30 years, the evolution of technologies such as the operating microscope, microsurgical instruments, magnetic resonance imaging (MRI), ultrasonic cavitation, and electrophysiologic monitoring has made aggressive surgical resection a low-morbidity mainstay of spinal tumor treatment.

Epidemiology

The incidence of intradural spinal tumors is reported to be between 1 and 2 per 100,000 population, and they account for 5% to 10% of central nervous system tumors.[7–9] In adults, extramedullary tumors predominate, accounting for 60% to 75% of intradural masses with intramedullary tumors accounting for the remainder. In children, however, intramedullary tumors are more common, accounting for greater than 35% of intradural masses.[8,10] Intradural tumors occur with equal frequency in both sexes, with the exception of a higher incidence of meningiomas in women. The most frequent intradural extramedullary tumors are nerve sheath tumors and meningiomas, with filum terminale ependymomas being a distant third.[10,11] Ependymomas and astrocytomas are the most common intramedullary lesions, followed by hemangioblastomas and cavernous malformations.[8,10,12] One institution's large experience is summarized in Box 90.1.

Clinical Presentation

Intradural tumors are typically slow-growing, benign lesions that may be asymptomatic or minimally symptomatic for years before presentation. The most common presenting symptoms for intramedullary tumors are sensory deficits, motor weakness, gait ataxia, and pain.[10] Pain is often worse at night and awakens the patient from sleep, but pain from a tumor may

be difficult to differentiate from common degenerative back pain.[13] In patients harboring slow-growing tumors, there is an indolent progression of symptoms from nonspecific pain and sensory disturbance to loss of balance, motor weakness, and other signs of myelopathy.[14,15] Patients may present with symptoms at any point along this continuum; however, since the advent of the MRI, tumors are being discovered earlier, resulting in less severe deficits at presentation. Intramedullary tumors can be associated with a suspended dissociated sensory loss.[7,16] This pattern of sensory disturbance is attributable to dilatation of the central cord by the tumor or an associated spinal cord syrinx causing an interruption of the pain and temperature fibers crossing in the anterior commissure. In fact, spinal axis imaging with contrast is an important step in the workup of an unexplained spinal cord syrinx in order to rule out an underlying spinal cord tumor.

The most common presenting symptoms for extramedullary tumors are as follows: pain, sensory disturbances, motor deficits, and gait ataxia. Schwannomas are derived from the nerve root sleeve and are more likely to present as unilateral radiculopathy; meningiomas, derived from the dura, are more likely to present with diffuse pain or symptoms of cord compression.[17,18] Yet, these symptoms are not mutually exclusive and patients often present with a mixture of nonspecific signs and symptoms.

The presenting signs and symptoms of intradural tumors are also influenced by the tumor's spinal level.[19] Both cervical and thoracic tumors can enlarge or compress the cord, resulting in cord impairment with prominent motor weakness and myelopathy. Cervical tumors are more likely to present with occipitocervical pain, arm pain, hand clumsiness, and sensory disturbances. Thoracic tumors often present with myelopathy and sensory disturbances in the lower body but can also produce pain that is mistakenly attributed to the heart and visceral organs. Tumors of the cauda equina typically cause back and leg pain that is classically worse while lying down and relieved by standing. This is thought to be due to positional pressure fluctuations in the epidural venous plexus.[20]

Radiologic Diagnosis

In the treatment of intradural tumors, the advent of MRI has allowed earlier tumor discovery, superior lesion characterization, precise localization, and improved surgical planning. MRI has supplanted computed tomography (CT) and contrast myelography as the imaging modality of choice in the diagnosis of intradural tumors. In most cases, MRI is now a stand-alone imaging modality with CT for certain tumors, and CT myelogram is reserved for use in patients with contraindications to undergoing an MRI (e.g., those with implanted ferromagnetic objects).[21] Plain radiographs are rarely important in the setting of intradural tumors but are useful when looking for abnormal alignment or structural instability in patients who have undergone a previous tumor resection.

In the evaluation of spinal tumors, MRI with gadolinium greatly increases the ability to identify a mass, show its relationship to the spinal cord, identify surrounding vascular structures, and give clues as to the pathologic diagnosis. Additionally, it can help differentiate tumors from less ominous lesions, such as arachnoid cysts, lipomas, and neurenteric cysts. On T1-weighted images, intradural tumors are typically isointense or slightly hypointense to the spinal cord. In T2-weighted sequences, cerebrospinal fluid (CSF) has a high signal and intramedullary tumors are often hyperintense. Spinal cord edema and syrinx associated with tumors are best identified with T2 images.[22] After the intravenous administration of gadolinium (paramagnetic ions), T1-weighted MRI detects contrast that leaks through the compromised blood–spinal cord barrier at the tumor interface. The subsequent delay in T1 relaxation time by the gadolinium within the tumor is interpreted as enhancement. Most intradural tumors display some degree of contrast enhancement. In certain cases in which multiple intradural lesions are discovered, the use of a positron emission tomography/CT (PET/CT) may be helpful to determine the degree of metabolic activity within the tumor. Certain tumors—such as chondrosarcomas, renal cell carcinomas, and lymphomas—may be hypermetabolic on PET/CT imaging; PET/CT becomes especially useful for patients with a previous history of treated cancer.[23–25]

Intramedullary tumors are generally contrast enhancing, can be either well circumscribed or diffuse, may have associated cysts, and can expand the spinal cord. Extramedullary lesions are usually well rounded, contrast enhancing, and compress the cord rather than expand it. Cauda equina tumors and nerve sheath tumors are usually heterogeneously enhancing with areas of cystic degeneration, hemorrhage, or necrosis. Imaging characteristics of specific tumors are discussed in the subsequent sections.

Extramedullary Tumors

Meningiomas

Intraspinal meningiomas are the most common type of intradural extramedullary tumors and occur predominantly in

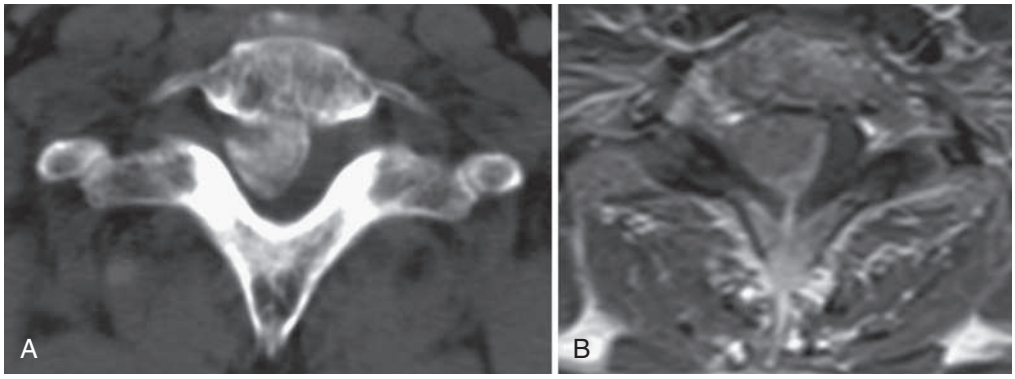

FIG. 90.1 (A) Axial computed tomographic image of a tumor showing homogeneous calcification and the ventral dural attachment. (B) Axial gadolinium-enhanced magnetic resonance image of the same tumor shows an enhancing ventral cervical meningioma with the spinal cord displaced laterally.

women (75% to 85%). They typically present in the fifth to seventh decades of life with pain, paresthesias, weakness, and long tract signs.[26,27] Meningiomas are homogeneously enhancing, smooth-bordered masses on MRI and can contain calcifications that help differentiate them from nerve sheath tumors (Fig. 90.1). With suspected meningiomas, preoperative CT scans are helpful to determine the presence and extent of tumor calcification, which can significantly affect surgical strategy. Seventy-five percent of intraspinal meningiomas arise in the thoracic spine and are typically dorsolateral to the cord; however, cervical tumors (20%) do occur and are frequently located in the upper cervical region and ventral to the cord.[20,28] Lumbar meningiomas are the least common. Spinal meningiomas are thought to arise from arachnoid cap cells in the dura near the nerve root sleeve laterally but may also grow from dural fibroblasts or pial cells, explaining their occasional ventral or dorsal location.[29] Meningiomas invariably arise and derive their blood supply from a broad dural base that is often visible as a dural tail on MRI. These tumors are typically benign, encapsulated, slow-growing masses, but other growth patterns are seen, including en plaque, atypical, and invasive malignant meningiomas.[10,30] Treatment for symptomatic tumors is surgical, with the goal of gross total resection; however, total removal may not be possible with en plaque or ventral calcified tumors.[28,30] Overall, spinal meningiomas are amenable to surgical removal and have low recurrence rates after complete resection.

Nerve Sheath Tumors

Tumors of the nerve sheath account for up to 30% of spinal neoplasms and are categorized as either schwannomas or neurofibromas.[31] They typically arise from the posterior sensory nerve root near its entrance into the neural foramen. Although both tumors are thought to be of Schwann cell origin, their significant histologic, epidemiologic, and biologic differences warrant discussing them separately.

Schwannomas are common intradural extramedullary neoplasms that make up 85% of nerve sheath tumors.[18] They occur equally in men and women, with a peak age of presentation between the fourth and sixth decades. Most appear as solitary tumors and occur equally throughout the spinal canal. Although rare, there are patients with multiple schwannomas but nearly always in the setting of neurofibromatosis 2 (NF2) and schwannomatosis.[32] Radiographically, schwannomas are well-demarcated masses associated with a nerve root, intensely enhance, can include cystic areas, and may grow along the root into the extraspinal space (Fig. 90.2A). Up to 30% of schwannomas grow through the neural foramen, giving the classic "dumbbell" shape on imaging (Fig. 90.2B).[18] At surgery, schwannomas are smooth, well-demarcated tumors that are discretely attached to an intact nerve root and can usually be separated from the root without nerve injury. The goal of surgery should be complete tumor removal and can usually be achieved. However, if complete resection is not possible, aggressive debulking with preservation of the root can relieve symptoms and the patient can be monitored radiographically for recurrence.

Neurofibromas are less common than schwannomas, accounting for approximately 15% of nerve sheath tumors, and more than half are associated with neurofibromatosis 1 (NF1).[18,33] Patients with NF1 can harbor single or multiple neurofibromas and are more likely to have malignant tumors.[34] Neurofibromas typically, but not exclusively, arise from the sensory root. Consequently, patients most commonly present with pain. Radiographically, neurofibromas are similar to schwannomas but are solid, not cystic. Yet they, too, can extend through the dural root sleeve as a dumbbell tumor (Fig. 90.3). Tumor cells characteristically arise from central nerve root fibers and expand the root, making dissection of the tumor from the root unrealistic. Optimal treatment for symptomatic neurofibromas includes total surgical removal of tumor, often necessitating the sacrifice of the nerve root.[31]

Ependymomas of the Filum Terminale

Ependymomas of this region are slow-growing tumors that arise from the filum terminale near the junction with the conus. At the terminal filum, ependymomas are thought to arise from ependymal rests ectopically deposited during development. They typically present in the third to fourth decades of life with slowly progressive low back pain, sensory

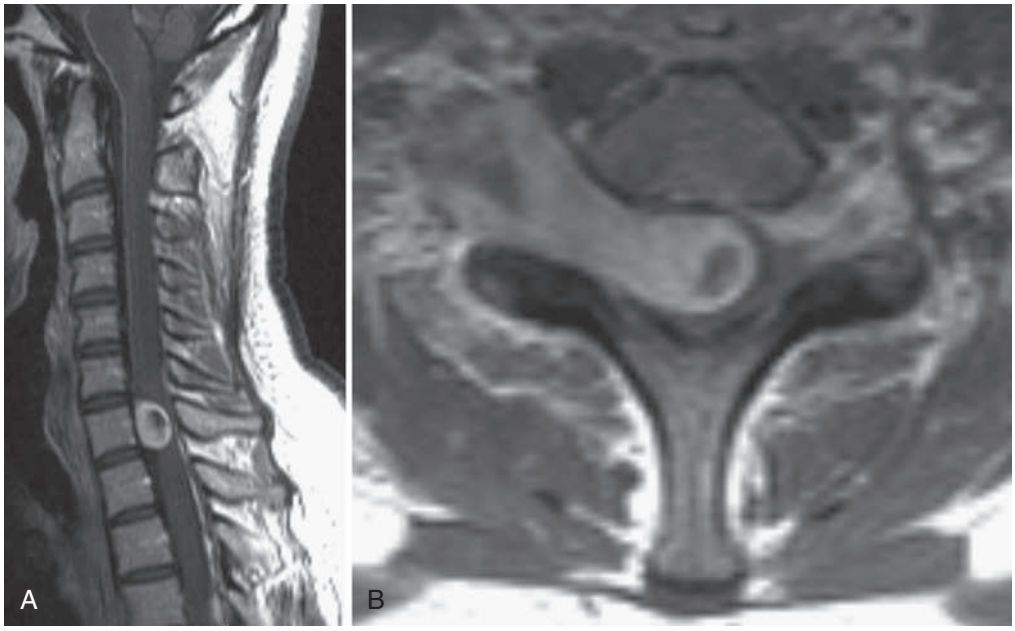

FIG. 90.2 (A) Sagittal T1-weighted gadolinium-enhanced magnetic resonance imaging (MRI) scan showing heterogeneously enhancing, well-demarcated, extradural schwannoma. (B) Axial T1-weighted gadolinium-enhanced MRI of the same cervical schwannoma showing dumbbell-shaped tumor extending through the right neural foramen.

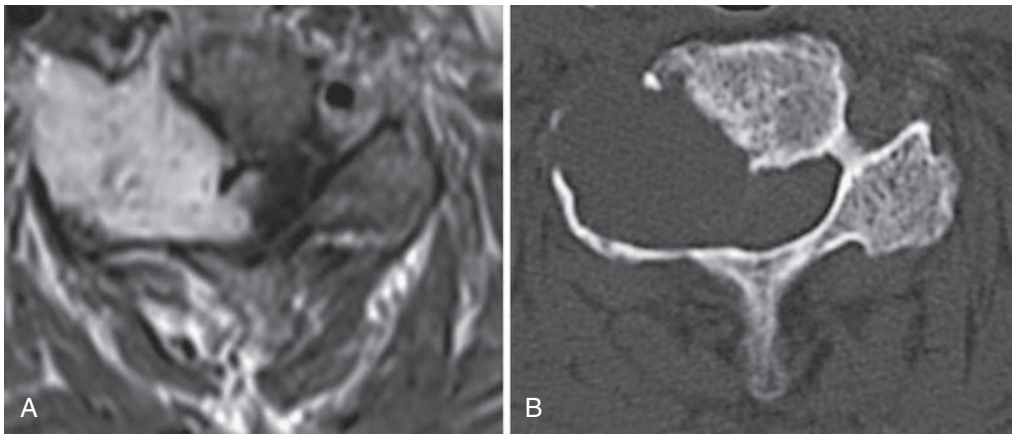

FIG. 90.3 (A) Axial T1-weighted gadolinium-enhanced magnetic resonance image of a malignant neurofibroma expanding the right neural foramen and extending into the extraspinal space. (B) Axial computed tomography of the same mass showing the extensive bony erosion caused by the tumor.

deficits, and even sphincter and sexual disturbances.[10] Histologically, filum terminale ependymomas are overwhelmingly of the benign myxopapillary pathologic subtype, but cellular and papillary histiotypes do occur.[35] On MRI, these tumors exhibit intense contrast uptake and can be anywhere on a spectrum from small, well-circumscribed tumors at the inferior tip of the conus to massive septated tumors filling the spinal canal (Fig. 90.4). An MRI of the neural axis should be obtained because cauda region ependymomas can disseminate along the neural axis via CSF or can be the result of intracranial cranial tumor seeding to the spine. Therapy is surgical, with a goal of gross total resection; however, this is often not achievable with massive tumors that are adherent to neural structures. Even after gross total resection of larger tumors, the recurrence rate is up to 20% and patients may need multiple surgeries for recurrences.[36,37]

Less Common Extramedullary Tumors

Paragangliomas

Paragangliomas are benign, well-circumscribed vascular tumors that typically arise from the filum terminale or cauda equina. They are clinically and radiographically similar to filum terminale ependymomas but are thought to arise from sympathetic nerve cells. Histologically, they resemble

FIG. 90.4 Sagittal T1-enhanced magnetic resonance image demonstrating a large filum terminale ependymoma filling the lower thoracic–upper lumbar spinal canal and encasing the cauda equina. Note the more inferior tumor nodule at the L4 level junction representing a drop metastasis.

the parasympathetic tumors of the carotid body and glomus region. Despite their sympathetic origin, they are nonsecreting tumors. Some of these tumors can be locally aggressive, with a penchant for recurrence. Optimal treatment is complete surgical excision, and radiotherapy may be indicated for incompletely removed tumors or recurrences.

Lipomas

Spinal lipomas have many forms, but the most common type arises in the lumbosacral region in the setting of occult spinal dysraphism. Most types of lipomas present during childhood, but intradural tumors can present in adults. They are considered benign but are often intimately associated with nerves of the cauda equina. When indicated to relieve symptomatic compression, surgery should be conservative because aggressive attempts to clear neural elements of tumor can lead to neurologic injury.

Arachnoid Cysts

Although not tumors, these structures can appear as a cystic mass compressing the spinal cord on MRI. They are composed of arachnoid membranes that have become loculated with CSF under pressure. The most common place for symptomatic arachnoid cysts is in the thoracic region. They typically present with pain and signs of myelopathy. Surgical excision relieves spinal cord compression and is the mainstay of treatment for symptomatic lesions.[38]

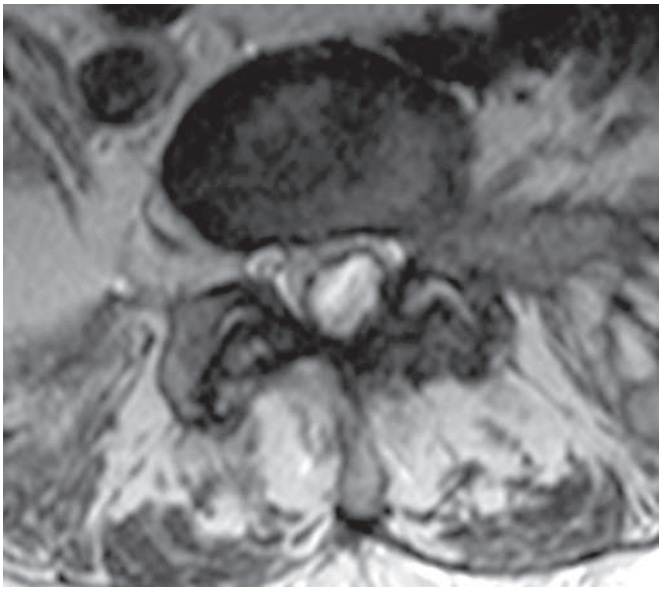

FIG. 90.5 Axial T2-weighted magnetic resonance image sequence of a large left L4 synovial cyst expanding from the facet into the spinal canal. These lesions can mimic spinal tumors.

Synovial Cysts

These extradural structures are cystic enlargements of the facet capsule that can enlarge to displace the thecal sac, compress the cord, or impinge nerve roots, causing radiculopathy. They are most common in the lumbar region, especially at L4–L5, but have been reported in the cervical spine.[39] These cysts are thought to result from excess motion at a vertebral level, leading to facet capsule hypertrophy and cystic enlargement. These lesions are filled with synovial fluid and can mimic intradural lesions on plain MRI (Fig. 90.5). Large or persistently symptomatic lesions can be managed with image-guided percutaneous drainage or more definitively with surgical removal.[40,41]

Intramedullary Tumors

Ependymomas

Intramedullary tumors of the spinal cord are rare, accounting for 15% to 30% of intradural spinal lesions. Ependymomas are the most common type of intramedullary spinal cord tumor and usually present in the middle-age years with pain, mild sensory changes, motor weakness, and signs of myelopathy.[42] There is a curious association of intramedullary ependymomas and NF2. A significant portion of NF2 patients harbor intramedullary ependymomas, and genetic studies on tumor cells have shown NF2 gene mutations in spontaneous intramedullary ependymomas.[43–45] Ependymomas of the cord are typically solitary tumors that arise from the ependymal lining of the central canal, cause a diffuse enlargement of the cord over several levels, and have an associated syrinx in up to 50% of cases.[45] Among the four ependymoma histologic subtypes, all are considered benign.[12,46,47] On MRI, intramedullary ependymomas are sharply demarcated lesions that are isointense on

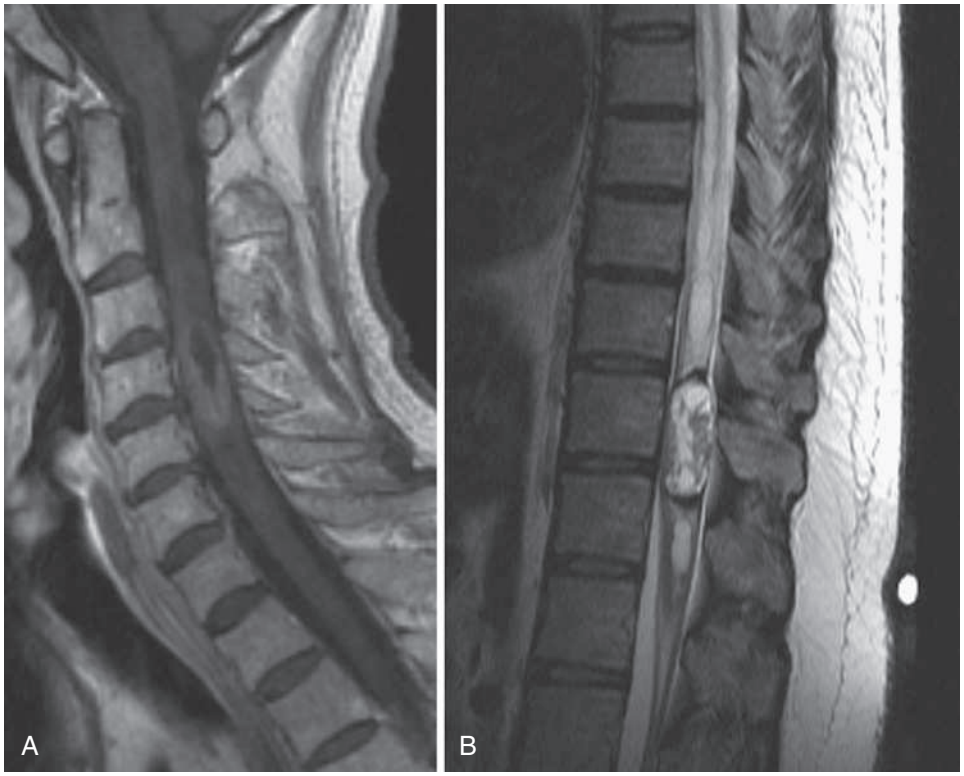

FIG. 90.6 (A) Sagittal T1-weighted gadolinium-enhanced magnetic resonance image (MRI) showing a midcervical enhancing ependymoma with a central cystic component. (B) T2-weighted thoracic MRI of a different spinal cord ependymoma showing a tumor with a large cystic component and a syrinx extending rostral and caudal to the lesion.

plain T1 sequences and enhance homogeneously with gadolinium (Fig. 90.6A). Classic radiographic features of spinal cord ependymomas include a distinct tumor–spinal cord border, an associated syrinx, cysts within or adjacent to the mass, and hemosiderin deposits or "caps" near the poles of the tumor on T1- and T2-weighted images (Fig. 90.6B).[48] The treatment of choice is gross total surgical resection. In contrast to intracranial ependymomas, intramedullary spinal cord ependymomas have a good prognosis and a low rate of local recurrence after complete resection, but cases of malignant transformation after resection have been reported.[49–51]

Astrocytomas

Astrocytomas are the second most common intramedullary spinal cord tumor in adults, representing 6% to 8% of intradural tumors. In children, they are the most common histologic type of intramedullary tumors, accounting for 60% to 90% of these lesions.[8,52] Patients harboring astrocytomas present most commonly with pain, motor weakness, and gait ataxia that can either be of long duration or of relatively brief onset before presentation.[10,53] The average symptom duration before presentation is between 12 and 29 months. Astrocytomas of the spinal cord are infiltrative tumors that are often eccentrically located dorsal or lateral to the central canal. Large tumors can expand and rotate the cord, making identification of landmarks difficult during surgery.[12] On MRI, astrocytomas have intermediate T1 signal intensity, can demonstrate heterogeneous or homogeneous T1-weighted contrast enhancement, often contain cystic areas, and can rarely grow exophytically into the extramedullary space. The tumor boundaries may be better identified on T2 sequences (Fig. 90.7). In contrast to ependymomas, spinal astrocytomas infiltrate functional cord, have ill-defined borders with normal cord, and are consequently more difficult to remove successfully. Fortunately, intramedullary astrocytomas in adults are largely low grade (WHO grade I and II) with approximately 25% considered high grade (Kernohan grade III and IV). In children, in whom pilocytic astrocytomas predominate, high-grade lesions are even less common, occurring at a rate of 10% to 15%.

Hemangioblastomas

Hemangioblastomas represent 2% to 6% of intramedullary spinal cord tumors and approximately one-third are associated with von Hippel-Lindau disease (VHL).[54,55] Spontaneous hemangioblastomas are usually solitary, but patients with VHL can harbor multiple hemangioblastomas, especially in the posterior fossa.[55] Patients who present with hemangioblastoma in the spinal column should be evaluated for lesions associated with VHL including the presence of other hemangioblastomas in the neural axis, retinal hemangioblastoma, renal/adrenal lesions, and less commonly endolymphatic sac tumors. Hemangioblastomas have a 2:1 male-to-female predominance and usually become symptomatic in the third to

fourth decades of life. Because of their predilection for the dorsal cord, numerous patients present with posterior column dysfunction or experience it after surgery. Histologically, these tumors consist of a vascular tuft surrounded by pale stromal cells, and there is often an associated cyst that accounts for much of the tumor volume. Radiographically, the tumors can be predominantly cystic masses with a small enhancing nodule of tumor cells located on the cyst wall or a solid homogeneously enhancing mass (Fig. 90.8). They are predominantly dorsal or dorsolaterally located and often grow to and expand the pial surface of the cord. Up to 89% have an associated syrinx that always resolves after tumor removal.[45,55] Treatment of spinal hemangioblastomas is surgical resection. Removal of these tumors carries the lowest surgical morbidity and best neurologic outcomes of all the intramedullary tumors.

Less Common Intramedullary Lesions

Lipomas

True intramedullary lipomas are rare lesions composed of metabolically normal fat cells ectopically deposited within the cord during embryologic development. Patients typically present in their 20s to 40s complaining of indolent neurologic symptoms that can rapidly progress over several months.[56] MRI is diagnostic, and the tumor signal follows that of normal fat. Treatment of symptomatic lesions is internal debulking to relieve symptoms.[57] Complete excision is difficult due to poor dissection planes, and delayed recurrence is common.

An expansile duraplasty may be helpful during dural closure to create more room in the spinal canal around the tumor site and delay compressive symptoms in the event of tumor recurrence.

Dermoid and Epidermoid Cysts

These tumors arise from an anomalous deposition of ectodermal cells during embryonic neural tube closure, but some cases have been linked to epidural cells implanted into the lumbar canal during lumbar puncture.[58] Patients present in the second to fourth decades with typical neurologic complaints of intramedullary masses; however, acute presentations secondary to aseptic

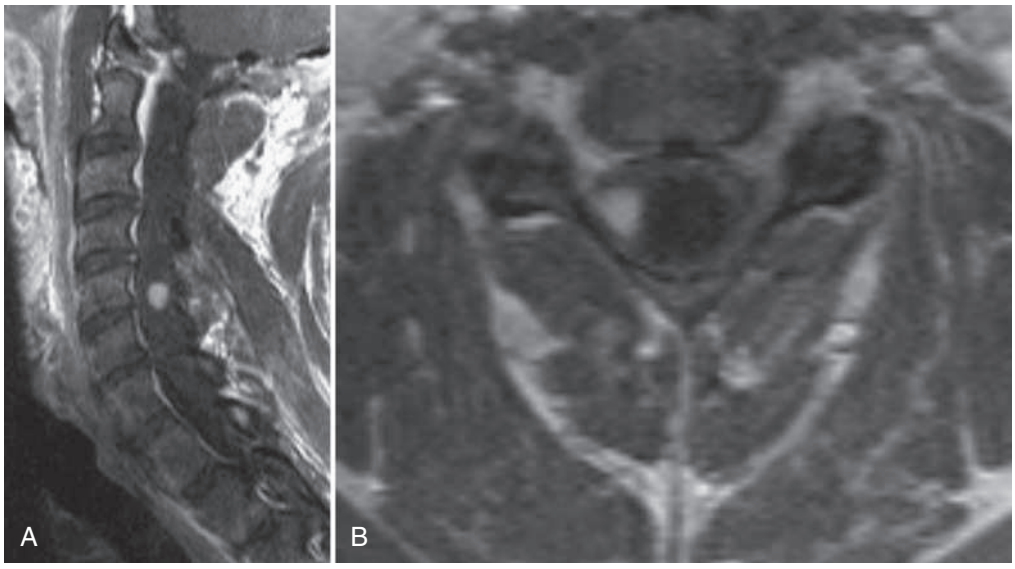

FIG. 90.8 (A) Sagittal T1-weighted contrast-enhanced image of a cervical hemangioblastoma showing a well-defined homogeneously enhancing mass. (B) An axial T1-weighted, contrast-enhanced MRI sequence of the same tumor revealing a large central cyst with a typical small, enhancing peripheral nodule.

meningitis or abscess formation have been reported.[59,60] Optimal treatment is complete surgical excision, but the cyst wall is often adherent to the spinal cord substance and incomplete resections are often performed with low recurrence rates.[61,62] Again, expansile duraplasty can be helpful after resection to delay symptoms in the event of a recurrence.

Cavernous Angiomas

These lesions are not tumors but rather are angiographically occult vascular malformations composed of tightly packed venous-like channels without intervening neural tissue. They represent 1% to 3% of intramedullary spinal cord lesions. Spinal cord cavernomas can be asymptomatic, present with slow stepwise decline of neurologic function due to small hemorrhages, or present as an acute neurologic deterioration from a larger bleed.[61] Most cavernomas are well-defined single lesions, some have ectopic portions nearly invisible under the pial surface, and rarely they are multiple. Cavernomas are best seen on T2-weighted MRI sequences, often have a mulberry-like appearance, and do not enhance (Fig. 90.9). Patients with symptomatic lesions should undergo surgical excision to prevent neurologic morbidity from future bleeds.[63]

Metastasis

The spinal cord parenchyma is a rare site of metastasis for systemic cancer and may occur in patients with extensive disseminated disease. The most common tumors that metastasize to the spinal cord are lung cancer (54%), breast cancer (14%), and melanoma (9%).[64,65] These patients generally have a grim prognosis related to their primary disease; however, surgical excision of cord lesions should be considered in those with radioresistant tumors and in those with a low systemic burden of disease who have symptomatic, surgically accessible solitary lesions.[66] Surgical excision of these lesions is also indicated in cases in which there is rapid neurologic decline in a surgically accessible location.

FIG. 90.9 Sagittal T2-weighted magnetic resonance image of a cervical cavernoma with heterogeneous signal characteristics and suggestion of a surrounding hemosiderin ring (low T2 signal).

Surgical Treatment

Intradural Extramedullary Tumors

Extramedullary tumors are almost exclusively approached through a posterior midline approach. Anterior tumors may require a facetectomy for adequate tumor exposure; dumbbell tumors with significant extraspinal extension may necessitate a lateral extracavitary approach.[67] Purely anterior surgical approaches are fraught with high complication rates and are necessary only in exceptional cases. To perform a posterior midline approach, the patient is positioned prone and a laminectomy is performed. The laminectomy usually does not need to be wide and the facets are spared to preserve the structural stability of that bony segment. When the bony exposure is complete, intraoperative ultrasound can be useful to localize the tumor before dural opening.[68] Once the dura is opened and the tumor is visualized, the tumor is dissected from the surrounding tissues. Care must be taken not to damage the cord parenchyma by excessive manipulation or damage vascular structures compromising cord blood flow. After exposure, removal may be performed en bloc, piecemeal, or with ultrasonic cavitation for internal debulking and, finally, capsule removal. After tumor resection, the spinal cord should be carefully dissected from arachnoid adhesions to the dura that often develop with chronic cord compression and local inflammation. In general, the goal of surgery is maximal tumor removal without neurologic injury. However, some extramedullary tumors force a decision between sacrificing the parent nerve root for complete tumor removal versus subtotal resection with root preservation. This decision is usually based on function of the involved root, tumor pathology, and tumor characteristics.

Meningiomas are abnormal dural outgrowths that push the spinal cord away from the dural attachment zone. These tumors are usually removed by cautery of the capsule, internal debulking, release of the dural attachment to free the tumor, and, finally, excision of the dural attachment zone. En plaque, infiltrating, and calcified tumors may be more challenging to remove due to cord adherence, heavy calcification, and involvement of tumor with cord blood supply. These tumors may not be amenable to complete resection. Complete tumor removal requires excision of the dural attachment zone and application of a dural patch graft. However, when complete removal is not possible, the surgeon may perform a partial dural dissection or coagulation of the attachment zone to maximize tumor cell removal in the setting of a subtotal resection. Recent series suggest that Simpson grade II/III resection

in high-risk settings should be considered to avoid morbidity from aggressive surgical resection.[69–71]

Nerve sheath tumor removal is dependent on tumor location and characteristics. Most schwannomas are dorsolateral and easily accessed, but more anteriorly located or dumbbell tumors with paraspinal extension may require extended posterolateral exposures.[67] Most nerve sheath tumor capsules are adherent to the arachnoid of the nerve root, and this layer must be incised to reach the lesion. The capsule is generally cauterized to shrink and decrease vascular input to the tumor; then, the tumor–nerve root attachment can be visualized. Piecemeal tumor removal or internal debulking with an ultrasonic aspirator should be used with large tumors. Nerve root sacrifice may be required due to tumor inside the root of large tumors encasing it. However, the incidence of permanent neurologic deficit from transection of a tumor-enveloped root is lower than might be expected, usually due to poor preoperative function of the root secondary to the tumor.[72,73] Care must be taken to carefully assess root function and weigh the benefit of complete tumor removal against loss of function before and during surgery.

Ependymomas of the filum terminale are variable in size and degree of involvement with the cauda equina. Smaller ependymomas should be resected in toto if possible to avoid CSF tumor seeding. Larger encapsulated tumors should be carefully debulked with CSF suction and surgical adjuncts placed around the tumor to decrease tumor dissemination. Tumors filling the lumbosacral spinal canal usually lack a discernable capsule and tend to infiltrate the conus and cauda equina nerve roots, making complete resection difficult. In these cases, care should be taken to maximally debulk the tumor without injuring the enveloped neural structures. Expansile duraplasty can be useful, especially in these extensive tumors, to enlarge the spinal canal and delay symptom recurrence if the tumor regrows. If a postoperative CSF leak is anticipated or encountered, a C1–C2 CSF diversion drain can be placed with fluoroscopic guidance and prevent the need for lumbar drain placement at the surgical site.

Intramedullary Tumors

The role of surgery in the treatment of intramedullary spinal cord tumors has expanded considerably in recent decades. With the advent of the operative microscope, MRI, ultrasonic aspiration, and electrophysiologic monitoring, experienced surgeons can now safely remove or greatly debulk most intramedullary lesions. Neuroprotection is an important consideration during spinal cord tumor surgery, and perioperative steroids are commonly employed. Recently, intraoperative hypothermia using intravenous cooling catheter systems has emerged as a potential neuroprotective adjunct during spinal tumor surgery. Our 4-year experience with intraoperative hypothermia has found it to be safe (unpublished data), but randomized controlled trials will ultimately be necessary to judge its efficacy. Surgery is nearly always performed through a posterior midline approach with laminectomy at the tumor level as well as one level above and one below. Ultrasound can be useful to confirm the tumor location and confirm that it is within the limits of the bony exposure.[68,74] Then, a midline dural incision is made. With the aid of an operative microscope, the midline is identified and a myelotomy is made in the posterior median sulcus. Of note, the midline is often difficult to identify with larger tumors due to an expanded and often rotated cord, but the midpoint between dorsal root entry zones can be used as a rough estimate of the midline in such cases. The myelotomy is deepened until the tumor is identified; then, the resection is guided by the presence or absence of a dissection plane between the tumor and cord parenchyma. Intraoperative frozen sections can be helpful if suspicion is high for an unusual diagnosis, such as demyelinating disease or metastasis; however, frozen sections can be unreliable in differentiating between astrocytomas and ependymomas. Tumor resection is performed to the maximal extent possible while avoiding neurologic injury.

Ependymomas are centrally located, smooth, red-gray, well-demarcated lesions that often have cystic areas at their superior and inferior limits. When the cord is exposed, small blood vessels are commonly seen running across the tumor surface. There is usually a good cleavage plane between tumor and cord, and they can be removed completely in 70% to 95% of cases.[75,76] Smaller tumors can often be removed in one piece by gentle capsule dissection and light bipolar coagulation to shrink the mass. Larger tumors must be internally decompressed and then the capsule carefully dissected from the cord. The final removal is often achieved by gentle retraction of the superior tumor pole and cauterization of the last arterial feeders. At this point, a common surgical error is to aggressively resect a layer of slightly discolored but ultimately functional tissue that can surround the tumor at the parenchyma-tumor interface. Resection should not continue past obvious tumor into the glial tissue to avoid unnecessary neurologic injury.

Astrocytomas are generally low-grade infiltrating tumors that tend to be asymmetrically located in the spinal cord. Intraoperatively, the tumor appears grossly different than cord parenchyma, but most often tumor cells infiltrate functional cord tissue, preventing the development of a safe dissection plane. This makes complete tumor resection hazardous. Some authors have argued for aggressive resection of low-grade astrocytomas, but there is an unclear relationship between extent of resection and survival. Therefore, resection of obvious tumor without risking neurologic deterioration is recommended.[10,51,74,77] Patients harboring high-grade astrocytomas have poor prognosis regardless of the degree of tumor removal, and resection of high-grade lesions is typically conservative. Several long-term survivals have been reported in grade IV astrocytoma patients with tumors below T1, including two patients in the senior author's (B.A.G.) personal series.[74,78]

Hemangioblastomas are highly vascular, well-demarcated, often cystic lesions that can rise to the dorsal surface of the spinal cord. These tumors are extremely vascular; thus, the superficial and deep arterial supply should always be interrupted and the capsule shrunken away from the cord with bipolar coagulation before the tumor is entered or removed. Entering the capsule before interrupting the tumor arterial feeders risks a large hemorrhage. Hemangioblastomas should

be completely resected because residual tumors will lead to a recurrence. Preoperative embolization has been advocated by some authors but is not commonly performed because most feeders are surgically accessible.[79]

Radiation/Chemotherapy/Adjuvant Treatments

Intradural Extramedullary Tumors

Surgical excision is first-line therapy for extramedullary intradural tumors, with radiation and chemotherapy being rarely indicated for benign pathologies. Adjunctive radiation therapy and chemotherapy is typically reserved for World Health Organization grades III and IV extramedullary tumors. Radiotherapy for spinal atypical meningiomas (WHO grade II) also should be reserved for tumor progression/recurrence as gross total resection only seems to provide adequate tumor control.[80] Fractionated radiation is not routinely used for extramedullary low-grade lesions, but some authors advocate radiation for residual or recurrent large filum terminale ependymomas.[81] Radiosurgery, however, has recently been proposed as an alternative to surgery for poor surgical candidates harboring low-grade lesions.[82] The studies are small, and follow-up is brief. Delayed radiation-induced spinal cord toxicity is a feared complication of spinal cord radiotherapy; more follow-up data are necessary to determine its safety, which is of vital importance when treating benign pathologies.[82,83]

Recently, image-guided laser interstitial thermal therapy has also been proposed to control epidural metastases. Laser interstitial thermal therapy (LITT) works by introducing a catheter into the lesion that delivers controlled thermal energy into the lesion to allow for tumor necrosis prior to adjuvant stereotactic radiosurgery.[84] However, theoretically, LITT may pose more risks in the spinal cord than the brain; LITT ablates the tumors in close proximity to the spinal cord and does not reduce tumor mass effect immediately. Nevertheless, LITT remains a potential option for metastatic epidural disease and may be tested for malignant intradural pathologies in the near future.

Intramedullary Tumors

Gross total resection is the treatment of choice for most common intramedullary pathologies, with radiation and chemotherapy having limited roles. Chemotherapy regimens are generally reserved for high-grade lesions and typically mirror the regimens given for intracranial tumors of the same pathology. New-generation intrathecal pumps can deliver measured doses of chemotherapy directly to the intrathecal space, and intrathecal chemotherapy regimens are being explored.

Ependymomas are generally amenable to safe, complete removal with low recurrence rates. MRI is a noninvasive method for monitoring for tumor regrowth or seeding of the subarachnoid space and can obviate the need for early radiation after surgery. Radiation may be indicated in the setting of a malignant ependymoma or when a significant portion of a tumor cannot be resected.[85,86]

Intramedullary astrocytomas are typically low-grade tumors treated by surgical resection and monitored for recurrence by clinical and radiographic follow-up. In the setting of subtotal tumor removal, some authors have advocated radiation to the residual tumor, but there is no compelling evidence that radiotherapy alters the natural history.[74,87] Patients with grade III astrocytomas may be candidates for adjunctive radiation and chemotherapy.[88] Malignant astrocytomas of the spinal cord, however, have a poor prognosis and radical resection results in high morbidity; therefore, conservative tumor removal for tissue diagnosis followed by radiation therapy is common practice.[74,89] Alternatively, one group has reported extended survival times for malignant astrocytoma patients treated with radiocordectomy, and long-term survival for spinal cord grade IV astrocytomas has been reported after surgical cordectomy, including two long-term survivals in the senior author's personal series (unpublished).[78,90]

Stereotactic radiosurgery for intramedullary tumors has been described in small studies with brief follow-up.[91,92] In the future, this treatment strategy may prove useful in select cases in which complete surgical excision is not possible or after multiple recurrences. However, more studies are necessary to determine safety and long-term efficacy, especially in light of the proven success of surgery and the low-grade pathologies of most intramedullary tumors.

Outcomes

Intradural Extramedullary Tumors

The surgical morbidity and mortality in the removal of extramedullary tumors is low while the neurologic prognosis is generally good. Postoperative neurologic function is generally predicted by the preoperative neurologic status, patient age, and duration of symptoms.[20,26,31] In one large series of intradural extramedullary tumors, there was a 12.3% rate of postoperative neurologic worsening, but most deficits were transient and only 2.3% of the patients had a permanent postoperative loss of function.[10] Overall, intradural extramedullary tumors have a recurrence rate of 8.9% to 32% at 5 years, with the strongest predictors of recurrence being histologic grade and previous surgical resection.[93] Meningiomas have a 4% to 8% long-term recurrence rate after gross total resection with higher-grade tumors recurring more frequently. After surgery, recovery of neurologic deficits is common, with 80% to 90% of patients showing improvement of preoperative neurologic deficits.[28] In the absence of NF2, the recurrence rate for schwannomas is 6% to 12%, but in patients with neurofibromatosis, it is increased fourfold.[93,94] Completely resected neurofibromas recur in approximately 12% of patients.[95] Intradural malignant nerve sheath tumors are rare but must be managed aggressively, as outcomes are generally poor with a 5-year survival rate of 44%. Tumors that stain negative for S-100 tend to be more aggressive and recur more quickly.[96] A recent review suggests that extent of resection in patients with intradural spinal nerve sheath

tumors remains one of the most important prognostic factors for patients, while presence of neurofibromatosis and cervical tumors was associated with higher rates of recurrence.[97] Large filum terminale ependymomas have a high recurrence rate. Even after gross total resection, the recurrence rate is up to 20% and patients may need multiple operations for revision debulking.[37,67]

Intramedullary Tumors

The neurologic morbidity for intramedullary tumor removal is significantly higher than for extramedullary tumors. Preoperative neurologic status is the number one predictor of postoperative functional status, but other factors—such as aggressive tumor pathology and thoracic location—also portend worse functional outcomes.[98,99] Up to 57% of postsurgical patients experience a transient neurologic worsening, but only 10% to 20% are left with a new permanent deficit.[10,51] Dorsal column dysfunction is common after midline myelotomy.[42] Despite the new deficits, however, most patients recover to baseline functional status within 1 year.[10]

After complete resection, ependymomas have good neurologic outcomes, low recurrence rates, and long survival times.[47,85] Tumors that are not completely resected tend to have less improvement in function and higher recurrence rates.[10,75,93,100] Survival rates at 5 years are reported to be between 83% and 95% for postoperative intramedullary ependymoma patients.[51,101]

Astrocytomas are more difficult to completely remove surgically and have a higher recurrence rate. Astrocytoma patients have shorter survival times than those harboring ependymomas. Extent of tumor resection seems to modestly affect local recurrence rates, but this has not been conclusively demonstrated in the literature.[10,12,98] The 5-year survival rate has been reported to be 63% to 77% for grade I and II tumors and 27% for grade III and IV tumors.[74] Median survival for high-grade lesions is around 1 year, with grade IV tumors having a particularly poor prognosis.[102–104]

Hemangioblastomas are amenable to complete resection, have low surgical morbidity, and have low recurrence rates.[105–107] The presence or absence of VHL seems to have little impact on outcomes. Intramedullary hemangioblastoma patients experience the lowest surgical morbidity and the best neurologic prognosis of all the common intramedullary spinal cord tumors.

Summary

Technical advances in diagnostic modalities—such as MRI and operative adjuncts such as the operating microscope, bipolar cautery, neurophysiologic monitoring, intraoperative ultrasound, and ultrasonic cavitation—have ushered in the modern renaissance of surgical treatment of spinal tumors. In the near future, advances in the area of intraoperative neuroprotection—including meticulous intraoperative blood pressure control, steroids, and modest hypothermia (33°C)—may prove to lower surgical morbidity. The goal of surgery for intradural tumors is maximal tumor removal with minimal neurologic morbidity. Yet, even after gross total removal, a cure is not guaranteed and recurrences are common. The continued evolution of surgical tools, emergence of new biologic therapies, and development of adjunctive technologies will undoubtedly shape the future of the diagnosis and treatment of intradural spinal cord tumors. However, it remains the surgeon's careful preoperative assessment, tailored surgical strategies for each individual patient, and a well-executed tumor removal that define effective spinal tumor surgery.

PEARLS

1. A patient's postoperative neurologic status is most strongly predicted by his or her preoperative neurologic status.
2. MRI with and without contrast is the preferred imaging technique for investigating intradural tumors.
3. When assessing an intradural tumor on imaging, first determine if it is intramedullary or extramedullary by noting whether it displaces the spinal cord or is within and expands it. Then, create a differential diagnosis on the basis of imaging characteristics of the lesion, age of the patient, and clinical history and physical examination.
4. Patients with multiple neurofibromas or multiple hemangioblastomas should be investigated for the presence of NF1 and VHL disease, respectively.
5. Complete removal of a hemangioblastoma will be followed by resolution of the associated syrinx.

PITFALLS

1. Schwannomas arise from the nerve root, whereas neurofibromas infiltrate it; therefore, nerve root sacrifice is necessary for complete removal of neurofibromas but rarely for schwannomas.
2. Intramedullary astrocytoma tumor cells typically infiltrate functional nervous tissue, creating an indistinct tumor-cord border. Achieving true gross total resection can result in neural injury.
3. When removing a cystic hemangioblastoma, always completely remove the enhancing nodule or the tumor will recur.
4. Care should be taken not to create an unnecessarily wide laminectomy to prevent postoperative kyphosis.
5. Patients with spinal metastasis often have disseminated primary cancer and carry a poor overall prognosis.

KEY POINTS

1. Preoperative MRI with contrast is essential for formulating a differential diagnosis and an appropriate surgical plan.
2. Intradural extramedullary tumors account for approximately two-thirds of intradural tumors, are typically benign, and can usually be completely excised. With nerve sheath tumors, functional status of the involved nerve root function is important if root sacrifice might be necessary for complete resection.
3. Intramedullary tumors are less common and usually benign but carry a greater risk of iatrogenic neurologic morbidity with surgical excision. Intraoperatively, careful observance of the tumor-parenchyma border is important for safe removal of intramedullary tumors.
4. Intradural spinal tumors are nearly always approached via a standard posterior midline approach. However, intradural extramedullary tumors with extensive lateral extraspinal growth may require an extended posterolateral approach.

5. Survival and recurrence rates for intraspinal tumors are heavily influenced by tumor grade and extent of resection.
6. Surgical resection is the preferred treatment for intradural tumors. Radiation and chemotherapy are used in a secondary role to aid in the treatment of recurrence or residual tumor that is not amenable to resection.

CHAPTER 91

Spinal Intradural Infections

SECTION XIII

Walter J. Jermakowicz
Samuel H. Cass
Allan D. Levi

Introduction

The spinal cord and subdural space are the regions of the central nervous system (CNS) least likely to harbor infections. Since the first description of a spinal subdural infection in 1927,[1] cumulative knowledge of these infections has been limited to sparse case reports and small series due to their low prevalence, their variable presentation and outcomes, and inaccurate diagnostic methods. Despite the rarity of spinal subdural infections, the reported incidence has been on the rise due to improved imaging techniques and an increase in spinal infections linked to immunocompromise and invasive spine procedures. In 2013, spinal infections hit the mainstream media after a string of aspergillosis infections linked to contaminated epidural steroid injections from a common manufacturer affected more than 700 patients and killed 61.[2] As drug resistance among common microbes evolves, rates of diabetes mellitus (DM) and intravenous (IV) drug use increase, and the number of invasive spinal procedures performed continues to increase, it is clear that a greater understanding of these infections is necessary. This chapter focuses on the presentation, diagnosis, and treatment of the most common spinal intradural infections. Emphasis is placed on advances in imaging for the diagnosis of spinal subdural infections as well as on lessons learned from the recent epidural steroid injection–related epidemic.

Bacterial Pathogens

Spinal Subdural Abscess

Background and Demographics

Infections of the spinal subdural space are the rarest localized infections of the CNS. Since their initial description by Sittig in 1927,[1] there have been only 86 cases of spinal subdural abscess (SSA) reported in the literature, namely, in case reports and small case series; thus, their incidence remains unclear. However, reporting of these infections is on the rise due to a suspected increase in their incidence and due to improvements in imaging tools that help identify SSAs earlier and guide their management.[3–13]

Apart from the rarity of SSAs, understanding of their natural history and pathophysiology has been hindered by their variable clinical course. Age of presentation varies from the fourth week to the eighth decade of life, with roughly 50% of patients reported presenting in the fifth to seventh decades of life. In adults, SSAs have a predilection for the lumbar spine, with a slight predominance of females over males; in pediatric patients, the infections tend to occur in the thoracic spine, with males outnumbering females 2:1.[4,5,13] Of the 86 reported cases of SSA, only two are considered idiopathic and the rest have been linked to immunocompromise (DM, IV drug use, alcoholism, cancer, human immunodeficiency virus [HIV]), anatomic abnormalities (dermal sinuses, cysts, degenerative disc disease, trauma) or prior intervention (epidural injections, catheters, surgical implants).[3–13]

Pathophysiology

Advances in the understanding of the anatomy of the subdural space have helped explain the relative paucity of SSAs compared to epidural or intramedullary spinal infections.[11,14,15] Contrary to the classic view of the subdural space existing as a potential space between the dura and the arachnoid, several cytoarchitectural studies have shown that the dura and arachnoid are bridged by specialized fibroblasts called dural border cells that eliminate this potential space, making formation of an abscess less likely. This dural border layer, however, is thought to be structurally weaker than the dura or arachnoid, occasionally allowing a hematoma or infection to dissect through the border cells and form a pathologic subdural extramedullary collection.[11] In addition, the subdural space is relatively avascular compared to the epidural space and spinal cord, which reduces the risk of seeding from a distant infection.[14,15] The significantly lower incidence of SSAs compared to cranial subdural abscesses has been explained by (1) centripetal blood flow in the spine compared to centrifugal in the cranium; (2) the lack of air sinuses in the spine that may

directly spread infection to the subdural space of the cranium; and (3) the lack of an open epidural space in the cranium, unlike in the spine, where the epidural space filters out pathogens before they reach the dura.[4,11,14,15]

The pathogenesis of SSAs has been historically classified into four main categories. The first, and considered most common, is seeding of bacteria from a distant primary infection.[16–18] Many different primary infection sources have been described, such as urinary tract infections, endocarditis, upper respiratory tract infections, and septic abortions. However, Bartels et al. found skin ulcers and cellulitis to be the most common primary site.[4] The second category, which is growing in frequency as the number of invasive spine procedures increases, is iatrogenic. This includes lumbar punctures, epidural injections, and incidental durotomies during spine surgery.[4,7,17] Unlike the recent US outbreak of fungal intradural infections after injection of contaminated methylprednisone during epidural steroid injections, only three bacterial subdural infections have been attributed to epidural injections: two from epidural steroid injections and one from epidural anesthesia.[2,4] The third category involves direct extension of infection into the subdural space. This extension is mostly considered to be due to dermal sinus tracts or destruction of dura by local infection or trauma.[5,7,11,19–22] A recent report by Usoltseva et al.[12] describes direct seeding of an SSA from a decubitus ulcer in a 55-year-old paraplegic male with an acutely worsened motor examination. Cultures from the SSA and ulcer both grew *Bacteroides fragilis* and *Enterobacter cloacae*, but blood cultures were negative. In the pediatric population, over half of SSAs have been attributed to spinal dysraphism or other congenital anomalies.[11,19,22,23] The fourth and least common category is idiopathic subdural infections, for which no primary source can be identified.[18,24–26]

Whereas the anatomic location of an SSA along the spine largely determines the neurologic deficits that will be present, other important pathologic features include the presence of a capsule and the rate of growth of the abscess. Review of prior literature on spinal subdural infections reveals the often interchangeable use of the words "abscess," which describes the accumulation of purulent material in a fibrous capsule, and "empyema," which is the accumulation of this material in a preexisting space. Despite the pathologic distinction between abscesses and empyemas, studies do not indicate a significant difference in the treatment or prognosis of these disease entities. The age of an SSA also affects the clinical picture. Chronic SSAs have less specific features than acute SSAs. Clinical features of chronic SSAs are less focal and of slower onset, and laboratory markers are usually normal. Chronic SSAs are also more difficult to identify by imaging than acute SSAs and have been frequently confused with tumors[3–13] (Box 91.1).

BOX 91.1 Spinal Subdural Empyema Organisms

Staphylococcus aureus
Staphylococcus species
Streptococcus species
Escherichia coli
Pseudomonas aeruginosa
Streptococcus pneumoniae
Peptococcus magnus

Clinical Presentation

The diagnosis and treatment of SSAs has historically been made difficult by their diverse clinical presentation. The classic triad of symptoms was initially described by Fraser et al. in 1973 and includes fever, neck/back pain, and symptoms of cord or cauda equina compression.[14] Bartels et al. in 1992 suggested three stages to the temporal progression of SSAs.[4] Stage 1 includes fever with possible neck/back pain. Stage 2 shows symptoms of compression resulting in motor, sensory, or bowel/bladder deficits. Stage 3 shows complete motor and sensory loss below the lesion. In practice, however, it is unclear how many SSA patients fit this clinical picture. In their study, Bartels et al. found 87% of SSA patients with fever, 84% had neck/back pain, and 82% had neurologic deficits.[4] Other reports suggest a more variable presentation, however. Levy at al. found only 18 of 47 patients in their study to fit the classic triad.[27–31] Sandler et al.[11] found in their review of the pediatric literature that 50% present with fever, 34% with urinary dysfunction, 56% with motor weakness, and only 21% with neck/back pain. A total of 37% of the pediatric patients also presented with symptoms of meningismus. The lack of spine tenderness was previously considered a distinguishing feature of SSAs from spinal epidural abscesses but has since been commonly reported in patients with SSAs. Levy et al. found 14 of 47 patients with spine tenderness[31] and the pediatric review by Sandler et al. found 10% of patients with tenderness.[11]

The onset of SSA symptoms in cases linked to epidural injections also appears to be variable. The two patients with SSAs after epidural steroid injections presented 5 days and 11 weeks after the injections. The patient with SSA following epidural anesthesia for delivery presented 1 week after the treatment.[2,4,7]

Laboratory Evaluation

Obtaining labs and cultures is an important component of the workup for SSAs, but results are usually nonspecific and of little therapeutic value.[4] Blood leukocyte count, erythrocyte sedimentation rate, and C-reactive protein are usually mildly elevated but may also be normal. Lumbar puncture is generally not recommended since the clinical utility is low and there is risk of spreading infection from the subdural space into deeper meningeal layers or of causing cord herniation if an obstruction of cerebrospinal fluid (CSF) flow is present. Even when a CSF sample is obtained, results are usually more suggestive of a parameningeal process rather than meningitis due to frequent encapsulation of the pathogens, generally showing moderately increased pleocytosis and protein content, normal to low glucose, and negative cultures. Blood cultures are generally recommended for all spine infection patients. Whereas the concordance between spinal epidural abscesses and blood cultures is near 100%, the concordance between SSAs and blood cultures is unknown but presumed to be significantly lower due to the sparse vasculature of the spinal subdural space.[11,16,18,32]

Imaging

Whereas findings on computed tomography (CT) are generally nonspecific,[33–35] magnetic resonance imaging (MRI) has remained the most important imaging modality for diagnosis of SSAs.[36,37] Generally, a subdural collection or mass that is hypointense on T1 and hyperintense on T2 with a thin, variable-thickness, contrast-enhancing rim points toward an SSA. The abscesses are usually crescentic in shape and the overlying dura may be thickened and subarachnoid space narrowed or obliterated in severe cases. Differentiating SSAs and epidural abscesses remains difficult in certain cases. Compared to epidural abscesses, SSAs tend to have preserved epidural fat on the MRI. In addition, whereas SSAs are confined to the spinal canal, epidural abscesses may extend further laterally and into the neural foramina. Distinguishing subdural and epidural spine infections is further complicated by their occasional co-occurrence.[4,11,16]

Recent advances in MRI have improved preoperative characterization of SSAs.[36,37] Fat suppression techniques that remove effects from epidural fat and bone marrow allow for better definition of SSAs. Diffusion-weighted imaging has emerged as an important sequence for showing the extent and multiplicity of spinal abscesses. This aids not only in diagnosis but also in planning surgical treatments for these abscesses. Restricted diffusion for the diagnosis of SSAs becomes especially crucial in cases in which gadolinium contrast cannot be administered[37] (Fig. 91.1).

Treatment and Prognosis

Nearly all prior reports of SSAs advocated for immediate surgical decompression followed by 4 to 6 weeks of antibiotics tailored to the cultures. Conservative measures have been advocated in cases in which patients may not tolerate surgery or in which infectious organism is known, but the unpredictable progression of these infections makes delaying surgery very risky.[3–13] When surgery is performed, the exposure should encompass the entire extent of the abscess and copious irrigation needs to be used.[37] The use of drains following surgery is inconsistent and has not been shown to be of benefit. Since obtaining a definitive organism to treat is usually a major indication of the surgery, antibiotics should be withheld until intraoperative cultures have been collected. When empiric antibiotics are given, coverage of gram-positive cocci is of highest priority both in adult and pediatric populations. It has been argued that antibiotics prior to surgery may reduce inflammation at the time of the surgery, but this has not been adopted into practice. The administration of dexamethasone prophylactically to prevent thrombophlebitis has been previously advocated but also lacks support in the literature.[14,16,24,27,37]

The sparse incidence and variable nature of these infections makes outcomes difficult to predict. Generally, however, early diagnosis with preserved neurologic function is correlated with better postoperative outcomes. In a review of 45 patients by Bartels and colleagues,[4] 82% of patients who underwent surgery had a complete recovery or improvement in symptoms and 18% died. In a group of 5 conservatively treated patients they analyzed, only one survivor was found. Likely as a result of improved diagnosis and treatment of these infections, deaths from SSAs are rarely reported in the modern literature and, when reported, are usually the result of multiple comorbidities.[4] The three previously reported cases of SSAs associated with epidural injections all had complete or near-complete recovery of their symptoms after surgical decompression and antibiotic treatment.[2,4,7]

As expected, pediatric SSA patients have lower mortality and greater recovery of neurologic function compared to their adult counterparts.[11,19,22,23] In a review of 72 pediatric cases with SSAs for which decompression was performed, Sandler et al.[11] found complete recovery in 52% of patients and residual disability in 37%. No deaths were reported in their review. Functional outcomes were highly correlated with underlying pathology. In 51 children with dysraphic or abnormal spines, only 16 (31%) showed a complete recovery. In addition, children infected with *Mycobacterium tuberculosis* or *Echinococcosis granulosus* had better functional outcomes generally (59% complete recovery) than children who cultured other organisms.

Intramedullary Spinal Cord Abscesses

Background and Demographics

Intramedullary spinal cord abscesses (ISCAs) are suppurative infections similar to pyogenic brain abscesses but with much lower incidence. The incidence of ISCAs reported in the literature is on par with SSAs; similarly, knowledge of this entity is restricted to case reports and small retrospective reviews.[38–42] Since the initial description of an ISCA in 1830 by Hart, there have been fewer than 150 reported cases. In 1944, Arzt reviewed all cases of the preantibiotic era.[27] Then, in 1977, Menezes et al.[41] and DiTullio et al.[40] independently published the first reviews of these infections in the postantibiotic era. Although these and more recent reports suggest that the incidence and severity of ISCAs dropped after the advent of antibiotics, there continue to be cases reported, mostly in association with immunocompromise, IV drug use, DM, invasive spine procedures, and trauma.[41] Very few ISCAs have been considered idiopathic.[43,44]

Compared to the subdural abscesses described earlier, ISCAs have a different demographic. First, ISCAs tend to occur in younger patients. Although there is a broad age range (1 month to 72 years), it has been reported that roughly 25% of all cases involve patients younger than 10 years.[45–50] In a recent review of 45 pediatric cases, the mean age of presentation was 27 months.[50] Among adult patients, cases tend to present in the fourth decade of life.[38–42] Second, ISCAs tend to occur in males over females, both in the pediatric (78%)[51] and adult populations (60%–70%).[38] Third, compared to subdural abscesses, ISCAs have less of a predilection for the lumbar spine. Byrne et al. found that, of reported ISCAs, 36% involve the cervical cord, 29% the thoracic cord, and 36% are in the conus.[52] These abscesses may be multiple in 26% of the cases.[44]

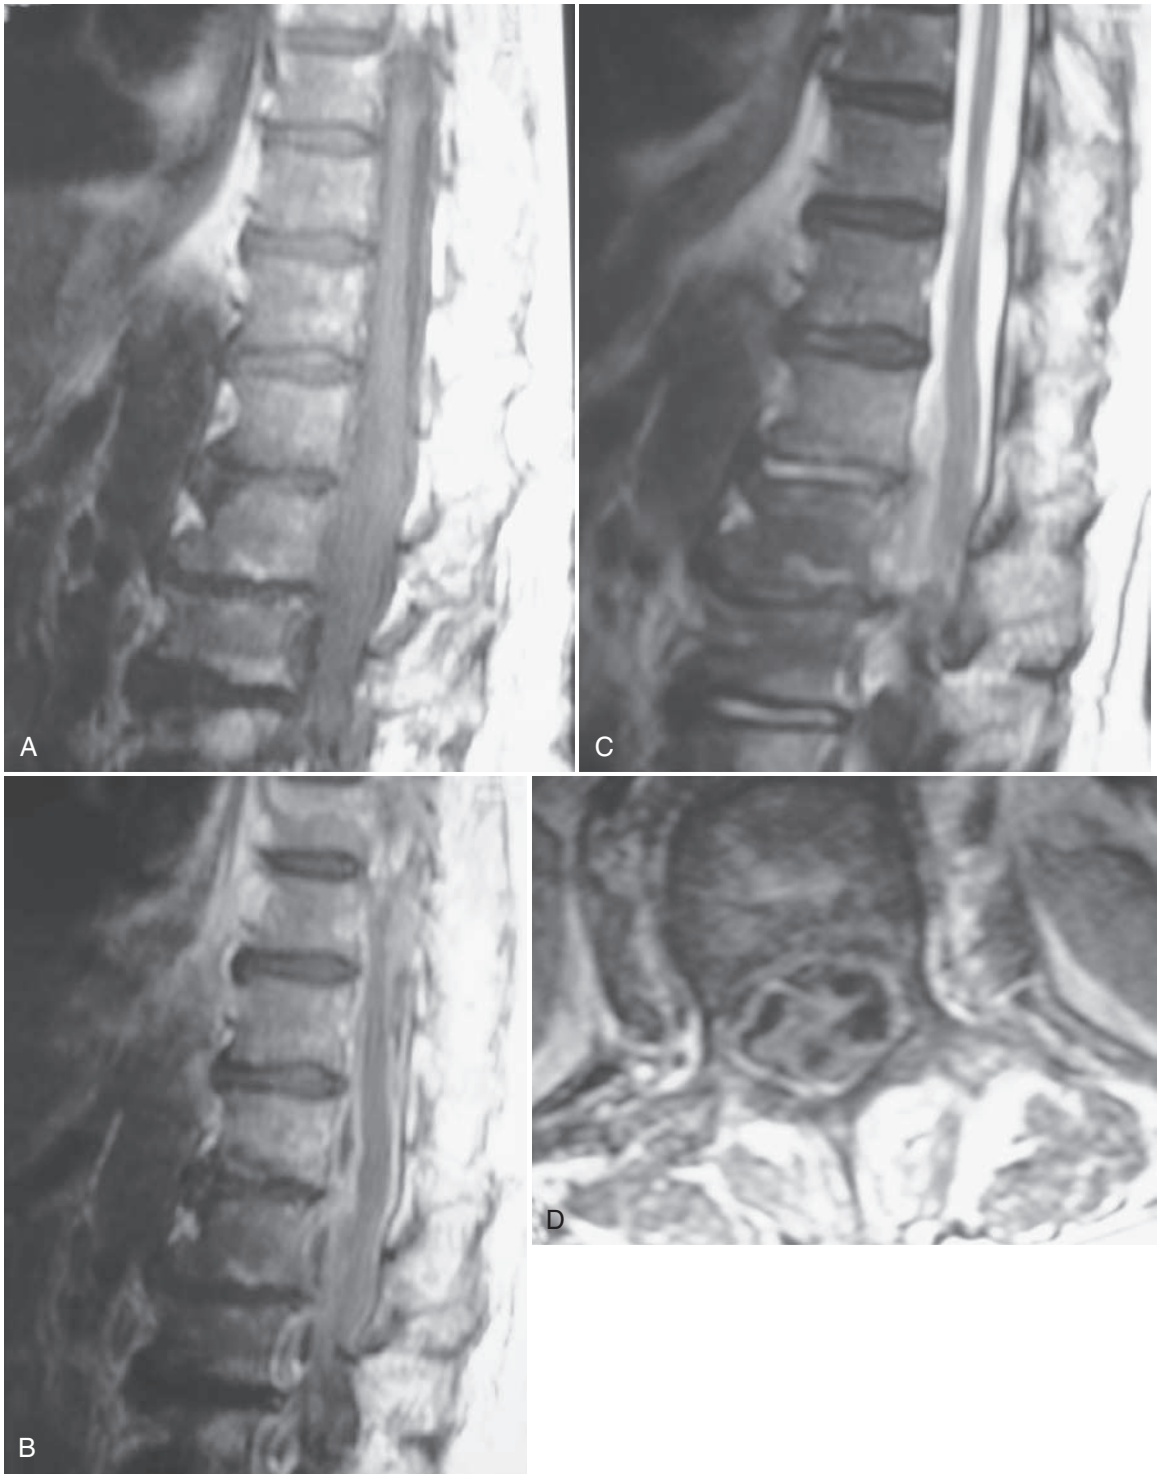

FIG. 91.1 Spinal subdural empyema secondary to *Escherichia coli.* An 86-year-old woman with a history of intractable lower back pain was treated with epidural corticosteroid injections. She presented 2 months after her last epidural injection with increasing lower back pain, fever, paraparesis, and altered mental status. She underwent T12–L1 decompressive laminectomy and intradural exploration. Intraoperative cultures grew *E. coli.* Significant improvement in lower extremity strength was achieved after surgery. Magnetic resonance imaging showed an intradural infection extending from T11 to L4, which was isointense on T1-weighted image (A), isointense to hyperintense on T2 weighting with associated edema of the spinal cord (C), and homogeneously enhancing with gadolinium (B, D).

Pathophysiology

ISCAs are suppurative infections similar to brain abscesses with purulent myelitis surrounding a region of central necrosis. They are thought to begin in the central gray matter with peripheral extension into the white matter. ISCAs initially develop as microscopic nodules with an abundance of polymorphonuclear cells with enzymes that induce liquefactive necrosis in surrounding tissue. These necrotic areas are walled off by a capsule produced by fibroblasts. These abscesses are usually in proximity to blood vessels, and organisms can usually be identified both in the abscess and the vessel. Small punctate areas of hemorrhage are usually observed in the vicinity of these infections, and surrounding veins may become thrombosed. The surrounding meninges are often inflamed and infiltrated with polymorphonuclear cells and lymphocytes.[53,54] Chronic abscesses typically have three well-defined layers. The center primarily contains collagen fibers and polymorphonuclear cells. The middle layer consists of fibroblasts, capillaries, histiocytes, and plasma cells; the outer layer is a connective tissue capsule. The abscesses grow caudad and cephalad separating the fiber tracts and may extend from medulla to the conus medullaris, but significant compression is not caused until later in the disease.[38–42]

In adults, ISCAs are historically thought to occur through the spread of pathogens through one of three mechanisms: direct extension, hematogenous seeding, or via lymphatics. Direct extension leading to the formation of ISCAs has been described with epidural abscesses, discitis, dermal sinus tracts, spine trauma, meningitis, and with invasive spine procedures.[54–59] Several reports have also described the formation of ISCAs in association with preexisting masses.[60,61] The tumors most frequently associated with ISCAs have been ependymomas and epidermoid tumors; however, recent papers describe the co-occurrence of acute ISCAs with astrocytomas, typically resulting in disastrous consequences despite aggressive management.[60]

The hematogenous route remains a common mechanism of pathogen spread leading to the formation of ISCAs, even in the postantibiotic era.[38–42] The arterial network of the spinal cord contains many collaterals with various feeders, while the venous system of the spine is a low-pressure system that communicates with the venous systems of the chest and abdomen. Thus, with changes in intraabdominal pressure, retrograde flow of blood may seed pathogens from the chest and abdomen in the spine. This sluggish flow of blood combined with the watershed zone of the thoracic cord have been used to explain the increased incidence of ISCAs in thoracic cord relative to other types of spine infection. The most common sites of origin for metastatic ISCA are the lung, heart, and urinary tract, but many different sources have been reported.[38–42,62–64] Applebee et al.[43] described a 47-year-old woman who developed complete paralysis at the T3 level 1 week after a dental cleaning. An ISCA was discovered upon imaging and oral flora were cultured intraoperatively.

Despite the rich vasculature of the spine and the low-pressure venous flow, the spinal cord is very resistant to infections compared to other organ systems. Although the reason for this is not understood, early work by Hoche[65] helped shed light on the mechanism of abscess formation in the CNS. In his experiments, when bacterial pathogens were injected into the arterial supplies of the brain or spinal cord, abscesses did not develop. However, abscesses did form when he injected either septic emboli or aseptic emboli later followed by bacteria. These data suggest that for an ISCA to occur not only does a microbial pathogen have to be present but there has to be structural pathology that allows the organism to seed. This is likely why, in adults, nearly all cases of ISCAs are associated with preexisting pathology (trauma, discitis, tumor, and so on).[38–59] The study also suggests a mechanism by which subclinical bacterial infections can lead to ISCAs that are later classified as cryptogenic.

The spread of bacterial pathogens to the spinal cord by the lymphatic system has been suggested but is less clearly understood than the other routes. Experiments by Galkin in the 1930s[66] demonstrated that lymphatic channels that drain the chest, abdomen, and retroperitoneum have connections with the Virchow-Robin spaces of the spinal cord. Thus, infections may potentially spread directly into the cord via the lymphatics. Although several case reports have suggested lymphatics as a possible route for ISCA formation, this has never been demonstrated definitively in the laboratory or clinical setting.[38–40]

Ultimately, the majority of cases in adults are cryptogenic, possibly a result of transient bacteremia from mucosal surfaces or clinically unrecognized extraspinal infections. Most reviews from the antibiotic era categorize 50% to 64% of ISCA cases as cryptogenic.[38–42] Chan and Gold[39] compared 25 of their patients treated during the antibiotic era (1977–1997) to 42 ISCA patients from the preantibiotic era (1830–1944) that were reviewed by Arzt.[27] They found a trend toward increases in cryptogenic cases in the postantibiotic group. They attributed this to the effectiveness of antibiotics in treating primary infections since in the preantibiotic group, 45% of abscesses were attributed to hematogenous spread from an extraspinal source but in the postantibiotic group, only 8% of abscesses were associated with hematogenous spread.

The pathogens responsible for ISCAs reflect the mechanism of abscess formation and source of primary infection. A causative organism was identified in 64% of cases reviewed by Chan and Gold[39] and 60% of cases reviewed by Bartels et al.[67] Whereas cultures of ISCAs caused by hematogenous spread typically reflect cultures of the primary infection site, cases of cryptogenic ISCA are usually associated with *Listeria monocytogenes,* viridans streptococci, *Haemophilus* species, *Actinomyces*, or oral flora. The high association of *L. monocytogenes* with ISCAs is attributed to its tropism for the CNS.[39,67–69] Postsurgical cases, however, are most frequently associated with *Staphylococcus epidermidis*, *S. aureus*, Enterobacteriaceae, and *Pseudomonas aeruginosa.*[38–42]

Contrary to adults, in the pediatric population only about a quarter of ISCAs are cryptogenic. Instead, they are typically caused by spinal cord developmental abnormalities that allow direct extension of the organisms into the cord.[45–50] In a recent review of pediatric cases of ISCA, 53% were associated with anatomic defects, such as dermal sinuses, myelomeningoceles,

bony lumbar malformations, and sacral decubitus ulcers. Dermal sinuses are epithelialized tracts formed as a result of imperfect separation of cutaneous and neural ectoderm early in fetal life and are considered the leading cause of ISCAs in the postantibiotic era. Only 1% of dermal sinus tracts are located in the cervical area, 10% are in the thoracic area, 41% in the lumbar area, and 35% in the lumbosacral area.[49] Dermal sinuses account for about half of the ISCAs reported in children but only account for about a quarter of ISCAs in adults.[44] Bacterial flora associated with dermal sinus tracts include *S. epidermidis*, *S. aureus*, Enterobacteriaceae, *B. fragilis*, and *Proteus mirabilis*[45–50] (Box 91.2).

Clinical Presentation

The classic presentation of ISCAs includes fevers, back pain, and compromise of neurologic function at and below the level of spine affected. In practice, however, there is great variability. Studies of ISCAs from the postantibiotic era report that, at the time of diagnosis, 83% to 94% of patients have some degree of motor weakness, 60% to 78% have sensory loss, and 51% to 56% have loss of sphincter control. The percentage of spinal patients that are febrile at the time of diagnosis is 25% to 50%, and 36% to 60% report pain in the affected area at some point prior to diagnosis.[38–42] Presentation of ISCAs after invasive procedures is also variable. Four cases of ISCA after lumbar puncture have been reported, each presenting with lower extremity weakness, with time to presentation of symptoms varying from 12 hours to 27 days.[51] Less frequently, ISCAs have been reported to present with hydrocephalus, brain stem findings, and Horner syndrome.[39,70,71]

The neurologic deterioration caused by an ISCA is related to its mass effect and rate of expansion. ISCAs were categorized by Foley[72] into three clinical groups with significant prognostic indications based on the severity and chronicity of symptoms. Acute abscesses typically present with more severe neurologic compromise and are more likely associated with fever and leukocytosis. The subacute group has symptoms for up to 6 weeks and the chronic group beyond 6 weeks. The presentation of ISCAs in these latter two groups more closely mirrors the presentation of an intramedullary tumor and patients are usually afebrile.

Laboratory Evaluation

Laboratory studies are usually of little diagnostic value in the diagnosis of ISCAs, though cultures may be important for tailoring treatment, especially in conservatively managed cases. Leukocytosis and elevations in erythrocyte sedimentation rate and C-reactive protein are more likely in acute ISCAs but may also be present in the subacute and chronic groups. CSF analyses are usually normal; if abnormal, they usually show elevated white blood cell (WBC) counts and mildly elevated protein, consistent with a likely parameningeal process.[38–42] Reports of ISCAs in pediatric patients suggest that abnormal CSF studies are more common than in adults in as many as 78% of cases with positive cultures obtained in 64% of patients[51]; however, these studies have been of little diagnostic significance in the recent published literature.

Imaging

Together with clinical presentation, imaging usually provides the most valuable information for the diagnosis of ISCAs. While ISCAs are rare and often difficult to distinguish radiographically from tumors, infarcts, resolving hematomas, or demyelinating disease, a degree of suspicion for these lesions needs to be maintained given the acuity of treatment required with ISCAs. Plain radiographs will not detect ISCAs but often show associated conditions, such as osteomyelitis, trauma, or dysraphism.[73–77] Myelography was the early method of choice for diagnosis of ISCAs prior to the advent of the MRI. The contrast of a myelogram shows symmetrical thickening of the spinal cord with partial or complete obstruction of CSF flow in the region of the abscess. CT scans of the spine are an integral component in the evaluation of any decline in motor function but are usually nonremarkable in the case of ISCAs. Plain CT may reveal widening of the spinal cord and when used with intravenous contrast can show an intramedullary process. Postmyelographic CT scans are more likely to show the cord widening and blocked CSF flow characteristic of ISCAs; however, the use of this modality has become obsolete together with conventional myelography.[40,41]

Since its widespread use, MRI has remained the gold standard in the diagnosis of ISCAs. Typical MRI features of these abscesses include widening of the spinal cord, hypointensity on T1-weighted images, hyperintensity on T2 images, and peripheral enhancement after administration of gadolinium. However, it has become clear that MRI features vary depending on stage of the ISCA and often reflect changes observed in the evolution of cerebral abscesses. Early stages have greater hyperintensity on T2-weighted images but less contrast enhancement on T1 images compared to later stages. The well-defined ring enhancement classically described with abscesses has been reported to occur around 7 days after initial presentation. After capsule formation, however, this is also variable. The T2 signal becomes less intense with time and usually resolves over several weeks after treatment of the lesion.[73–77]

Several recent studies have shown the value of diffusion-weighted imaging (DWI) in diagnosing ISCAs and initiating prompt treatment. The purulent fluid of abscesses impairs the diffusion of water molecules, which is observed as a hyperintense signal on DWI with reduced apparent diffusion coefficient values compared to surrounding tissues.[74–76] Hood et al.[44] described the case of a 57-year-old physician transferred from

an outside hospital several days after developing hemiparesis and dysesthesias. He had been afebrile, CSF studies were negative, and MRI with contrast from the outside hospital (without DWI) showed an enhancing lesion but could not distinguish intramedullary tumor from ISCA. Urgent DWI posttransfer showed restricted diffusion consistent with abscess and the patient was emergently decompressed on the basis of this finding with subsequent good neurologic recovery. It is noteworthy that ISCAs have been diagnosed that possessed no findings on DWI, likely reflecting the dependence of these findings on age of the lesion and stage of encapsulation.[74–76]

Treatment and Prognosis

The two factors that most closely correlate with good outcomes in the management of ISCAs are clinical presentation and administration of antibiotics. Menezes et al.[41] showed in their review of 55 cases from 1830 to 1977 that chronicity is a particularly important component of the clinical presentation. In their review, mortality was 90% in patients presenting acutely, 66% in subacute patients, and 53% for those with chronic symptoms. Seventeen patients reported in their study were treated in the antibiotic era and had only 23% mortality. Chan and Gold,[39] in their comprehensive review of ISCAs from the pre- and postantibiotic eras, suggested 90% mortality without use of antibiotics (1830–1944) and only 8% mortality with antibiotics (after 1944). Deaths from ISCAs in the modern era are rare and generally occur due to the presence of multiple CNS abscesses or other related comorbidities. Even in the modern era, however, around 70% of adult patients retain some degree of neurologic disability. Antibiotic therapy usually starts empiric but is then tailored to cultures, if available. There are no guidelines for duration of antibiotic therapy; however, most studies use a 4- to 6-week course. The recurrence rate of ISCAs is reported to be around 25%.[38–42]

The standard of therapy for ISCAs is urgent surgical decompression and administration of antibiotics.[38,39] Very few reports of conservatively managed ISCAs exist in the modern era since any change in motor examination associated with imaging findings generally warrants decompression. Because ISCAs extend rostrally and caudally, displacing fiber tracts, the goal of surgery is not only to preserve viable tissue in the area of the abscess but also to prevent its spread through the cord. Most authors advocate that surgery should include laminectomies at least at the levels involved, intradural exploration, midline myelotomy, and washout of the abscess cavity.[78,79] Focused surgical exposure and drainage, however, have been advocated in cases with focal imaging findings and presentation.[44] Permanent CSF shunting has been used for hydrocephalus caused by ISCAs.[39]

Since around half of ISCAs in children are associated with dermal sinus tracts (DSTs), experts advocate for thorough screening and complete resection of DSTs prophylactically.[38,45–51] When an abscess is associated with the DST, the current recommendation is for limited laminectomy and myelotomy.[38] In their extensive review of pediatric ISCA cases, da Silva et al. report 20% mortality, residual neurologic deficits in 60%, and full recovery in 60% of patients.[51]

Mycobacterial Pathogens

Spinal Intradural Tuberculosis

Background

Tuberculosis (TB) is an infectious disease caused by *M. tuberculosis*, an acid-fast bacillus that typically infects alveolar macrophages, leading to focal granulomatous lesions of the lungs. While Robert Koch first identified its causative agent in 1882, TB continued to be a plight to society until the 1945 discovery of streptomycin's anti-TB effects.[80] TB remains a leading infectious disease killer, especially among the immunodeficient. Although TB is predominantly described in the lungs, organisms can disseminate hematogenously and reactivation of latent infections can arise in nearly any tissue.

The first mention of spinal TB was in 1779, when Percivall Pott described treatment of a patient with paraplegia by surgically draining a spinal abscess.[81] Neurologic involvement of this infectious mycobacterium can present in four ways: Pott disease (tuberculous spondylitis), nonosseous spinal tuberculoma, tuberculous arachnoiditis, and tuberculous meningitis.[82] Because Pott disease presents as a vertebral infection and tuberculous meningitis primarily presents as intracranial dysfunctions, these will not be discussed in this chapter.

Since the development of anti-TB drugs, the worldwide incidence has declined in both developing and developed countries; the incidence has declined, on average, 1.5% per year since 2000, according to the World Health Organization.[83] Regardless of this success, TB still remains a leading cause of death worldwide alongside HIV. In 2014, there were 1.5 million TB-related deaths and 1.2 million HIV deaths.[83] Tuberculosis is transmitted from person to person via respiratory droplets. Thus, the populations at risk include those who live in crowded conditions, the malnourished, and the immunocompromised. Those especially at risk are the HIV infected and patients who undergo solid organ transplants (SOT).[84] In 2015, 1 in 3 HIV deaths worldwide was due to TB. Furthermore, SOT patients are 20 to 74 times more likely to be infected with TB.[83]

In 2013, there were 5.4 million new cases of TB, 800,000 of which were extrapulmonary in nature. In the United States, among 253,299 new cases, 18.7% were extrapulmonary and 5.4% were specifically meningeal.[85] No statistics were available for intradural spinal cases, which is consistent with the rare nature of these findings. There are currently no standardized guidelines for the treatment of spinal intradural TB.

Two numbers have been reported for the incidence of CNS TB involvement. One claim is that 10% of patients with TB experience some sort of CNS involvement, though this statistic may not truly represent the number of cases of brain and spinal cord infection.[86,87] A more likely analysis puts the prevalence of CNS TB at 0.5% to 2%, most of which occurs as intracranial lesions.[84,88,89] Among these cases, infections of the spine are very rare. When TB does involve the spine, the incidence of associated pathologies is as follows: 64% Pott disease, 20% arachnoiditis, 8% intramedullary tuberculomas,

and 8% are other presentations, including extramedullary tuberculomas and abscesses.[90]

Spinal arachnoiditis frequently precipitates from intracranial TB meningitis. The incidence is slightly higher in females than males, with a ratio of 1.3 : 1; the median age of infection is between 27 and 28 years of age.[85] Spinal intramedullary tuberculomas are much rarer than their intracranial counterpart, at a ratio of 1 : 42. Spinal intramedullary tuberculomas are more common in males than in females (3.25 : 1), while extramedullary tuberculomas present at equal frequencies. The median age for the development of spinal tuberculomas is in the 20s and 30s.[88] Furthermore, MacDonnell et al. in their review found that 39 of 43 cases presented in developing nations, with only 4 cases coming from the United States and Italy.[91]

Pathophysiology

Occurrences of TB in the intradural space are secondary infections, usually originating from primary sites in the pulmonary system. *M. tuberculosis* is a species of aerobic acid-fast bacillus, most commonly transmitted via respiratory droplets and for which humans are the only natural reservoirs. Infections at secondary sites are the result of bacteremia, in this case, involving the formation of meningeal TB granulomas.[85] Granuloma formation arises from a delayed type IV hypersensitivity reaction, in which recruitment of lymphocytes by infected macrophages results in encapsulation and caseous necrosis by giant cells. Tuberculous foci can remain latent for an extended period of time, potentially leading to subacute presentation; it has been hypothesized that strains have evolved resistance to macrophage-mediated elimination, which has allowed them to induce this method of dormancy.[81,92] When immunity wanes, the granuloma can discharge the bacilli into the intradural space, leading to tuberculous meningitis, tuberculomas, arachnoiditis, and tuberculous abscesses.[93–95] For this reason, HIV-infected patients are at higher risk for intradural expression of TB.

The manifestation of TB in the CNS has been shown to critically depend on tumor necrosis factor-α (TNF-α) from microglial cells. The role of this cytokine seems to be important for granuloma formation and increasing permeability of the blood-brain barrier, critical for the development of infections in the spinal cord. The role of TNF-α is not entirely understood, though low levels of the cytokine are linked to TB overgrowth and high levels are linked to an overreactive immune response.[96]

The development of spinal TB is derived from three routes of dissemination. First, the intradural infections can represent the first manifestation within the CNS via direct dissemination from the primary site.[97] While direct hematogenous dissemination to the spinal cord is rare, intradural tuberculomas, along with intracranial tuberculomas, are often seen in conjunction with miliary TB. The second route is downward extension of exudate from intracranial infection; descent from intracranial tuberculous meningitis is the most common cause of intradural arachnoiditis.[97,98] Last, the most rare route involves the infection of intradural space via adjacent vertebral disease.[99]

TB meningitis is the most commonly recorded intradural TB infection but is seen in the brain much more often than the spine. Overall, the incidence of spinal cord involvement compared to brain involvement is represented by an overall ratio of 1 : 42, which reflects the weights of spinal cord to brain (1 : 47).[84,88,91] Spinal arachnoiditis is frequently the direct result of intracranial TB meningitis, but can also arise from meningeal TB lesions or spread from adjacent vertebrae, as previously indicated. A literature review from 1966 to 2003 indicated 78 cases of spinal arachnoiditis from the inferior extension of TB meningitis.[86] Thoracic cord involvement is most frequently cited; the thoracic region contains 45% of spinal volume, which is believed to be responsible for these rates.[85,86,93] Arachnoiditis results in collagen deposition from proliferating fibroblasts, causing subsequent matting of nerve roots as pia and arachnoid are adhered. A more severe case has been described as adhesive arachnoiditis when this results in the encapsulation of atrophied nerve roots.[85,95,96,99]

Tuberculomas appear in the intradural spinal cord as either intramedullary or extramedullary. Intramedullary tuberculomas directly involve infection of the spinal cord, while extramedullary tuberculomas involve the subdural space.[84,86–88] Intradural tuberculomas, tuberculous abscesses, and arachnoiditis can all lead to the encasement of emerging nerve roots by exudate. This compression of the spinal cord and its roots can also coincide with edema, inflammation, and potentially even spinal cord infarction due to thrombosis of spinal vessels.[87]

Finally, paradoxical reactions leading to extrapulmonary TB infections are not uncommon in literature reviews. A paradoxical reaction is the escalation or reappearance of granulomas in response to a seemingly effective anti-TB treatment regimen.[85,96] In a 2013 study, 76 HIV-negative patients with extrapulmonary TB were studied and 19 (25%) demonstrated paradoxical reactions.[96] The pathogenesis of this has been hypothetically linked to regulatory T cells, whose levels are shown to increase in patients with active TB. These regulatory lymphocytes modulate tolerance and prevent autoimmunity through inhibition of interleukin 10 (IL-10) and interferon γ (IFN-γ) production. Although the mechanism of action is unknown, dysfunction of regulatory T cells has been linked to the promotion of paradoxical reactions.[96]

Clinical Presentation

The clinical symptoms of intradural tuberculomas most commonly present as subacute or acute spinal cord compression syndromes.[90] Therefore, the presentation mimics spinal cord neoplasms. The most frequently affected age group are young adults in their 20s and 30s. Development in pediatric patients has been presented, though the incidence of this is rare.[88] In a review of patients with spinal intradural tuberculomas, 94% were implicated with myelopathy that progressed over several months.[91] Symptoms vary depending on location, from upper cervical spine to the cauda equina. Lower limb weakness and progressive paresthesia are among the most prevalent manifestations; headaches, fever, rigidity, altered sensation and seizures have also been recorded.[84,86–88,100,101] The second

most common indication is bowel and bladder dysfunction, with a prevalence of 67% among those affected.[91] Finally, 33% experienced back pain, representing the third most common manifestation of the spinal tuberculomas.[86–88,91,97,102] Many of these symptoms are due to spinal cord cavitation and edema caused by the tuberculoma. Many deficits can arise from spinal cord compression syndromes. Intradural tuberculoma patients, especially those positive for tuberculous meningitis, may present with abscesses in the brain; due to this location, cerebral ischemia and hydrocephalus can be serious developments.[96]

Arachnoiditis presents in a similar fashion, though with variable rates. Both develop most commonly in the thoracic spine but with various frequencies. Intramedullary tuberculomas are more prevalent in males, with the ratio of male to female at 3.25:1; extramedullary tuberculomas have equal frequencies. Arachnoiditis is more common in females, with a ratio of 1.3:1.[85] The median age of spinal arachnoiditis is similar to that of tuberculomas, with a median age between 27 and 28 years of age.[85] The clinical presentation of spinal arachnoiditis is repeatedly described in reviews as monoradicular and polyradicular pain syndromes that correspond with progressive deficits in the sensorimotor system.[93] There are many recurring and relevant symptoms, many of which overlap with the development of intradural spinal tuberculomas: subacute paraparesis with reflex deficits, paresthesias, radiculopathies, hypotonia of the lower limbs, and bladder dysfunction. Among patients with arachnoiditis of the spine, paraparesis is the most frequent clinical presentation, occurring 58.8% of the time.[85,93,103] Spinal arachnoiditis has also been reported to be asymptomatic, though this is rare and dependent on location.

Tuberculous exudate presenting around lumbosacral nerve roots leading to cauda equina syndrome has also been described. Unlike classic cauda equina—characterized by asymmetrical paraplegia, loss of perineal sensation, and bladder dysfunction—a common motor deficit among patients with tuberculous lesions on the cauda equina is the absence of ankle reflexes, though extensor plantar reflexes remain intact.[85]

Imaging Studies

Upon recognition of the aforementioned clinical presentations and evidence of TB, imaging of the patients should begin with chest radiographs. Recognition of active or prior pulmonary TB in the patient is crucial for understanding the risk of spinal intradural TB infection. After physical examination for sensorimotor deficits, spinal radiographs can be performed in the appropriate locations. Plain radiographs are generally useless for tuberculomas, but a negative result can remove suspicion of Pott disease.[91,97,104,105] Axial CT scans can show growth in the spinal column, but the most informative and thorough radiographic method is the MRI.[84–86,88,89,96]

Intradural tuberculomas are undetectable by myelography. Through investigation by MRI, intradural tuberculomas are detectable at three stages of development.[85,88,90] Initial development begins as a noncaseating granuloma. At this level, inflammation and edema within the subdural space is evident, while a collagen capsule is not. On T1- and T2-weighted images, lesions appear isointense and are homogeneously enhanced. The second stage takes the form of a caseating granuloma with a solid center; as the capsule enriches with collagen, a reduction or outright disappearance of edema is often seen. T1-weighted images will remain isointense. Lesions will also show isointense to hypointense signal intensity on T2-weighted images and ring enhancement with hypointense centers at this stage. The third and most developed stage is a caseating granuloma with a liquid necrotic center. At this point, T2-weighted images demonstrate diverse findings, from a hypointense target to a hyperintense rim. Spinal cord edema can also be demonstrated by surrounding hyperintensity of T2-weighted images.[84–86]

In 2014, Chittem et al. demonstrated the "precipitation sign" as a new MRI diagnostic sign for spinal intramedullary tuberculomas.[106] This term refers to a mass of precipitated tubercular pus. Initial MRI images in their study showed an intradural mass at the conus equina that demonstrated hypointensity at T1-weighted images and hypointensity to isointensity at T2-weighted images, which did not enhance with contrast. Their hypothesis of precipitation of tubercular pus along the spinal canal via gravity was confirmed intraoperatively. Thus, a precipitation sign paired with hyperintensity on T2-weighted images can be indicative of intramedullary tuberculomas.[106]

Spinal arachnoiditis should also be imaged using MRI, though images can demonstrate variable findings.[85] Depending on staging and location, images can show clumping of roots, subarachnoid space destruction, and loss of spinal cord outline. Irregular cord surface and CSF loculation are also frequently seen. Absence of spinal cord border can be the result of increased protein in the CSF.[84–86,96] Variation in signal intensity can also be explained by edema, myelitis, or ischemia. Postcontrast studies can be used for clarification. Arachnoiditis can be confirmed by smooth and linear enhancements of the spinal cord or its emerging nerve roots. Last, meningeal enhancement is the most prevalent MRI finding for arachnoiditis, occurring among 80% of confirmed patients.[85,86]

Treatment and Prognosis

Due to the rarity of intradural spinal tuberculosis, standardized treatments are controversial. Medical treatment rather than surgical intervention is considered curative and, thus, the frontline approach.[82,84,87,88,91,96] However, in one-third of patients demonstrating spinal cord compression syndrome, systemic TB is not diagnosed and surgical intervention is warranted for treatment and diagnosis.[88]

As soon as a TB diagnosis is made, anti-TB therapies should be initiated and continued for at least 9 months.[85,96] At least four anti-TB drugs should be used, such as isoniazid, rifampin, pyrazinamide, streptomycin, and ethambutol; four of these drugs constitute the initial intensive phase that should last 2 months.[96] A continuation phase should be used for the duration of the treatment; this phase administers a two-drug regimen.[85,88,96]

Corticosteroids are also routinely used in treatment protocols, though the mechanism of action is not fully understood.[85,81,96] However, in tuberculous meningitis patients with spinal cord involvement, high-dose corticosteroid use has demonstrated effectiveness in treatment. The steroids have been shown to reduce death as well as reduce lasting neurologic deficits in patients with eliminated infections.[85] Nonetheless, these are not universally used.

A study using nonrandomized patients demonstrated that the use of intrathecal hyaluronidase can be valuable in the treatment of tuberculous spinal arachnoiditis; hyaluronidase enzymatically degrades hyaluronic acid and other mucopolysaccharides in connective tissue.[85] This treatment, however, is still under investigation and not frequently used.

Surgical approaches are not considered to be the frontline treatment but are commonly used due to the mysterious nature of these infections. There are two indications for surgical intervention.[84] The first is simply an uncertain diagnosis; this is common with spinal cord compression in the absence of evidence of TB. The second is a failed response to medical treatment. This can include three forms of its own. First, the patient may experience a poor response to the medical management of the infection. Next, if neurologic assessments show progressive deterioration in mental status, surgery is indicated. Finally, lesion enlargement on imaging following medical treatment indicates the need for surgical removal.[84,85,96]

The most common surgery involves the excision of an intradural tuberculoma. Typically, the tuberculomas are encapsulated and, thus, well circumscribed; surgical removal can be performed effectively without compromising the neurologic system. The most common surgical approach for spinal arachnoiditis involves decompressive laminectomy.[85,96]

Overall, the prognosis for patients presenting with isolated forms of intradural spinal TB is good. MacDonnell et al. found that 65% of these patients demonstrated neurologic improvements.[91] Furthermore, there is no significant difference in outcomes between those treated medically and those treated surgically.[91] However, because intradural TB occurs more often in the immunocompromised or those with concurrent tuberculous infections in other organs, the prognosis is generally unpredictable.

Fungal Pathogens

Spinal Intradural Fungal Infections

Background

Fungal infections of the CNS are very rare and historically have been limited to immunocompromised patients. However, recent outbreaks associated with epidural anesthesia injections have brought much attention to the disease.[2,107–110] In 2005, five cases of fungal meningitis resulted in Sri Lanka after medical equipment contaminated by damp conditions from the recent tsunami was used for spinal anesthesia during cesarean sections. *Aspergillus fumigatus* was identified in all five cases. Three of the cases ultimately resulted in death.[107] Then, in 2012, a fungal outbreak associated with preservative-free methylprednisolone acetate for spinal epidural anesthesia was noted in Tennessee and soon spread to 20 other states. Several vials linked to the infections were tied to a single compounding pharmacy; soon after initiation of the investigation, government agencies had recovered *Exserohilum rostratum* from unopened vials of the same lot. One year later, over 749 cases of infection had been reported, leading to death in 61 patients (8%). Although paraspinal and epidural abscesses were the most common fungal infections associated with this outbreak, intradural infection was reported in 17% to 26% of cases and these were the patients who most frequently succumbed to death.[108,109] Through a quick concerted response from the government, hospitals, and laboratories, this outbreak was identified and addressed quickly. Since then, several reports have been published that elaborate on the CNS findings associated with the outbreak, increasing our understanding of spinal intradural fungal infections.[2,108–110]

Fungi are ubiquitous organisms that are generally of low virulence and can be divided into two groups. True pathogens, which cause infections in patients with normal immune systems, include *Coccidioides immitis*, *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and *Histoplasma capsulatum*. The other group, opportunistic pathogens, cause infections in immunocompromised hosts and include *Candida albicans*, *A. fumigatus*, *Nocardia asteroides*, and *Mucor* (Zygomycetes class).[111,112] Typical causes of immunosuppression in these patients include HIV/acquired immunodeficiency syndrome (AIDS), immunosuppression after transplants, chronic steroid use, chemotherapy, DM, IV drug use, and congenital diseases of cellular immunity.[112–114]

Pathophysiology

Although the pathogenic mechanism of CNS fungal infections is not clear, it is evident that these organisms have evolved features that make the infections elusive and difficult to treat. Some of these properties include the presence of a capsule in some species, ability to grow at 37°C, and dimorphism, which allows the fungus to change between mycelial and unicellular morphologies when invading host tissues.[111,112] Spread to the spinal cord is usually by direct extension or via systematic spread. Direct extension is usually caused by osteomyelitis, discitis, epidural abscess, trauma, or iatrogenic causes. Most cases involving systematic spread originate from the lungs.[108,109,111,112]

Spinal intradural fungal infections may be extramedullary and/or intramedullary. Extramedullary infections typically involve arachnoiditis with chronic fibrosis and granulomatous processes containing giant cells.[108–111] A specific pathology unique to intradural extramedullary fungal infections of the spine is septic thromboemboli to the arterial supply of the spine, resulting in strokes. These strokes may also be caused by direct extension from acute purulent arachnoiditis. A common finding on microscopy is occlusion of arteries by fibrinoid thromboemboli containing fungal elements.[115] The associated spinal cord infarct also typically shows evidence of fungal invasion. Intramedullary fungal infections of the spine, on the other hand, manifest as granulomas of the spinal cord. Similar to other fungal infections of the CNS, these lesions are

BOX 91.3 Subdural Fungal Infection Organisms

Exserohilum rostratum
Aspergillus spp.
Candida albicans
Histoplasma capsulatum
Rhizopus spp.
Cryptococcus neoformans

necrotic, noncaseating, and highly cellular with Langerhans multinucleated giant cells.[116,117]

The organisms most frequently associated with intradural fungal infections of the spine have been the *Aspergillus* species, both for immunocompetent and immunodeficient patients.[111,116] Incidence of *Exserohilum* has greatly increased recently as a result of the recent spinal epidural injection–associated outbreak. Another common iatrogenic cause of these infections is the *Candida* species.[2,108–110] *Candida* gains access to blood vessels by means of intravenous lines, urinary catheters, surgical implants, or during surgeries (mostly abdominal) and then may spread to the spinal cord[111,116] (Box 91.3).

Presentation

The classic presentation of spinal intradural fungal infections is a focal neurologic deficit secondary to spinal cord compression, infarction, or both. Localized neck or back pain often precedes the deficit and the rapidity of symptom onset is variable, ranging from a few days to over a year. Other conditions typically high on the differential include neurosarcoidosis, meningeal carcinomatosis, or bacterial infection.[118] Systemic manifestations associated with intradural fungal infections of the spine include malaise, anorexia, and weight loss. Most focal intradural fungal infections are localized to the thoracic cord followed by the cervical cord. Disseminated infections of the entire spine have also been reported.[108,112,116]

The epidural analgesia–associated epidemic of 2012 further shows us the diversity of the presentation of spinal intradural fungal infections.[2,108–110] Although reported infections occurred due to a similar iatrogenic mechanism and had a common source, the natural course and imaging findings were very diverse. In a report published a year after the outbreak, Smith et al. reported that, of 13,534 potentially exposed persons, there were 749 reported cases of fungal CNS infection.[110] The median age of patients was 64 years (range, 15–97 years) and the median incubation period was 47 days (range, 0–249 days). In these patients, 43% had spinal or paraspinal infections only, 31% had meningitis only, 20% had meningitis with spinal infection, 5% had peripheral joint infections, and 1% presented with stroke (likely from meningitis).[109] During this outbreak, factors associated with a significantly increased risk of developing an intradural fungal infection in patients who received the drug from contaminated lots included multiple epidural injections, female sex, translaminar (vs. transforaminal) epidural approach, and methylprednisolone lot age above 50 days.[2]

Interestingly, these iatrogenic fungal infections were initially associated with meningitis, but after about 6 weeks, the meningitis became less prevalent and spinal and paraspinal abscesses became the primary manifestation of the contaminated epidural steroid injections.[108] For patients with spinal or paraspinal infection, back pain was the predominant symptom (70%) followed by headache (35%). Neurologic deficits were rare presenting symptoms and included numbness (6%) and incontinence (2%). The back pain was often described as typical chronic back pain but more severe and unrelenting at the injection site. For patients who presented with fungal meningitis, headache (73%), neck pain (32%), light sensitivity (32%), nausea (44%), and vomiting (22%) were the most common presenting symptoms. Fever was noted in 17% of patients presenting with solely meningitis and in only 4% of patients presenting with spinal or paraspinal infection.[109]

Laboratory Evaluation

Serum WBC count, erythrocyte sedimentation rate, and C-reactive protein are rarely elevated in cases of spinal intradural fungal infections. Analysis of CSF is the most important component of the laboratory evaluation. The CSF profile is suggestive of a parameningeal inflammatory process rather than meningitis. Mild to moderate leukocytosis is usually associated with increased protein. Glucose levels are typically normal and cultures most often negative.[112,116] In their analysis of all 749 cases of fungal infections caused by the 2012 epidural injection–associated outbreak (64% of whom had spinal or paraspinal infection), Smith et al. reported that median CSF WBC count was 83 (interquartile range, 12–850), protein was 84 (interquartile range, 47–141), and glucose was 53 (interquartile range, 12–850).[110] Fungal CSF cultures are usually positive in 10% to 30% of reported patients.[109–110]

For patients presenting with progressive focal neurologic symptoms who are immunocompromised, have implanted medical devices, or previous interventional procedures and have equivocal initial CSF results, a degree of suspicion must be maintained for fungal infection of the spine and further analysis of the CSF is warranted. Such tests include CSF cytology, polymerase chain reaction (PCR), analysis and antigen testing. Cytology is typically negative but can provide a quick result. Experienced pathologists with knowledge of the clinical picture should be consulted. Antigen detection tests used for detecting certain fungal infections (e.g., *Cryptococcus*, *Aspergillus*) have shown success recently but they are still being refined and their utility remains unknown. CSF PCR analysis has become an important tool in diagnosis of fungal genetic sequences.[112,116] During the epidural injection–associated outbreak, PCR analysis of CSF samples detected *E. rostratum* in roughly half the patients eventually diagnosed with a fungal infection of the spine.[108,109]

Imaging

Many patients with spinal cord pathology are usually first evaluated by radiograph or CT. In most published reports, these radiographs are typically normal. They may reveal evidence of osteomyelitis/discitis, however, which are often

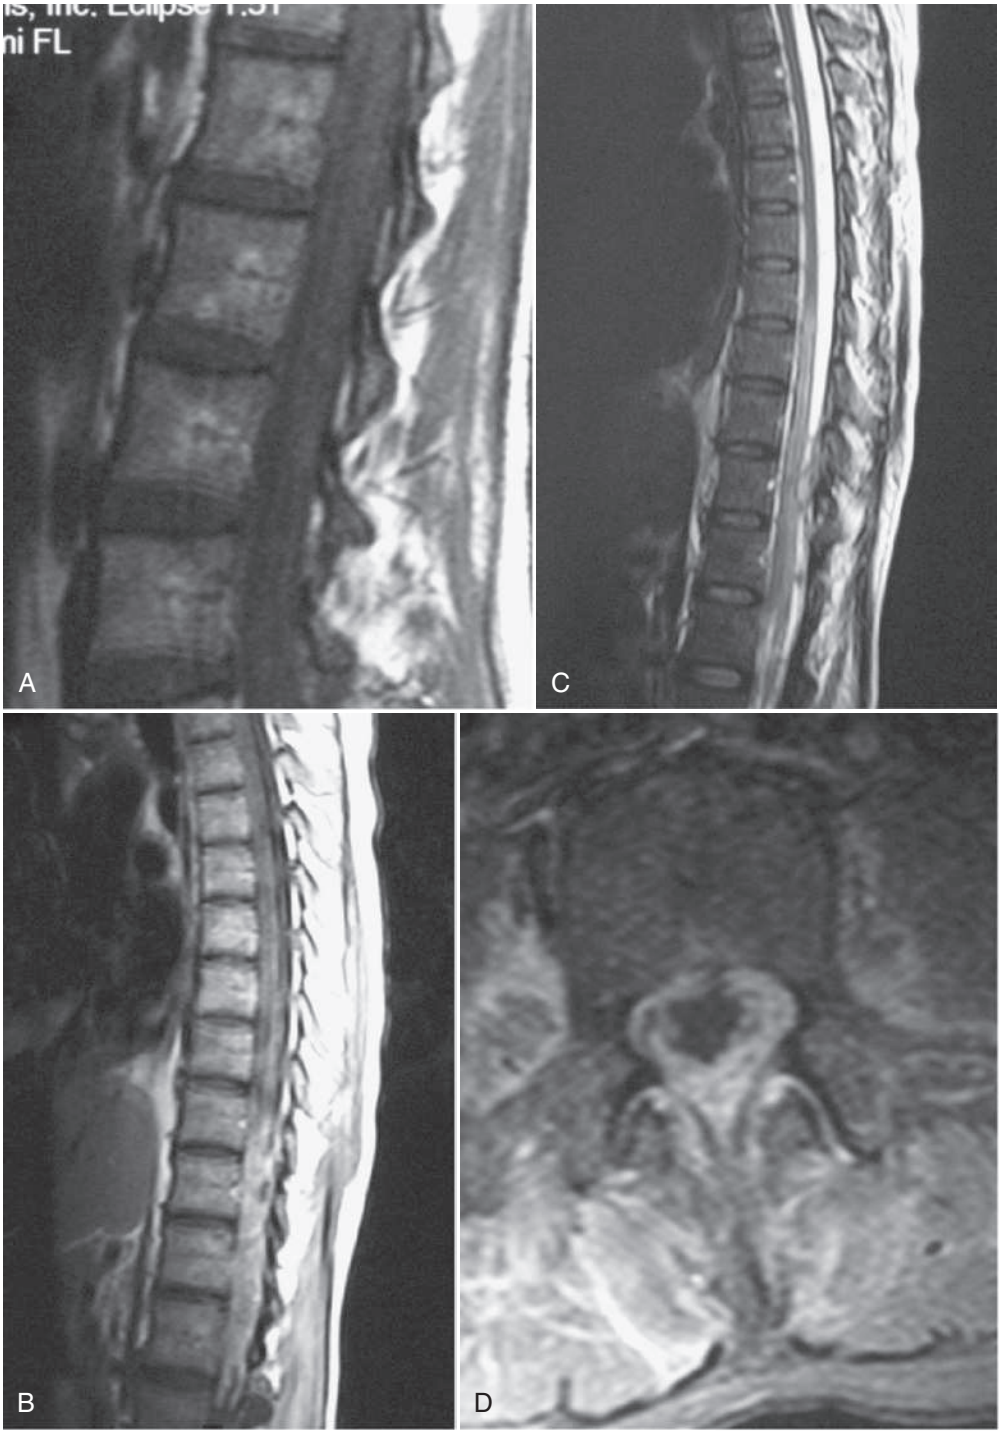

FIG. 91.2 Spinal intradural fungal infection secondary to *Aspergillus fumigatus*. A 31-year-old woman had a history of intractable lower back pain after minor trauma. She was treated with epidural injections and intradiscal thermal electrocoagulation without relief. She then underwent an L5–S1 discectomy without relief. She eventually had epiduroscopy. One month postepiduroscopy, she developed increasing lower back pain, tenderness to palpation, bowel/bladder dysfunction, and paraparesis. She required a T12 decompressive laminectomy and intradural exploration; intraoperative cultures grew *A. fumigatus*. Her paraparesis improved, but she was left with neuropathic pain and neurogenic bowel and bladder. Magnetic resonance imaging showed an intradural infection centered at T11 and epidural abscess from T11 to S1 with associated T2-weighted hyperintensity of the spinal cord. The lesion is isointense on T1 weighting (A), isointense to hyperintense on T2 weighting (C), and homogeneously enhancing (B) with loculated collections surrounding the spinal cord (D).

considered a common source of intradural fungal infections, but this is usually of little prognostic value. In the pre-MRI era, myelography was frequently used, which occasionally identified varying degrees of contrast block in the spinal canal, especially in cases in which the fungal infection was a result of intramedullary granulomatous disease. This was useful for localizing the level of lesion in the spinal cord but was not particularly specific for identifying infectious pathologies.[109,116]

Since its advent, MRI has been the method of choice for evaluating spine infections and recent advances continue to increase its utility. Because of the rarity of spinal intradural fungal infections, little was known about their MRI characteristics until recently, but the epidural anesthesia–associated outbreak gave us a better understanding of their MRI features. In certain patients, initial MRI results were negative but then were found to have intradural phlegmon or abscesses on repeat imaging. In their characterization of MRI findings associated with the outbreak, Kainer et al. identified MRI abnormalities in 30% of exposed patients when an MRI of the head was obtained and in 46% of patients in whom an MRI of the spine was obtained.[2] MRI abnormalities of the spine included arachnoiditis, neuritis, epidural abscess, psoas or paraspinal muscle abscess, or subarachnoid hemorrhage. Fat-suppressed postcontrast MRIs are considered particularly sensitive and effective at distinguishing these infections from other sources of enhancement.[108]

Malani et al.[108] provided even further characterization of MRI findings associated with the epidural anesthesia–associated outbreak by analyzing imaging findings in 172 patients from a pain clinic who had been exposed to the contaminated lots but had not yet presented with symptoms. All patients received an MRI with and without contrast within 1 year of exposure to the drug. The MRIs were abnormal in 35 (21%) of the patients. Findings included spinal or paraspinal abscess or phlegmon, arachnoiditis, osteomyelitis, or discitis. Of those 36 patients with spine MRI findings, 35 met Centers for Disease Control and Prevention criteria for probably or confirmed fungal spine or paraspinal infection and underwent therapy. All those patients received antibiotic therapy and 24 received surgical debridement. Interestingly, 17 of the 24 patients, including five who denied symptoms prior to surgery, had laboratory evidence of fungal infection of the spine at the time of surgery (Fig. 91.2).

Treatment and Prognosis

Treatment strategies and outcomes for fungal infections of the CNS depend on both host and pathogen factors. A medication's ability to cross the blood-brain barrier and activity in the CNS are also important factors to consider. In most early reports of intradural fungal infection of the spine, patients were treated with 3 to 9 months of amphotericin B, with 5-fluorocytosine or rifampicin often used as adjuvant therapies.[109,116,119] In the case of CNS aspergillosis, the Infectious Diseases Society of America recommends 6 to 8 weeks of treatment with voriconazole in immunocompetent patients and potentially indefinite treatment in patients with chronic immunosuppression.[117]

In patients in whom there is suspicion of an infections process of the spine, as was the case with the epidural anesthesia–associated outbreak of 2012, positive cultures should not be mistaken for contamination. Early antibiotic therapy and aggressive surgical debridement may reduce disease burden and improve patient outcomes. During the 2012 outbreak, nearly all patients were treated with voriconazole and most patients (53%–75%) also received amphotericin B.[2,109]

There are generally two reasons for decompressing the spine in a patient with suspected intradural fungal infection. The first is to provide decompression in the case of a space-occupying mass causing neurologic deficits. The second reason is to obtain samples for diagnosis, which is usually obtained by means of direct tissue culture or histopathology. In cases that involve granulomas (intramedullary or extramedullary), the surgery may involve resection of a discrete lesion.[118–121] During the 2012 outbreak, the most common intraoperative findings identified in patients who had MRI evidence of arachnoiditis were foci of purulent material and clumping of nerve roots encased in inflammatory tissue.[109]

Once intramedullary extension occurs, appropriate pharmacologic and surgical therapies are often unable to control the ensuing spread of infection, often resulting in death. Prior to the 2012 outbreak, 14 cases of intradural fungal infection had been described, resulting in 10 deaths. All 4 survivors, 3 of whom made complete recoveries, were treated with aggressive decompression and antifungal medications. Only three of the 10 mortalities had been treated with surgery and antibiotics.[2,112,119] During the 2012 outbreak, roughly 10% of patients died from the disease. Half of those patients who died had evidence of intradural extension of the infection, although only 17% to 26% of all patients involved in the outbreak had intradural spread. The lower mortality rates from intradural fungal infections associated with the outbreak have been attributed to the quick public health response and thorough screening of all patients exposed to the infected methylprednisolone lots.[110]

PEARLS AND PITFALLS

1. Intradural infections remain rare entities; thus, high clinical suspicion is essential to early diagnosis.
2. Aggressive surgical therapy combined with an antibiotic regimen is the most effective treatment for bacterial infections.
3. Medical therapy with judicious use of surgical intervention (diagnosis and decompression) is the most effective approach for management of spinal intradural infections.
4. One must look for the primary site of infection, especially in mycobacterial and fungal infections. Bacterial infections are often cryptogenic, but fungal and mycobacterial infections are often secondary infections that begin in the lungs. For mycobacterial infections, the genitourinary tract must also be investigated.
5. Good recovery is possible with all pathogens, although fungal infections remain the most difficult to cure.

KEY POINTS

Spinal Subdural Empyema

1. Pathogenesis: Hematogenous, iatrogenic, direct extension, and cryptogenic (most common).
2. For more than 50% of cases, the organism is *S. aureus*.

3. Classic triad: Fever, pain, and spinal cord/cauda equina compression
4. Primary treatment is surgical drainage followed by long-term antibiotic therapy.
5. Conservative therapy results in 80% mortality and 20% recovery. Surgical therapy results in 17.9% mortality and 82.1% recovery.

Intramedullary Spinal Cord Abscess

1. Pathogenesis: Hematogenous (arterial/anterograde flow or venous/retrograde flow), direct inoculation (neuroectodermal defects), and cryptogenic (most common)
2. For hematogenous spread, septic embolus or aseptic embolus is needed, followed by bacteremia; bacteremia alone is insufficient.
3. Organisms: *Staphylococcus* species followed by *Streptococcus* species
4. Presentation: Acute (<2 weeks), subacute (2 to 6 weeks), or chronic (>6 weeks)
5. Primary treatment is surgical drainage followed by long-term antibiotic therapy.
6. Prognosis depends on chronicity: Acute presentation = worse outcome; chronic presentation = better outcome.

Mycobacterial Pathogens

1. Four categories: Subdural tuberculomas, intramedullary tuberculomas, arachnoiditis, and meningitis
2. Rare occurrence but increased incidence since 1985 due to HIV/AIDS
3. Demographics: Developing countries = younger patients, developed countries = older and HIV/AIDS patients
4. Pathogenesis: Secondary site of infection, with primary being respiratory or genitourinary
5. Presentation: Most common is spinal cord dysfunction. Only one-third will have constitutional symptoms or pain.
6. Medical management is primary treatment modality with anti-TB regimen for 1 year. Surgery is frequently necessary for diagnosis or for spinal decompression.
7. Prognosis: Generally good neurologic recovery

Fungal Pathogens

1. Two primary manifestations: Extramedullary disease (arachnoiditis) and intramedullary disease (granulomas)
2. Pathogens: True (immunocompetent patients) and opportunistic (immunocompromised patients)
3. Presentation: Pain and spinal cord dysfunction
4. Pathogenesis: Cryptogenic. If hematogenous, then the primary site is pulmonary.
5. Treatment: Long-term antifungals with surgery necessary for diagnosis and decompression
6. Prognosis remains poor.

KEY REFERENCES

1. Bartels RH, de Jong TR, Grotenhuis JA. Spinal subdural abscess: case report. *J Neurosurg*. 1992;76:307-311.
   Spinal subdural abscesses are rare. A review of previous reports describes the clinical course of symptoms, which include initial findings of fever and spinal pain, progression to motor and sensory deficits, and ultimately paralysis and total sensory loss. A staging system is proposed from stages 1 to 3 describing the progression of symptoms.
2. DiTullio MV Jr. Intramedullary spinal abscess: a case report with a review of 53 previously described cases. *Surg Neurol*. 1977;7:351-354.
   Intramedullary spinal cord abscesses are diseases of the young with a higher prevalence in males. Bacterial infections of the spinal cord occur most frequently in the thoracic spinal cord. Early surgical intervention resulted in improved functional outcome, mandating early diagnosis and aggressive treatment.
3. MacDonnell AH, Baird RW, Bronze MS. Intramedullary tuberculomas of the spinal cord: case report and review. *Rev Infect Dis*. 1990;12:432-439.
   Reported cases of intramedullary tuberculomas of the spine originate predominantly from developing countries with a higher prevalence in females and the young. Presenting signs and symptoms are consistent with compression of the spinal cord. The presence of tuberculoid disease outside the vertebral canal was common. Medical intervention is favored, with surgical excision and drainage suggested for failure of medical management.
4. Menezes AH, Graf CJ, Perret G. Spinal cord abscess: a review. *Surg Neurol*. 1977;8:461-467.
   Case reports of spinal cord abscesses are reviewed, and pathophysiologic mechanisms for spinal cord inoculation are proposed. Direct inoculation of the spinal cord can occur, such as in trauma. In addition, hematogenous spread via venous backflow from shifts in intraabdominal pressure and lymphatic spread to spinal cord have been proposed as potential routes.
5. Smith RM, et al. Fungal infections associated with contaminated methylprednisolone injections. *N Engl J Med*. 2013;369(17):1598-1609.
   This is a review of the epidemiology, treatment, and outcomes associated with the spinal epidural anesthesia outbreak that began in 2013. From 17% to 26% of patients showed intradural infection, and these patients were associated with worse outcomes. Radiographic and laboratory features of the outbreak are presented in great detail.

CHAPTER 92

Vascular Malformations of the Spinal Cord

SECTION XIII

John E. O'Toole
Paul C. McCormick

Vascular lesions of the spinal cord are a rare cause of neurologic dysfunction, representing less than 5% of all intraspinal pathology.[1] This heterogeneous class of entities encompasses a wide range of etiologic, anatomic, pathophysiologic, and clinical features. They occur throughout the spine and may affect any age group, although the vast majority present between the third and fifth decades of life.[1] Symptoms and signs result from ischemia, venous congestion, hemorrhage, or mechanical compression of the spinal cord and roots. Most spinal vascular lesions are characterized by an abnormal arteriovenous shunt, which may be located within the dura, on the spinal cord surface, within the substance of the spinal cord or, rarely, extradurally.[2–5] The shunt may take the form of a simple direct arteriovenous fistula (AVF) or a more complex nidus of dysmorphic arteries and veins without an intervening capillary bed. Whereas the latter lesions are typically congenital, the more common fistulous lesions are often acquired.[6]

The evaluation and management of spinal vascular lesions have evolved considerably over recent decades as a result of accumulating clinical experience and the role of selective spinal angiography and embolization therapies. A fundamental understanding of the anatomy and pathophysiology of these lesions coupled with refinements in endovascular and operative techniques has permitted successful definitive therapy with minimal morbidity in most patients harboring vascular shunts of the spinal cord.

Classification

Various nomenclature and classification systems have been employed in the description of spinal vascular lesions.[4,7–9] As a first approximation, these lesions can be broadly divided by the presence or absence of an arteriovenous shunt. The vascular lesions without a shunt are cavernous malformations, a lesion of capillary structure.[10] Spinal cord arteriovenous shunts are separated into four types on the basis of the location and angioarchitecture of the abnormal arteriovenous connection (Box 92.1). Types I and IV represent direct AVFs that occur within the dural root sleeve (type I) or on the spinal cord surface (type IV). Type II arteriovenous malformations (AVMs) are true congenital malformations, similar to their intracranial pial counterparts. Type III AVMs are also congenital but demonstrate extensive contiguous involvement of intramedullary, intradural-extramedullary, and extradural-paraspinal tissues.

Spinal Arteriovenous Fistula/Malformation

Type I

Type I AVFs, the most commonly occurring type of spinal vascular malformation, have also been termed long dorsal AVMs; single-coiled vessel AVMs; angioma venosum racemosum; dural AVF; micro-AVF; and, more recently, intradural dorsal AVF.[4,7,8,11–17] A more sophisticated understanding of the anatomy and pathophysiology of these fistulas has developed since the seminal description by Wyburn-Mason,[17] who characterized these as purely venous lesions. The advent of selective spinal angiography in the 1960s reclassified them as slow-flow AVFs. Early surgical treatment was directed at stripping the long dorsal vein off the spinal cord surface. It was assumed that tiny feeding vessels, too small to be seen angiographically, supplied this dilated vein throughout its length. This treatment approach did stabilize or improve symptoms in some patients, but postoperative neurologic deterioration was seen in many others. Kendall and Logue,[13] in 1977, correctly recognized these lesions as simple AVFs between a radicular or radiculomedullary artery and a medullary vein, with the fistulous connection located in the dural root sleeve (Fig. 92.1). The entire intradural portion of the malformation, therefore, represents the enlarged spinal cord venous system that has been pathologically engorged from retrograde flow from the fistula into the spinal cord veins (Fig. 92.2). These malformations are likely often acquired and arise predominantly at thoracic and thoracolumbar levels. As mentioned earlier, these shunts and their venous drainage are almost universally dorsally located, with ventral communications being exceedingly rare.[18]

Type II

These malformations are known as glomus, nidus, or simply intramedullary type AVMs.[4,7] They are angiographically and

BOX 92.1 Classification of Spinal Vascular Malformations

Lesions With Arteriovenous Shunts

Type I (dural root sleeve AVF)
Type II (glomus AVM)
Type III (juvenile AVM)
Type IV (intradural AVF)

Lesions Without Arteriovenous Shunt

Cavernous malformations
Hemangioblastoma (?)

AVF, arteriovenous fistula; AVM, arteriovenous malformation.

FIG. 92.1 Anteroposterior view of right L1 selective angiography demonstrates the typical fistula (*arrow*) of a type I AVF and the characteristic intradural medullary draining vein that extends on the dorsal surface of the spinal cord over many rostral segments.

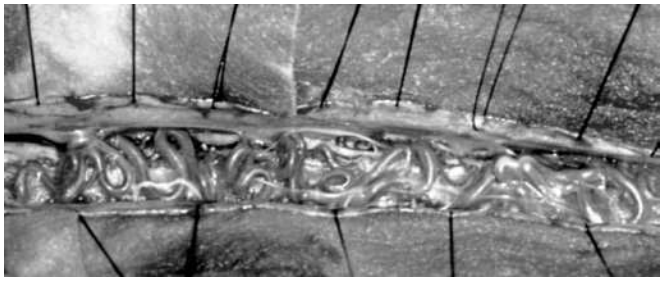

FIG. 92.2 Intraoperative image of a type I arteriovenous fistula shows an enlarged coiled vein on the dorsal spinal surface. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

operatively well-defined lesions consisting of a distinct conglomeration of dysmorphic arteries and veins in direct communication without an intervening capillary bed (Figs. 92.3 and 92.4).[19,20] The location of the nidus may be completely or partially intramedullary and only rarely is confined to the epipial tissue of the cord. These latter lesions are sometimes referred to as perimedullary type II AVMs and most commonly occur dorsally at the cervicomedullary junction (Fig. 92.5).

Typical type II AVMs may arise anywhere within the spinal cord but predominantly are found at the cervical and lumbar enlargements or the conus medullaris. Type II AVMs of the cervical spinal cord frequently have multiple feeding vessels of anterior spinal, posterior spinal, and radiculomedullary arteries, whereas type II AVMs of the thoracic spinal cord or conus are often supplied via a single enlarged branch of the anterior spinal artery. Latent anastomotic channels invariably exist, however, which may emerge after proximal ligation or endovascular occlusion of the primary feeding vessel (Fig. 92.6).

Type III

Also known as juvenile or metameric AVMs, type III malformations are fortunately rare. These lesions do not possess a discrete nidus but rather consist of diffuse arteriovenous shunts with variable degrees of involvement of the spinal cord, vertebral, and paraspinal tissues (Fig. 92.7). Other metameric anomalies of associated organs and the skin are commonly associated with these lesions.

Type IV

Type IV malformations are completely intradural fistulas, variably referred to as perimedullary AVF, macro-AVF, or intradural ventral AVF.[4,7,8,12,21,22] Most occur in the thoracolumbar region as a fistula between the anterior spinal artery (ASA) and anterior spinal vein on the ventral spinal cord surface. Gueguen and colleagues[23] as well as Anson and Spetzler[12] subdivided these arteriovenous shunts according to the complexity and size of the lesion. A type IV-A malformation is a small, simple direct fistula with a single ASA feeder. Type IV-B lesions are medium-sized fistulas and have additional smaller feeding vessels arising from either the ASA or posterior spinal artery. Type IV-C fistulas are giant sized and demonstrate several enlarged ASA and posterior spinal artery feeding branches with dilated venous outflow. The subtypes may represent progressive changes resulting from venous congestion, thrombosis, collateral vessel recruitment, or ischemia. The sporadic nature of these malformations suggests an acquired rather than congenital nature, but their rarity makes their etiology difficult to determine.

Pathophysiology and Symptomatology

The pathophysiology of vascular malformations reflects localized derangements in spinal cord blood flow that are related

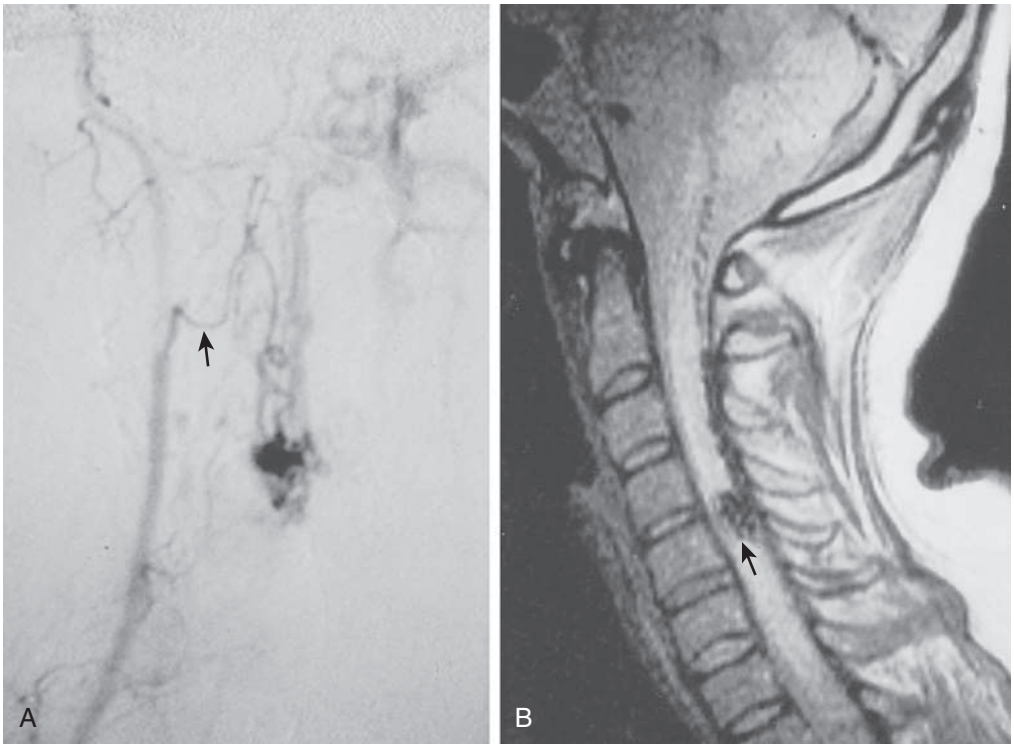

FIG. 92.3 (A) Selective spinal angiography reveals type II arteriovenous malformation of the cervical spinal cord supplied by a branch of the anterior spinal artery (*arrow*). (B) Sagittal magnetic resonance imaging demonstrates intramedullary location of the lesion (*arrow*). (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

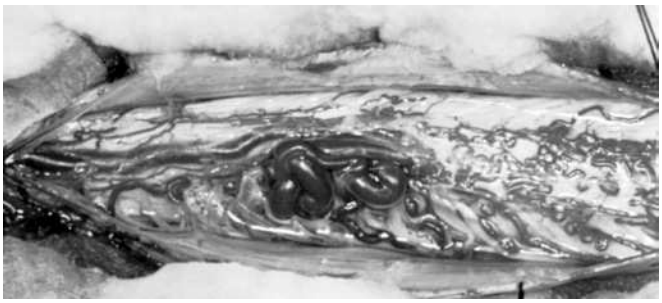

FIG. 92.4 Intraoperative image of a type II arteriovenous malformation shows a dorsally superficial arterialized vein overlying the intramedullary nidus that expands the circumference of the spinal cord. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

primarily to the specific type of malformation. Similarly, the presenting symptoms and signs of spinal vascular malformations depend on whether the pertinent pathophysiologic process is venous congestion, hemorrhage, ischemia, or localized mass effect. Each type of lesion is discussed separately in this section, but, in general, relatively slow-flow lesions have typically chronic progressive courses indicative of high venous pressures, whereas high-flow lesions often have more abrupt presentations related to hemorrhage or ischemia.

Type I

Type I AVFs produce progressive spinal cord ischemia from venous hypertension.[7,11,15,16,24–28] Despite slow flow through the shunt, intradural venous pressures become markedly elevated and may approach systemic mean arterial pressure. Because spinal cord perfusion pressure is equal to mean systemic arterial pressure minus venous pressure, progressive spinal cord ischemia may ensue. The elevation of intraspinal venous pressures during activity or exercise accounts for the reversible ischemic symptoms often seen in these patients. Venous hypertension may be further exacerbated by structural changes, such as reductions in venous diameter and compliance secondary to intimal thickening and hyalinization seen with chronic exposure to high intravenous pressures (Fig. 92.8). Episodic acute neurologic deterioration in these patients may occur as a result of venous thrombosis. In rare cases, patients may present with subarachnoid hemorrhage mimicking that of intracranial aneurysm rupture.[29,30]

It follows, then, that type I AVFs produce symptoms usually in middle and advanced adult years with a mean age at symptom onset around 50 years. Men are four to five times more commonly affected than women. The majority occur in the thoracic or thoracolumbar region. Symptoms typically arise insidiously with back and leg pain and mild sensorimotor dysfunction. In early stages, symptoms may mimic those of neurogenic claudication secondary to spinal stenosis. Neurologic examination, however, often reveals mixed upper and lower motor neuron disease and patchy sensory loss, clearly differentiating the clinical picture from degenerative lumbar stenosis. The natural history of type I AVFs produces an inexorable progression of symptoms occasionally punctuated by episodes of acute worsening, as in the classic Foix-Alajouanine

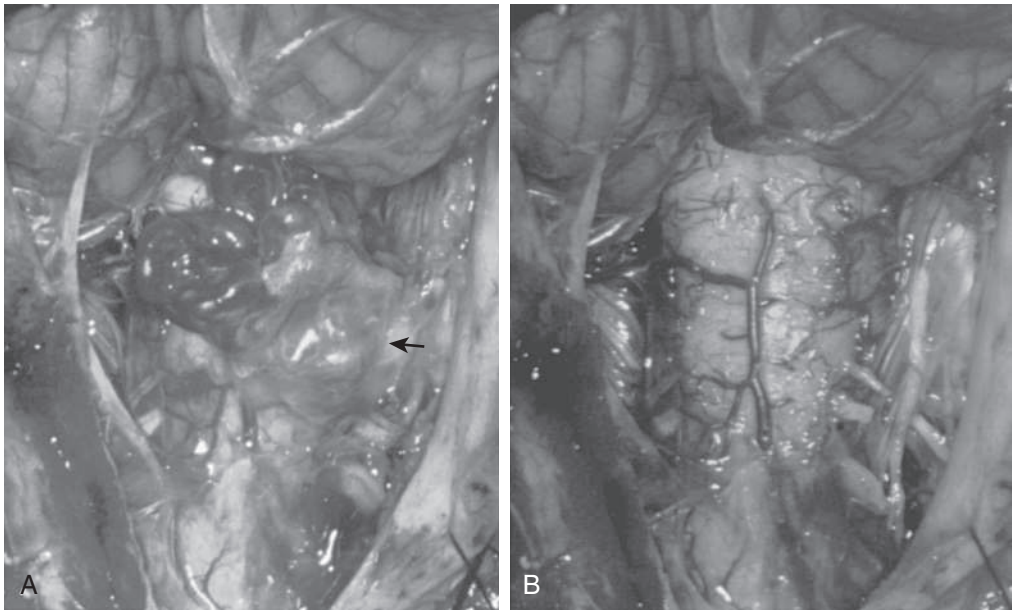

FIG. 92.5 Intraoperative photographs (A) before and (B) after surgical resection of a dorsal cervicomedullary junction type II AVM with associated venous aneurysm (*arrow*). (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

syndrome. If untreated, these lesions lead to significant disability and wheelchair dependence in most patients within 6 months to 3 years after symptom onset.[15]

Numerous investigators have demonstrated that preoperative neurologic status is the most important predictor of posttreatment outcomes.[28,31–33] Median time from symptom onset to diagnosis in modern series ranges from 15 to 23 months.[32–36] If type I AVFs are treated early in their course, symptoms are often reversible. However, in more chronic cases, progressive ischemia ultimately leads to irreversible neuronal loss and infarction. Therefore, definitive treatment should be administered as early in the disease as possible because function is unlikely to improve in the presence of severe incapacity.

Type II

As in types III and IV, type II AVMs are high-flow lesions in which the AVM nidus acts as a low-resistance sump siphoning blood away from the surrounding normal spinal cord producing ischemia. In addition to such "vascular steal" mechanisms, the high pressure and flow characteristics through these dysmorphic vessels render them susceptible to hemorrhage, in most cases on the venous side of the malformation, often from a venous aneurysm. Finally, enlarged tortuous feeding vessels or draining veins may cause localized mass effect with compression of the spinal cord or spinal roots, resulting in myelopathy or radiculopathy, respectively.

Type II AVMs present in childhood or adult years. An acute presentation from subarachnoid hemorrhage or intramedullary hemorrhage is most common.[16] As mentioned earlier, the presence of venous aneurysms seems to increase the risk of a hemorrhagic event. The acute onset of severe neck or back pain ("coup de poignard"[37]) approximates the level of the malformation and is typically the first symptom of AVM hemorrhage. The occurrence and progression of neurologic deficit are variable and dependent on the location and severity of the hemorrhage. For example, typical headache and nuchal rigidity may be the only symptoms of a spinal subarachnoid hemorrhage and usually lead to the standard evaluation for an intracranial ruptured aneurysm.[38] On the other hand, objective deficits are typically seen with intramedullary hemorrhage. These deficits evolve over minutes to hours; some degree of recovery is usually seen after incomplete lesions.

Types III and IV

Similar to type II AVMs, these high-flow lesions produce symptoms due to vascular steal/ischemia, hemorrhage, and mass effect. Type III AVMs have been associated with genetic syndromes such as Klippel-Trenaunay-Weber.[39] Type IV lesions have an equal incidence in males and females. Symptoms may arise at any age, although most patients present in childhood and early to middle adult years. Associations with hereditary hemorrhagic telangiectasia (Rendu-Osler-Weber disease) and Kartagener syndrome have been noted in younger patients.[7,8,40,41]

Radiology

Selective spinal angiography remains the gold standard for the definitive diagnosis and characterization of spinal vascular malformations. This imaging study identifies the locations and flow characteristics of vascular shunts as well as the sites of critical radiculomedullary arteries (e.g., artery of Adamkiewicz).[13,20-22,42-46] Its inherently invasive nature, however, has led to the development and use of alternative modalities as

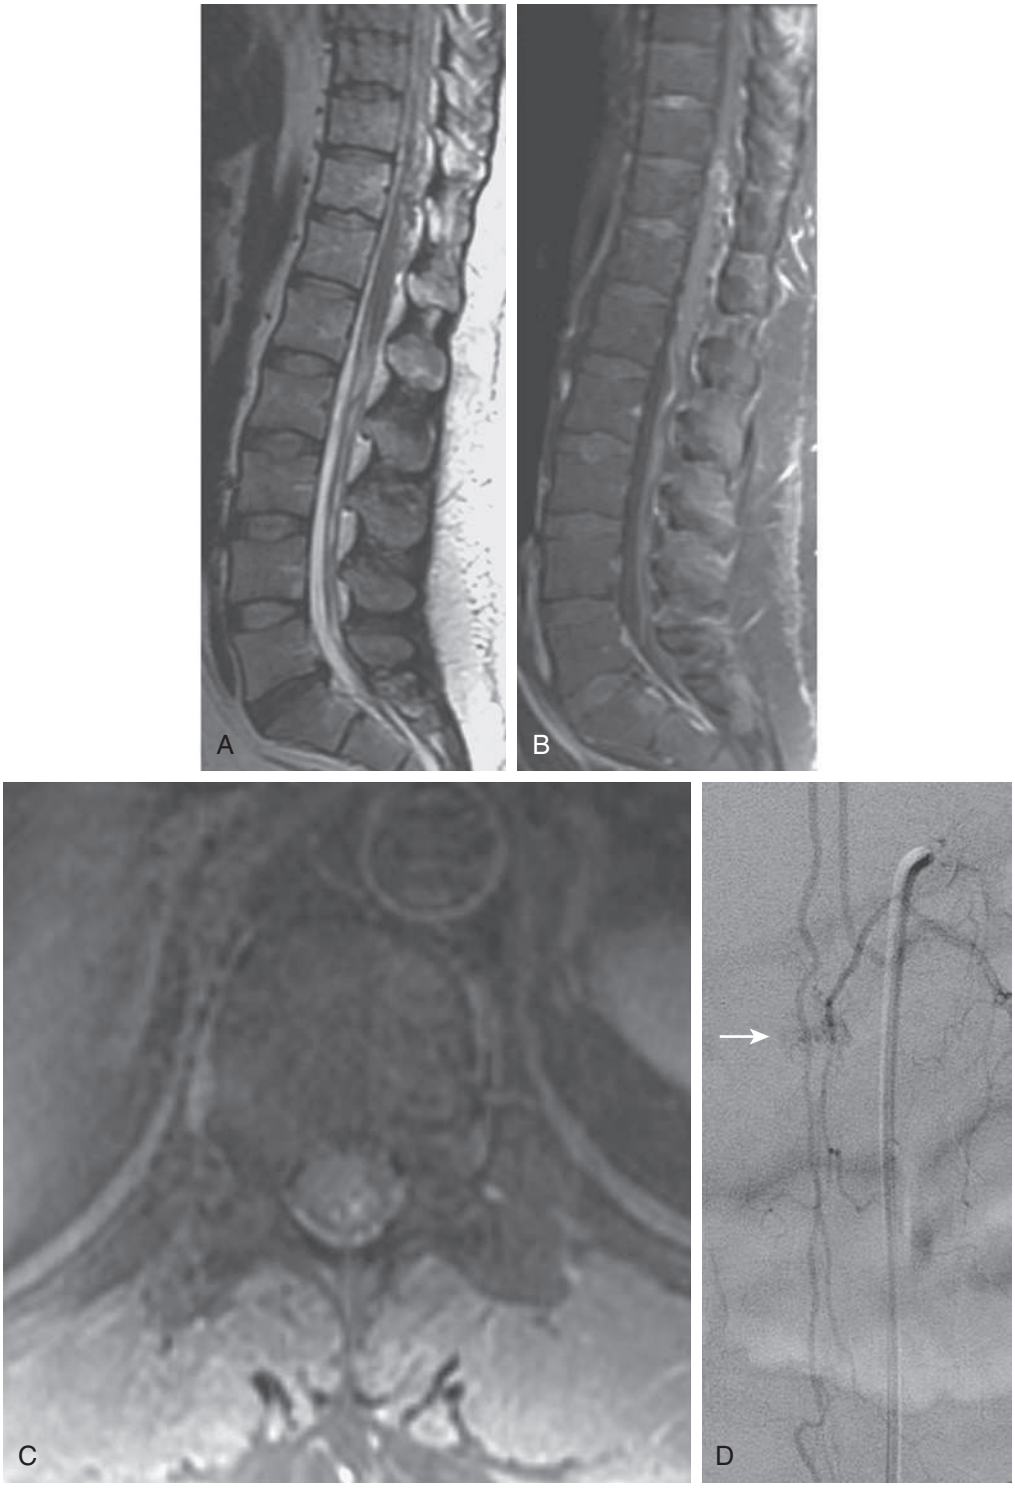

FIG. 92.6 (A) Sagittal T2-weighted magnetic resonance image (MRI) demonstrates numerous serpiginous flow voids over the dorsal surface of the lower thoracic spinal cord in a patient who had undergone prior embolization of a type II arteriovenous malformation (AVM) in this region. (B) Sagittal and (C) axial T1-weighted MRI with gadolinium show enhancing nidus of vessels in the substance of the cord at the level of the T10–T11 disc space. (D) Selective angiographic injection of the left T10 artery reveals the AVM nidus (*arrow*) and the associated shunting into the medullary venous system rostrad and caudad.

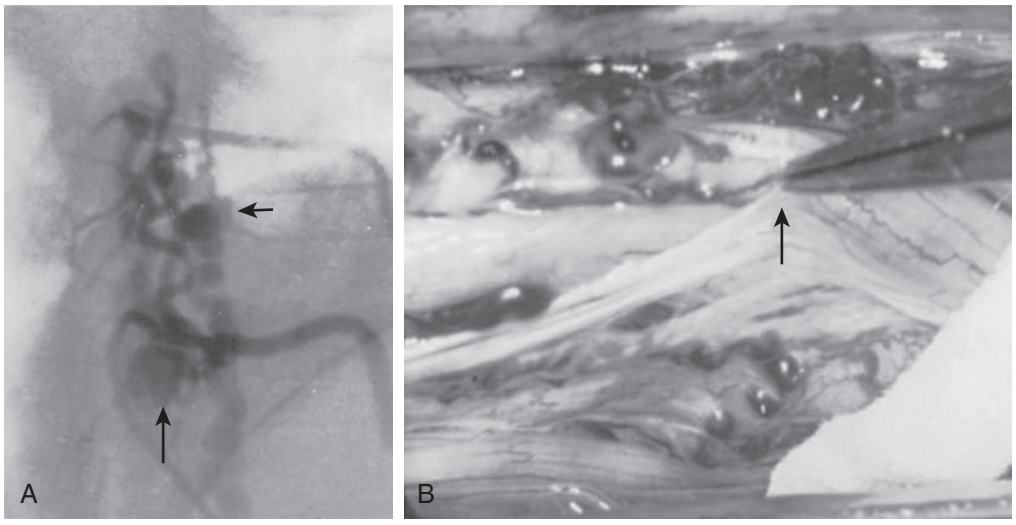

FIG. 92.7 (A) Spinal angiogram shows the intramedullary and extramedullary nature of a type III AVM (*arrows*). (B) Intraoperative image of another type III AVM demonstrates the dorsal, dorsolateral, and ventral location of the lesion permeating the intramedullary and extramedullary compartments and preventing safe resection. The cord is rotated by grasping the dentate ligament (*arrow*). (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

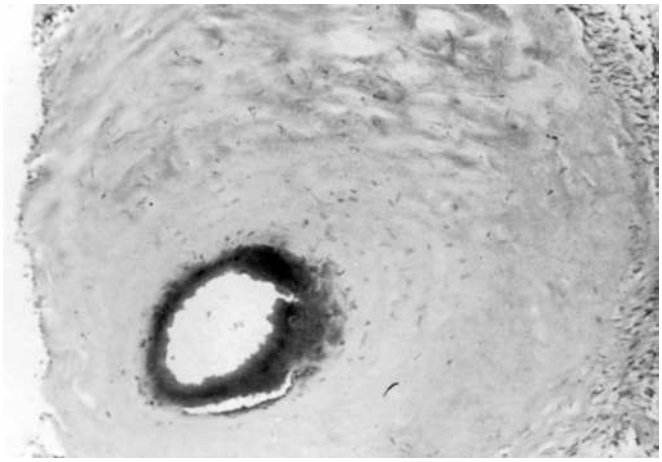

FIG. 92.8 Histologic cross-section of a vessel from a spinal cord vascular malformation demonstrates hyalinization and endarteritis obliterans with a minimal lumen. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

FIG. 92.9 Anteroposterior thoracic myelography reveals a typical long serpentine filling defect characteristic of type I arteriovenous fistula. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

screening procedures. These currently include magnetic resonance imaging (MRI), magnetic resonance angiography (MRA), computed tomographic (CT) angiography (CTA), and CT myelography. Myelography has a long history in the diagnosis of spinal AVMs, particularly for type I AVFs, in which the characteristic serpentine filling defect on the dorsal spinal cord surface is often apparent (Fig. 92.9). These enlarged vessels are commonly identified on screening magnetic resonance scans (Fig. 92.10). If the filling defect extends toward a neural foramen, the level and side of the fistula may be suggested. The dilated venous filling defect should be differentiated from the venous dilatation seen rostral to high-grade extradural stenotic blocks.

MRI and MRA are useful for the initial screening of AVFs and are critical in the evaluation of intramedullary malformations, particularly with regard to operative planning and understanding the relationship of the malformation to the normal spinal cord. As with CT myelography, both MRA and CTA may permit more targeted selective angiography.[47,48]

Three-dimensional angiography is also emerging as a potential aid in angiographic delineation of the structural

FIG. 92.10 T2-weighted sagittal magnetic resonance image of the spine demonstrates multiple signal voids on ventral and dorsal aspects of the spinal cord.

anatomy of spinal vascular malformations and their relationship to the surrounding spine and normal vessels.[49]

Treatment

Successful treatment of spinal vascular malformations requires the total obliteration or excision of the abnormal shunt. [11,12,14,15,21,26,38,44–46,50–52] Procedures that only partially reduce the shunt or address only proximal feeders may provide temporary benefit but all too often lead to delayed recurrences.

Surgical Therapy: General Considerations

The surgical approach to spinal cord vascular malformations depends on the level and anatomic position of the lesion. Nevertheless, the majority are dorsal or dorsolateral and therefore can be approached via a standard posterior laminectomy of appropriate number of levels. In general, routine perioperative antibiotics and corticosteroids are administered at the time of surgery. Neurophysiologic monitoring, including somatosensory evoked potential and motor evoked potential, are also routinely used. Whereas authors such as Malis[53] have described the use of the sitting or oblique positions for the posterior removal of malformations, we prefer the prone position for all such laminectomies. Although the sitting position decreases venous pressure and respiratory excursions, it also precludes the effective use of an assistant during the operation. With the patient in the prone position, the surgeon and assistant work together across the operating table.

The laminectomy is centered over the extent of the lesion, as identified on preoperative imaging. The bony exposure should be moderately wide and the dura opened with preservation of the arachnoid until the lesion can be visualized. The operating microscope is used from the time of dural opening. Malformations with an extramedullary component are immediately apparent, with the exception of small type IV fistulas on the ventral surface of the cord. Those lesions with a primarily intramedullary location (e.g., type II or cavernous malformations) are often identified by a bulging or discoloration of the spinal cord. The techniques for the removal of these latter lesions are similar to those used with intramedullary spinal cord tumors and are described in greater detail later.

For complex cases, intraoperative confirmation of shunt elimination may be obtained. The standard method employed is intraoperative angiography.[54,55] This, however, has its limitations with regard to both patient positioning and image resolution. For types I and IV fistulas, some authors have described the use of intraoperative micro-Doppler ultrasound or infrared imaging of spinal vascular blood flow to demonstrate successful obliteration of the shunt.[56–58]

After satisfactory occlusion or removal of the vascular shunt, hemostasis is meticulously achieved and a primary dural closure is performed. Should the latter not be possible, a dural substitute, either as onlay or sutured graft, may serve to reduce the risk of cerebrospinal fluid leak and postoperative scarring from the paraspinal musculature.

Endovascular Therapy: General Considerations

The role of endovascular techniques in the treatment of spinal vascular malformations continues to evolve. Advances in catheter technology, image resolution, and embolization materials have allowed increasing success and safety in the elimination of certain vascular lesions. The wide variety of embolic materials used in the endovascular treatment of spinal vascular malformations includes *N*-butyl cyanoacrylate, Onyx, polyvinyl alcohol, coils, cellulose acetate polymer, and trisacryl gelatin microspheres.[33,59–62]

The more widespread use of liquid adhesive embolic agents such as *N*-butyl cyanoacrylate and ethylene vinyl alcohol copolymer (Onyx Micro Therapeutics Inc) has generally been associated with more durable results and less recanalization as compared with particulate embolic materials (e.g., polyvinyl alcohol). Both neurophysiologic monitoring and pharmacologic provocative testing have emerged as important adjuncts in the endovascular treatment of spinal vascular malformations. Somatosensory evoked potentials and motor evoked potentials and testing with intraarterial injections of agents such as amobarbital (Amytal) and lidocaine have been shown to allow safer embolization of spinal AVMs.[62–64]

Whether endovascular techniques occupy a primary or adjunctive role depends not only on the type of vascular lesions but also on institutional experience. Whereas embolization may clearly be the procedure of choice for extradural fistulas and type III vascular malformations,[2] surgery remains the gold standard for type II lesions. For types I and IV lesions, some authors advocate initial treatment attempts with embolization,

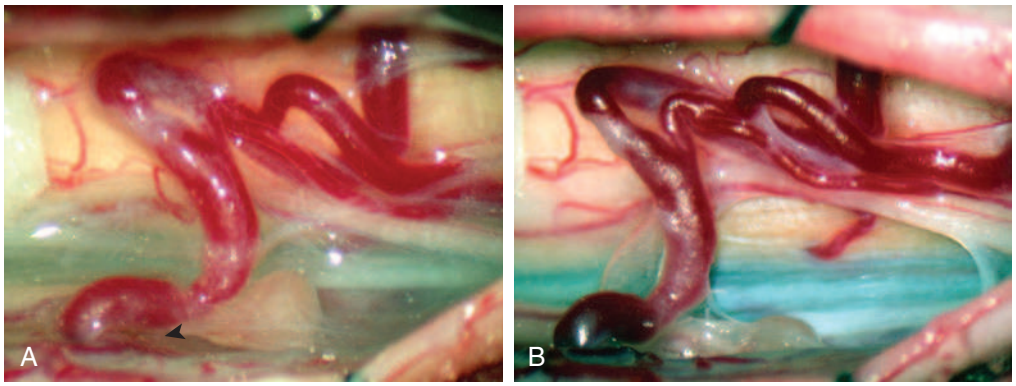

FIG. 92.11 (A) Intraoperative image of a type I arteriovenous fistula shows a T5 feeder arterializing dorsal spinal veins. Note the lateral dural entry point of the draining vein (*arrowhead*). (B) After coagulation of the vein at the dural entry point, the spinal venous system is noticeably less engorged.

reserving surgery for failures, but others prefer surgery as first-line treatment.

Type I

Treatment of type I dural AVFs has been simplified over the years. Operative stripping of the long dorsal vein off the spinal cord surface was recognized as a tedious and unnecessary procedure that was responsible for neurologic morbidity due to removal of normal spinal cord venous drainage. Currently, these lesions are treated by simpler and more refined surgical technique or by endovascular occlusion.

Operatively, type I shunts may be treated by excision of the dural fistula or interruption of the intradural draining vein (Fig. 92.11).[11,24,25] This can easily be accomplished via a two-level hemilaminectomy and partial medial facetectomy, exposing the dural root sleeve and foramen. A paramedian longitudinal dural incision allows exposure of the intradural nerve root and initial segment of the associated draining vein of the shunt. Simple interruption of the draining vein is the generally preferred technique, particularly in circumstances in which the radicular artery that supplies the fistula also supplies a spinal cord medullary artery. This, fortunately, occurs in less than 10% of cases. In cases of more complex or recurrent type I AVFs, fistula excision definitively prevents reestablishment of retrograde intradural venous drainage through collateral longitudinal extradural venous channels at adjacent radicular levels. Several millimeters of the feeding radicular artery and intradural draining vein may be cauterized, divided, and contiguously excised along with a small window of dura on the root sleeve. This dural defect can be primarily repaired with sutures. The wound is then closed in layers in a typical fashion.

Outcomes following the treatment of type I AVFs are generally good, with most reports demonstrating neurologic improvement or stabilization in 70% to 99% of patients.[31,32,36,65–68] Interestingly, motor and gait disturbances seem to improve to a greater degree than sensory or sacral deficits.[31,65] Surgery produces a 98% fistula obliteration rate, and endovascular embolization produces a 25% to 66% obliteration rate.[32,35,36,66,68–70] In general, then, for most type I lesions, we recommend surgery as a primary therapy to avoid the progressive myelopathy associated with a delay in definitive treatment that can be seen with endovascular treatment failures.

Type II

As mentioned earlier, type II lesions are classic AVMs and, as such, are often approached in an interdisciplinary manner using both endovascular and operative techniques. Endovascular occlusion of primary feeding vessels may reduce the overall shunt and assist removal at open surgery.

The type II malformations that form a simple nidus in a perimedullary location are the easiest to understand and treat. Circumferential interruption of their feeding arteries at the exact margin of the glomus is the surgical technique of choice. Interruption of the venous side of an AVM first can lead to hazardous elevations in pressure in the remaining venous drainage system, producing either excessive bleeding around the AVM or rupture of associated venous aneurysms.

Malformations that are largely intramedullary are similarly treated incorporating techniques used for intramedullary spinal cord tumors. The locus of the lesion is visualized, and a myelotomy is made over the dorsal surface of the malformation identifying both rostral and caudal poles of the malformation. Typically, irrigating bipolar cautery is used during the obliteration of the malformation. Only the largest vessels are clipped; from a practical point of view, this means clipping few or no arteries because the application of metallic clips to intramedullary lesions often proves difficult or dangerous. As expected, the AVM is approached from the arterial side first, serially coagulating and dividing arterial contributions to the AVM as it is gently peeled away from the cord substance on its venous pedicle, which is ligated just prior to final removal. As mentioned earlier, early interruption of the venous drainage should be avoided. Aneurysmal venous dilatations are prone to rupture even with minor surgical manipulation. Bipolar cautery can be used to shrink these venous aneurysms, but care must be taken not to violate the thin vessel wall. In some cases, the venous aneurysm may be gently teased out of the cord (Fig. 92.12).

In any case, the removal of the malformation and associated aneurysms leaves a surgical defect similar to that seen with

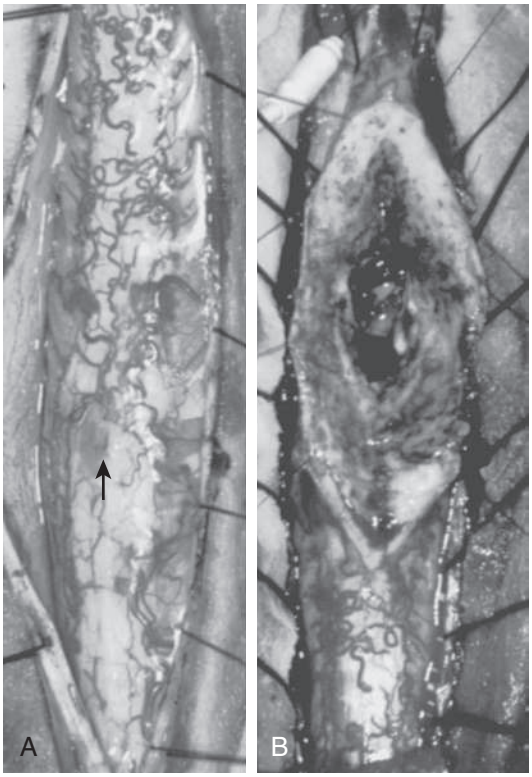

FIG. 92.12 (A) Intraoperative image demonstrates a large type II arteriovenous malformation (AVM). The *arrow* indicates a partially thrombosed venous aneurysm within the substance of the cord. (B) Total extirpation of the AVM and venous aneurysm was achieved via midline myelotomy. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

excision of intramedullary tumors. It is indeed remarkable how thin the remaining spinal cord substance can appear and yet still produce functional neurologic outcomes postoperatively.

Type III

These lesions are the most difficult to treat. They penetrate the spinal cord, and histologic examination indicates violation of presumably functional cord tissue interspersed with vascular channels of the malformation. These AVMs do not have well-defined margins and comprehensively involve the intramedullary, intradural-extramedullary, and extradural compartments over many spinal segments. Although these are generally unresectable lesions, partial treatment through endovascular embolization, surgical decompression, and limited arterial ligation may produce some clinical benefit (Fig. 92.13).[4]

Such improvements are usually not durable, however, and the significant risk associated with aggressive treatment of type III AVMs must be carefully weighed before initiating any invasive therapies.

Type IV

Treatment of type IV AVFs depends particularly on the size and complexity of the lesion.[21,22] For small type IV-A shunts, surgical ligation of the fistula is definitive. Adequate exposure of these ventral intradural shunts often requires more

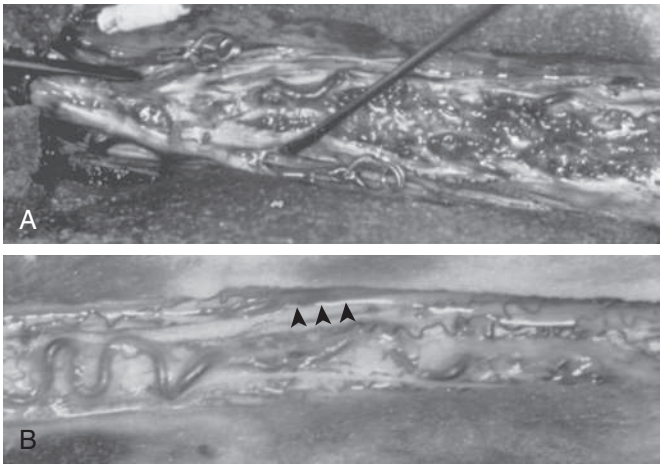

FIG. 92.13 Intraoperative images demonstrate interruption of (A) bilateral (*clips*) or (B) single (*arrowheads*) arterial feeders to type III arteriovenous malformations without radical excision of the extensive malformations. (From Youmans JR. *Neurological Surgery*. 3rd ed. Philadelphia: WB Saunders; 1990.)

aggressive posterior or posterolateral bone removal including facetectomy, as well as spinal cord rotation with suture retraction of the dentate ligament. Alternatively, anterior or anterolateral approaches to such ventral lesions may be used, with special attention paid to the need for spinal reconstruction and the attendant risk of cerebrospinal fluid fistulas.[71,72] Intraoperative intravenous administration of near-infrared indocyanine can be useful in assessing the completeness of the resection of difficult spinal cord vascular malformations.[73]

For more complex, higher-flow lesions (types IV-B and IV-C), endovascular obliteration of the shunt may be the preferred primary treatment or at least a preoperative adjunct.[22,40,74]

Cavernous Malformations

Cavernous malformations are benign congenital vascular lesions that occur in every organ system, including the brain and spinal cord. Pathologically, cavernous malformations consist of endothelial-lined capillary-like chambers and sinusoids without intervening neural tissue. They are slow-flow lesions without a direct arteriovenous fistula. Hemosiderin-stained neural tissue is often present at the peripheral margin of these malformations, indicative of prior hemorrhage or vascular leakage.

The etiology of cavernous malformations is unclear. Most are sporadic and solitary, but up to 10% to 15% of patients have more than one lesion, either in the spinal cord or brain.[75] A similar percentage of patients have a family history of cavernous malformations supporting a genetic risk factor.

Pathophysiology and Symptomatology

Based on the prevalence of cavernous malformation, it is likely that the vast majority of these lesions are incidental and asymptomatic throughout life. Therefore, the discovery of an incidental spinal cord cavernous malformation does

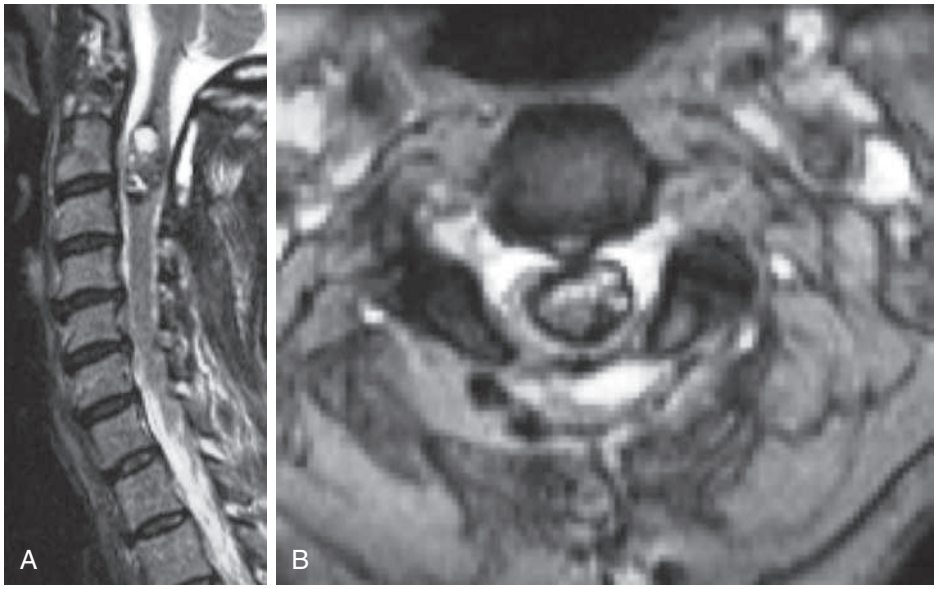

FIG. 92.14 T2-weighted (A) sagittal and (B) axial magnetic resonance imaging shows heterogeneous mass consisting of intralesional hemorrhagic/blood products surrounded by a well-defined low-signal hemosiderin margin.

not require consideration of treatment or periodic imaging surveillance. Symptomatic cavernous malformations generally present with acute hemorrhage and neurologic deficit. The deficits are generally mild to moderate in severity and often demonstrate significant improvement over the following weeks to months. The occurrence of an acute hemorrhage increases the risk of further hemorrhagic events.[76]

Radiology

Because cavernous malformations are slow-flow capillary lesions without arteriovenous shunting, angiography is usually unrevealing. Fortunately, due to the often enlarged blood-filled interstices of cavernous malformations, MRI is usually both characteristic and diagnostic for these lesions. T1- and T2-weighted MRI are particularly useful. On T1-weighted images, these lobulated masses tend to be isointense and hyperintense with an edge of hypointensity, which represents the reactive gliotic capsule. On T2-weighted images, the lesions are also heterogeneous, with a predominant hyperintensity surrounded by a hypointense rim after hemorrhage (Fig. 92.14). The heterogeneity is one of the characteristics of these lesions, which gives them the classic "popcorn" or "mulberry" appearance.[77]

Treatment

The treatment for symptomatic cavernous malformations is surgery. Neither radiosurgery nor embolization has been shown to be effective. As previously noted, surgery is usually not performed for asymptomatic lesions. The decision to recommend surgery for symptomatic lesions depends on an individualized patient evaluation that considers the severity of the symptoms as well as the risk of future hemorrhage and the risk of surgical intervention. For small, dorsally located lesions that reach the surface of the spinal cord, the risk of surgery is quite low. On the other hand, large and/or ventral lesions present a greater surgical risk.

The surgical technique for cavernous malformation resection depends on the relationship of the lesion to the spinal cord. For pial-based lesions, a circumscribing pial incision allows detachment and delivery of the cavernous malformation from the superficial substance of the spinal cord. Deeper intramedullary lesions are exposed by a midline myelotomy. Although unencapsulated, these malformations are generally well circumscribed and present a clear dissection plane.[10] Uncommonly, a more diffuse lesion permeates the spinal cord tissue and precludes surgical removal. Epidural cavernous malformations are exceedingly rare entities, but treatment follows that of other well-demarcated extradural pathologic processes.[78]

Summary

Vascular malformations of the spinal cord are rarely encountered, even in tertiary care centers with specialized microsurgical and endovascular staff. Nevertheless, these lesions produce a high rate of incapacity in a relatively young group of patients.

The primary aim in the treatment of spinal cord vascular malformations is obliteration or excision of the abnormal arteriovenous shunt. This is routinely achieved with the current techniques available in microsurgery and endovascular therapy for most malformations of types I, II, and IV. As with the excision of most cavernous malformations, successful treatment can be accomplished with preservation of neurologic function. Type III AVMs remain a clinical challenge awaiting novel approaches for treatment. The role of new therapeutic modalities, such as stereotactic radiosurgery (e.g.,

CyberKnife), in the management of these lesions has only begun to be explored.[79]

Outcomes in the care of patients with spinal vascular malformations have become quite satisfactory in most cases. Still, a poor preoperative neurologic condition predicts a poor outcome. Therefore, it is critical to recognize these lesions early in their clinical course and institute proper therapy by a surgical and endovascular team versed in the treatment of spinal, intramedullary, and vascular diseases.

PEARLS

1. Successful treatment of spinal vascular malformations requires total obliteration or excision of the abnormal shunt.
2. Type I AVFs may be treated by excision of the dural fistula or, more typically, by simple interruption of the intradural draining vein.
3. Surgical resection of type II AVMs should proceed in the same manner as removal of intramedullary spinal cord tumors, with identification of rostral and caudal poles of the glomus and circumferential interruption of the feeding arteries along the margin.
4. Alternative surgical approaches to standard posterior laminectomy, including anterior corpectomy and reconstruction, may be considered in the treatment of ventral lesions such as type IV-A fistulas.
5. More complex lesions often require interdisciplinary approaches using both endovascular and surgical techniques to achieve satisfactory radiographic and clinical results.

PITFALLS

1. In the embolization or surgical interruption of malformations, care must be taken not to sacrifice feeding radicular arteries that also supply spinal cord medullary arteries.
2. In the surgical resection of type II AVMs, arterial feeders should be eliminated first because early interruption of the venous drainage may produce excessive bleeding or venous aneurysm rupture.
3. With the exception of select cases, both surgical and endovascular treatments for type III AVMs infrequently provide long-lasting benefit and should therefore be cautiously applied, if at all, to these difficult entities.

KEY POINTS

1. Vascular malformations of the spinal cord are divided into four types. Types I and IV represent direct AVFs that occur within the dural root sleeve (type I) or on the spinal cord surface (type IV). Type II AVMs are intramedullary lesions similar to their intracranial counterparts. Type III AVMs have extensive involvement of intramedullary, intradural-extramedullary, and extradural-paraspinal tissues.
2. Preoperative neurologic status is the most important predictor of posttreatment outcomes, particularly for type I AVFs. Early diagnosis and treatment are critical to favorable outcomes in spinal vascular malformation patients.
3. Spinal vascular malformations should be entertained in the differential diagnosis of progressive myelopathy of uncertain etiology. Therefore, advanced diagnostic imaging, including spinal MRA or CTA to screen for such lesions, must be considered in the radiographic evaluation of such patients. Selective spinal angiography may then be used in a targeted manner to better assess suspicious regions of interest.
4. Endovascular embolization has a 33% to 75% failure rate in the obliteration of type I AVFs. Therefore, surgery should largely be considered as the primary treatment modality. In any practice setting in which embolization represents first-line treatment for these lesions, early and deliberate follow-up angiography is required to detect possible recurrence.
