The musculature is examined next. The paraspinal muscles should be palpated. Spasm can be noted in addition to tenderness; this may be present as a "ball" of contracted muscle in one region. These findings are nonspecific and are of minimal diagnostic value. Muscular atrophy can be a sign of long-standing neural compression and is more likely isolated to one motor group. Generalized, symmetric muscle atrophy can suggest a more systemic neurologic disorder, such as a demyelinating disease.

Neurologic Examination

A neurologic examination is required in all patients with suspected herniated discs. Sensation of light touch is tested along dermatomes from L1 to S1. Standard dermatomal charts can be helpful, but there is variability among individuals; thus, this is highly subjective. In testing the upper lumbar roots, there is often a significant amount of overlap. The most discrete levels of testing are for L4, L5, and S1 nerve roots.[37] These nerve roots are the most often affected by lumbar disc herniations. L4 sensory function is tested at the medial ankle; L5, at the first webspace between the great and second toes; and S1, at the lateral aspect of the sole of the foot. Sensation is difficult to "grade." It is more useful to document sensation as normal, diminished, or absent. Sensory function should be compared with the contralateral side because this may help detect differences. The examiner should be wary of the presence of a glove-and-stocking distribution sensory loss, which can indicate a peripheral neuropathy—such as that associated with diabetes, or functional overlay—as it is not anatomic.

The motor examination should proceed in a routine manner. In the lower extremity, it is better to test movements rather than specific muscles. S1 motor function is assessed by testing plantarflexion, whereas L5 is tested by toe dorsiflexion, particularly the great toe (extensor hallucis longus), and hip abduction. L4 involvement most often affects ankle dorsiflexion (anterior tibialis), although quadriceps function can be compromised. There is a significant amount of overlap of upper lumbar motor innervation. Knee extension can be considered L3 function (although L2 and L4 contribute); hip flexion, an assessment of L1–L2 function; and hip adduction, an assessment of L2 function. Motor function is graded as 0 to 5, with 5 being full strength against active resistance (Table 47.2). In particular, S1 function should be assessed by asking the patient to toe raise repeatedly or toe-walk. Because of the enormous strength of the gastrocnemius complex, even a weakened muscle can overcome the examiner's hand. Toe-walking can show smaller differences, however, from side to side by using the weight of the patient's body as the resistance. Repetitive toe raising may help detect smaller differences.

TABLE 47.2 Motor Strength Grading System by Physical Examination

Grade	Definition
0	No visible muscle contraction
1	Visible muscle contraction; no joint movement
2	Can move joint, but not overcome gravity
3	Able to overcome gravity, but cannot overcome any examiner resistance
4	Able to overcome some, but not full, examiner resistance
5	Full strength; able to resist full examiner force

Deep tendon reflexes are tested at the patella and Achilles tendons. The patellar tendon reflex may be diminished or absent with L3 or L4 involvement, whereas the Achilles tendon reflex is affected primarily by S1. There is no specific reflex that reliably reflects L5 function. Reflexes are tested bilaterally and can be graded. Symmetrically decreased reflexes are not helpful in isolating a lesion. Generally, reflexes are anticipated to be decreased in response to nerve root compression from a herniated disc. Increased reflexes (hyperreflexia), especially if bilaterally symmetric, can indicate spinal cord compression at the thoracic or cervical level.

Specific Tests

The straight-leg raise (SLR) test is an extremely useful provocative test in examining patients with a herniated disc (Fig. 47.9). The classic test is performed with the patient in the supine position. The heel of a relaxed leg is cupped by the examiner's hand and elevated slowly. The knee is kept in extension while the hip is flexed. The test is considered positive if sciatic pain is reproduced between 35 and 70 degrees of elevation. Studies have determined that in the first 35 degrees of elevation, the slack in the nerves is taken up, and at 35 degrees or more, tension is placed on the nerves. More than 70 degrees of elevation causes no further stretch of the nerve roots. The SLR test is best for eliciting L4, L5, or S1 radiculopathy. It is not useful for upper lumbar roots, for which a femoral stretch test should be used. A positive SLR test is indicative of nerve root compression in 90% of cases.[38] It does not implicate a herniated disc as the source of compression, however, because foraminal encroachment or other mass lesions can lead to a positive SLR test as well.

The SLR test should always be performed bilaterally. If raising the contralateral leg reproduces symptoms in the ipsilateral side, this is highly suggestive for a herniated disc. It should be considered strong evidence of the diagnosis and is more specific for a free disc fragment. The Lasègue maneuver is a modification of the SLR test. The leg is raised until radiating symptoms are produced. Then, the foot of the ipsilateral leg is maximally dorsiflexed. By increasing the tension along

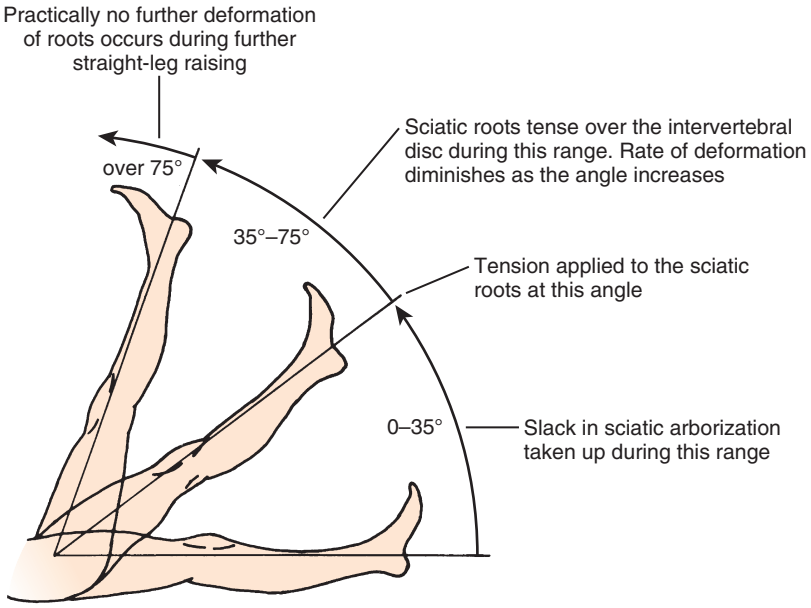

FIG. 47.9 Supine straight-leg raise test.

the sciatic nerve and lower lumbar nerve roots, dorsiflexion exacerbates pain and is considered a positive examination.

An important variant of the supine SLR test is the seated SLR test. When a patient is initially examined, the patient is usually seated at the side of the examining table with the knees and hips flexed at about 90 degrees. In this position, the heel is cupped, and the leg is extended at the knee. With a herniated fragment causing nerve root tension, the patient reflexively extends at the hip and leans back to relieve the ensuing sciatic pain. If the patient is comfortable with the seated SLR test but has a positive supine SLR test, symptom magnification must be considered because these findings are pathoanatomically contradictory.

The so-called slump test is a variant of the Lasègue test and SLR test. This test is performed in the seated position; the patient is asked to flex the thoracic and lumbar spine while fully flexing the neck. Next, the SLR test is performed while the foot is dorsiflexed on the same side, as denoted by the Lasègue test. The combination of these maneuvers adds cephalad gliding of the spinal cord to the examination, whereas the SLR test and Lasègue test by themselves produce only caudal tension on the nerve roots. A more recent study found that the slump test was more sensitive than the SLR test in patients with lumbar disc herniations, whereas the SLR test was more specific.[39]

Another tension sign is the bowstring test. Starting with a typical SLR test, the leg is raised until symptoms are produced. The leg is flexed at the knee, and the tibial and peroneal nerves (distal aspect of the sciatic nerve) are placed on tension by palpation in the popliteal space. Reproduction of pain is considered a positive sign of root tension.

The femoral stretch test is performed in the prone position. The leg is flexed at the knee while pulling the hip into extension. Reproduction of anterior thigh pain is indicative of upper lumbar root pathology.

Differential Diagnosis

The differential diagnosis should be narrowed based on history, physical examination, and selected imaging tests. Radicular pain can be caused by numerous compressive disorders, such as spinal stenosis, abscess, tumor, or vascular disease. Intrinsic nerve problems, such as nerve tumors or multiple sclerosis, can produce similar symptoms. Peripheral neuropathies, such as tarsal tunnel syndrome, meralgia paresthetica, and obturator or piriformis syndrome, can also lead to similar sciatic-type pain.

Diagnostic Imaging

We use a simple imaging algorithm for patients with suspected lumbar herniated discs. If the patient presents acutely, within the first 2 weeks of the incident, the examination is typically masked by a large amount of spasm, back pain, and generalized tenderness. If the mechanism of injury involved substantial trauma, plain radiographs are obtained. For low-energy injury, radiographs can be delayed until the follow-up examination at 6 weeks. Numerous patients will have recovered substantially by 6 weeks, obviating the need for further workup. For patients whose pain has not improved or perhaps has worsened, plain radiographs are obtained. Advanced imaging is reserved for patients in whom pain is persistent, the diagnosis is unclear, or surgical treatment is planned. "Red flags" in a patient's history that should prompt early MRI include constitutional symptoms (i.e., fever, chills, and sweats),

a history of malignancy, osteoporosis, progressive neurologic deficits, or bowel and bladder incontinence.

Plain Radiographs

Plain radiographs cannot show a herniated disc. They can show changes that are suggestive of a herniated disc, however. As stated previously, a scoliotic list can be present on radiographs. This list may be convex or concave to the ipsilateral side and is not specific for a level.

Other findings that can be noted on plain films are changes consistent with disc degeneration, including osteophytes; disc space narrowing; or subtle changes in translation, facet hypertrophy, or changes in sagittal alignment. Most commonly, plain films are negative, especially in younger patients with an acute herniation. Plain films are important in ruling out obvious underlying problems, such as lytic lesions, tumors, infections, inflammatory spinal disorders, or instabilities (e.g., spondylolisthesis).

High-quality anteroposterior (AP) and lateral radiographs are prerequisites to planning operative interventions such as discectomy. It is crucial to recognize if there is an anomalous number of lumbar vertebrae, such as spines with a "lumbarized" first sacral segment (i.e., six lumbar vertebrae), because this can influence intraoperative identification of the correct disc level. Plain films can help detect other congenital anomalies, such as spina bifida occulta defects, which can influence surgical exposure and dissection.

Magnetic Resonance Imaging

MRI is the most popular modality for advanced imaging of lumbar disc herniations. MRI is superior to CT in delineating soft tissues. The disc and fragments that may have herniated from it are readily visualized. Free fragments (sequestered) can be differentiated from extruded disc herniations (Fig. 47.10), and a symmetric bulge can be differentiated from a contained protrusion. The neural elements themselves are well visualized. Neural encroachment can be detected within the spinal canal, the foramina, or extraforaminally. MRI is also useful in differentiating disc herniations from tumors, vascular anomalies, or bony compression.

Numerous features of a herniated disc can be noted on MRI. The size and type of disc herniation can be reliably determined using MRI, which may have prognostic significance.[11,40,41] Carragee and Kim[11] correlated outcomes with herniated fragment size and its effect on canal area. Larger discs (>6 mm) were more likely to have a positive SLR test or femoral stretch test (Wasserman sign). In the operative group, larger discs were predictive of a better outcome. The fair and poor outcomes in operative patients were in patients with small discs (<6 mm).

Attempts to correlate MRI findings with clinical symptoms have been made. In 33 patients in whom disc herniation was diagnosed clinically and 5 control patients with low back pain alone, Kikkawa and colleagues[42] performed three-dimensional MRI using a fast low-angle shot with gadolinium enhancement. Dorsal root ganglion enhancement was found to be nonspecific, occurring in controls and sciatica patients. Enhancement of the root proper was detected, however, in 11 of 30 symptomatic patients, with patients having a statistical tendency for more severe motor involvement. There was no significant association of diffuse versus local enhancement with the positivity of the SLR test or sensory changes. Central compression of the cauda equina did not lead to enhancement in any cases. Although these results are modest, they suggest a future use of gadolinium-enhanced MRI as a noninvasive method of determining the microvascular response to compression of neural structures.

FIG. 47.10 T2-weighted magnetic resonance image has myelogram-like appearance, in which cerebrospinal fluid within dural sac is bright. This makes compression from disc herniations readily visible, as can be visualized in this case of a large extruded paracentral disc herniation.

Komori and colleagues[41] studied the significance of enhancement around the herniated fragment itself. Patients with radiculopathy underwent initial and follow-up gadolinium-enhanced MRI to correlate clinical improvement with the degree of enhancement. Patients with marked decrease in size of the herniation showed good clinical resolution. This resolution was most significant in the "migrating"-type discs, which were closest to sequestered discs according to the authors' description. Decrease in fragment size was associated with a gradual increase in the area of enhancement in 17 of 22 sequestered disc herniations, all of which had improvement of radicular pain. Five cases of sequestered discs without enhancement or size decrease had a poor clinical result. Enhancement was less marked in extruded versus sequestered herniations; however, herniations that did show enhancement had a significantly better clinical course. From these data, Komori and colleagues[41] recommended this test as a prognostic tool in guiding the treatment of patients with extruded or sequestered herniated discs.

Of more recent interest is the influence of posture on the MRI appearance of discs and their relationship to the neural structures. Because images are traditionally acquired in the supine position, the spine is not axially loaded as it is during everyday activities. Weishaupt and colleagues[43] performed positional MRI in patients with low back or leg pain for 6 weeks that was not responding to conservative treatment. Images were obtained in the usual supine position and with a seated flexed and extended posture. Changes in foraminal size and neural compression occurred with flexion and extension. Changes in foraminal size correlated with increased pain scores. These findings are probably most significant for low-grade herniations (i.e., bulges or protrusions) in which there is still a fixed-volume system within the disc space provided by an intact outer annular layer. Similar findings have been shown using dynamic functional plain myelography.[44]

Magnetic Resonance Imaging in the Postoperative Spine

Not all patients respond well to surgical discectomy. Failures may be related to numerous factors, including psychosocial disturbance, recurrence, infection, wrong-level surgery, poor surgical indications, and improper operative technique. Residual or recurrent back and leg complaints often prompt practitioners to seek postoperative imaging. Plain radiographs can show overall alignment, with flexion-extension views useful in detecting instability, spondylolisthesis, or disc space collapse, which is a frequent occurrence after discectomy in adult patients. Contrast-enhanced CT is best to show if there is associated bone or soft tissue impingement of the space available for the neural elements.

As the modality of choice for imaging the neural structures, MRI is frequently obtained. Because of edema, hematoma, and formation of surgical scar, MRI is best delayed until 6 months after surgery,[45] if symptoms allow. The main challenge is differentiating scar from new-onset disc. On standard T1-weighted sequences, this differentiation can be difficult. In the early days of MRI, T2-weighted images were not as useful because of longer scan times with inadequate magnet strength.[46]

The superiority of MRI over CT to distinguish scar from disc has evolved with the introduction of gadolinium contrast agent; this is based on T1-weighted sequences and has been shown by many researchers. Opinions have been changing regarding this test as the gold standard. A herniated disc fragment may eventually enhance if enough time passes before it is imaged. This enhancement can lead to recurrent or residual disc fragments being interpreted as extradural fibrosis or scar. Enhancement of scar should occur within 15 minutes of injection.

Evidence suggests that sophisticated T2 image analysis might supplant the need for gadolinium-enhanced MRI. Barrera and colleagues[47] compared different imaging sequences with and without gadolinium contrast agent. These investigators documented 100% sensitivity for detecting scar for T2-weighted turbo-spin echo (TSE) and fluid-attenuated inversion recovery (FLAIR) sequences compared with T1-weighted images with gadolinium. Specificity was 94% and 92% for TSE T2 and FLAIR images. Barrera and colleagues[47] concluded that standard TSE T2 images acquired using a rapid sequence are extremely sensitive and specific in distinguishing disc from scar in most cases, and that the use of gadolinium contrast agent should be reserved for the rare situation in which that distinction cannot be made. These recommendations are supported by others.[46]

Grane and Lindqvist[45] studied the role of gadolinium enhancement of the nerve roots after discectomy. These investigators found intradural (within the cauda equina) nerve root enhancement in 59% of patients with recurrent clinical symptoms. Recurrent symptoms occurred, however, in 84% of patients with focal (extradural, after the nerve root has exited the cauda equina) enhancement and 86% of patients with nerve root thickening. Enhancement occurred in patients with and without evidence of nerve root displacement by scar or disc. This finding indicates that although symptoms may correlate with MRI enhancement, it is not associated with a compressive mass lesion.

In an early report on the use of MRI without gadolinium, Bundschuh and colleagues[48] studied 20 patients after failed disc surgery who had a strong likelihood of undergoing further surgery. In 14 patients, CT with contrast agent was also performed. The authors found that free fragments of disc had a mildly increased signal on T1 images compared with scar, whereas scar and disc were similarly hyperintense on T2 images. Overall, Bundschuh and colleagues[48] believed that MRI was at least comparable to CT with contrast agent in differentiating scar from disc, confirmed by intraoperative findings.

In general, patients requesting repeat imaging after a first episode of acute sciatica should be informed about the difficulty of MRI interpretation with respect to symptomatology. In a recent randomized clinical trial by Barzouhi et al., which compared surgery and prolonged nonoperative care for sciatica from lumbar disc herniation did not distinguish between patients with a favorable outcome and those with an unfavorable outcome.[49] Importantly, patients enrolled had an acute diagnosis of sciatica with a dermatomal pattern of pain distribution corresponding to the identified nerve root on MRI, and the character of the herniations were classified. Repeat MRI images at 1 year showed herniated discs in 35% of patients with favorable outcomes and in 33% of patients with unfavorable outcomes.

Myelography

Plain myelography previously was the imaging modality of choice in detecting herniated discs. It involves injection of intrathecal contrast material to outline the boundaries of the subarachnoid space and silhouette the enclosed neural elements. It is invasive and cannot show compression beyond the confines of the subarachnoid space. Extradural compression caused by a foraminal or extraforaminal disc can be missed. Advantages of myelography are that it is a dynamic test because images can be made with the patient standing.[44] Myelography should be reserved for cases in which noninvasive imaging, such as CT or MRI, are nondiagnostic, equivocal, or contraindicated. Currently, myelography is rarely used for the routine workup of herniated discs. When used, it is usually followed by a CT scan.

Computed Tomography

Before the advent of MRI, CT was the imaging modality of choice for evaluation of herniated discs. Using bone and soft tissue imaging techniques, herniations can be detected in various regions independent of the dural cavity. It has been shown to be 93% accurate in predicting surgical findings at discectomy. CT can also be performed with intrathecal contrast injection (CT myelography). We currently use this test for patients in whom MRI is contraindicated or cannot be obtained.

Some disc herniations can contain gas (Knuttson phenomenon), noted on CT images. Mortensen and colleagues[50] reported four such cases that responded well to surgical discectomy. It is unknown if the gas forms before or after herniation. The clinical significance of the gas is not well understood. Ford and colleagues[51] determined that intradiscal gas is composed predominantly of nitrogen.

Natural History

The key to enhancing one's skills as an intelligent diagnostician and patient advisor is understanding the available knowledge related to the natural history of degenerative lumbar disc disease. The exact natural history of lumbar disc herniations is variable and incompletely understood. A few well-performed natural history investigations are available. Some studies are of patients treated by various nonoperative methods. Others represent the nonoperative arm of operative versus nonoperative comparison studies.

In a widely quoted retrospective study, Saal and Saal[5] found a 90% good or excellent outcome in patients treated nonoperatively for a lumbar disc herniation diagnosed by clinical examination and CT. Inclusion criteria were strict, including patients with SLR test positive at 60 degrees or less, leg pain greater than back pain, and electromyographic evidence of radiculopathy. Of patients, 92% returned to work. Nonoperative treatment consisted of aggressive physical therapy and back school education. A possible confounding factor is that many patients were referred for a second opinion regarding surgical versus nonsurgical treatment because they were anxious to avoid surgery. This may have introduced preselection bias error because the authors of the study were not surgeons. Concern has been raised about eventual fibrosis formation with nonoperative treatment of herniated discs. In a follow-up MRI study,[6] the same investigators documented no increased risk for perineural fibrosis or adhesions with nonsurgical management.

Other authors have reported more modest results. In the nonoperative arm of Weber's[10] classic randomized study, the long-term outcome of lumbar disc herniations was observed in 49 patients. Inclusion criteria were clinical signs and symptoms of L5 or S1 radiculopathy in addition to myelographic evidence of nerve root compression. Treatment included full-time bed rest for 1 week followed by partial bed rest the second week and back school instruction as an inpatient. At 1 year, 33% had good results, 49% had a fair result, and 18% had a poor result. At 4 years, good results were reported in 51%, fair results were reported in 39%, and poor or bad results were reported in 10%. Because the tiered system is slightly different than that used by Saal and Saal,[5] a direct comparison of the studies is difficult. If Weber's good and fair results are equated to Saal's excellent and good results, an 89% success rate achieved in the former at 4 years may be considered comparable to the latter's 90% success. Many of Saal and Saal's patients ultimately dropped out of the study and underwent surgical discectomy; thus, their 90% success rate might represent an overestimation.

In another nonoperative arm of a comparative study, 10-year follow-up results from the prospective Maine Lumbar Spine Study showed 61% improvement in the predominant symptom, 40% resolution of low back symptoms, and 56% satisfaction rate.[7] Work and disability status were comparable between operative and nonoperative groups in this investigation. Similar findings were reported for the observational cohort of the Spine Patient Outcomes Research Trial (SPORT).[8]

In a subgroup analysis of SPORT data, obese patients, defined as having a body mass index (BMI) greater than or equal to 30 kg/m^2, were found to have less clinical benefit from both operative and nonoperative treatment. More important, the benefit of surgery over nonoperative treatment was not affected by BMI.[52] McGuire et al. found a greater surgical treatment effect for highly obese patients primarily due to the poor outcomes of nonoperative management.[53] Rihn et al., in an analysis of the as-treated SPORT data, found that duration of symptoms affected outcomes following the treatment of lumbar disc herniation.[54] For patients with symptoms present for more than 6 months prior to seeking treatment, outcomes of nonoperative treatment were statistically significantly worse than those with symptom duration less than 6 months.

Methods of Nonoperative Treatment

Physiotherapy

Bed rest should be limited to no more than 2 to 3 days.[55] Greater periods of inactivity can potentiate prolonged disability and continued or augmented pain. Exercise therapy and physical rehabilitation should be included in the nonoperative care of herniated discs. Treatment goals are to restore strength, flexibility, and function that were lost secondary to pain, splinting, and spasm. Postural education to avoid activities that can increase intradiscal pressure or neuromeningeal tension, or both, should be provided.

Various regimens have been advocated, with none clearly superior. In our practice, physical therapy prescription usually includes torso stabilization training; paraspinal muscle stretching and strengthening; and a focus on gluteal, hamstrings, and abdominal exercises. These muscles are important in the static and dynamic stabilization of the spinal column. Some authors suggest concentration on flexion or extension maneuvers. In our experience, it is difficult, however, to predict if one or both of these movements would aggravate pain or help. Provisions for either flexion or extension concentration, at times combined with lateral shifts, are best left

to the therapist's assessment because the therapist can actively assess what is provoking pain. Concomitant facet arthritis, painful disc degeneration, and muscular pain can influence pain patterns and aggravating movements.

Adjunctive modalities can aid in relieving some associated symptoms. These modalities include ultrasound treatment, electrical stimulation, and massage. These may be helpful in short-term, symptomatic relief of back pain. Traction is also commonly prescribed. It theoretically may diminish intradiscal pressure, increase foraminal dimensions, and possibly relieve radicular pain secondary to herniated discs.[56] The role of chiropractic manipulation is controversial. Although some patients believe that manipulations have "reversed" the herniation, there is no evidence to support the ability of chiropractic manipulation to alter the normal or pathologic morphology of the disc.[57]

Pharmacologic Treatment

Medications can be useful in decreasing disc-related symptoms. Because a local or systemic inflammatory reaction may participate in pain generation, antiinflammatory agents are believed to be beneficial. Nonsteroidal antiinflammatory drugs (NSAIDs) are first-line agents. Numerous choices are currently available, including cyclooxygenase-2 inhibitors. In prescribing NSAIDs, several important issues must be considered. The medications can have side effects. A history of gastrointestinal bleeding or peptic ulcers can be a contraindication to NSAID use. Although this risk is reduced with cyclooxygenase-2 agents, it is not nil, and the patient should be warned of the possibility. Additionally with NSAIDs, other systems, such as the kidneys and liver, may be detrimentally affected.

In the acute setting, back and radicular pain can be severe. Short-term narcotic use, such as a single dose of a morphine-derivative analgesic, can be useful. Narcotics should not be prescribed or administered in an extended manner; they should preferably be limited to a 2- to 3-day course. Also in the acute setting, a tapering dosage regimen of oral steroids can be helpful in decreasing inflammation-generated pain from nerve root irritation. In a randomized, double-blind, placebo-controlled trial of patients with acute sciatica due to herniated disc, Goldberg et al. demonstrated that a 15-day tapered dose of oral prednisone, compared with placebo, resulted in statistically significant, though modest, functional improvement without improvement in pain.[58]

So-called muscle relaxants are frequently prescribed. Although the drug class name implies a direct muscular effect, these medications have more significant sedative effects. Medications such as diazepam and methocarbamol should be used sparingly. Truly antispasmodic medications such as baclofen or cyclobenzaprine can have a more direct effect on muscle spasms.

Selective transforaminal steroid injections can produce symptomatic relief in many patients. In our treatment protocol, injections are offered to patients who have failed noninvasive measures but either are not interested in or are not good candidates for discectomy. In patients with more than one level of herniation, selective nerve root injection can be useful in determining the symptomatic level. That said, similar efficacy in pain relief between fluoroscopically guided epidural steroid injection and local anesthetic injection has been demonstrated in a recent double-blind, randomized controlled study.[59]

In a prospective series touted as a natural history study, Bush and colleagues[60] reported the results of 159 patients with CT-confirmed disc herniations treated with epidural steroid injections. Although 91% avoided surgery, this underscores a glaring problem of so-called natural history studies in that an interventional treatment was used. Although its exact biochemical effects are still being elucidated, steroid injections may be effective in "avoiding" surgery. In an analysis of SPORT data, Radcliff et al. noted that a higher percentage of patients randomized to surgery who subsequently received an epidural steroid injection switched to the nonsurgical treatment group (41%) compared to patients randomized to have surgery who did not have an epidural steroid injection (12%).[61] The authors concluded that this is confounded by the higher baseline desire to avoid surgery in the group of patients who received epidural steroid injections.

With TNF-α being considered a significant contributor to radicular symptoms associated with lumbar disc herniation,[62] recent attention has been paid to delivering anti-TNF-α medications into the epidural space. Freeman et al conducted a multicenter, randomized, double-blind, placebo-controlled phase IIa clinical trial to examine the efficacy of etanercept, a TNF-α inhibitor, injected transforaminally to treat symptomatic disc herniation.[63] Compared to placebo, etanercept was found safe and effective in providing significant therapeutic relief for patients with sciatica. When compared to epidural dexamthasone injection, etanercept has shown similar clinical efficacy in back and leg pain reduction, with no significant difference between the two medications.[64] There has also been recent interest in the use of transforaminal epidural clonidine injections, for its potential to dual action as an antiinflammatory and analgesic,[65] though this remains controversial.

In a well-designed retrospective study, Wang and colleagues[66] studied 69 patients who failed nonoperative (or, more accurately, noninvasive) care and had requested surgery as treatment. Instead, each patient was advised to undergo one or more transforaminal steroid injections at the affected root level. Of patients, 77% had clinical resolution and had not undergone surgery at an average follow-up of 1.5 years. In agreement with other studies, clinical success was not related to disc size, percentage canal compromise, or degree of motor weakness. From these findings, selective nerve root steroid injections seem to produce at least short-term relief of radicular symptoms from a herniated disc.

Operative Versus Nonoperative Treatment

The results of operative and nonoperative treatment for symptomatic herniated discs have been compared in numerous studies. The Maine Lumbar Spine Study group published

1-year and 5-year results of an ongoing comparison of surgically and nonsurgically treated patients.[1,67] More than 500 patients were included in the prospective observational study without stringent clinical or radiographic criteria except for disc-related sciatica treated with at least 2 weeks of nonoperative care within 2 months of onset. The decision to undergo surgery was determined on an individual basis and was not randomized. At 1-year follow-up, surgically treated patients were less symptomatic than patients in the nonoperative group, despite the former being *more* symptomatic at initial presentation. Relief of back or leg pain was reported by 71% of operated patients compared with 43% of the nonoperative group. High satisfaction levels and improved quality of life were documented for the operative group. For the workers' compensation group, there was no difference in time to return to work between operative and nonoperative groups. A criticism of the study is a substantial attrition rate, with 24% of patients unavailable for final follow-up.

In the 5-year outcome report, 70% of surgical patients reported back or leg pain improvement, whereas 56% of nonoperatively treated patients reported improvement.[1] As with the 1-year results, a similar percentage of patients were receiving workers' compensation benefits in both groups with no difference in return to work at final follow-up. Reoperations were performed in 20% of the operative patients; 16% of patients initially treated nonsurgically went on to operation. The authors noted that the benefits of surgery versus nonoperative treatment were greatest in the early part of the study, within the first 2 years, and that at final follow-up these advantages were less apparent.

Most recently, the Maine Lumbar Spine Study Group published their 10-year follow-up results.[7] Of the eligible patients initially enrolled, data were available for 85% of patients treated surgically and 82% of patients treated nonoperatively. A significantly larger percentage of surgical patients reported relief of low back and leg pain than patients treated nonoperatively. Similarly, surgical patients exhibited better function and satisfaction compared with nonoperative patients. Nonetheless, improvement in dominant symptoms was reported for both treatment groups. Work and disability status were similar for both groups.

The 2006 SPORT investigation was designed to be a rigorous, randomized, prospective, controlled study.[8,9,68] In its execution, there was a high rate of crossover between operative and nonoperative groups and a substantial portion of patients not willing to be randomized, resulting in a large observational group. The randomized and observational arms of the investigation reported improvement in bodily pain, physical function, and Oswestry Disability Index (ODI) scores regardless of intervention. In the randomized arm of the study, between-group differences favored surgical intervention, but these differences did not reach statistical significance in an intention-to-treat analysis. With the difficulties encountered with nonadherence to assigned treatments (i.e., crossover), the intention-to-treat analysis may not be reflective of the true outcomes. In an as-treated analysis, surgical treatment showed statistically superior results compared with nonoperative treatment. Similar results were found in the observational arm of SPORT. These results have proven to be durable, as there has been little to no degradation of outcomes in either the nonoperative group or the operative group in 8-year follow-up reports.[69] With the analysis adjusted for the treatment received, operated patients still maintained clinically significant greater improvement in all primary outcomes compared to the nonoperative group, as was reported at earlier follow-up time points.

The classic work by Weber[10] reported similar results to these findings. As briefly discussed in the prior section on natural history, Weber[10] compared surgery versus nonoperative care in a randomized, prospective study. There were three study groups: one group "required surgery"; another showed no indications for surgery; and the third was the "undecided" group, in which it was unclear if surgery would be beneficial. Only the third group was randomly assigned to surgical or nonsurgical treatment.

At 1 year, good results were reported in 33% of the nonoperative group versus 66% in the surgical group; at 4 years, 51% versus 66%; and at 10 years, 55% versus 57%. These findings show that operative and nonoperative treatment outcomes seem to converge with time, being nearly the same at 10 years, and that the benefits of surgery are early. The 5- and 10-year results from the Maine study are similar, although the larger numbers of the Maine study achieved statistical significance. Both studies are flawed by patient selection bias. Weber randomly assigned only patients in the "unclear" group, whereas the Maine group had no specific criteria and included patients per individual physician investigators' usual practice.

Alaranta and colleagues[70] also prospectively compared operated versus nonoperated patients. In contrast to other similar studies, the nonoperative group was subdivided into cases with and without myelographic evidence of nerve root compression, whereas all operated patients had a positive myelogram. At 1-year follow-up, 91% of operated and 82% of nonoperatively treated patients with positive myelograms had improved pain levels. Only 51% of nonoperatively treated patients with negative myelograms had improvement. These data suggest that a distinctly worse natural history exists for patients with sciatica and no evidence of root compression. Although not specified by the investigators, this group probably represents sciatica from an extraspinal or non–disc-related origin. In a companion study published by the same authors, they further identified this group as having a high incidence of generalized pain (e.g., concomitant occipital headaches), more physically strenuous jobs, and lower pain thresholds.[71] This study could possibly point to a preponderance of psychosocial and behavioral factors involved in the perpetuation of the symptom complex.

Operative Treatment

Indications

An absolute indication for lumbar discectomy is a progressive neurologic deficit. In this circumstance, operative intervention may be considered conservative care, provided that no medical contraindications exist. Progressive neurologic deficit

is most commonly associated with a cauda equina syndrome and is discussed in more detail later. The relative indications for discectomy vary among surgeons and patients. Discectomy, in its many shapes and forms, can produce symptomatic relief in appropriately selected patients. It is the surgeon's obligation to identify the patients in whom the anticipated benefits outweigh the attendant risks of surgery.

A prerequisite is radiologic identification of compressive pathology that is concordant with the patient's physical signs and symptoms. A patient with a large left L4–L5 level who presents with leg pain that radiates to the dorsum of the foot, weakness of toe dorsiflexion, decreased sensation in the first dorsal webspace, and a distinctly positive ipsilateral and contralateral SLR is an ideal candidate after failure of appropriate nonoperative treatment. In this "ideal" situation, the clinical and radiologic findings point toward compression of the L5 nerve root. To idealize the presentation further, the patient has a strong desire to return to work; is not involved in litigation, disability, or workers' compensation issues; and does not have any psychological issues. Important questions remain unanswered even in such cases, however, including optimal surgical timing, the method of disc excision, and the postoperative rehabilitation protocol.

Only a few patients match such textbook descriptions. Most patients lack one or more of the supportive diagnostic clues, making it more difficult to support the decision to operate. This situation does not represent a contraindication to surgery, however, because many published series show approximately 85% success rates in patient groups with lesser percentages of objective motor and sensory findings.[3,38,67,72–79] The slim chance of back pain relief in relation to leg pain with discectomy that surgeons obligatorily confess to their patients is also probably an underestimation because most series document at least modest improvements in back pain. It is incumbent on clinicians to discuss the advantages, disadvantages, risks, alternatives, and estimated expected outcomes with patients.

Available Techniques

A vast array of techniques exist for surgical treatment of herniated discs.[80–85] Standard open discectomy is the most common surgical approach.[72,77,86,87] It involves careful incision planning, laminotomy or partial laminectomy to provide adequate visualization of the pathology, gentle retraction of the neural elements, and direct excision of the herniation. As an adjunct to open discectomy, some surgeons advocate the use of a microscope for better visualization and minimizing incision size.[31,79,83,88,89] The purported advantage of the microscope is the ability for the surgeon and the assistant to visualize the operative field equally through a smaller surgical wound.

Alternatives to interlaminar techniques have been developed for excision of foraminal and extraforaminal lateral disc herniations, which involve exposures between the transverse processes and lateral to the pars interarticularis.[14,89] Although some surgeons have advocated the addition of fusion,[76,90] this practice is unpopular.[81] Advocates hold that fusion decreases the chance for reherniation; however, only a complete discectomy with interbody reconstruction can eliminate this risk. Long-term effects such as an adjacent-segment degeneration and the additional morbidity and complication rates are potential disadvantages.[76,81,90,91]

With increased interest in smaller incisions and minimally invasive surgery, various percutaneous methods of treatment have been developed. Some methods entail placement of a cutting device intradiscally to decompress the disc space to retract the herniated fragment.[92–95] Other methods involve percutaneous techniques of directly visualizing the neural elements and disc using an endoscope.[80,96] Chemical digestion of the disc (i.e., chemonucleolysis) had enjoyed popularity in the past. However, enzyme-related complications and results inferior to open discectomy limited continued popularity in the United States.[92,97,98]

Repair of the anulus fibrosus following lumbar discectomy is an emerging technology, with various techniques and devices introduced in recent years. There remains a paucity of published studies concerning the clinical outcomes of newer devices, though data are forthcoming. In one published prospective randomized trial, an annular repair technique did not show statistically significant benefit in patient symptoms, but did reduce the need for subsequent surgery.[99]

Open Simple Discectomy

Timing

Disagreement exists regarding the optimal timing for surgery. The question is how long should nonoperative care be continued (without improvement) before the outcomes of surgery are detrimentally affected? Stated another way, in patients who are not responding to nonoperative measures, when should surgery be performed? In evaluating the currently available surgical results, this interval may be 2 to 16 months. The clear exception to delaying surgery is a patient who is experiencing a progressive neurologic deficit or cauda equina syndrome.

Rotheorl and colleagues[33] stratified operatively treated patients according to time from presentation to surgery. Patients with symptom duration of more than 2 months had a statistically significantly worse outcome than patients operated on within 2 months. There was no difference if surgery was performed within 1 or 2 months. Likewise, Hurme and Alaranta[12] found the best results in patients operated on within 2 months of the onset of disabling sciatica. Nygaard and colleagues[32] reported worse results in patients with leg pain for 8 months or more; Jansson and colleagues[36] found similar results in their analysis of the Swedish registry data, which included greater than 27,000 patients. Sorensen and colleagues[34] found that symptom duration greater than 16 months was predictive of poor results, but this was highly influenced by patient personality and social factors. The disparity between these findings is difficult to explain. Randomized prospective data comparing early versus late surgery are lacking. In our practice, surgery is performed within 6 months from symptom onset if nonoperative care has failed. The important message

is that there is not an urgency to perform surgery. Nerve roots, as compared with the spinal cord, are fairly resilient.

Other factors can influence the time to surgery. Ito and colleagues[40] found that patients with uncontained herniations had surgery much earlier than patients with contained herniations. Specifically, 56% of patients with uncontained herniations and 21% of patients with contained herniations had surgery within 1 month. This finding was not correlated to outcomes but was influenced more by the severity of symptoms. Early surgery does not seem to affect the rate of neurologic recovery; objective improvements in motor and sensory deficits do not seem to correlate with symptomatic relief and overall success rates.[100]

Technique

General endotracheal anesthesia is induced. Alternatively, spinal anesthesia can be used. The patient is carefully logrolled into the prone position. An Andrews frame can be attached to a regular operating table to facilitate the prone kneeling position. Special spine frames, such as the sling attachment for the Jackson (OSI) table (Mizuho OSI, Union City, CA), can be used. These frames allow hip flexion to produce some flexion of the lumbar spine, which widens the interlaminar space (Fig. 47.11). The kneeling position also allows the abdomen to hang free, which helps indirectly to reduce the epidural venous pressure and reduce intraoperative blood loss. One set of hip pads is placed just distal to the anterior superior iliac crest. Adequate padding protects against lateral femoral cutaneous nerve injury. The thighs are allowed to flex at the hip, with the knees resting within the sling. The sling should be positioned low enough to allow adequate hip and knee flexion and is padded with gel pads and pillows. A pad is placed between the knees and medial malleoli to prevent pressure necrosis. The transverse chest pad is placed just above the xiphoid process.

With either table, the arms are placed in the 90-90 position with the cubital tunnels protected. The advantages of the Jackson table include that it allows a one-step turn to the prone position (avoiding the second step of pulling the patient's buttocks to the posterior pads with the Andrews frame) and its complete radiolucency. The disadvantage is that the table cannot be rotated away from the surgeon to allow better visualization by the assistant. With the patient secure, the superior aspects of the crests are palpated and marked; this usually corresponds to the level of the L4–L5 disc space or the L3–L4 interspinous process interval. The midline spinous processes are marked, and the interspinous regions are counted from the sacrum up. The target interspinous space can be indicated with a marker or scratched in the skin using a sterile 25-gauge needle after alcohol skin preparation. If the patient is unusually large and landmarks cannot be palpated, a radiograph can be taken to determine the level of skin incision before preparation. The lumbar region is then prepared and draped. A 3- to 5-cm midline skin incision is made, and can be extended if necessary in obese patients.

The subcutaneous tissue is dissected down to the level of the lumbar fascia. The spinous processes are palpated in the midline. The deep lumbar fascia is incised, on the side of the herniation, adjacent to the spinous process. The fascial incision spans the spinous processes of the adjacent segments. An intraoperative lateral radiograph should be obtained at this time to confirm the correct level. A marker, either a Kocher clamp or a spinal needle, can be placed along the interspinous ligaments. On the radiograph, the marker should point toward the operative disc space. It should angle superiorly in line with the interspinous process space.

The paraspinal muscles are subperiosteally elevated from the lateral aspect of the spinous processes using electrocautery. It is usually necessary to expose only the superior and inferior aspects of the adjacent segments. At the junction of the spinous process and lamina, blunt dissection is performed laterally along the interlaminar space using a large Cobb elevator. Care is taken to expose, but not violate, the facet joint.

A Taylor retractor is positioned to maintain exposure of the interlaminar space. The tip of the retractor is inserted lateral to the facet joint, and the instrument is levered laterally. A roller-gauze is looped underneath the surgeon's foot and tied to the handle of the Taylor retractor. Appropriate foot leverage maintains its position. Alternatively, numerous small retraction systems can be used. Meticulous hemostasis is achieved with a bipolar electrocautery. Extraneous posterior muscle and soft tissues that impair vision should be removed using a large curette and rongeur. The interspinous ligaments should not be disrupted.

A medium-sized curette is used to detach the ligamentum flavum from the inferior aspect of the superior lamina (Fig. 47.12). Because the ligamentum inserts along the anterior aspect of the lamina, the curette needs to be introduced at an angle with the spoon facing cephalad. The instrument is worked from side to side to release all layers of the ligamentum. In some cases, it is difficult to release the ligamentum flavum completely without removing a portion of the inferior

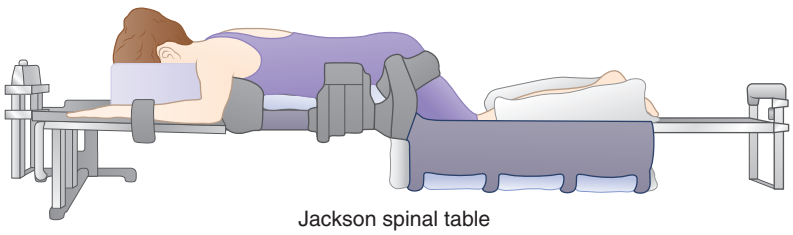

FIG. 47.11 The Jackson (OSI) table can be used to place the patient into a kneeling position, increasing interlaminar lumbar space while allowing the abdomen to hang free.

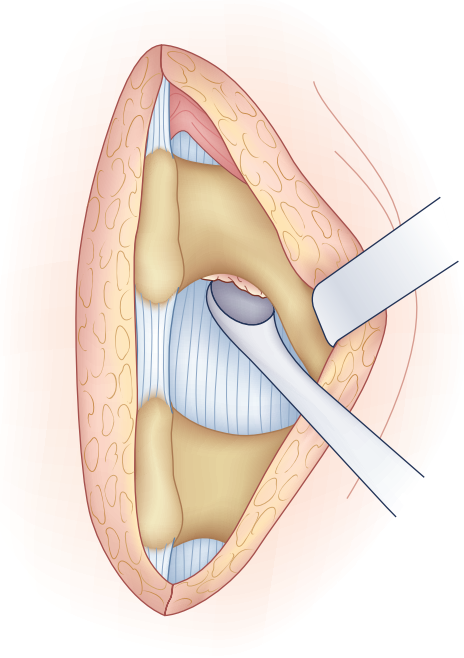

FIG. 47.12 The ligamentum is released from the inferior aspect of the superior lamina. The cup of the curette should face away from the dural sac to avoid inadvertent injury or tear.

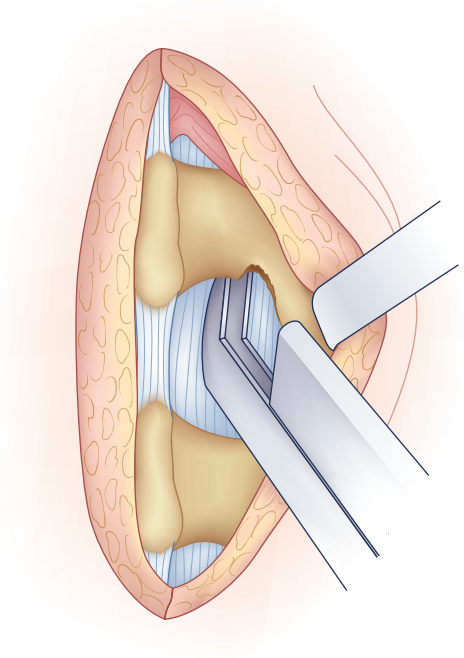

FIG. 47.13 In some cases, particularly above the L5–S1 level, a small portion of lamina must be removed to release the ligamentum flavum fully.

hemilamina (Fig. 47.13). Bone resection can be kept to a minimum but should not be avoided if it jeopardizes the exposure of the cauda equina and nerve root.

After the ligamentum is released superiorly, an angled probe, such as a Woodson elevator, can be inserted just deep to the ligamentum flavum (the yellow ligament). The Woodson elevator is positioned along the periphery near the bone. A long-handle No. 15 blade scalpel is carefully used to incise the flavum directly on top of the Woodson elevator, which protects the dural sac deep to it, which may often be displaced posteriorly by a large herniated disc. The blade should not be inserted deep to the ligament or the elevator. If concerns exist, the ligamentum flavum should be incised layer by layer with consecutive passes of the blade until the Woodson elevator pops through; this is continued along the periphery of the interlaminar window. Optionally, the medial aspect of the ligamentum flavum can be left attached, and the ligamentum can be flapped open. At the completion of the discectomy, the flap can be replaced to act as a barrier against epidural adhesions.

With the ligamentum retracted or removed, epidural fat is visualized. In some cases, the fat layer has thinned from a displaced or inflamed nerve root. If present, the epidural fat is swept away from the dura with a Penfield No. 4 elevator. The focus of this maneuver is to identify the lateral aspect of the exiting nerve root and cauda equina. Epidural vessels are coagulated using irrigating bipolar cautery, as necessary.

A medial facetectomy often must be performed to visualize the nerve root adequately. A 3-mm or 4-mm Kerrison rongeur can be used in a back-hand manner to resect the medial aspect of the facet joint. Excessive resection should be avoided because the integrity of the facet and pars interarticularis is crucial to maintaining stability. It is wise to protect the underlying dura by pointing the Kerrison rongeur in the direction of the exiting nerve root. The endpoint of resection is adequate visualization of the shoulder of the descending nerve root adjacent to the medial border of the pedicle.

Before discectomy, a blunt-tipped probe is passed along the root and out the foramen to assess the amount of space available. Using a Penfield No. 4 elevator, the nerve root is mobilized medially. This mobilization can be facilitated using the bipolar cautery to lyse adhesions between the dura and the posterior disc. Retracting the nerve root medially shows the posterior anulus or the herniated fragment, or both. A nerve root retractor is used to maintain retraction (Fig. 47.14).

The disc fragment may be extirpated using the Penfield elevator to ensure that it is free of dural adhesions. With clear visualization of the fragment and its distinction from the neural elements, a pituitary rongeur can be used to explant it. If the fragment is extruded or sequestered, one can often identify a tear in the posterolateral or central anulus. If the herniation is subligamentous, a No. 15 blade scalpel can be used to create a small annulotomy to gain access to the herniated nuclear material. A pituitary rongeur can be carefully inserted into the annular defect to remove the fragmented disc.

Caution must be used when removing an axillary disc herniation. The fragment is easily visualized, tempting the surgeon to proceed directly with excision with the pituitary rongeur. Removal of large fragments that extend deep to the cauda equina and nerve root can lead to excessive bleeding from the transverse anastomoses of the epidural veins in the axillary region. It is preferable to retract the root medially and remove the fragment from a lateral approach, if possible.

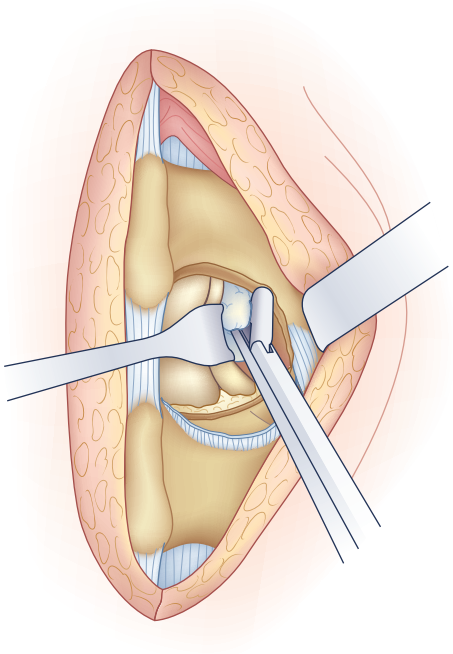

FIG. 47.14 A nerve root retractor is used to retract gently the descending nerve root and cauda equina toward the midline to visualize the disc space and herniation.

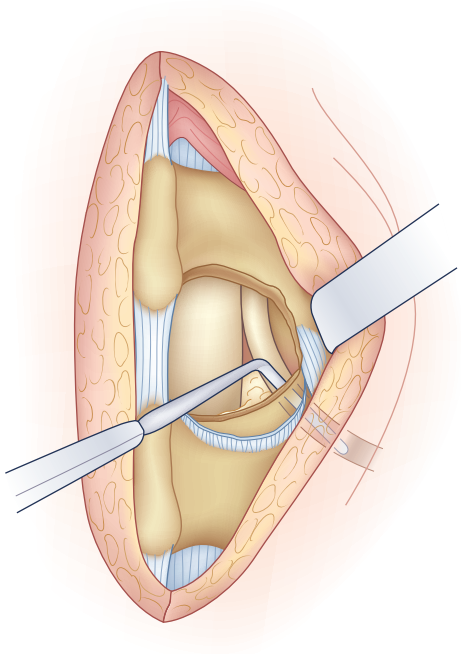

FIG. 47.15 After the herniated fragment has been removed, the spinal canal should be systematically inspected for any remaining fragments. A Woodson elevator is used to ensure that the neural foramen and nerve root are free. If the root is not completely free, additional fragments or compression may be present.

The mobility of the nerve root is assessed using a Penfield No. 4 or Woodson elevator (Fig. 47.15). After discectomy, the nerve root should be freely mobile and under no tension or compression. If it is not, additional pathology should be suspected. Using a Woodson elevator, the epidural space must be systematically inspected in a clockwise fashion, checking the canal ventral to the thecal sac and the patency of the foramen. A concomitant lateral recess or foraminal stenosis from bony encroachment is decompressed with Kerrison rongeurs. Finally, the disc space is irrigated with normal saline to dislodge any remaining loose fragments.

If the ligamentum flavum was spared, it can be loosely replaced. A fat graft placed over the dura does not improve clinical results but does facilitate reexploration and theoretically prevents adhesions from inhibiting normal neuromeningeal motion.[101,102] The wound is copiously irrigated. Adequate epidural hemostasis is ensured before closure. In most cases, a drain is not needed. All retractors are removed, and the deep lumbar fascia is approximated with interrupted No. 1 absorbable suture. The subcutaneous layer is closed in two layers, and the skin is approximated with a subcuticular stitch or staples. The wound is cleaned, and a sterile dressing is applied.

Postoperative Care and Rehabilitation

After an uncomplicated simple open discectomy, the patient is discharged on postoperative day 1 or 2. Outpatient discectomy can be performed on selected patients with appropriate presurgical planning and postdischarge discussion.[86] The level of activity in the first week after surgery usually is limited by incisional pain. If leg symptoms were predominant preoperatively, the patient typically reports immediate relief.

The activity level recommended after surgery varies among surgeons. Concerns are that aggressive movements and loads can predispose to reherniation or excessive scarring. This concern leads many surgeons to limit lifting and bending after discectomy for about 3 to 4 weeks. Although this is probably the predominant practice, there is little literature to support such extended periods of protected activity.

Unrestricted activity protocols have shown success rates comparable to other series. Carragee and colleagues[87] conducted an uncontrolled, prospective trial of 152 patients who were allowed full activity after lumbar discectomy. Approximately one-third of patients returned to work in 1 week, with most (97%) returning to work within 8 weeks. Recurrent sciatica occurred in 17 patients and was considered possible reherniation (11%). Nine of these patients experienced improvement, and eight underwent repeat surgery. This rate is similar to reherniation rates previously reported, which have ranged from 0% to 13%. Carragee and colleagues[87] concluded that an unrestricted activity protocol does not negatively affect results after discectomy.

Other studies have focused on possible advantages to an early rehabilitation protocol after discectomy. Kjellby-Wendt and Styf[103] performed a prospective, randomized, controlled study comparing an early active versus traditional training program. The focus of early activity was to reduce lumbar edema and maintain mobility of the neural elements through motion and trunk-strengthening exercises. A pain-coping program was included in the early active group that was not included in the traditional group. There was greater range of motion and decreased pain at 12 weeks in the early group.

At 1-year follow-up, both groups were equivalent. Patient satisfaction was ultimately greater in the early active group (88%) versus the control group (67%), although this was not statistically significant. In critique of the study, it was unclear why the difference in subjective outcome was not accompanied by sustained objective benefits. Inclusion of the pain-coping program in the study group, which would have minimal influence on range of motion, may have positively influenced patients' perception of their residual impairment. In support of the findings by Carragee and colleagues,[87] there was no difference in reherniation rates between the two groups.

Gencay-Can and colleagues performed a clinical trial comparing patients undergoing lumbar discectomy treated with a supervised aerobic exercise program starting 1 month after surgery in addition to home exercises with patients performing home exercises alone.[104] While there was no significant advantage in visual analog scale (VAS) back and leg pain, there was significantly better functional improvement in the aerobic exercise group as measured by the Roland Morris Disability Index. As one may expect, the functional recovery did not carry forward once the exercise program was discontinued.

Alaranta and colleagues[105] performed a randomized trial comparing an "immediate" versus "normal" rehabilitation program. Physical activities, such as sports and games, were encouraged in the immediate activity group; psychological and social counseling were also provided. Details of the normal rehabilitation protocol were not provided. At 1-year follow-up, there were no differences in subjective outcomes, postoperative impairments, or return-to-work statistics. These results further indicate that early activity programs do not seem to be harmful but offer only minimal, if any, long-term benefits. Our decision to initiate early return to unrestricted activity is made on an individual basis.

Outcomes

The outcomes of surgical discectomy are reliable when one adheres to strict preoperative selection criteria. Factors that can influence these outcomes, such as location of the herniation, preoperative psychological status, surgeon experience, and work status, have been extensively analyzed.

Carragee and Kim[11] correlated operative outcomes with herniated fragment size and its effect on the canal area. Using axial MRI, these authors recorded several parameters, including disc area, canal area, AP disc length, and AP canal length. Patients with larger discs (>6 mm) were more likely to have positive SLR or femoral stretch tests. Comparing patients with operative and nonoperative treatment, the former had larger AP disc lengths and larger ratios of disc to canal area. In the operative group, larger discs were predictive of a better outcome. In the nonoperative group, symptom duration less than 6 months before presentation, no litigation, and younger age were predictive of a better outcome. All of the fair and poor outcomes in operative patients were in patients with small discs (<6 mm). Summarizing these findings, it seems that larger discs respond to surgery better than small discs and that disc size is less predictive of outcomes in the nonoperative group. A criticism of this study involves the existence of a selection bias because the decision to treat operatively was nonrandomized.

Knop-Jergas and colleagues[106] analyzed the results of lumbar discectomy based on anatomic location. They characterized herniations as central, paracentral, intraforaminal, extraforaminal, or multiregional broad-based protrusions. The best outcomes were documented with paracentral and intraforaminal discs, with 80% yielding good or excellent results. Central discs and multiregional discs had worse results, with 47% and 54% good or excellent outcomes. There was only one extraforaminal disc, which had a poor outcome. The level of herniation was not predictive of outcome, with 59% occurring at L4–L5.

In contrast, other authors have found that the level of herniation can affect operative outcomes. Dewing and colleagues[107] reported that discectomy for L5–S1 herniations had significantly greater improvements in VAS leg and ODI scores compared with L4–L5 herniations. These authors also found that patients with sequestered disc fragments had significantly better outcomes than patients with contained disc herniations. In a post-hoc analysis of SPORT trial data, Pearson and colleagues[68] examined the influence of disc herniation location (central or lateral) and morphology (protrusion, extrusion, or sequestration) on the results of operative and nonoperative treatment. Their data suggest that the advantages of surgical treatment over nonoperative treatment were greatest for patients with lateral disc herniations. The magnitude of improvement from surgical treatment was not related to the location or morphology of the herniation.

Various preoperative and postoperative findings may also be predictive of results. Barrios and colleagues[73] found that the use of (and positive response to) traction as part of preoperative conservative treatment was predictive of a good outcome with surgery. In agreement with other studies, patients with sedentary, non–physically demanding jobs had better results than patients with more strenuous occupations. Jansson and colleagues[36] found that reduced preoperative walking distance and a history of back pain greater than 6 months were predictors of lower functional outcomes after discectomy. Jonsson and Stromqvist[108] found a persistently positive SLR test to be a reliable indicator of inferior results; this was particularly evident in patients in whom the test was positive for more than 4 months after discectomy.

As part of an ongoing study of lumbar discectomy, the Maine group published an investigation comparing operative rates and outcomes between high versus low rate of surgery regions within the state.[109] The data suggest that, in the high-rate region, the results were inferior compared with the low-rate region. These calculations were based on the rate of surgery per capita (population). The investigators concluded that this difference was most significantly related to the surgical indications used by the individual physicians and that, in the higher-rate areas, the indications may have been less stringent. This might have been true, but an additional factor was not highlighted, which we calculated from the data. In the high-rate region, there were more surgeries done per capita,

but the number of operations done per physician was lower, averaging 11 surgeries per surgeon. In the low-rate region, surgeons averaged 26 operations each, although the overall rate of surgery was lower per capita. This factor directly supports previous analyses of the results of total joint arthroplasty, which indicate better results in high-volume hospitals because of concentrated experience. From these data, discectomy is optimally performed by an experienced, high-volume surgeon who employs strict indications.

Psychological and social factors have been shown by many investigators to influence profoundly the surgical results of lumbar discectomy.[34,74] Sorensen and colleagues[34] found that preoperative psychological assessment was 86% predictive of surgical results after discectomy. Cashion and Lynch[74] found that patients with a good outcome were more self-confident individuals, were only mildly depressed, and were generally optimistic about the outcome of surgery. Slover and colleagues[35] found that a history of chronic headaches, smoking, depression, and self-rated poor health were associated with poor outcomes after discectomy. Jansson and colleagues[36] found that smoking was the most significant risk factor in patients who failed to improve after surgery. Olson et al. found that patients with higher education level demonstrated significantly greater improvement with nonoperative treatment, while surgical outcomes were not affected.[110]

With increased attention on the use of opioid analgesics in the United States, Radcliff et al. examined whether the use of these agents had an effect on outcomes for patients with lumbar disc herniation.[111] While patients who were treated with opioids had significantly worse baseline pain and quality of life, at 4-year follow-up, there was no long-term difference in outcome associated with opioid medication use. They also found that opioid use was not associated with surgical avoidance.

Spengler and colleagues[13] calculated preoperative assessment scores for 84 patients before discectomy and correlated these with outcomes. The four components of the score were neurologic signs, clinical tension signs, psychological factors, and imaging evidence of neural compression. Imaging studies were most predictive of operative findings but not of outcome. The best predictor of outcome was the psychological score. This was based on the Minnesota Multiphasic Personality Inventory.

Hurme and Alaranta[12] prospectively studied 220 patients after discectomy, analyzing preoperative and perioperative factors. Optimistic patients had better results. Patients who preoperatively decided not to return to work had poorer outcomes. Patients who perceived their jobs to be physically strenuous had inferior results. The most predictive factors of a poor outcome were the decision not to return to work, marital status (divorced or widowed), age older than 40 years, a protracted period of sciatic pain, and multiple nonspecific somatic complaints. Predictors of good results were a high preoperative pain index, higher education level, overall satisfaction with life, and the perception that the patient's job was of light or suitable duty. Patients with a highly positive SLR test and younger patients with large disc herniations tended to have better results. This study highlights the importance of psychological, social, and objective physical factors in predicting the outcome of lumbar disc excision.

Dvorak and colleagues[112] retrospectively applied a set of "accepted" operative indications—including radicular pain, positive SLR, contralateral SLR, dermatomal hypesthesia, motor deficit, and diminished deep tendon reflexes—to a series of patients who underwent discectomy. Of the patients, 65% fulfilled these criteria, and 35% did not. The long-term outcomes were not significantly different between these two groups. Patients who returned to work postoperatively were on disability compensation less than 2 months before surgery, whereas patients who did *not* return to work were on disability compensation an average of 4 months before surgery. Indications based on objective physical findings alone do not ensure a satisfactory outcome. The preoperative period of disability is a significant factor.

Some proponents of microscopically assisted discectomy purport that results are superior compared with standard techniques. In a published review of the literature by one of the strongest advocates of microdiscectomy, McCulloch[88] concluded that the available data are insufficient to show its superiority. He noted that successful results have ranged from 80% to 96%, regardless of the technique used, and highlighted the importance of patient selection as the more important determinant of outcome. Series of microsurgical discectomy report comparable rates of complications, such as dural tear and recurrent herniations.[113,114] In a report with 5-year follow-up, long-term outcomes for minimally invasive techniques are comparable to those reported using standard techniques.[115] It is important to note that radiation exposure to the surgical team and the patient can be 10 to 20 times greater with the use of minimally invasive techniques.[116]

There is disagreement regarding the efficacy of simple fragment excision (the so-called Williams sequestrectomy[117]) versus more extensive nucleus curettage. In a retrospective study of 200 patients, Faulhauer and Manicke[77] showed a lower reherniation rate with fragment excision alone. This comparison was inherently flawed. The standard discectomy group, by definition, had herniations that were in continuity with the disc space and could be characterized as subligamentous (contained). The fragment excision group obligatorily had displaced fragments that were not contained within the disc space. The most useful information perhaps is that when an extruded or sequestered (uncontained) fragment is found, acceptable results with a low herniation rate can be expected with fragment excision alone. Although aggressive methods of removal of further nuclear material may not be warranted, meticulous examination of all quadrants of the epidural space surrounding the nerve root and cauda equina should be performed in each case to avoid missing disc fragments.

Balderston and colleagues[72] compared 40 patients who underwent simple fragment excision in one center with 40 patients who underwent excision and curettage in another center. The reherniation rate was not significantly different: 12.5% in the former group and 11.6% in the latter group. There was also no difference in the rate of disc space narrowing between the two groups. The only difference was a higher rate

of postoperative back pain in the curettage group at a minimum 2-year follow-up. In distinction to Faulhauer and Manicke's work,[77] the types of disc herniation were not different between the two groups.

Carragee and colleagues[118] reported the results of a prospective, controlled study comparing subtotal versus limited discectomy. In the latter group, only the extruded disc material and loose fragments present in the disc space were removed. In the former, a more aggressive disc space curettage and debridement was performed in addition to removal of the extruded fragments. Early findings suggested a shorter convalescence in the limited discectomy group but decreased VAS and ODI scores in the subtotal group. These differences were not statistically significant at 2-year follow-up. Although the reherniation rate in the limited group was 18% compared with 9% in the subtotal group, this difference was not significant with the numbers available. Type II (beta) error cannot be excluded, however, because a significant difference may have been detected with greater patient numbers. The clinical significance of a 9% difference in reherniation rate may outweigh the lack of statistical significance.

Complications

Numerous complications can occur with lumbar discectomy, albeit at acceptably low rates. Recurrence rates range from 0% to 18%. In addition to differences in surgical technique and other factors, this broad range may reflect differences in the definition of recurrence. In some series, *recurrence* is defined as recurrent sciatica, whereas in others use of the term is limited to patients who required reoperation. The strictest definition is a true reherniation at the level and side previously operated, which ultimately leads to a frequency of 2% to 5%.

Wound infections have been reported in 0% to 3% of cases.[12,72,77,84,86,117] These may be superficial or deep. Superficial infections may be managed with local wound care and antibiotics. Deep infections should be surgically debrided and irrigated. Epidural abscess is rare, with reported rates of 0.3%, and should be managed with surgical evacuation.[119] The microscope has been considered a possible source of contamination because of the exposed unsterile optics that are in close proximity over the wound.[88,120] Infection rates are comparable, however, to cases performed without the microscope.

Pyogenic discitis may occur after discectomy 2.3% of the time.[12,119] Early detection is crucial in avoiding extensive bone involvement. Intravenous antibiotic therapy is usually successful, with rare cases requiring surgical debridement. MRI findings, including increased bone edema near the endplates and loss of disc space height, are difficult to discern from typical degenerative Modic-type changes. Laboratory evidence, such as elevated erythrocyte sedimentation rates and C-reactive protein levels, is important in confirming the diagnosis.

Vascular injuries are exceedingly rare. Injury to anterior vessels from perforation of the disc space have been documented in a few case reports.[121,122] Arteriovenous fistula has also been documented.[123,124] The most important component of managing these complications is prompt recognition and aggressive treatment, including vascular repair. Excessive epidural bleeding is uncommon, although one series documented blood loss of more than 300 mL in 4% of cases.[12]

Incidental durotomy occurs 0% to 4% of the time.[8,72,84,113,125] It has been associated with a poor outcome in some series. At an average of 10 years after surgery, Saxler and colleagues[125] reported a lower rate of symptom resolution and a greater rate of chronic pain and headaches in patients who sustained an incidental durotomy. This study did not discern between primary and revision cases, which may have been a potential confounder. The potential for long-term clinical sequelae after incidental durotomy during discectomy is most likely influenced by the size of the tear, the ability to repair it, and the coexistence of neurologic injury.

Instability is quite rare after discectomy. Preservation of the facet joints is helpful in avoiding this sequela, although in our experience, a large percentage of the facet joint can be resected unilaterally without adverse effect. Some authors have indicated that instability can occur 30% of the time. This percentage is highly dependent on the definition of instability. Padua and colleagues[126] found radiographic evidence of instability, detected by flexion-extension films, in 20% of patients who underwent discectomy. Only 6% seemed to be symptomatic, however. In contrast, Faulhauer and Manicke[77] defined instability by clinical findings, such as apprehension with flexion or extension, instead of radiographic measurements. These authors reported rates of 16% and 30% with two different operative techniques; 3% had severe enough symptoms to warrant a brace, and only one patient eventually went on to fusion. Kotilainen and Valtonen[119] found that the presence of clinical apprehension postoperatively was predictive of a poor result after surgery. These data highlight the importance of documenting preoperative radiographic and clinical instability so that the effects of the discectomy itself can be better assessed in the postoperative period.[127] Biomechanically, simple discectomy is not a destabilizing procedure if performed properly.

Recurrent Disc Herniations

The distinguishing histologic feature of recurrent disc herniation is the presence of large collagen bundles associated with a fibrillar framework.[128] Granulation tissue found in recurrences is not present in primary disc herniations. This fact indicates that the pathophysiology of recurrent disc herniations may be different than in primary cases.

Depending on the definition, recurrent disc herniations can occur in 18% of cases. Clinical presentation is usually of recurrent sciatic leg pain. Jonsson and Stromqvist[129] attempted to determine the relative frequency of clinical signs and symptoms after discectomy to differentiate better perineural fibrosis from true recurrent herniation. Pain reproduced by cough and a positive SLR were more frequent with recurrent disc herniations. These findings were also present in many

patients with fibrosis alone, however; thus, imaging modalities are crucial to the diagnosis. As discussed previously, MRI is best delayed for at least 6 months after surgery.

Recurrences can occur at the same level, same side, opposite side, or entirely different level. To be considered a recurrence, there must have been a pain-free (or relief) time period after the index surgery. A nonoperative treatment regimen, including a period of observation, physical therapy, medications, and other modalities, should be used in the initial treatment of recurrent disc herniations unless progressive neurologic deterioration occurs.

Important questions arise after the decision to proceed with surgery is made. The main focus of current investigations is whether or not comparable or inferior results can be expected after discectomy for a recurrent disc herniation. Some authors have documented inferior results after repeat surgery,[130] although most failures were reported in patients operated on without imaging evidence of neural compression.

Suk and colleagues[131] retrospectively examined their results in a highly select group of patients. Recurrence was defined as a reherniation at the same level (ipsilateral or contralateral) after a pain-free interval of 6 months or more. These authors used gadolinium-enhanced MRI to confirm the diagnosis. They found that the second surgery was significantly longer and that recurrent disc herniations were typically larger. Clinical success was documented in 71.1% of cases, which was comparable to their results after primary discectomy (79.3%). In a similar study, Cinotti and colleagues[132] examined their results with same-level contralateral reherniations only. At 2-year follow-up, surgery for recurrences resulted in satisfactory outcomes in 88% of cases and in 90% of primary discectomies. The only difference noted was more back pain in the reherniation group at 6 months, although this difference was not noted at 2 years.

Cinotti and colleagues[133] also studied a group of patients with ipsilateral lumbar disc reherniation and compared these patients with patients after primary surgery as a control group. Satisfactory results were reported in 85% of patients with ipsilateral lumbar disc reherniation and 88% of control patients. Noted differences were a higher degree of disc degeneration in the recurrence group. Although epidural fibrosis was abundant in the study group, its presence or amount did not adversely influence outcome. There was no difference in the psychological profiles of recurrent versus primary discectomy groups. In a similar study, Papadopoulos and colleagues[134] reported 85% improvement after discectomy for reherniations compared with 80% improvement for primary herniations at an average of 53.6 months follow-up. Herron[135] reported 69% good and 24% fair results after laminectomy and discectomy for recurrences at the same and other levels.

Most authors do not recommend fusion after a first-time recurrent disc herniation.[135,136] After any lumbar surgery involving facetectomy and bone resection, preoperative and intraoperative assessment of stability is a major determinant of the decision to fuse. Although investigational evidence is lacking, we consider fusion after a second reherniation at the same level.

Discectomy in Children

The role of trauma in causing disc herniations in children is believed to be more significant than in adults.[3,137,138] Children are unlikely to have disc degeneration or the antecedent period of back pain before herniation. Clinical signs and symptoms are similar to adults but are much more acute in onset. The clinical and imaging evaluation is similar to adults.

The literature of discectomy in children reveals prolonged length of follow-up. Initial results are excellent, but results tend to deteriorate with time. At 1-year follow-up, Papagenlopoulos and colleagues[139] reported 93% good or excellent results. At final follow-up, ranging from 12 to 45 years, 92% were good or excellent; however, there was a 28% reoperation rate. Parisini and colleagues[140] documented 95% success at short-term follow-up, whereas at long-term follow-up (average, 12.4 years), good or excellent outcomes were documented in 87% of cases. These investigators found a 10% reoperation rate at 10 years. DeOrio and Bianco[141] showed 96% good or excellent results at initial follow-up, trending down to 74% at final examination. Numerous other series document similar results.[3,137,142]

Fusion has been reported in a small percentage of pediatric patients. Well-defined selection criteria are lacking, however. The influence of congenital anomalies has been considered previously. There does not seem to be a correlation between any one anomaly and disc herniation. It is important to recognize anomalies, such as spina bifida, during routine preoperative planning to avoid iatrogenic neurologic injury.

Discectomy in Elderly Patients

Lumbar disc herniations are much less common in elderly patients. The nucleus desiccates with age and is less likely to herniate. Underlying stenosis and bony overgrowth is a more common problem. Regardless, herniations can still occur, with or without the presence of stenosis. The results of discectomy in this population are comparable to younger patients, assuming the correct diagnosis is made.

Maistrelli and colleagues[143] reported results of discectomy in 32 patients older than 60 years. Clinical findings were similar, with 81% of patients having root tension signs such as a positive SLR. At an average follow-up of 50 months, good or excellent results were found in 87% of cases. None of the patients had evidence of neurogenic claudication, which is an important distinguishing feature when making the diagnosis of a disc herniation versus stenosis. Jonsson and Stromqvist[144] also found disc surgery to be gratifying in patients older than 70 years, with good results documented at 2-year follow-up.

Foraminal and Extraforaminal (Far-Lateral) Herniations

So-called far-lateral disc herniations require special consideration. Surgical excision is more easily accomplished through

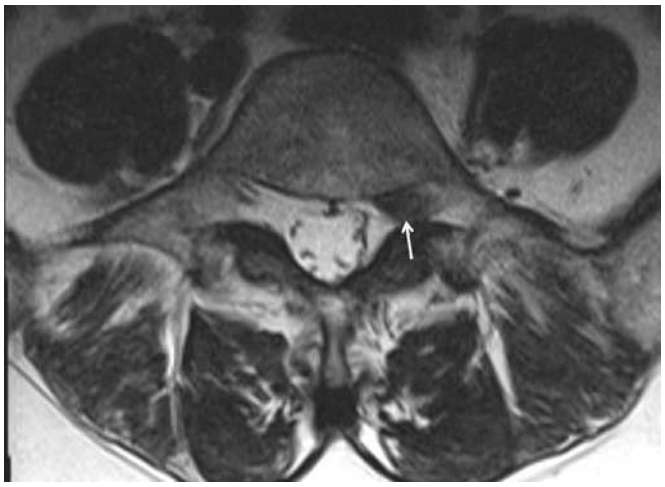

FIG. 47.16 Magnetic resonance imaging can readily show foraminal disc herniations that may otherwise be missed by computed tomographic or plain myelograms because neural compression is extradural.

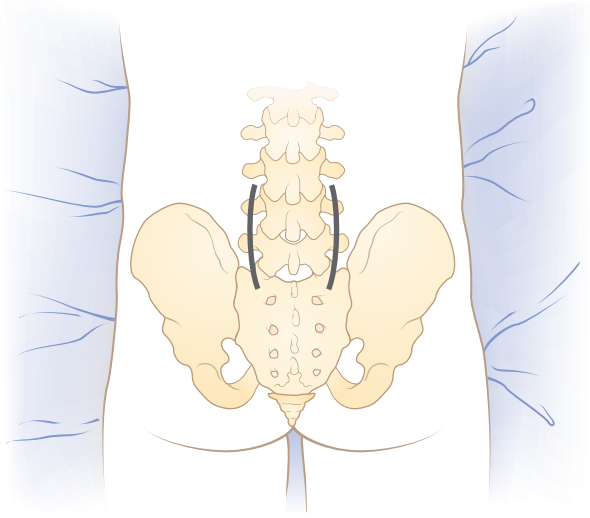

FIG. 47.17 The Wiltse muscle-splitting approach, using a paramedian incision, can be used to access the intertransverse process region.

modified operative techniques. Foraminal and extraforaminal disc herniations are more common in older patients. Symptoms are more likely to be isolated to one particular nerve root. In contrast to paracentral discs, they lead to compression of the exiting nerve root rather than the descending root. Diagnosis is best by MRI or CT (Fig. 47.16). Because the compression is usually extradural, myelography does not show a filling defect.

Different techniques have been advocated for the foraminal or extraforaminal herniation. Compression of the nerve root occurs outside of the spinal canal, making visualization of the herniation challenging through a standard laminotomy or laminectomy performed from within the canal. Garrido and Connaughton[145] advocated a unilateral facetectomy. Bone is removed along the entire path of the nerve root from its exit from the cauda equina out and through the foramen; this necessitates complete removal of the facet on the side of exposure. Although symptom relief was not well documented, painful radiographic instability was detected in only 1 of 35 (3%) cases. This patient had pain relief after fusion.

Donaldson and colleagues[146] advocated a less destabilizing procedure. They considered identification of the nerve within the intertransverse process "blind." As a solution, they performed a partial hemilaminectomy at the level above the disc at the point where the root exited the cauda equina. They followed it laterally beneath the bone of the remaining pars interarticularis. By placing a probe over the root and advancing it laterally, they were able to identify the root and facilitate its dissection between the transverse processes before discectomy was performed through this interval. They reported good or excellent pain relief in 72% of patients. No cases of instability were reported.

Melvill and Baxter[14] used the intertransverse approach for discectomy in 40 patients with extraforaminal herniations. They performed this using standard midline dissection that was extended subperiosteally out and over the facets to expose the transverse processes. This is in contrast to the classic description of the Wiltse paraspinal muscle–splitting approach. Complete resolution of leg pain was reported in 85% of cases. Melvill and Baxter[14] noted a fibrous band that was present tethering the nerve root to the lateral aspect of the disc in an associated cadaveric study.

In an investigation with midterm follow-up, satisfactory results were reported using the Wiltse paraspinal muscle–splitting approach for so-called lateral disc herniations.[147] Satisfaction was reported by 85% of patients, with 60% of patients reporting complete resolution of pain. At 5 years' follow-up, 20% of patients had developed some degree of instability, half of whom ultimately underwent fusion. Assuming uniformity of the definition of instability and indications for fusion in these cases, this finding is supportive of the hypothesis by McCulloch and Transfelt[31] that lateral disc herniations were a precursor to the development of degenerative spondylolisthesis.

A thorough knowledge of the anatomy in this region is imperative to performing an effective discectomy without undue bleeding or injury to the nerve root.[89] We prefer to excise foraminal or extraforaminal discs through a true Wiltse paraspinal muscle–splitting approach to the intertransverse interval. It is easiest through a paramedian incision (Fig. 47.17). Identification of the correct level of incision is crucial in minimizing the length of the incision.

Cauda Equina Syndrome

Cauda equina syndrome (CES) most commonly occurs from a herniated lumbar disc. It is more common with central herniation (27% of central herniations), although it can occur with paracentral or lateral herniations as well.[148,149] It is more frequent in men in their fourth decade. The odds of developing CES are significantly higher in overweight and obese individuals.[150] An L4–L5 disc is the usual cause.[148] CES should be considered a true surgical urgency because neurologic results are affected by the time to decompression. The clinical

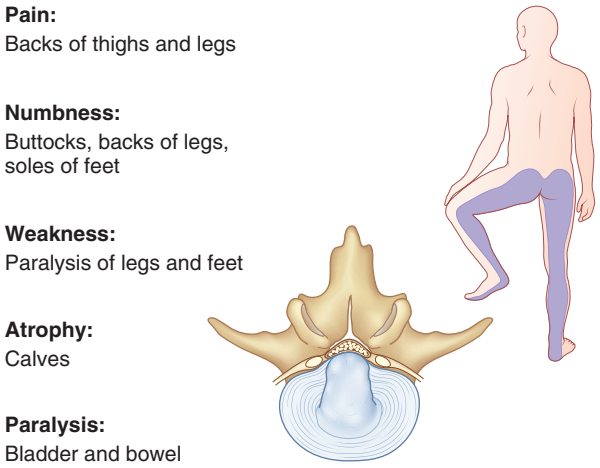

FIG. 47.18 Cauda equina syndrome is characterized by saddle anesthesia, motor weakness, and loss of bowel and bladder control.

diagnosis of CES relies on many components, including perineal sensory deficit (so-called saddle anesthesia), bowel or bladder incontinence, new-onset lower extremity sensory deficit, and a new or progressive motor deficit (Fig. 47.18). In addition to a meticulous physical examination, evaluation of CES should include measurement of a bladder postvoid residual. Normally, the postvoid residual should be less than 50 to 100 mL. The postvoid residual is often abnormal preoperatively and can be an important parameter to follow postoperatively.[151]

Decompression and discectomy can be via a laminotomy or through a formal laminectomy. Proponents of laminectomy believe that this provides superior visualization of the dura and avoids excessive traction.[152–154] Adequate exposure is particularly relevant for removal of central disc herniations.

The effect of timing of surgery on outcomes continues to be debated. Although a number of studies have reported that surgical decompression within 48 hours of the onset of symptoms is a safe time point within which to perform surgery, more recent systematic reviews have concluded that there is no strong support for the often-cited 24- or 48-hour thresholds nor that the earlier the decompression, the better the outcomes.[151,154–156]

DeLong et al., in a metaanalysis of a number of observational cohort series, found a statistically significant relative risk for timing of surgery greater than 24 hours.[157] These authors remarked that higher-quality scientific study is difficult to obtain on this subject since equipoise is lacking, making a prospective randomized study difficult to execute. In analyzing the effect of early surgical decompression on urinary function, it is important to differentiate patients who have incomplete cauda equina syndrome (CES), characterized as "altered urinary sensation, loss of desire to void, poor urinary stream, and the need to strain in order to micturate" from CES with retention, characterized as "painless urinary retention and overflow incontinence, when the bladder is no longer under executive control," the former of which was found to have a better prognosis.[158] In one study, decompressive surgery within 24 hours of onset of autonomic symptoms in CES reduces bladder dysfunction at initial follow-up, while no statistically significant difference was observed in CES with retention regarding timing of operation.[159]

Strength may continue to improve for 1 year after surgery.[154] Although the postvoid residual usually decreases to less than 110 mL by 6 weeks, bladder function may continue to improve for 16 months.[149] Early surgery does not seem to substantially affect the resolution of postoperative pain compared with delayed intervention.[160] In a systematic review of the literature reporting dysfunction of micturition, defecation, and/or sexual dysfunction following CES secondary to herniated disc, Korse and colleagues reported considerable continued impairment. At a minimum of 17 months follow-up, 42.5% of patients reported micturition dysfunction, 49.6% reported defecation dysfunction, and 44% reported sexual dysfunction.[161] Above all, preoperative neurologic status seems to be the greatest predictor of recovery.[162] This is evident in that many patients are found to have residual neurologic deficits despite timely and effective surgical intervention.[160]

Alternatives to Standard Discectomy

Endoscopic Discectomy

The use of the endoscope to perform lumbar discectomy has enthusiastic proponents. Improvements in equipment have made the technique more user-friendly and facile. Still, endoscopic discectomy remains a technically demanding procedure, and the results depend heavily on surgeon experience.[163] It is beneficial to have prior training in minimally invasive spine surgery.[164] Although it is not yet a replacement for standard discectomy techniques, more recent series have shown the ability to achieve comparable results in some surgeons' hands.[80,165,166]

Purported advantages of endoscopic lumbar discectomy include less intraoperative blood loss and smaller surgical wounds. A study by Pan and colleagues did not show a significant difference in patient-reported pain when comparing endoscopic and traditional open discectomy, though postoperative inflammatory markers such as interleukin-6 and C-reactive protein were reduced in the endoscopic group.[167] DeAntoni and colleagues[96] reported results of translaminar epidural endoscopic discectomy in 190 patients. Using a lateral decubitus position, the technique uses a small paramedian incision for introduction of the instruments. Dilators are used to strip the muscles subperiosteally from the adjacent lamina as far lateral as the facet joint. The arthroscope (endoscope) is inserted through a 6-mm working cannula. An additional lateral paraspinal incision is made for an outflow cannula. A shaver is used to remove bone within the interlaminar window until the attachments of the ligamentum flavum can be visualized. The ligamentum flavum is elevated using a Penfield dissector and removed with a Kerrison rongeur, similar to a standard open approach. A root retractor pulls the nerve root and dura medially, allowing access to the disc space. The anulus is incised, and the herniation is removed. The endoscope can be inserted into the disc space to look for any additional loose fragments (so-called discoscopy). Good or

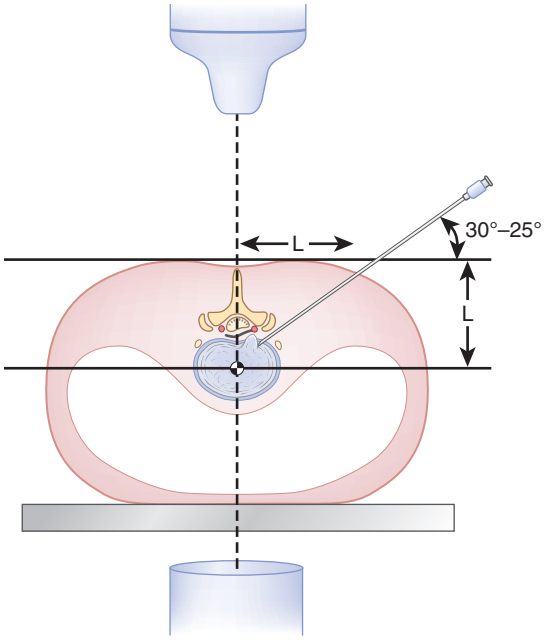

FIG. 47.19 The transforaminal endoscopic approach for disc excision. (From Yeung AT, Tsou PM. Posterolateral endoscopic excision for lumbar disc herniation. *Spine (Phila Pa 1976).* 2002;27:722–731.)

excellent results were documented in 92% of cases with a minimum 2-year follow-up. There was only one dural laceration that did not need repair, there was no instability, and there were no neurologic injuries.

Yeung and Tsou[80] reported results of 307 endoscopically assisted transforaminal discectomies. The patient is positioned supine on a radiolucent table. Local anesthesia with light sedation is used. In this technique, intraoperative fluoroscopy is crucial. A standard discogram is performed first, injecting blue dye into the disc space to help identify the herniated tissue. Along the same path, a series of dilators and ultimately a single working cannula is inserted percutaneously through the intervertebral foramen (Fig. 47.19). One cannula is used for inflow, outflow, and instrument insertion. The cannula has a shielded tip that allows aggressive discectomy with the use of graspers and shavers while retracting the exiting nerve root. As stated, this is performed through the intervertebral foramen. The nerve root can be visualized by rotating the cannula, allowing assessment of its integrity and mobility. Satisfactory results were reported in 89.3% of patients. Six patients (2%) had lower extremity dysesthesia that lasted longer than 6 weeks, two had thrombophlebitis, two had discitis, and one had a dural tear that did not require repair. Yoshimoto and colleagues demonstrated transforaminal microendoscopic decompression to be effective for treating far-lateral disc herniations.[168]

This technique has been shown to be safe and effective for recurrent disc herniations as well.[166] In a prospective evaluation of 262 consecutive cases of reherniation treated by an endoscopically assisted transforaminal technique, Hoogland and colleagues[166] reported an 85% success rate and 3.8% complication rate at 2-year follow-up. Kim and colleagues reported that percutaneous endoscopic interlaminar discectomy can be successful for reherniation by avoiding the iliac crest, which can be prohibitive with transforaminal techniques at L4–L5 and L5–S1.[169]

Lee and colleagues prospectively studied the influence of patient position on the location of abdominal organs using preoperative prone and supine CT scans, and found that safe approach angles were significantly more horizontal in the prone position.[170] The prone abdominal CT scan was more helpful in determining the trajectory and feasibility of the endoscope. A true lateral approach was possible for 75% of the discs at L3–L4 and 76.7% of the discs at L4–L5.

Several authors have sought to compare the results of microendoscopic discectomy with more traditional techniques.[171–173] Ruetten and colleagues[173] compared the results of endoscopic interlaminar and transforaminal discectomy with microsurgical discectomy. They showed no clinically significant differences between the endoscopic and microsurgical groups and identical reherniation rates (6.2% for each).[173] Analogous findings have been reported with comparisons of endoscopic and standard open discectomy.[171,172] However, Teli et al. reported higher rates of dural tears and recurrent herniation in endoscopic surgery compared to traditional techniques, with similar patient-reported outcomes at 2 years.[174] Garg et al., in a prospective randomized study, reported shorter hospital stay and earlier return to work in the microendoscopic group compared to the open discectomy group.[174a] In a systematic review of randomized controlled studies comparing microendoscopic technique with open discectomy or microdiscectomy, Smith and colleagues found that patient-reported outcome measures were similar with all three techniques.[175]

In a recent retrospective review of over 10,000 patients who had undergone percutaneous endoscopic lumbar discectomy, Choi and colleagues sought to find common causes of surgical failure, defined as a case requiring reoperation within 6 weeks.[176] They found that 4.3% of cases were failures, and over half of these were due to incomplete removal of herniated disc, of which inappropriate positioning of the working channel was the cause in 33.6% of cases. Exiting root injury is another complication of endoscopic surgery. Choi et al. analyzed the radiologic risk factors for exiting root injury by retrospectively reviewing the preoperative MRIs of patients undergoing endoscopic discectomy who experienced this complication.[177] They determined that if the distance between the exiting nerve root and the superior articular process of the caudal level is inadequate to accept the diameter of the working cannula without compressing the nerve root, an alternative technique, such as microdiscectomy or open discectomy, should be employed.

Percutaneous Automated Discectomy

Because of the evolution of percutaneous techniques of discectomy, there is considerable "overlap" in the names of different procedures. Although endoscopic discectomy can be considered percutaneous, it is not what is typically considered *percutaneous automated discectomy*. This term refers specifically to a procedure introduced in the early 1980s.

Using a posterolateral approach, a tissue-removing device is introduced into the disc space in a similar path as the needle of a discogram; this is guided by intraoperative fluoroscopy. Earlier techniques used a direct lateral approach that led to (or raised concern of) viscous perforation in some patients. The instrument is used to remove nucleus material in small increments. This removal theoretically can decrease intradiscal pressure. There is no direct visualization of the nerve roots, dura, or disc material. Neurologic decompression cannot be assessed with this technique.

Results of automated discectomy are inferior to standard open discectomy. Shapiro[93] showed only partial improvement of leg pain in 57% of patients undergoing this procedure. More disappointing was that only 5% had complete sciatica relief. All patients had disc bulges or protrusions, with none having free fragments. These results are less positive than the results documented with open discectomy.

In contrast, Hoppenfeld[94] reported more successful results, with relief of sciatica and sensory deficit in 86% of patients. He determined, however, that patients with sequestered discs do not reliably respond well to the procedure. Kotilainen and Valtonen[95] treated 41 patients with small protrusions or prolapses (bulges) with percutaneous automated discectomy. Sciatica had completely resolved in 78% of patients. From these data, it can be inferred that automated discectomy can be reasonably effective in patients with small disc bulges or protrusions that are in direct continuity with the remaining nucleus. Only in this select group of patients is there the possibility of relieving the neural compression. The procedure should not be used in patients with sequestered or extruded fragments (uncontained herniations) or most patients with disc herniations.

Chemonucleolysis

Chemonucleolysis involves the chemical digestion of nucleus material via injection of an agent, such as chymopapain, into the intervertebral disc. Ideally, the agent not only decompresses the central aspect of the disc space (producing a similar effect as percutaneous automated discectomy), but also might directly attack the herniated fragment. The clinical success of the procedure has not been supportive.

Chemonucleolysis has been rigorously examined in numerous clinical investigations. In a randomized prospective trial comparing chemonucleolysis and standard discectomy, Muralikuttan and colleagues[98] concluded that it leads to inferior results. There was a high rate of conversion to open surgery in the chemonucleolysis group because of continued, unrelieved symptoms. Crawshaw and colleagues[178] found extremely high failure rates—47% to 52%—after chemonucleolysis compared with 11% with open surgery. van Alphen and colleagues[82] documented increased radicular pain after chemonucleolysis in 22% of patients treated. Salvage discectomy after failed chemonucleolysis leads to worse results than primary surgery.[82,98,178] In addition to these poor results, neurologic complications, such as transverse myelitis associated with the use of chymopapain, have all but eliminated the procedure from continued use in the United States.

PEARLS

1. Most lumbar disc herniations respond well to conservative treatment within the first 3 months from the onset of symptoms.
2. In patients who fail conservative treatment, surgery consistently showed better outcomes than continued nonoperative care.
3. The type and size of disc herniations and psychosocial factors are the primary determinants of outcomes after discectomy.
4. Although minimally invasive techniques, such as endoscopic and percutaneous laser discectomy, can be effective in experienced hands, it is unclear whether they would ever replace the gold standard operation of open discectomy (with or without the use of a microscope).

PITFALLS

1. Patients with extraforaminal (far lateral) and central disc herniations should be advised that surgical outcomes may be inferior compared with outcomes for more common and typical paracentral herniations.
2. Patients should be informed that a lumbar discectomy is primarily indicated for leg pain. Back pain, numbness, and weakness are less reliably alleviated after surgery.
3. Recurrent disc herniations, which can occur in 18% of patients, remain problematic and may be more prevalent in patients who have large annular defects after discectomy.
4. Although simple discectomy for a recurrent disc herniation can yield outcomes equivalent to the index procedure, the addition of fusion may be considered after a second recurrence.

KEY POINTS

1. Patients should be carefully counseled preoperatively on the risk and benefits of surgery so that they may make a well-informed decision according to their specific functional demands and expectations.
2. Positioning a patient in a flexed or kneeling position can help open the interlaminar window to allow easier entry into the spinal canal.
3. Regardless of the technique of discectomy, a successful operation is contingent on adequate exposure that enables careful and minimally traumatic identification of the cauda equina, descending nerve root, and exiting nerve root before retraction to retrieve the herniated fragments.
4. During discectomy, the amount and location of the disc herniation should be commensurate with that shown on preoperative MRI.
5. The spinal canal and disc space should be thoroughly inspected before closure to avoid retained disc fragments.

48 CHAPTER Annular Repair

Gregory Lopez
Gunnar B.J. Andersson

Introduction

The anulus fibrosus is an important part of the intervertebral disc. Like the other disc components, the anulus undergoes changes with aging and with degeneration.[1,2] The degenerative process leads to a weakening of the anulus; delamination, fissures, and cracks result. Occasionally, the nucleus pulposus can herniate into those cracks and actually through the entire annular wall, causing pain due to both local inflammatory response and nerve root ischemia. Also, as part of surgical procedures to address contained disc herniations, iatrogenic holes in various shapes and locations are made into the anulus.

In recent years, there has been increasing interest in strengthening the annular structure, which is important to regain the normal function of the disc.[3] There is also interest in repairing degenerative and iatrogenic cracks, tears, and holes in the anulus to prevent recurrence of disc herniations, and to slow the degenerative process following discectomy. The purpose of this chapter is to review some of these strategies and put them in the context of successful treatment of different types of painful spinal conditions. The focus will be on the lumbar discs.

Anulus Fibrosus

The anulus fibrosus is a laminate structure surrounding the central nucleus pulposus and inserting into the endplates and vertebral body. It consists primarily of water, collagen, proteoglycans, and noncollagenous proteins. The laminates are organized in layers, mainly composed of type I collagen fibers, which alternate in angles with respect to the transverse plane. Between the layers are so-called interlaminar spaces containing proteoglycans (aggrecan, versican) and other link elements.[4] In the center, the fibers insert into the cartilaginous endplates; in the periphery, they bypass the endplates and insert into the bone, called Sharpey's fibers. The inner and outer parts of the anulus are different in that, in the inner part, the layers are less well organized and more widely spaced. The proportion of type I collagen increases from the inner anulus to the outer anulus; type II collagen is more common in the inner than outer anulus. Small proteoglycans (decorin and biglycan) are found primarily in the outer anulus, while elastin is present throughout. Elastin constitutes 1.7% to 2.0% of the dry weight of the anulus. In the outer anulus, elastin is present within the lamella running parallel to the collagen and in the same direction.[5] In the inner anulus, elastin is also organized within the lamellae. Fiber networks bind adjacent lamellae together, preventing them from separation.[6,7] Table 48.1 compares the outer and inner anulus.

The cell density in the anulus pulposus is about twice that of the nucleus pulposus.[8] In the outer anulus, the cells are fusiform shaped and align with the collagen fibers alternating with each lamella. These cells produce mainly type I collagen. In the inner anulus, the cells are more similar to those of the nucleus pulposus. They are chrondrocyte-like and produce mainly type II collagen.

The mechanical exposures of the different parts of the anulus are initially different. The inner anulus is primarily subjected to the hydrostatic pressures of the nucleus pulposus; the outer anulus is more under compression or tension, depending on the direction of movement. As are other connective tissue structures, the anulus is anisotropic and adapted to the principal directions of load.

Effect of Aging on the Anulus Fibrosus

A variety of chemical and structural changes occur with aging. These changes appear to occur first in the inner anulus, which loses a large part of its proteoglycan and water and gradually assumes a more nucleus-like structure.[2]

Both the overall proteoglycan and collagen concentrations decrease with aging, probably reflecting a decrease in cellular biochemical activity. Among smaller nonaggregating proteoglycans, decorin levels decrease with aging in the outer anulus, while biglycan and fibromodulin levels increase. In the inner anulus, decorin levels have been found to increase with aging. The mechanical properties are altered with aging as well. Peak compressive stresses are increased by 160%, and the width of the anulus is thickened by 80%.[9]

TABLE 48.1 Characteristics of the Outer Versus the Inner Anulus

	Outer Anulus	Inner Anulus
Collagen	40–60% dry weight	25–40% dry weight
Type collagen	Type I mainly	Type II mainly
Proteoglycan	5–8% dry weight	11–20% dry weight
Cells	Fusion from	Chondrocyte-like

Healing of the Anulus

Early studies in dogs showed comparatively poor healing when larger defects were created in the annular wall.[10] Smith and Walmsley[11] reported that after an incision, the outer anulus healed by fibrous tissue ingrowth from the sides and that there was also a gradual healing of the inner anulus over a 1-year period. Long-term collagen fibers gradually invaded the nuclear tissue, some of which remained in the annular incisions. Fazzalari et al.,[12] in an ovine model, introduced needle punctures and concentric tears, and tested the specimen mechanically up to 18 months. Significant changes occurred in disc biomechanics in both cases, and remained significant over time. The annular lamellae thickened and the adjacent vertebral body bone volume fraction increased. While this model is not a herniation model, it shows the poor healing of concentric tears and their effect on disc biomechanics. There is limited information on annular repair in humans after discectomy. Current information suggests a limited healing potential after annulotomy. This increases the risk of reherniation. Reoperation rates for recurrent herniations ranging from 3% to up to 27% have been reported.[13–16] The frequency of reoperations appears to be related to the size of the annular defect.

Biologic Repair

At least four types of annular repair are discussed in the literature: collagen modification, cell therapy, gene therapy, and tissue-engineered scaffolds. Gene and cell therapies are unlikely to repair existing cracks, tears, and incisions unless combined with scaffolds. Also, current gene delivery systems use virus-mediated gene transfer to enhance matrix deposition within the disc[17,18]; however, infection is always a risk with viral delivery systems.

A number of studies have been published in which scaffolds have been populated with cells, with various success rates reported. Most of these studies have been performed in vitro, but a few animal studies have been reported. Gene and growth factor therapies can repair annular needle punctures in the early stages. Most anulus fibrosus scaffolds use collagen type II, despite type I being more abundant in the outer layers of the anulus. Saad et al. demonstrated a higher production of extracellular matrix with type II collagen.[19] Many growth factors appear to have a stronger effect on proteoglycan than collagen. Zhang et al.[20] reported that collagen synthesis was enhanced by bone morphogenetic protein 13 (BMP-13) and Sox9.

Bron et al.[3] list a number of requirements for anulus fibrosus scaffolds. The scaffolds should:

- Fix and/or repair the anulus fibrosus gap to contain the nucleus pulposus (or its replacement).
- Allow fixation to surrounding structures.
- Allow anulus fibrosus cells (or stem cells) to survive and secrete extracellular matrix.
- Have the characteristic anisotropic behavior to maintain/restore the mechanical properties of a spinal motion segment.
- Not irritate or adhere to the perineurium.

To date, no single approach has met all these requirements, but several scaffolds hold promise.[21–24]

Surgical Repair

A few alternatives have been developed to address the closure of an annular defect caused by a discectomy. In an in vitro study, a laboratory simulation of intradiscal pressures of the lumbar spine was conducted to compare nonrepaired versus repaired annular defects. Bartlett and colleagues concluded that repair of the anulus may be beneficial to retaining disc material and preventing reherniation.[25] Synthetic materials are advantageous as well, as the materials are predictably reproduced. Wang et al.[26] put gelfoam, platinum core, bone cement, and tissue glue into an 18-gauge needle defect. Gelfoam appeared to have the best result. The size of the defect in this model is so small, however, that it is difficult to extrapolate this model to a discectomy. Sutures have been used in a sheep model.[27] The healing effect was not statistically significant.

More recently, sutures with anchors (Xclose) have been introduced (Anulex Technologies, Inc.; Fig. 48.1). A retrospective case series presented in 2009 at a society meeting compared 133 microdiscectomy cases without anulus repair to 59 with anulus repair. There were 16 reoperations within 12 months in the nonrepair group (12.9%) compared to four in the annular repair group (6.8%).[28] More recently, Bailey et al. reported their results using the Xclose from a prospective, multicenter, single-blind, randomized, controlled clinical trial of individuals who were candidates for a one- or two-level discectomy with persistent leg pain.[29] Although visual analog scale leg and back pain, Oswestry Disability Index, and Short Form-12 outcomes improved, there was no statistically significant difference between the groups at any of the follow-up points. Symptomatic reherniation rates also did not statistically differ at any of the follow-up points. To what degree sutures can be used when larger defects exist remains unknown. It is also not clear how well they reverse the biomechanical changes caused by the defect.

Barricaid is another commercially available implant that anchors into the vertebral body and supports a woven mesh barrier inserted into the defect (Intrinsic Therapeutics Inc.; Fig. 48.2). In a multicenter prospective cohort study, recurrent herniation, disc height loss, and pain scores were monitored, with 2-year follow-up. Thirty patients underwent implantation of the device, while 46 had no implant placement. Although not statistically significant, at 2 years no patient with

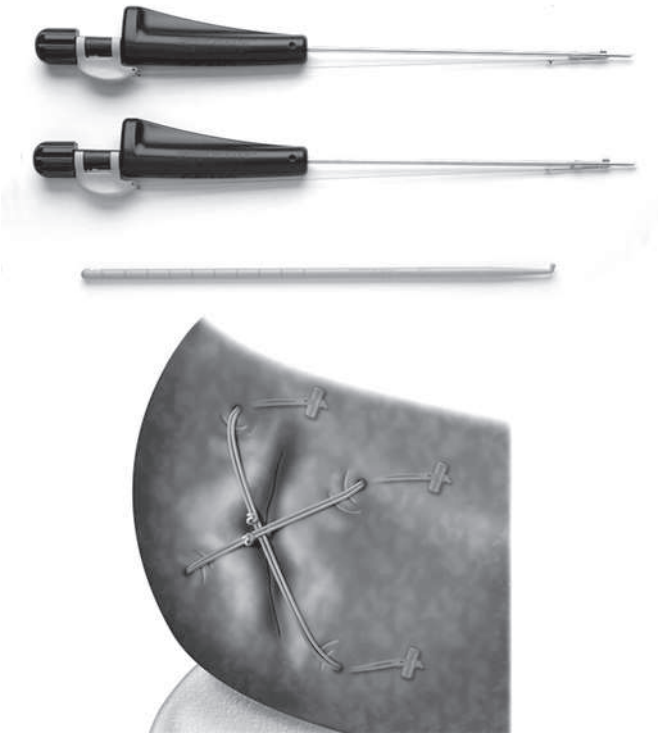

FIG. 48.1 Xclose implant. (Courtesy Anulex Technologies, Inc., Eden Prairie, MN.)

FIG. 48.2 Barricaid implant. (Courtesy Intrinsic Therapeutics, Inc., Woburn, MA.)

an implanted device had a symptomatic recurrent disc herniation, while there were three in the control group. Significant scores were achieved with the implanted device cohort as they reported less leg pain, back pain, and disability at 1 year postoperatively.

Other implants are in various stages of development and likely to be presented at meetings in the near future.

Summary

Annular repair is an exciting developing technology to address the age- and degeneration-related changes of the anulus, as well as annular tears occurring from disc herniations or in the treatment of herniations. We can expect clinical data in the next several years, but it may take a decade or more to determine how effective annular strengthening is in retarding the development of degenerative and age-related changes.

49 CHAPTER Lumbar Disc Degeneration: Anterior Lumbar Interbody Fusion, Degeneration, and Disc Replacement

Robert Johnson
Richard D. Guyer

Low back pain has long been noted to be one of the most disabling conditions in the United States and the Western world. Disability from back pain has been reported to cost approximately $100 billion annually.[1] Lumbar disc degeneration is often divided into three basic categories: internal disc derangement, degenerative disc disease (DDD), and motion segment instability. Internal disc derangement[2] encompasses annular tears and dark disc disease. DDD describes isolated disc resorption and spondylosis. Motion segment instability involves listhesis and scoliotic changes. This description of lumbar disc degeneration, although oversimplified, encompasses a dynamic process with overlapping findings at individual and adjacent levels. DDD, although controversial in its exact role in patients with back pain, has been shown to be a pain source generator.[3,4] Removal of the pain generator, the intervertebral disc, is a viable and logical approach for selected patients.

Determining the ideal candidate for surgical management of DDD can be more challenging than performing the procedure itself because of the unclear relationship between patient symptoms, diagnostic studies, and surgical outcomes. The patient should have not responded to conservative management—including oral medication, lifestyle modification, active rehabilitation, and injections—before surgical intervention for a minimum of 6 months. To maximize the predictive value of lumbar interbody fusion or disc replacement for the treatment of lumbar disc degeneration, the patient's history should be consistent with mechanical back pain, and radiographic studies should show degeneration at discrete levels. While a good history, physical examination, and diagnostic radiographs—including standing flexion and extension views along with MRI—will allow diagnosis of discogenic pain, discography is useful in those equivocal cases and should reproduce concordant pain and show abnormal disc morphology (Fig. 49.1). Patients with a significant behavioral component to their pain should be considered poor surgical candidates. Preoperative psychological screening can be helpful in the evaluation of those patients.[5]

Anterior lumbar interbody fusion (ALIF) and total disc replacement (TDR), as options for treating DDD, have had a tumultuous history with increasing and decreasing interest and success over the years. ALIF as a procedure favors load transmission through the anterior column, recreates lordosis, restores disc height, and tensions lateral and posterior annular or ligamentous fibers (Fig. 49.2).[6] TDR likewise removes the diseased disc, indirectly decompresses posterior structures, and replaces the diseased disc with an artificial one while preserving aspects of normal biomechanical function. Direct anterior exposure allows complete removal of disc material, increasing the fusion rate,[7] and prepares the disc space while avoiding trauma to the posterior musculature, making it an attractive option for the treatment of DDD. In the United States, most approaches to the anterior spine are performed by general/vascular surgeons, though, depending on training, some US spine surgeons do their own.

Anterior Lumbar Surgical Approach

Relative contraindications to anterior lumbar approaches include advanced atherosclerosis of the major vessels and obesity. Some consideration should be given to patients who have previously undergone prior abdominal surgery or have inflammatory diseases because these conditions create significant scarring that may increase the risk or preclude one from successful surgery. Both the retroperitoneal and transperitoneal approaches may be used in these patients, but extra care and consideration should be taken into account. Transperitoneal approaches have been associated with higher rates of retrograde ejaculation in comparison to retroperitoneal with elevation of the hypogastric plexus. Given the decrease in the rate of peritoneal scarring and retrograde ejaculation with retroperitoneal approaches, it has become the preferred approach by many surgeons. Therefore, the retroperitoneal approach will be the primary approach covered in this chapter.

The retroperitoneal approach can proceed from various incisions, including vertical midline, paramedian, oblique, and transverse. Extensive lateral incisions should be avoided because this may denervate the medially situated rectus muscle. The incision needs to take into account the spinal level and number of lumbar levels to be exposed. An infraumbilical transverse or vertical incision can accommodate most approaches to the L4–L5 and L5–S1 disc levels, whereas a more obliquely or vertically oriented incision is favored for

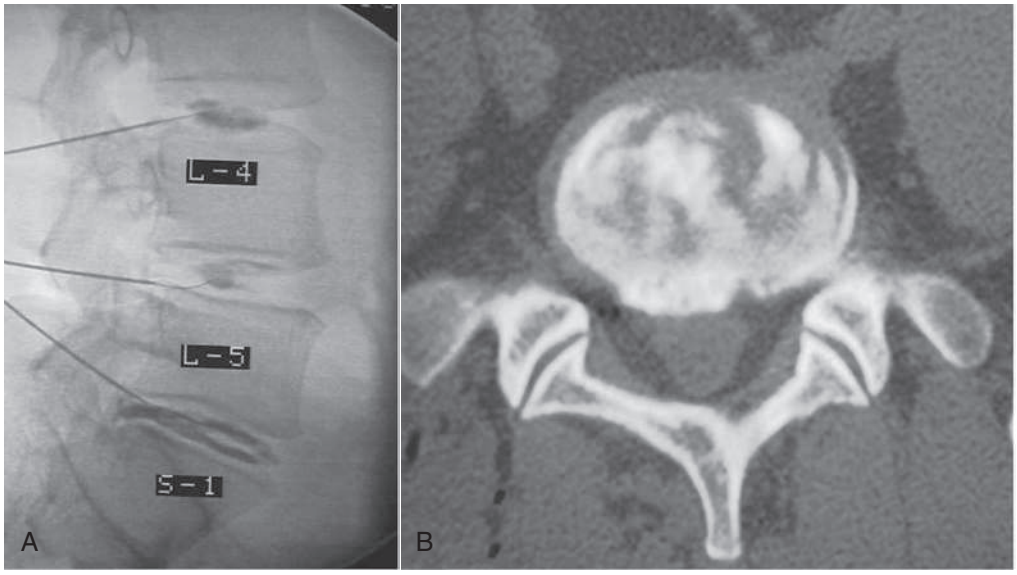

FIG. 49.1 (A) Lateral fluoroscopic image after discography with dye leaking into periphery of an abnormal L5–S1 disc. (B) Axial computed tomographic scan after discography shows abnormal disc morphology and dye extrusion into the peripheral anulus.

access to disc levels above L4 (Figs. 49.3 and 49.4). This incision allows for access to the L2–L3 disc level and possibly the L1–L2 disc level in patients with a favorable body habitus.

In most nonobese patients, palpation by an experienced access surgeon can be used to locate the sacral prominence to identify the L5–S1 disc space. An approach to the L4–L5 level should be directed at approximately the level of the anterior superior iliac spine, although fluoroscopic confirmation should be used if there is any question. All of the landmarks can be confirmed by fluoroscopic guidance. Fluoroscopy is especially important in patients who have distorted spine anatomy, who have had prior spine surgery, or are obese.

The incision is made and cautery is used to deepen the incision to the level of the anterior rectus sheath fascia. The fascia is incised; superior and inferior fascial flaps are then raised at the linea alba. Care should be taken in patients who have had previous Pfannenstiel incisions because they may have unrecognized midline incisional hernias. The mobilization of the fascial flaps provides for less tethering of the deeper tissues and rectus muscle. The left rectus muscle is bluntly mobilized to a lateral position, taking care to identify the inferior epigastric vessels and small perforators. By dissecting deep to these vessels, they can be preserved; however, they can be clipped and divided if necessary.

Inspection and gentle finger dissection can be used to identify the inferior edge of the posterior rectus sheath. This provides the landmark to begin blunt separation of the peritoneal cavity laterally to start the exposure into the retroperitoneal space (Figs. 49.5 and 49.6). The left ureter easily rolls up as part of this maneuver. The landmark to feel is the bulge of the psoas muscle and the pulse of the common iliac artery. A common mistake is to persist in aggressive dissection lateral to the psoas muscle thinking that the planes may be adhesed.

When the peritoneum has started to roll medially and the iliac artery has been palpated, the next landmark to be palpated should be the L5–S1 disc level. The L5–S1 disc space can be mobilized with the use of Kittner dissectors. The middle sacral vessels can be mobilized and divided between ligatures or small clips. Occasionally, anomalous venous drainage may be present across the sacral spine. This may include a single vessel as a bridging iliac vein to a confluent venous plexus across the region. The iliolumbar vein typically branches off posterior to the common iliac vein at the L5 vertebral level, and is an important consideration for exposure for the L4–L5 disc space above. Most of the time, it may be identified within 2 cm of the L4–L5 disc space. In a small percentage of patients, it may not be present. The common iliac artery can be easily visualized lateral to the vein and is usually bifurcating into the internal and external iliac arteries at the L5–S1 level. Blunt dissection generally can be used to expose the entire face of the L5–S1 disc level without significant need for major vascular mobilization (Fig. 49.7). Care should be taken during the mobilization to elevate the superior hypogastric plexus with the peritoneum, helping to avoid nerve injury and retrograde ejaculation in males. This plexus typically feels like a fibrous band within the peritoneal fat, and typically elevates with the peritoneal packet.

The L4–L5 disc level is generally the most difficult level to provide full access to for the spine surgeon. It is often at this level where the bifurcation commences, and can be difficult to mobilize. It is also important to look for vascular calcifications because calcification increases the potential risk for complications with an exposure at the L4–L5 level. After the retroperitoneum has been exposed, a plain film can be obtained to confirm the disc level. Gentle blunt dissection can be used to mobilize the left common iliac artery. This dissection should be continued distally well onto the external iliac artery to minimize potential trauma to the artery. Generally, the vascular structures should be mobilized as paired structures. If it is a high bifurcation, a thorough mobilization of the left common

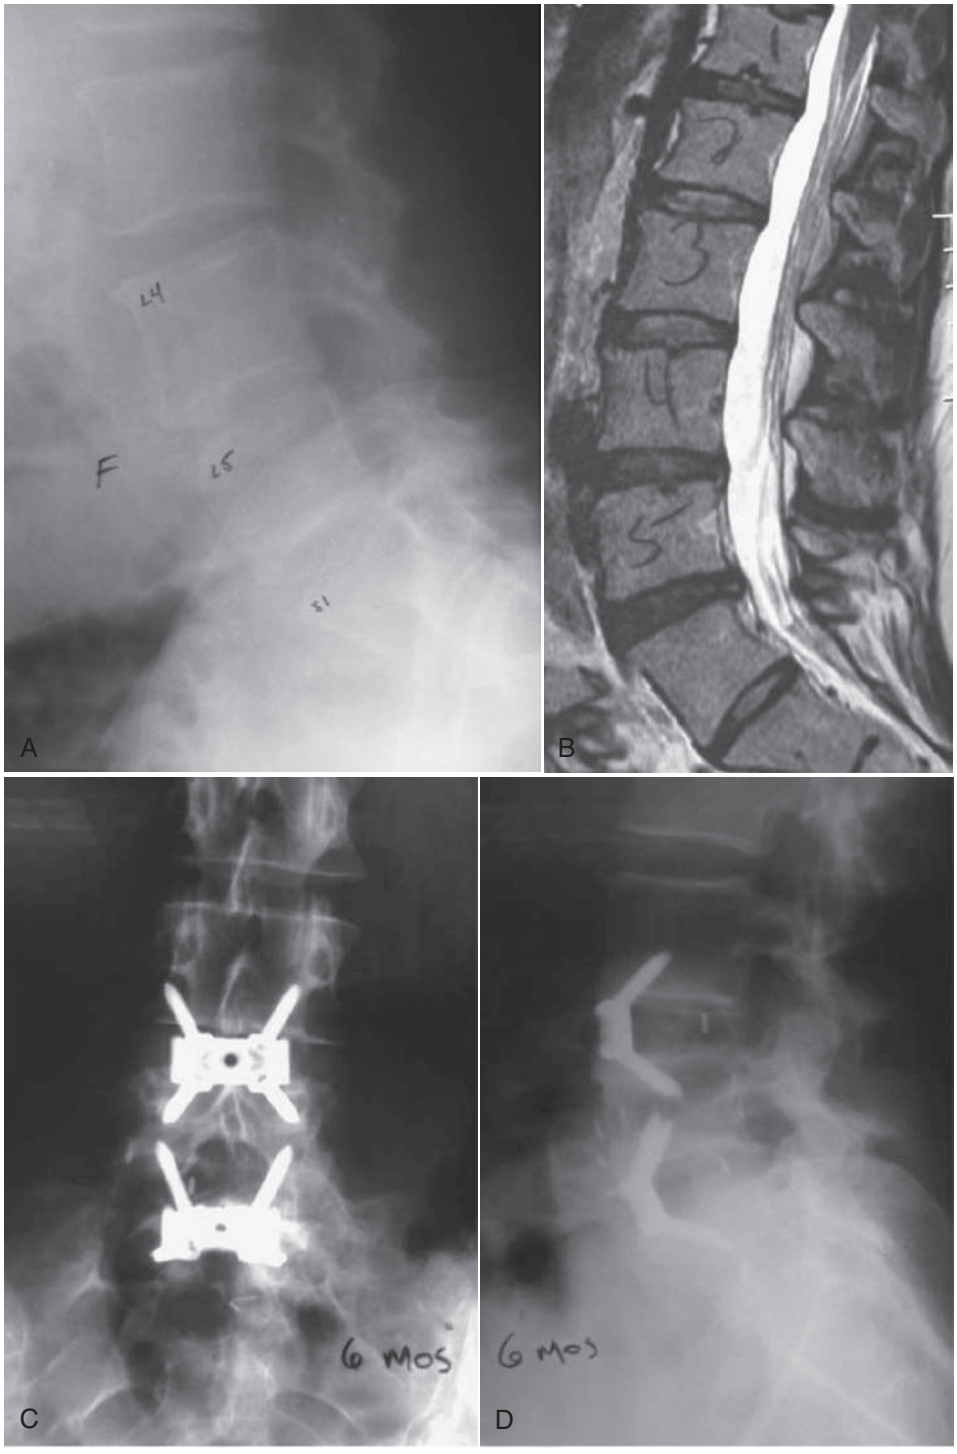

FIG. 49.2 (A) Preoperative plain radiograph and (B) T2-weighted sagittal magnetic resonance image showing two-level degenerative disc disease and 6-month postoperative plain (C) anteroposterior and (D) lateral radiographs. Note significant disc space and foraminal restoration using an anterior interbody spacer.

iliac artery and vein may allow them to be retracted laterally. Gentle Kittner dissection shows the iliolumbar vein as it branches off the posterolateral aspect of the common iliac vein, inferior to the L4–L5 disc. If it is not identified within approximately 15 to 20 mm of the disc space, it may not impede the exposure and, if not under tension, may be left intact.

Additional mobilization of the segmental vessels immediately adjacent and superior to the L4–L5 region is sometimes necessary (Fig. 49.8). Pulse oximetry, though optional, can be helpful when mobilizing vascular structures. Before retraction or mobilization, the oxygen saturation and waveform of a left lower extremity pulse oximeter should be evaluated. When retraction has been applied, if the saturation diminishes to

zero, the surgeon has approximately 45 to 50 minutes before the retraction should be released to allow for resumption of unimpeded blood flow. The waveform should normalize over a brief period before replacement of the retractors. This can be repeated with periodic release of the retractors every 30 minutes or so after that. If there is not a return to baseline over a few minutes, vascular examination with ultrasound should be performed.

Indications for Interbody Fusions

Choosing to proceed with operative intervention on the spine should be a joint decision reached by the patient and the physician. Prospective patients should have tried and failed nonoperative management, and the clinical and radiographic picture should correlate to maximize results and patient satisfaction. ALIF can be chosen to aid patients with (1) DDD and the spectrum of clinical and radiographic changes noted under this umbrella term; (2) pain after prior posterior surgery, such as laminectomy, in which significant epidural scar may complicate a revision surgery; and (3) significant low back pain with two or more recurrent herniated discs.

Axial back pain caused by the degenerative process of the disc and spine as a whole is currently the main indication for ALIF. By correctly identifying discogenic pain via radiographs, magnetic resonance imaging (MRI), and provocative discography, one can remove the pathologic disc and stabilize the segment with an interbody graft (see Figs. 49.1 and 49.2). Using an ALIF procedure, patients with associated radicular leg pain secondary to foraminal narrowing can be indirectly decompressed by restoring the foraminal height, elongating redundant posterior and lateral anulus (if not removed), and realigning overlapping incongruent facet joints and more directly decompressed by removing compressive nuclear material.[8,9] Patients with a herniated nucleus pulposus can undergo direct decompression and discectomy via an anterior exposure. Interbody implants placed through an anterior approach can be used alone or in conjunction with posterior fusion techniques for cases requiring a more robust fusion construct.

Interbody Implants and Graft Material

The race between temporary mechanical support and biology has been run since the origins of orthopaedic care. In the spine, the goal of any interbody device is to provide anterior column mechanical support while a bony fusion develops. A single question remains to be answered: How rigid does a construct need to be to provide early stability without negatively affecting the spine when fusion is present? Creating an unnecessarily stiff construct may lead to stress shielding,[10] additional surgery, and implantation of costly implants; however, too little stiffness leads to biomechanical failure or pseudarthrosis. Pilliar and colleagues[11] showed that small micro-motion of 28 µm does not affect bone ingrowth into porous-surfaced implants and large micro-motion greater

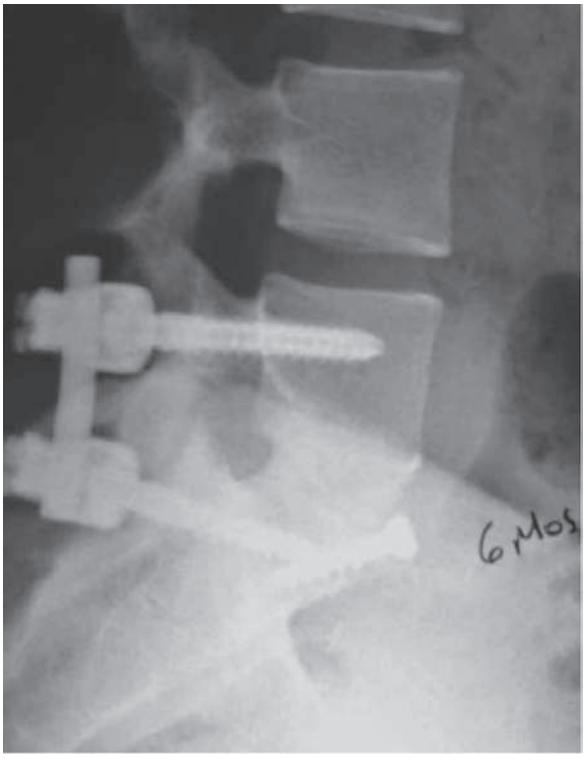

FIG. 49.9 Six-month follow-up lateral radiograph of graft using femoral ring allograft and bone morphogenetic protein, with posterior bilateral pedicle screws showing bone bridging and solid fusion.

than 150 μm can produce a fibrous interface. Nevertheless, the current consensus seems to be that adequate stabilization must greatly increase the stiffness above the native segment.

Femoral ring allograft (FRA), a frequently used method, obviates the need for cortical autograft and provides a strut with significant compressive strength,[12,13] incorporates with host bone, and provides a medium easier than metal to evaluate graft incorporation (Fig. 49.9). Previously, allograft rings were fashioned by surgeons on back operating room tables, but now can be commercially obtained. To augment fusion, allograft or autograft cancellous bone can be placed in the center of the cortical ring. FRA as a stand-alone intervertebral spacer has been shown to have a high rate of pseudarthrosis and subsidence.[14,15] Anterior or posterior augmentation has been recommended.

Transforaminal lumbar interbody fusion and posterior lumbar interbody fusion have allowed surgeons to place interbody grafts from posterior approaches, providing anterior column support and negating anterior exposures. Posterior-based surgery has been shown, however, to have increased operative time, patient morbidity, and complications compared with anterior-based surgery.[16,17] Also, patient anatomy and the degree of pathology can make achieving an adequate discectomy and ideal graft size and position and placement a challenge. These factors have contributed to less restoration of disc height, less than complete fusion bed preparation, and less mechanical stability at the time of implantation than with ALIF.

Previously, stand-alone anterior interbody grafts were fraught with reported complications, such as migration, subsidence, and pseudarthrosis. As interbody graft technology has progressed, there has been renewed interest, however, in stand-alone anterior interbody fusion, single-approach procedures. Biomechanical studies have reported that stand-alone anterior interbody grafts without fixation are weakest in shear strength, rotation, and extension.[18] The addition of a blocking screw or plate for FRA and synthetic spacers such as polyetheretherketone (PEEK) has minimized the occurrence of anterior migration. Currently available in PEEK, metal carbon fiber, and machined allograft and other various materials and combinations, interbody synthetic grafts have been optimized compared with their predecessors. Cage design from cylindric to a box shape has led to better matching of the endplate geometry and has been shown to decrease motion at the intervertebral segment.[19] Grant and colleagues,[20] performing a human cadaveric biomechanical investigation, showed that lumbar endplate density and thickness increased toward the periphery, with the strongest being posterolateral just in front of the pedicles.

Larger, more robust, locking and nonlocking plates have been used to augment a stand-alone interbody graft; although effective, these plates require increased exposure and have a large anterior profile. To negate the exposure necessary for plating and minimize soft tissue and vessel irritation, anterior interbody synthetic products with incorporated plates or fixation through the graft into the vertebral bodies have been developed. By increasing their stand-alone biomechanical strength to minimize extension and shear forces, one hopes that these products may negate the need for a robust anterior plating and posterior surgery.

Many studies have shown the stability-enhancing effect of integrated anterior instrumentation and a biomechanical argument for stand-alone ALIF (Figs. 49.9 and 49.10). Kuzhupilly and colleagues[21] looked at stand-alone FRA versus industrial FRA with integrated crossed cancellous screws into the adjacent vertebral bodies. They found significant improvement in extension stability only. Le Huec and colleagues[22] tested a lateral entry–placed cage with plate augmentation and found a significant increase in stiffness in all loading directions. No statistical significance was noted whether or not the plate was attached to the cage.

Schleicher and colleagues[23] compared the SYNFIX LR (DePuy Synthes) and the STALIF (Centinel Spine), two stand-alone ALIF cages, and found a statistically significant increase in stiffness over the native in vitro segment, with the SYNFIX LR, a locking four-screw implant, showing a higher stabilizing effect in lateral bending than the STALIF. Flexion-extension finite element analysis revealed that the cage bears most of the force in flexion, and the screws and the screw–plate interface take most of the stress in extension. Cain and colleagues[24] showed the SYNFIX LR had equal stiffness versus 270-degree and 360-degree constructs. The test device showed a higher ability to withstand axial torque compared with standard pedicle screw instrumentation. At the present time, a few products have US Food and Drug Administration (FDA) approval for stand-alone interbody use, with many more devices seeking approval.

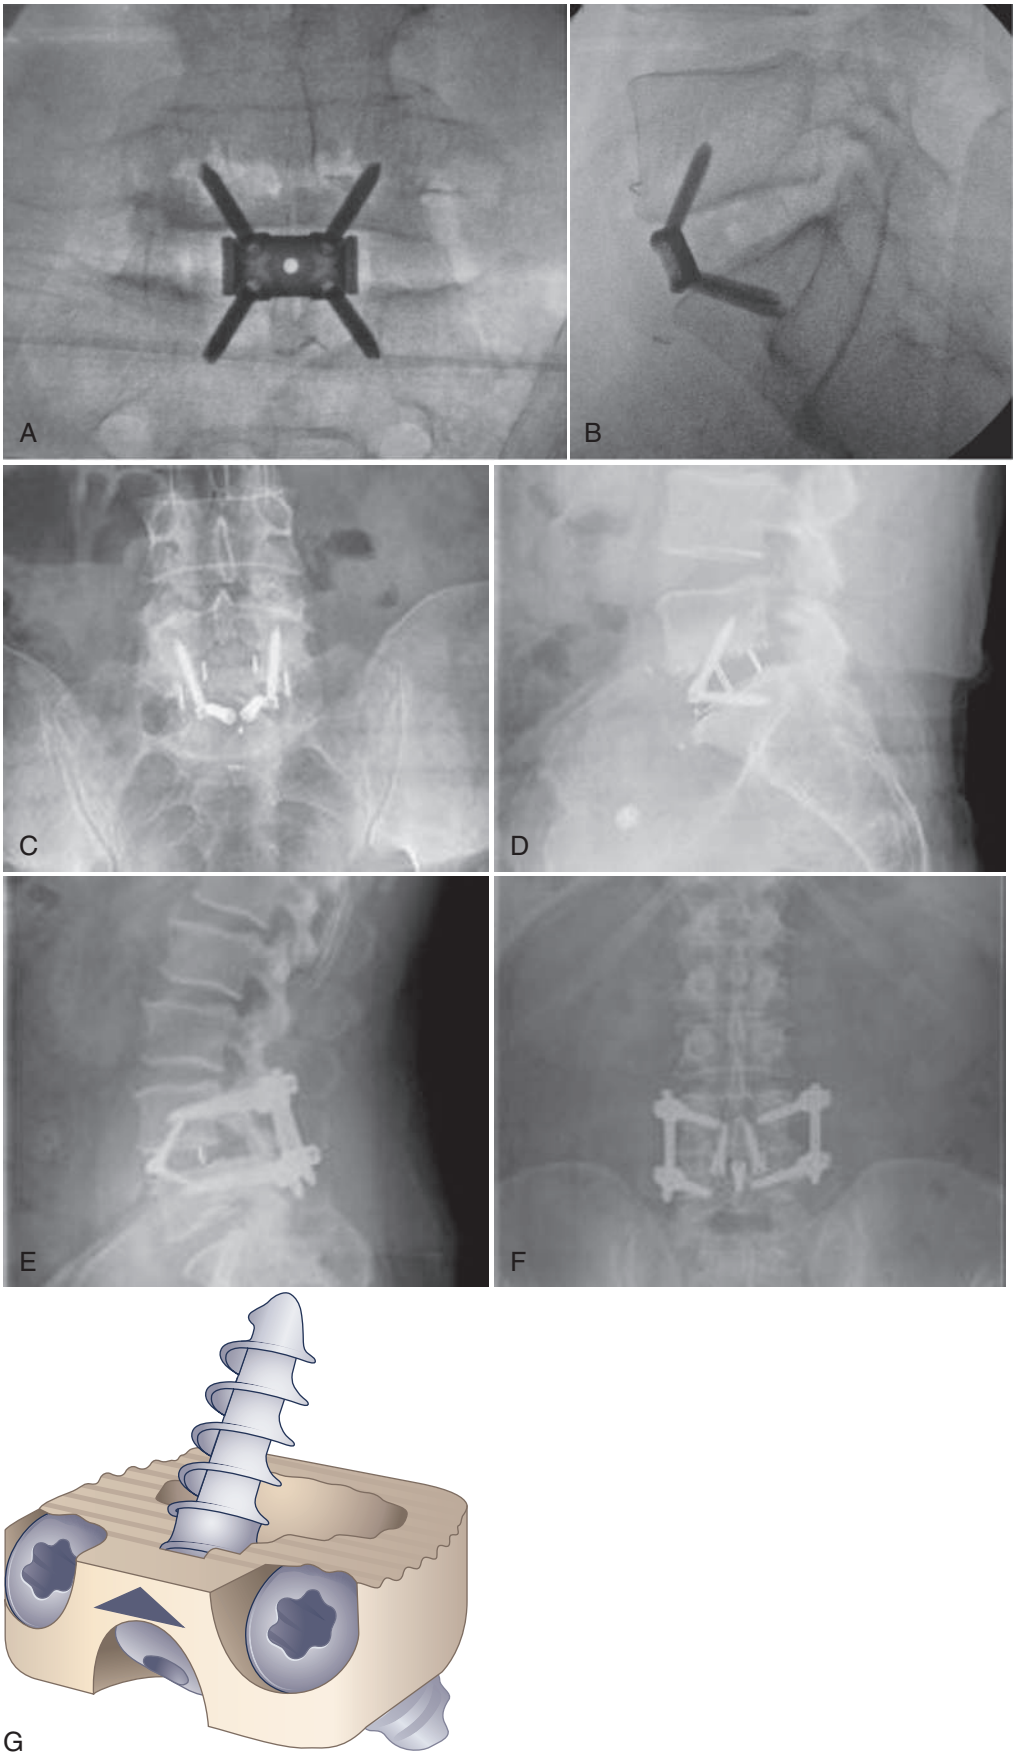

FIG. 49.10 (A) Anteroposterior and (B) lateral radiographs of the lumbar spine demonstrating a standalone L5–S1 interbody fusion cage (Arcadius L, Aesculap). (C) Anteroposterior and (D) lateral radiographs of MIDLINE II (Centinel Spine) cage utilized in a 360-degree fusion construct. (E) Lateral and (F) anteroposterior radiographs of MIDLINE II (Centinel Spine) cage in a 360-degree fusion construct. (G) Depiction of MIDLINE II. (G, Courtesy Centinel Spine, West Chester, PA.)

Most current implants allow the incorporation of graft material to augment the fusion process. Historically, the gold standard has been autogenous morcellized bone graft; however, to minimize patient morbidity, allograft and biologic materials have been developed. Multiple studies have evaluated allograft efficacy in fusion patients as extenders and stand-alone with good results.[25] The addition of the recombinant human bone morphogenetic protein (rhBMP-2) Infuse Bone Graft (Medtronic) has been shown to promote osteoinduction and to stimulate early incorporation of grafts (see Fig. 49.9).[26,27] Burkus and colleagues[27] reported 100% fusion rate with stand-alone interbody fusion using threaded cylinder allograft dowels with rhBMP compared with autograft. Pradhan and colleagues[28] showed, however, that the use of rhBMP-2 with stand-alone FRA can lead to an aggressive early osteoclastic response, causing graft and endplate osteolysis with potential subsidence risk. These authors believed that augmenting with intersegmental instrumentation can support the FRA with bone morphogenetic protein during this mechanically vulnerable time. Although bone morphogenetic protein has been shown to enhance fusions, it still remains controversial due to its perceived link to increased rates of cancer and retrograde ejaculation.[29]

Now the technology is moving to incorporate titanium porous-coated surfaces to allow better initial interference fit and to promote bone ingrowth into the cage (MIDLINE II [Centinel Spine], Arcadius^{XP} L [Aesculap Implant Systems], Lucent Ti-Bond [Spinal Elements]), making the cages not only function as spacers and carriers of the graft, but as part of the fusion mass. Some of these new cages are prior PEEK cages that have been impregnated with porous titanium at their contact with bony endplates, while others are completely made out of metal alloy. Some even go further by incorporating new manufacturing procedures, such as three-dimensional printing, to give increased surface area for bone ingrowth (ALIF Spine Truss System [4WEB Medical]). These newer cage designs may also be classified as bioactive implants.

Indications for Total Disc Replacement

Although similar to ALIF patients in many ways, TDR patients have some very important differences when it comes to patient selection. The most common indications are listed in Box 49.1.[30] The majority of patients who qualify for TDR are younger than 60 years, with the FDA studies recommending skeletally mature adults from 18 to 60 years of age. This excludes most patients with degenerative processes in dorsal spinal structures (e.g., facet degeneration, ligamentum flavum hypertrophy) and with inadequate bone stock as quantified by evaluating bone mineral density. It is recommended that a patient have a T-score of at least –1.0 to be considered secondary to TDR implants relying on vertebral endplate fixation and ingrowth for stability. Evaluation of posterior structures is typically done through radiographic studies, and facet blocks may be used to diagnose facet-mediated pain. Even though ventral insertion of a TDR may offer some indirect decompression, circumferential stenosis is best treated by direct decompression of neural elements through a dorsal approach with fusion, if needed. Studies have shown that the disc space preparation necessary for insertion of a TDR can increase rotational instability of the spine. The currently available semiconstrained disc replacements do not fully restore this stability.[31] Therefore, TDR in a spine with preexisting rotational instability (Cobb angle >11 degrees) might be expected to result in higher failure rates, thus is not recommended.

BOX 49.1 Common Indications and Contraindications for Lumbar Total Disc Arthroplasty

Indications

- Age 18 to 60 y
- Symptomatic degenerative disc disease L3–L4 to L5–S1 with or without confirmatory discography
- Failure of nonoperative therapy for at least 6 mo
- No significant facet disease
- Bone density dual-energy x-ray absorptiometry T-score >–1.0
- No previous retroperitoneal approach
- No significant arterial calcification
- Spondylolisthesis or pars defects
- Recurrent disc herniation contiguous with disc space with significant low back pain in a patient with no other contraindication who would be considered to be a fusion candidate

Absolute Contraindications

- Poor bone quality (e.g., osteoporosis, osteopenia, metabolic bone disease, tumor)
- Severe facet degeneration
- Spondylolisthesis and spondylolysis
- Circumferential stenosis
- Scoliotic deformity >11 degrees
- Current or past trauma to involved vertebrae
- Morbid obesity
- Infection
- Autoimmune disorder

Relative Contraindications

- Age older than 60 y
- Psychosocial disorder
- Multiple degenerative disc disease levels
- Obesity
- Previous lumbar surgery if facet joint compromised

Implants and Design

Only two TDR implants have been approved by the FDA, the ProDisc L (De Puy Synthes) and the activL Artificial Disc (Aesculap). The Charité (DePuy Synthes) was a previous TDR that was removed from the market due to a business decision by the manufacturer. ProDisc L was developed in 1990 in France and has undergone one design revision. It was first implanted in the United States in October 2001 (Fig. 49.11). It contains two cobalt-chromium endplates, with a ultrahigh-molecular-weight polyethylene insert that is monoconvex and locks into the distal metallic endplate. This results in a ball-and-socket joint that limits translation but allows rotation and limited bending, making it a constrained device in terms of translation. A central keel on the endplates and plasma-sprayed titanium coating allow for bony fixation and ingrowth.

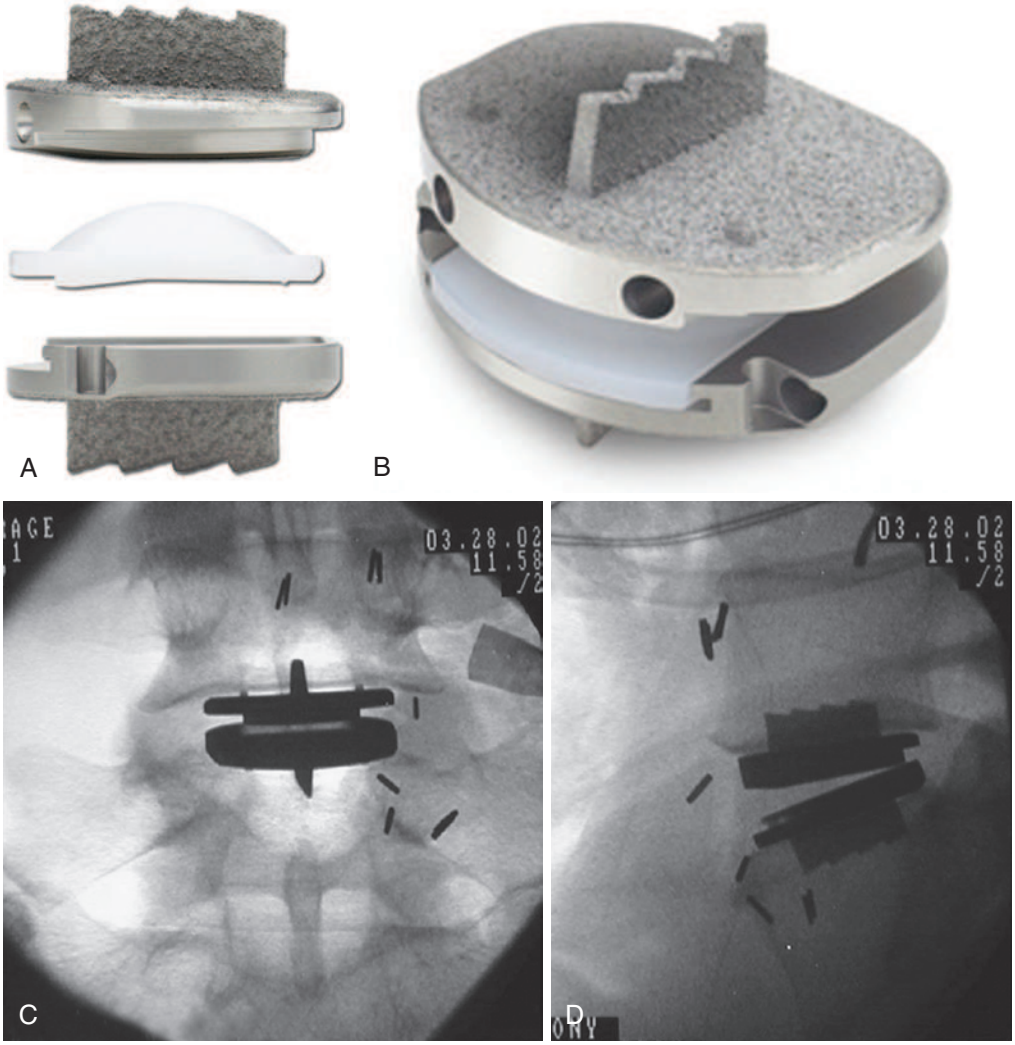

FIG. 49.11 ProDisc L lumbar disc replacement. (A) Three components. (B) Implant with ultrahigh-molecular-weight polyethylene component attached to caudal endplate, nested with cephalad endplate as it rests in vivo. (C) Anteroposterior and (D) lateral radiographs of device in vivo. (A and B, Courtesy DePuy Synthes, West Chester, PA.)

It is important when discussing disc replacements and their ability to maintain spinal motion to classify them in terms of degrees of freedom and constraint. There is controversy regarding the level of constraint in these implants. Most are classified as semiconstrained due to partial loss of degrees of freedom. The ball-and-socket articulation of the ProDisc L classifies it as being semiconstrained (see Fig. 49.11).

The activL was first released in June 2015 in the US market (Fig. 49.12). It is classified as a mobile bearing implant secondary to its translational abilities along with its traditional ball-and-socket attributes. The activL allows for continued rotation and bending motion, but also allows anterior to posterior translation. It also has a titanium coating (Plasmapore), making it a bioactive implant similar to the ProDisc L. The activL comes in a spike-and-keel version, but only the spike design is FDA approved in the United States. It does offer a wider range of implant sizes and angles, along with a sacral-specific design, than the ProDisc L. At this time, other designs have been approved for use in Europe with similar designs and features, but they have yet to be approved in the United States (Table 49.1). Many discs have undergone the investigational device exemption (IDE) trials, but have never been approved secondary to various reasons, including implant design (metal on metal), product safety, patient issues, and the extensive financial burden of the approval process.

Numerous studies have demonstrated the effectiveness of lumbar TDR. There are multiple FDA IDE trials with 2-year and 5-year follow-up and one with 10 years in a subset of patients.[32–40] There are multiple studies from Europe with over 10 years of follow-up.[34,41–43] There are three FDA IDE randomized control trials comparing TDR to fusion (ProDisc L, Charité, Maverick [Medtronic]) that consistently found TDR to have similar or superior outcomes compared with fusion.[35,36,44] The other 5-year study was an FDA IDE trial comparing two TDRs (Kineflex [SpinalMotion] vs. Charité) with good results in both groups.[45] Two studies have had a

TABLE 49.1 Current Lumbar Total Disc Replacement Designs

Implant	Manufacturer	Key Features	Approved Use
Charité	DePuy Synthes	Two metal endplates with biconvex mobile with unconstrained motion and UHMWPE insert	Single-level lumbar disc replacement (discontinued 9/2011)
ProDisc L	DePuy Synthes	Two metal endplates with fixed uniconvex UHMWPE insert, ball-and-socket articulation with fixed center of rotation and constrained motion	Single-level lumbar disc replacement
Maverick	Medtronic	Two metal endplates with metal-on-metal articulation ball-and-socket type with constrained motion	Withdrawn due to patent issues
FlexiCore	Stryker Spine	Two metal endplates with metal-on-metal articulation ball-and-socket type with constrained motion	Withdrawn by Stryker
Kineflex	SpinalMotion	Two metal endplates with metal-on-metal articulation and semiconstrained motion	Withdrawn by sponsor
activL	Aesculap	Two metal endplates with UHMWPE insert with constrained motion	Single-level lumbar disc replacement
Freedom	Axiomed	Two titanium bead–coated endplates with rails for short-term fixation, notched endcap for device positioning with viscoelastic polymer core	FDA IDE study data collection is ongoing
M6 L	Spinal Kinetics	Two metal plates with UHMWPE artificial anulus and artificial polymer nucleus and viscoelastic motion	Not yet studied in the United States, but used in Europe
Mobidisc	Zimmer Biomet	Two metal endplates with self-centered UHMWPE creating an unconstrained motion	Being implanted in Europe

FDA, Food and Drug Administration; IDE, investigational device exemption; UHMWPE, ultrahigh-molecular-weight polyethylene.

2-year follow-up comparing TDR to fusion (ProDisc L two-level IDE, FlexiCore [Stryker]) with TDR outcomes similar or superior to fusion.[33,39]

Specifically, the ProDisc L two-level study enrolled 237 patients with 2-year follow-up that resulted in significantly less operative time, blood loss, and hospital stay compared with fusion.[33] The TDR group demonstrated preservation of range of motion (ROM) with greater improvements in visual analog scale (VAS) and Short Form-36) scores as well as patient satisfaction. In regard to two-level surgery, results of

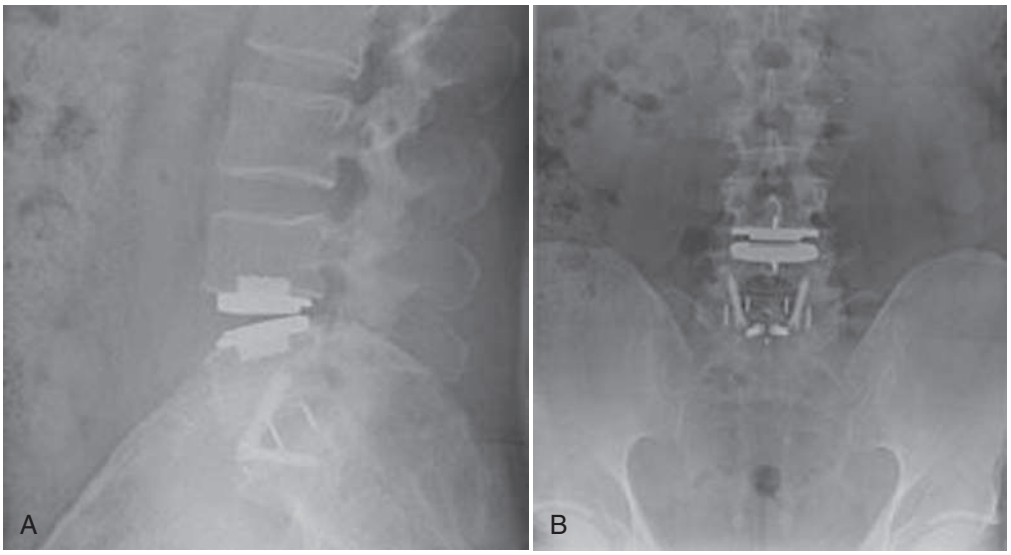

FIG. 49.13 Anteoposterior (A) and (B) lateral radiographs of a hybrid implantation with a ProDisc L and Arcadius L stand-alone interbody fusion device in a patient with two-level disc pathology with differing stages of degeneration.

10-year follow-up have been reported in a relatively small sample of patients from one site participating in the FDA trial.[41] They found that patient satisfaction was 92%, with 85% clinical success. The significant improvement in Oswestry Disability Index (ODI) scores were maintained during the long-term follow-up. Overall, there was a trend of similar or superior outcomes in the studies done in the United States comparing TDR to fusion and comparing different TDRs done for one- and two-level DDD.

Multiple studies from Europe have had a 5- to 10-year follow-up. In a 5-year study from Siepe et al., with a more than 90% follow-up rate, the satisfaction rate was 86.3% and there was a 2.2% adjacent-segment reoperation rate.[46] They also found that a one-level TDR had statistically better results on some measures compared with a two-level TDR, including a lower complication rate (11.9% vs. 17.6%), lower VAS and ODI scores, and higher satisfaction. Another long-term study was by Lemaire et al., with a minimum 10-year follow up with the Charité.[32] More than 90% of patients returned to work, and good/excellent outcomes and maintenance of ROM were found in over 95% of patients. Other studies with more than a 10-year follow-up replicated the results. Regarding other implants, there is a study from Lovi et al. with 51 patients from two centers in Europe using the Maverick at a single level.[34] They reported that back pain was improved in 84% of patients. There were no significant changes in adjacent discs and facet joints based on MRI at 10-year follow-up. Overall, studies in Europe had longer follow-up and replicated the results from the United States.

One of the major potential clinical benefits of lumbar TDR is reducing the occurrence of adjacent-level degeneration. Biomechanically, fusion increases intradiscal pressure, facet loading, and hypermobility above and beyond natural history. Risk factors for adjacent-level disease are pedicle screws, facet joint violation, sagittal malalignment, and fusion length. There is evidence showing significant difference in adjacent-level disease comparing TDR versus fusion (9.2% vs. 28.6%, respectively).[35] In the same study, among patients with normal adjacent levels preoperatively, significantly more TDR patients had no changes in these levels at 5 years postoperatively (90.8%) compared to fusion (71.4%). Adjacent segments were reoperated in 1.9% of patients who underwent TDR and in 4% of fusion patients.

A *hybrid construct* refers to the use of a lumbar disc replacement adjacent to a fusion. The TDR may be performed along with fusion of an adjacent level, or it may be performed adjacent to a previously fused level (Fig. 49.13). Both of these clinical scenarios are considered off-label use for the prostheses currently available for use in the United States based on the inclusion and exclusion criteria from the FDA IDE trials. The theoretical advantages of preventing adjacent-segment disease may have more utility when used in hybrid constructs. The advantages would be increased in longer fusions, which have a higher incidence of adjacent-segment disease.[47–50] Aunoble and colleagues[51] implanted hybrid constructs in 42 patients and followed them prospectively. At 2 years, ODI decreased by 53%. However, no prospective randomized level 1 data or long-term prospective data exist to support the regular use of these hybrid constructs.

Despite the overwhelming amount of scientific data supporting TDR in the lumbar spine, there still is a lack of approval by insurance companies for its use, with many of the major insurance carriers claiming TDR is still experimental or that it is a more costly procedure. However, when compared to fusion, as previously mentioned, it shows higher patient satisfaction outcomes and is more cost-effective than ALIF and anteroposterior procedures.[52–56] Along with almost no catastrophic failures or high revision rates, the TDR revision burden fell within range of hip and knee replacement, which are generally considered successful and cost-effective procedures.[52–56]

Postoperative Management

Postoperative management is quite similar for ALIF and TDR. Patient-controlled analgesia is instituted for pain control and weaned as bowel function and oral tolerance allow. The patient is mobilized the day of surgery, starting with chair transfers and assisted ambulation. A liquid diet is started after surgery and progressed as tolerated. Hospital stay is typically 1 to 3 days, based on patient type and surgery performed. Bracing is variable, dependent on stability of fixation, and is surgeon specific, ranging from an abdominal binder for comfort and incision healing to a rigid orthosis. The addition of instrumentation, bone morphogenetic proteins, and similar substances may obviate the need for rigid bracing in fusion patients. Activity should include limited bending and twisting motions, and lifting initially should be limited to 10 pounds or less. TDR patients are explicitly counseled to refrain from extension of the spine during the immediate postoperative period. Return to activities of daily living is progressively allowed and encouraged. Return to work and sports depends on the patient and surgeon, based on the patient's requirements, status of fusion, and fixation method. In general, TDR patients are released for all activities at 3 months.

Evaluation of fusion progression can be difficult in the presence of an interbody graft. Evaluation of fusions that is 100% reliable is available only with histologic examination, which is rarely possible or done. Radiolucent and nonferromagnetic implants, such as carbon fiber and polymer synthetics, have been developed to allow better visualization of surrounding bone and soft tissues on plain radiographs, MRI, and computed tomography (CT). Cizek and Boyd[57] evaluated cadaveric implant models radiographically and found neither CT nor radiographic interpretation reliable. Evidence of a fusion can be evaluated by the following radiographic features: (1) no motion on flexion-extension films (≤5 degrees has been accepted as fused in the literature and by the FDA); (2) anterior or posterior bridging bone across the disc space, called the *sentinel sign*[58]; (3) bridging trabecular bone across the intervertebral space and endplates; and (4) the absence of "a windshield wiping halo," or lucency around instrumentation, indicating implant motion.

In disc replacement patients, fixation of the implant is equally difficult. Once soft tissues are healed, fixation of the implant to the endplates is best judged on plain film radiographic images demonstrating good endplate–implant interface apposition and secondary bony integration, which usually occurs by 3 months. As with fusion and other implants, radiolucency of the bone-implant interface is indicative of motion and loosening.

Complications

The incidence of complications in anterior spinal surgery is often difficult to assess because of the different types of procedures, surgeons performing them, implants used, and experience of the operative team. Poor outcome is the number one surgical complication, and poor patient selection is often to blame; one must be vigilant in diagnostic workup and adhere to surgeries that address the patient's pain generators.

Vascular injury to the common iliac vessels with L5–S1 exposure is most commonly seen upon exposure for both TDR and ALIF patients. Clear identification of the disc space before discectomy must be obtained and maintained during the operation. In particular, the common iliac vein, being compressible and dorsal to the artery, can be mistaken for soft tissue during the approach. The iliolumbar vein, also called the *ascending lumbar vein,* is at risk during approaches to the L4–L5 interspace, and should be controlled as dictated by the amount of exposure necessary. Some surgeons believe that ligation of this vessel should be obtained in 100% of exposures to minimize the risk of tearing during retraction. Arterial thrombosis from aggressive retraction or injury, or both, has also been reported.[59,60]

Retrograde ejaculation as a result of hypogastric plexus injury has been reported to range from 0.4%[61] to 8%.[62] In one of the largest single ALIF trials to date, Kuslich and colleagues[63] reported a 4% rate in 591 patients. Loguidice and colleagues[64] in 58 patients and Brau[65] in 686 exposures each noted only one case of retrograde ejaculation. The preaortic (prevertebral) sympathetic plexus runs along the anterolateral edge of the vertebral bodies, adjacent to the psoas, then traverses over the aortic bifurcation and common iliac vessels forming the hypogastric plexus. Blunt dissection to mobilize the more cephalad prevertebral plexus before the hypogastric plexus can aid the exposure. Aggressive electrocautery should be minimized during the approach in this area and during the disc space preparation. Male patients should be counseled on this potential adverse event and advised that there also is a chance of spontaneous recovery. Most patients, even if retrograde ejaculation occurs, are still able to achieve sexual satisfaction, but may still have difficulty fathering a child. If the patient is concerned, he can predonate and store sperm, or some urologists recommend recovery of the sperm in affected individuals.

Injury to the alimentary tract can be minimized by packing the peritoneum behind self-retaining retractors. Postoperative ileus occurs and can be effectively managed with restricted oral intake, proper fluid hydration, and gastric suction, as indicated. Damage to the bladder and ureter, rare in primary cases, can be minimized by routine use of a Foley catheter and, in revision cases, with proper identification and the placement of preoperative ureteral stents.

Fusion implant-related complications, such as graft subsidence, malposition, extrusion, and pseudarthrosis, as alluded to previously in this chapter, can be minimized with careful patient selection, careful implant selection, and meticulous discectomy to optimize the fusion bed without disrupting the structural integrity of the subchondral bony endplates. The proper height graft should be selected to restore "normal" disc height, avoiding overdistraction.

Complications in TDR surgery can be divided into previously mentioned approach-related, device-related, and patient-related complications.[66] Device-related complications

include implant subsidence, migration or extrusion, malposition, and material wear or reaction. Subsidence is by far the most common issue, seen in up to 9% of TDRs in older studies and from 0% to 3% of patients in more recent trials.[30,36,67] Subsidence has also been observed in up to 67% of patients with failed TDR outcomess.[68] Of note, no clear clinical effect of subsidence on outcomes has yet been demonstrated. This complication may be minimized by excluding patients with poor bone quality and seating the largest implants on the more cortical peripheral edges of the vertebral endplates. The risk of device migration or extrusion depends significantly on implant design, placement, and sizing. A TDR inserted in the midline—which can be fixed to bone with spikes or keels, promotes bony ingrowth to the endplates, and is sized to provide good soft tissue tension—would have a very low chance of migrating. In earlier studies, the rates of migration were up to 7%,[68] but with improved designs and surgical experience, more recent studies have shown rates of 0% to 2.4%.[36,42] There have been several reports of confirmed adverse reactions to particulate wear debris. There are also controversies surrounding metal-on-metal implants, mostly due to the concerns existing about the release of metal ions into the bloodstream.[69] Most device-related complications are iatrogenic and can be minimized with proper patient selection, operative technique, and implant sizing and position. Malpositioning is the main reason for significant wear in these implants.

Patient-related complications include adjacent-level disc degeneration, same-level facet degeneration, and heterotopic ossification. Successful motion preservation is the main mechanical goal of lumbar TDR. This has been well documented.[37,70] Adjacent-segment degeneration seen after arthrodesis is thought to be related to increased stress at adjacent segments due to transfer of extra motion and loads from the fused segment. Currently, there is only one long-term study that definitively shows that motion preservation using TDR avoids accelerated adjacent-segment degeneration in a 5-year follow-up.[35] Intermediate-term data by Huang et al. using the PRODISC show that ROM of at least 5 degrees is needed for improved clinical outcomes and reduction in degeneration of adjacent discs.[71]

The presence of degenerative disease in the facet joints is a contraindication to lumbar TDR. Early disease in the facets may be missed during initial screening, and patients may continue to experience pain after surgery from persistent motion in these degenerated posterior structures. In a study assessing 175 patients complaining of persistent pain after PRODISC II implantation, facet joints were confirmed as a source of pain by fluoroscopically guided blocks in 12.6% of patients, mostly at the index level (84%).[43] Van Ooij et al. reported facet joint arthrosis in 42% of patients with persistent pain after Charité TDR.[68] All 29 patients with failed TDRs in a study by Rosen et al. had evidence of facet distraction or compression on CT.[57] Facet distraction was also associated with radiculopathy, likely from capsular stretch.

TDR design may also affect the manner in which the facets are loaded. In the normal lumbar spine, facets are loaded with ventral shear forces. Implants with a fixed center of rotation, such as the ProDisc, absorb anteroposterior shear forces, thus creating greater stress within the implant and at the implant–bone interface, while sparing the facets. The fixed center of rotation creates a greater arc of motion to compensate for the lack of translation. This changes the kinematics of a facet joint, causing greater stresses at the extremes of flexion and extension.[72]

Heterotopic ossification, limiting TDR's ROM, is of some concern. Although it was observed often with earlier implant designs, studies with modern TDRs show significantly lower rates. In addition, Tortolani et al. reviewed data from the Charité IDE study and evaluated the clinical significance of heterotopic ossification.[73] Of 276 patients, 12 (4.3%) had radiographic evidence of new bone formation. All of these patients had ROMs and clinical outcomes similar to the rest of the study population.

The complication rates with TDR surgeries are relatively low. Nevertheless, strategies for revision have been developed. If additional surgery is necessary, either an anterior or a posterior approach is used. Repeat ventral surgery carries a significantly higher risk of intraoperative complications. In the Charité IDE study, the incidence of vessel injury during reoperation was significantly greater than that with the index operation (16.7% vs. 3.6%), mostly because of scarring to the vertebral column.[74] Other structures at risk due to scarring and distorted anatomy are the ureters and the lumbosacral trunk. These complications may be minimized with use of preoperative angiography and the intraoperative placement of intravascular balloons and ureteral stents.

An alternative revision procedure involves posterior fusion with rigid instrumentation. This strategy avoids the area of previous surgery and solves problems of instability. Cunningham et al. performed an in vitro biomechanical analysis of such a construct. They found that augmentation of an anteriorly placed TDR with posteriorly placed pedicle screws provided stability similar to that of the combination of anterior cage and posterior pedicle screws (circumferential fusion construct).[75] If TDR components must be removed because of dislodgement or malposition, however, the posterior approach is inadequate. Alternative approaches, such as transperitoneal, contralateral retroperitoneal, and transpsoas (for levels L4–L5 and above), have been described.[76–78] A prophylactic strategy involves placing an antiadhesive barrier over the vertebral column after TDR implantation to prevent scarring after a primary anterior approach. Various liquid and solid products are available and have been shown to be effective in adhesion prevention with abdominal and pelvic surgery.[79]

Acknowledgment

We thank Karl Lelkes, MD, and Ernesto Lopez, MD, for their contributions to this chapter.

PEARLS AND PITFALLS: ALIF

1. Careful patient selection is the key to successful surgery and maximization of outcomes.
2. Meticulous disc space preparation that avoids endplate violation is important for proper fit of the implant.

3. Selection of an implant depends on the disc space anatomy to allow the best fit and contact with endplates.
4. An implant of the proper height should be selected to restore "normal" disc height, avoiding overdistraction.

PEARLS: TDR

1. Level 1 scientific evidence for the efficacy of lumbar TDR exists for one- and two-level DDD, although US FDA approval is currently only for single-level use.
2. Preoperative CT scans should be considered in all lumbar TDR patients to assess for facet arthrosis and to ensure that there is no preoperative unrecognized spondylolysis.
3. DEXA scans should be obtained preoperatively in patients older than 50 years or if there are other clinical risk factors for osteoporosis because osteopenia (T-score of ≤–1.0) is a contraindication to lumbar disc replacement.
4. Care should be taken to preserve the bony endplates. Endplate insufficiency is an indication to convert to fusion.
5. Radiographic confirmation of the midline in the coronal plane (on anteroposterior fluoroscopic view) is imperative before final disc space preparation and implant insertion.

PITFALLS: TDR

1. Failure to identify the patient's pain generator adequately may lead to a higher clinical failure rate than published series.
2. Extremely easy mobilization and distraction of a collapsed disc space may point to unrecognized defects in the pars interarticularis.
3. Failure to mobilize the motion segment adequately before implant insertion or attempts to stuff the disc space with the tallest TDR implant would result in limited postoperative ROM.
4. Implant insertion with inadequate anterior exposure may result in device positioning unacceptably off the midline.
5. For revision anterior surgery for device removal, the surgeon should consider an alternative approach to the disc space from the original approach.

KEY POINTS: ALIF

1. Knowledge of the retroperitoneal anatomy is essential.
2. Both TDR and ALIF are safe and effective procedures in the hands of experienced spine surgeons.
3. Patient selection is key to a successful outcome.
4. A wide variety of graft materials and constructs are available with varying degrees of stability that may or may not necessitate posterior fixation.
5. Complications can be kept to a minimum with careful surgical technique.

KEY POINTS: TDR

1. The US FDA IDE clinical trials for the various devices provide level 1 prospective randomized data showing clinical success for fusion and TDR for properly selected patients with chronic back pain secondary to disc degeneration.
2. Despite the noninferiority design of the clinical trials, the published data seem to indicate that a well-implanted, functional disc replacement can result in a better clinical outcome than a fused segment.
3. Revision and removal of the current lumbar TDR devices remain quite technically challenging.
4. Long-term results are also needed to see if current motion preservation designs are effective in preventing adjacent-segment degeneration seen with lumbar fusions.

CHAPTER 50

Posterior Lumbar Interbody Fusion

SECTION VI

William J. Molinari III
Nathan H. Lebwohl

Introduction

The technique of posterior lumbar interbody fusion (PLIF) has become an important part of the modern spine surgeon's armamentarium. This was not always so; for nearly half a century after the introduction of this technique, it was performed routinely by only a handful of surgeons. Most surgeons condemned the technique as unnecessary, technically difficult, or even dangerous.[1,2] Controversy persists regarding the safety of PLIF compared with other approaches to the intervertebral space and regarding the benefit that PLIF adds to the outcome of surgical treatment for various spinal pathologies.

PLIF is an operation in which the disc space is exposed from a posterior approach, similar to that used in a discectomy, and a fusion is performed by directly grafting the intervertebral space. Classically, PLIF is performed via bilateral exposure of the disc space, with some retraction of the dura to expose the disc. When PLIF was first described, before the era of spinal instrumentation, advocates of the operation argued that it prevented collapse of the disc space after discectomy and maintained the height of the neural foramen, keeping the root free of bony compression. These advocates also believed that placing bone graft directly in the disc space would more likely result in healing of the fusion because the bone would be subject to compressive forces. Critics argued that the operation required excessive epidural dissection and nerve root retraction with a high risk of dural tear, epidural fibrosis, nerve root injury, and chronic arachnoiditis, and that graft displacement could lead to late neurologic compromise.

Historical Perspective

Attempts to identify the first surgeon to perform an interbody fusion from a posterior approach are muddled by several reports appearing in the published literature beginning in 1944,[3–5] but no one disputes that credit for initially developing the techniques and key principles of the operation as it is practiced today belongs to Cloward,[6] who emphasized the importance of a wide exposure of the spinal canal to minimize nerve root injuries, the use of structural graft to prevent intervertebral collapse, and the complete removal of nuclear material from the disc space and replacement with bone to promote fusion. Cloward was widely criticized for his operation, probably as much because he advocated that it be included as part of the routine surgical treatment for all lumbar disc herniations as for the frequency of poor outcomes and complications when it was attempted by other surgeons. A few surgeons embraced Cloward's operation, and several large surgical series were published in the literature reporting good outcomes and high fusion rates.[7–10] Widespread interest in and acceptance of PLIF as a valuable technique did not occur, however, until the introduction of pedicle screw instrumentation.

With the early generation of pedicle instrumentation, screw fracture was a common occurrence. Fracture especially occurred if a dramatic change in spinal alignment was achieved, such as in the reduction of a high-grade spondylolisthesis. Even without large changes in alignment, screw fracture occurred commonly in overweight patients or when the disc space was distracted.[11] In those cases, the mechanical loads that the instrumentation was subjected to exceeded the fatigue properties of the screws. Surgeons, in particular Steffee and Sitkowski,[12] recognized that a structural graft placed in the disc space would divert some of the load, decreasing the forces on the posterior instrumentation, and reduce the frequency of instrumentation failure. Steffee and Sitkowski[12] reported their experiences with reduction of high-grade spondylolisthesis. In each of the first three patients treated with pedicle screws, the instrumentation failed, and alignment was lost. In the next 11 patients, an interbody graft was placed. All of these patients developed solid fusions with no loss of alignment. With PLIF, the load-sharing anterior column support could be added to protect the pedicle screws without the need for a separate anterior incision (Fig. 50.1).

Simultaneous with the benefit of PLIF on reducing failures of the new instrumentation, pedicle instrumentation had a beneficial effect on the outcome of PLIF surgery. For the first time, rigid fixation was available that could effectively stabilize the lumbar spine after laminectomy. This fixation virtually eliminated the complication of graft displacement

FIG. 50.1 Screw fracture and loss of alignment is a common complication after reduction of spondylolisthesis if anterior column support is not added.

that had previously been associated with PLIF in some surgeons' hands.

The addition of instrumentation also improved the fusion rate of PLIF. Many of the previously held objections to PLIF surgery were no longer applicable when PLIF was combined with pedicle instrumentation.

Another development that favored the adoption of PLIF was the invention of the interbody fusion cage by Brantigan and the titanium mesh cage by Harms. Their designs eliminated the need to harvest a structural graft from the iliac crest, which was a major source of morbidity previously associated with the PLIF procedure. The cage provided the structure,[13] and the osteogenic potential for fusion came from cancellous bone packed into the cage, which could be obtained from the iliac crest more easily than a structural graft, with less injury to the patient. Before the invention of the cages, it was possible to avoid the morbidity associated with graft harvest by using allograft bone, as advocated by Cloward.[14,15] Concerns about availability, disease transmission, healing potential, delayed healing, and wide variation in the structural integrity of available grafts all contributed to the limited enthusiasm for the use of allograft bone for interbody fusion.[16,17] The availability of cages overcame another common objection to the PLIF operation.

The availability of pedicle screw instrumentation and intervertebral cages contributed to progressively greater acceptance of the operation first pioneered by Cloward. Better alignment and higher fusion rates are routinely achieved using these devices. The training of surgeons and marketing of these devices by their manufacturers have also contributed to wider adoption of PLIF in surgical practice. Not all of these devices have proven to be successful, however. Cylindrical threaded fusion cages enjoyed brief popularity as PLIF devices that did not require supplementary fixation, but mediocre results and high complication rates associated with their use resulted in their virtual disappearance as a posterior spinal implant.[18] The clinical experience with threaded implants and the study of the relevant biomechanics have helped surgeons understand the PLIF operation better, however, and develop the operation that is currently performed. Although more recent advances, such as the development of the transforaminal and direct lateral approaches to the disc space, have decreased the frequency with which PLIF is performed, PLIF remains an important and powerful tool for spinal surgeons.

Indications for Interbody Fusion

Some surgeons believe that an interbody fusion is indicated whenever a lumbar fusion is done. They argue that the intervertebral space is biologically and mechanically superior for fusion compared with the intertransverse plane because of the larger surface area of the highly vascular bony endplate and because the interbody bone graft is subject to compressive forces. In addition, they criticize the large amount of muscle damage that occurs from exposure of the spine for posterolateral fusion. Despite these theoretical advantages, it is difficult to show clinical superiority of interbody fusions over posterolateral fusions for most lumbar degenerative conditions, and most published studies comparing the techniques reveal similar outcomes regardless of what fusion technique is used.[19–22] There are, however, certain circumstances when interbody fusion offers definite advantages. Adding an interbody fusion to a posterolateral fusion increases the rate of achieving successful arthrodesis. This is especially true when a long fusion extends to the sacrum, which is historically associated with a high risk of lumbosacral pseudarthrosis.[23]

Some authors have argued that interbody fusion should be combined with posterolateral fusion in other patients at high risk for failed fusion, such as smokers.[24] Witham et al. reviewed 103 patients that were either treated with a posterolateral arthrodesis alone or a posterolateral arthrodesis with PLIF or transforaminal lumbar interbody fusion (TLIF) for degenerative or isthmic spondylolisthesis. They found that a posterolateral fusion combined with an interbody fusion correlated with a greater amount of correction as well as a decreased need for reoperation related to pseudarthrosis, progression of listhesis, instrumentation failure, and adjacent-segment disease. They argue that adding an interbody fusion to the index procedure is most worthwhile to decrease the need for reoperation, which is more than seven times likely in the posterolateral fusion–only group.[25] In patients with pseudarthrosis after failed posterolateral fusion, an interbody fusion is a good salvage operation, allowing the fusion to occur in a well-vascularized bony bed rather than attempting fusion again in the scarred devascularized posterolateral space.[26] Interbody fusion offers a particular advantage in the treatment of scoliosis and kyphosis or flatback deformities. The destabilizing effect of disc space preparation facilitates rotational correction,

and distraction of the intervertebral space allows correction of segmental kyphosis and asymmetrical tilt of the vertebrae. In patients with isthmic spondylolisthesis who undergo deformity reduction, it has been well shown that an interbody graft offers a biomechanical advantage, which protects instrumentation by load sharing, helping to maintain the alignment achieved at surgery. Also, the L5 transverse process is often hypoplastic in these patients; thus, the increased bone surface area of the vertebral endplate offers a vastly larger area to which bone can fuse.

Most series evaluating the role of interbody fusion in isthmic spondylolisthesis show substantial clinical and radiographic benefit.[27,28] Finally, the most common indication for interbody fusion, but probably the most controversial, is ablation of the disc space in patients with discogenic pain.[29,30] Many advocates for surgical treatment of this entity argue that only interbody fusion can completely remove motion of the painful disc and that complete removal of nuclear material is necessary to eliminate the anatomic source of pain.

Regardless of the indication, interbody fusion can be performed from anterior and posterior approaches. The relative advantages of these approaches are influenced by many factors, and it is essential that the spinal surgeon be well trained in various approaches so that the most appropriate one can be chosen for each unique clinical situation. Specific advantages of the posterior approach include the ability to simultaneously decompress the spinal canal directly and stabilize the spine more effectively with instrumentation. Although safe techniques of anterior fixation have become available more recently, if multilevel instrumentation is needed, posterior approaches are preferred. In patients with spinal deformity, bilateral facet resection allows more effective destabilization of the motion segment, allowing greater corrections than can be obtained by anterior disc removal alone, again favoring a posterior approach to the intervertebral disc. Posterior approaches avoid manipulation of the great vessels, of special concern in patients with atherosclerosis or a history of venous thrombosis. Also, posterior approaches avoid injury to the hypogastric plexus, which can result in retrograde ejaculation and sterility; thus, they are generally preferred in young men.

When there has been extensive posterior surgery and scarring, anterior approaches to the disc space avoid the increased risks of dural tear and nerve root injury associated with reoperation on the spinal canal. If a conjoined root is identified on preoperative imaging, the risk of root injury is also higher, and an anterior approach is preferred. A wider exposure of the disc space can also be achieved anteriorly, theoretically allowing better preparation of the endplates and more complete packing of the interspace with bone graft. Some surgeons prefer the anterior approach in patients at high risk for pseudarthrosis. An anterior approach may also be preferred when trying to increase lordosis. Dividing the anterior longitudinal ligament may allow for greater anterior distraction and more lordosis. Despite this theoretical advantage, in our experience, anterior approaches are more effective than posterior approaches in achieving lordosis only when the facet joints are highly mobile or have first been resected through a posterior approach.

Biomechanics of Interbody Fusion

An appreciation of the mechanical properties of the spine after interbody fusion is essential to understanding the benefits and pitfalls of this operation. It seems intuitively obvious that placing a solid block in the disc space would prevent flexion of the vertebral motion segment. This is what occurs—whether the graft is placed from an anterior or posterior approach. This fact has important implications for protection of posterior instrumentation. Interbody grafts significantly decrease the strain in posterior spinal implants when they are subjected to compression or flexion loads, which are the common modes of failure of these constructs in clinical practice. Various authors have shown that placing intervertebral cages decreases forces and strain in posterior implants by 56% to 80%,[29,30] and the clinical benefit of establishing anterior load sharing to prevent implant and construct failure is well established (Fig. 50.2).[31]

Increasing stability when the spine is subject to flexion loading does not mean that the spine is more stable when subject to forces in every direction. After interbody graft placement, the motion segment is more unstable in certain directions. The pattern of instability is determined to a great extent by the direction from which the graft is placed and represents the destabilizing effect of the surgical approach[32] and the preparation of the disc space. Grafts placed from an anterior approach result in increased motion when force is applied in extension; this likely represents the effect of dividing the anterior longitudinal ligament. Grafts placed from a posterior approach result in increased axial rotation of the motion segment owing to the resection of the posterior facet complexes necessary to avoid excessive dural retraction.[33–37] The design of the cage—vertical, box, or threaded, and whether or not the cage engages the endplates—does not seem to matter with regard to the patterns of instability created by intervertebral placement. Only the structures sacrificed during the approach to the disc are important in determining instability of the final construct (Fig. 50.3).[38,39]

Most surgeons make the assumption that a PLIF procedure is a stabilizing operation. The biomechanical data show that this is not entirely true. Understanding that placing an interbody graft or cage can lead to destabilization of the motion segment in certain directions is important for understanding why interbody fusion done without supplementary fixation has a high failure rate, especially when done from a posterior approach. Proponents of threaded fusion cages, which were designed to be used without supplementary fixation, argued that distraction of the disc space would stabilize the motion segment through ligamentotaxis. This argument is true. Increasing the size of the cage used to distract the disc space results in greater stabilization of the motion segment on mechanical testing.[40] After cyclic loading, some subsidence is inevitable, however, and biomechanical tests done after cyclic loading of threaded cage constructs reveal decreased stability in all directions.[41]

The destabilizing effects of interbody fusion are overcome by adding pedicle screw instrumentation; this is true whether

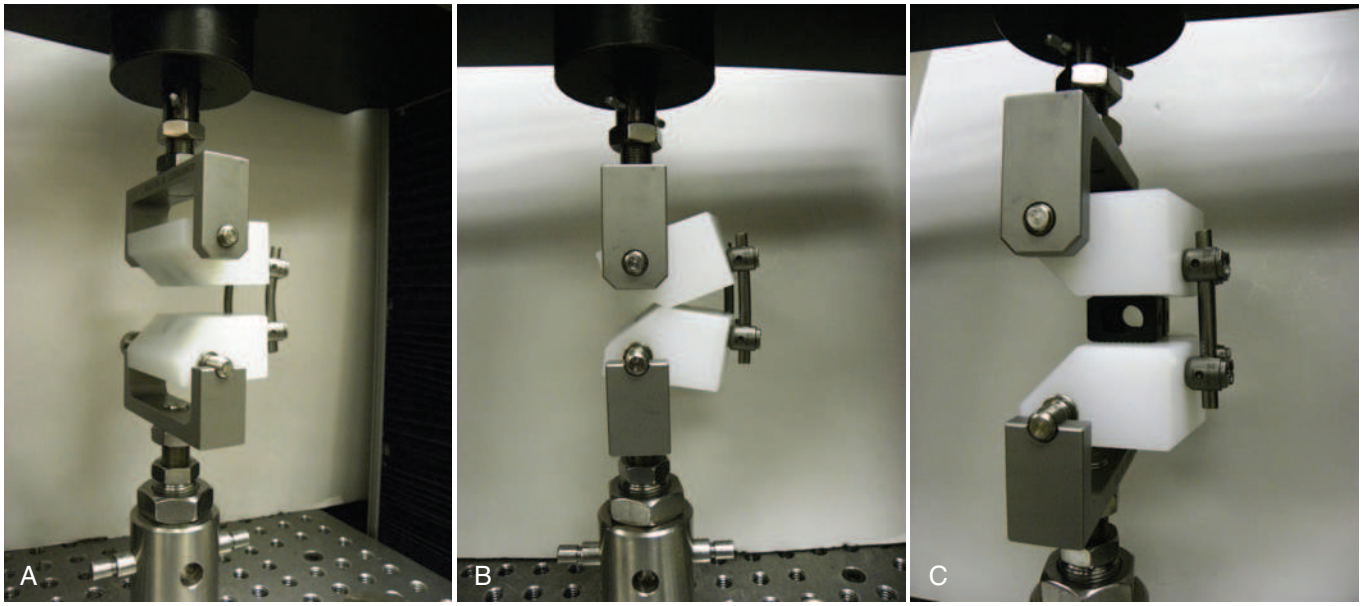

FIG. 50.2 Reduction in strain on posterior implants when a cage is placed in the intervertebral disc space. This model of a spinal motion segment with pedicle screw fixation has no anterior column support. (A) Alignment with no load applied. (B) Loss of alignment with only 700 N of load, the physiologic equivalent of standing in place. (C) Protective effect of an implant placed in the disc space. (Courtesy Hassan Serhan, PhD.)

FIG. 50.3 Summation of five biomechanical studies of stability after anterior (ant) cage placement in human cadaver models, and three studies of posterior (post) cage placement. The data for each direction of testing is presented as the ratio of range of motion (ROM) after interbody cage placement compared with the motion of the unoperated segment. A ratio of 1.0 implies the same motion as the intact specimen. Note that placement from an anterior approach stiffens the spine in flexion, axial rotation (rot), and lateral bending (Lat bend), while placement from a posterior approach only stiffens the spine in extension (Ext). When testing axial rotation, placing a cage from a posterior approach creates more motion than the unoperated spine. (Modified from Oxland TR, Lund T. Biomechanics of stand-alone cages and cages in combination with posterior fixation: a literature review. *Eur Spine J.* 2000;9:S95–S101.)

the fusion is done from an anterior or posterior approach. These biomechanical data correlate well with the substantially greater clinical reliability of achieving an arthrodesis when interbody fusion is done with supplementary pedicle fixation compared with the variable results reported with stand-alone interbody fusion procedures.

Although cage design characteristics do not seem to have a significant effect on segmental motion, these characteristics do influence the risk of subsidence, the healing of bone within the cage, and the alignment achieved. In addition, endplate preparation and vertebral bone density have important effects on the extent of subsidence.

Cage Characteristics

The optimal cage material is unknown. Cloward[42] advocated the use of ethylene oxide sterilized allograft bone. Brantigan and colleagues[16] tested 18 tricortical iliac specimens obtained from bone banks and determined that 3 were not strong enough to sustain anticipated loads without collapse.

Current allograft products available for intervertebral use are made primarily of cortical bone and have adequate compressive strength. In designing his cage, Brantigan chose carbon fiber–reinforced polymer because of its strength and because its modulus of elasticity is similar to that of cortical bone.[13] In the United States, other materials commonly used in commercially available cages are polyetheretherketone, a nonreinforced polymer, and titanium, which has a modulus of elasticity significantly greater than that of cortical bone. The stiffness of the cage is determined not only by the mechanical properties of the material but also by the shape and design characteristics of the cage. The ideal stiffness and its role in limiting subsidence or enhancing fusion are unknown. Finite-element data have suggested that stiffer cages are more likely to subside,[43] but animal data have not supported this hypothesis,[44] and clinical reports have not convincingly shown that metal cages are more likely to subside than cages made of polymer (Fig. 50.4).

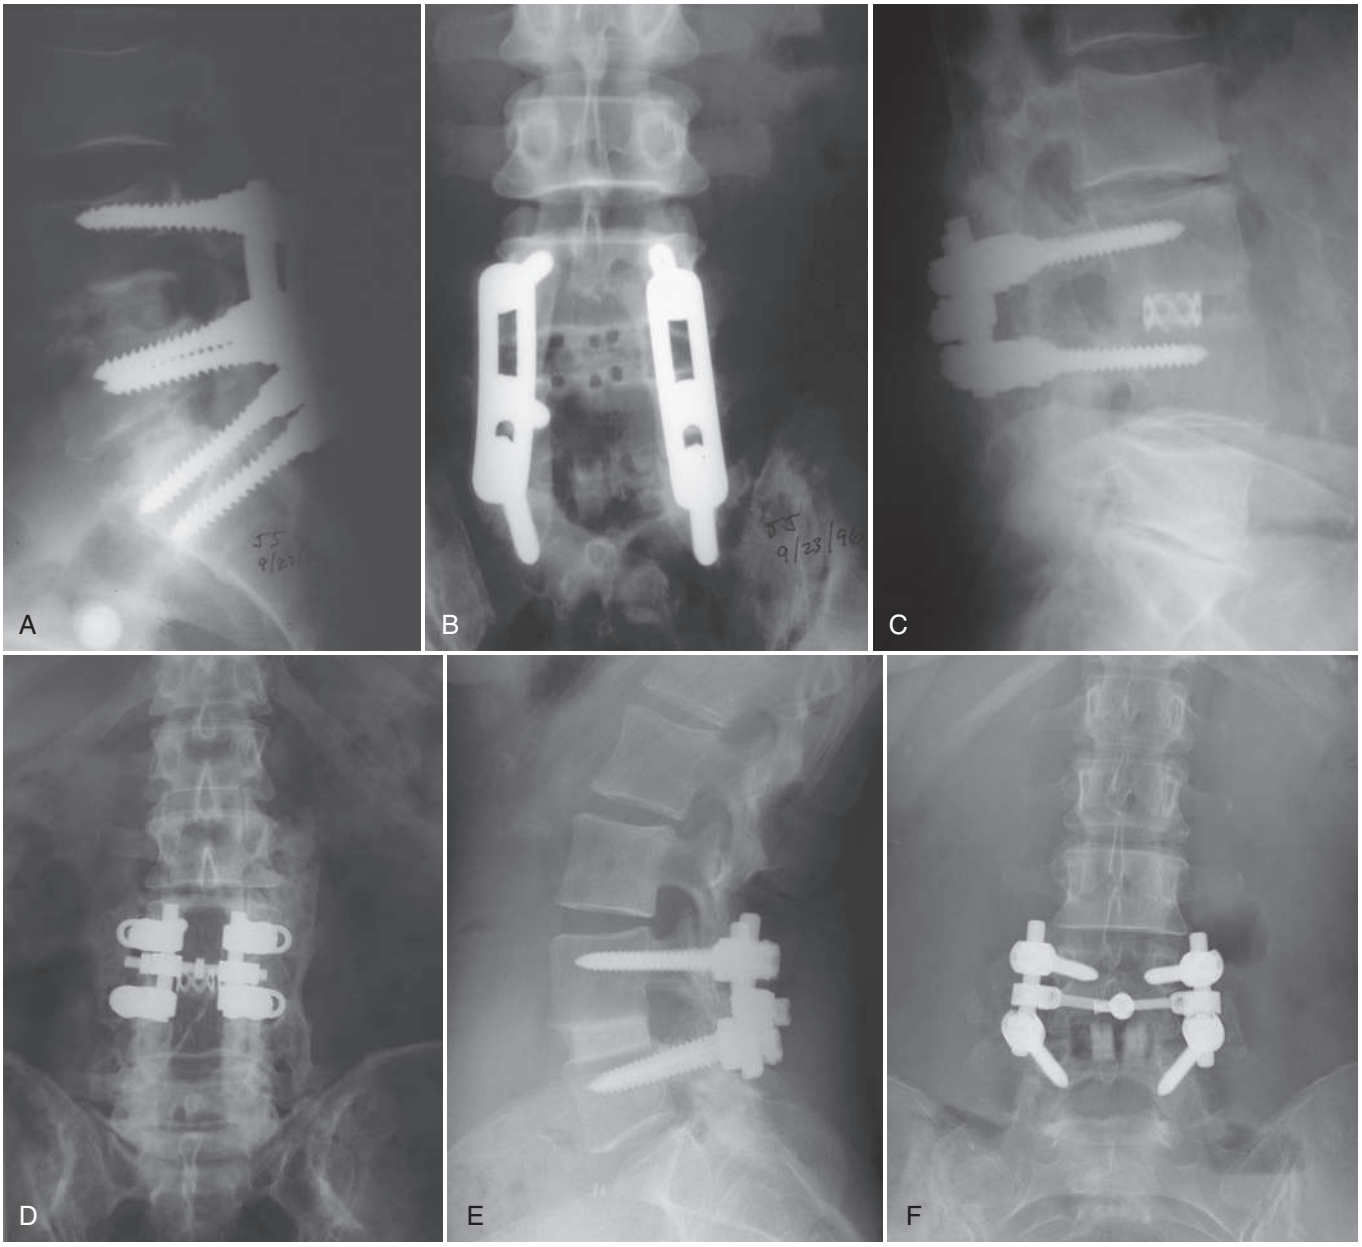

FIG. 50.4 Anteroposterior (AP) and lateral radiographs of successful interbody fusions with (A–B) carbon fiber–reinforced polymer cages, (C–D) titanium mesh cages, and (E–F) allograft wedge spacers. Incorporation of bone graft and replacement by new bone is most easily visualized with the polymer cages because they are radiolucent. The outline of the polymer can be seen on the AP view as four radiolucent squares at the periphery of the implant. With titanium mesh cages, healed bone graft is visualized in front and behind the implants, but assessment of the graft within the cage is difficult with standard radiographs. When nonunion occurs with allograft implants, a radiolucency is usually seen adjacent to the allograft. (A–B, Courtesy John Brantigan, MD.)

Kanayama and colleagues[45] studied the effect of cage design on stress shielding of the graft inside the cage. They determined that it was the pore size, not the stiffness of the material, that determined the load experienced by the graft. The total pore size was not important; rather, it was the size of the largest contiguous opening that determined how much force was transferred to the graft. It was implied that minimizing stress shielding is important to promote fusion, but no data were presented to support that presumption. One clinical study consistent with this hypothesis compared narrow and standard carbon fiber–reinforced polymer cages. The pore opening in the narrow cage was 36% smaller than the pore opening in the standard cage. There was a small but statistically significant reduction in fusion rate, 91.1% compared with 98.9%, but the conclusions have limitations because of methodologic flaws.[46] A larger pore size seems desirable as long as the design of the cage provides adequate structural support for the endplate.

Trabecular metal, another material often used for interbody fusion, offers a porous tantalum surface for fusions. This

differs from the standard cage design in which there is space in the center of the cage to fill with additional graft material. Tantalum has a modulus of elasticity similar to cancellous bone and a friction coefficient substantially higher than autograft, allograft, or other common implantable materials. Van de Kelft and Van Goethem[47] have shown that these trabecular metal spacers do provide an adequate environment for interbody fusions when used in a stand-alone fashion or reinforced with pedicle screw fixation. They reported a 94% and 97% fusion rate, respectively, when comparing stand-alone trabecular spacers versus trabecular spacers with pedicle screw fixation in single-level interbody fusions. Subsidence rates were acceptably low in both groups.

Implant design also influences the alignment achieved. An increasingly large body of evidence shows that maintaining or restoring lumbar lordosis is an important surgical goal and that lordosis correlates with the outcome of surgery.[48] Early cage designs were rectangular and tended to force the vertebral endplates into parallel alignment. It is possible to achieve lordosis with rectangular cages, either by resecting bone posteriorly or by compressing the posterior disc space and causing the posterior portion of the cage to subside.[49] A disadvantage of this approach is that it results in loss of posterior disc space height, which can lead to foraminal narrowing. A better solution is to use a cage that is tapered to achieve lordosis.[50–52] It is commonly said that anterior distraction is necessary to achieve lordosis, but distraction of the disc space with an implant that is not tapered flattens the spine. Placing large cages to achieve lordosis is a mistake. They require more root retraction to place, which is more likely to result in nerve injury. A better solution is to use a tapered device and not to strive for maximal anterior height restoration (Fig. 50.5).

Subsidence

In addition to achieving fusion, avoiding subsidence to maintain alignment is an important goal of interbody fusion surgery. In mechanical testing, endplate failure has a linear correlation with decreased bone density,[53] and severe osteoporosis is considered to be a relative contraindication to interbody fusion because of the risk of endplate collapse. Severe osteoporosis, according to Oh et al., is defined as a T-score less than –3.0 on bone mineral density scanning.[54] This study group found subsidence of cages 3 mm or greater more prevalent in their severely osteoporotic study population compared to those patients with higher T-scores. Although the incidence of subsidence was greater, they did not correlate this finding with a negative impact on clinical outcomes.[54] The strength of the endplate is not uniform, and the central portion, where most surgeons place their grafts, is the weakest. Mapping studies have shown that the posterolateral portion of the endplate is most resistant to compression.[55,56] Placing the cage or graft in the area where the bone is strongest makes biomechanical sense,[57] but may not be consistent with the goals of an individual surgical case. If it is necessary to increase lordosis, better results are achieved by anterior placement. Putting the graft in the posterolateral position might be stronger, but would block compression of the posterior disc space and limit lordosis. This is especially true with rectangular cage designs or vertical titanium mesh cages.

Cage designs that optimize contact with the strongest portions of the endplate are desirable, and include cloverleaf designs and large round cages, both of which have peripheral endplate contact.[58] Practical use of large round cages is limited to anterior surgery because of the excessive dural retraction

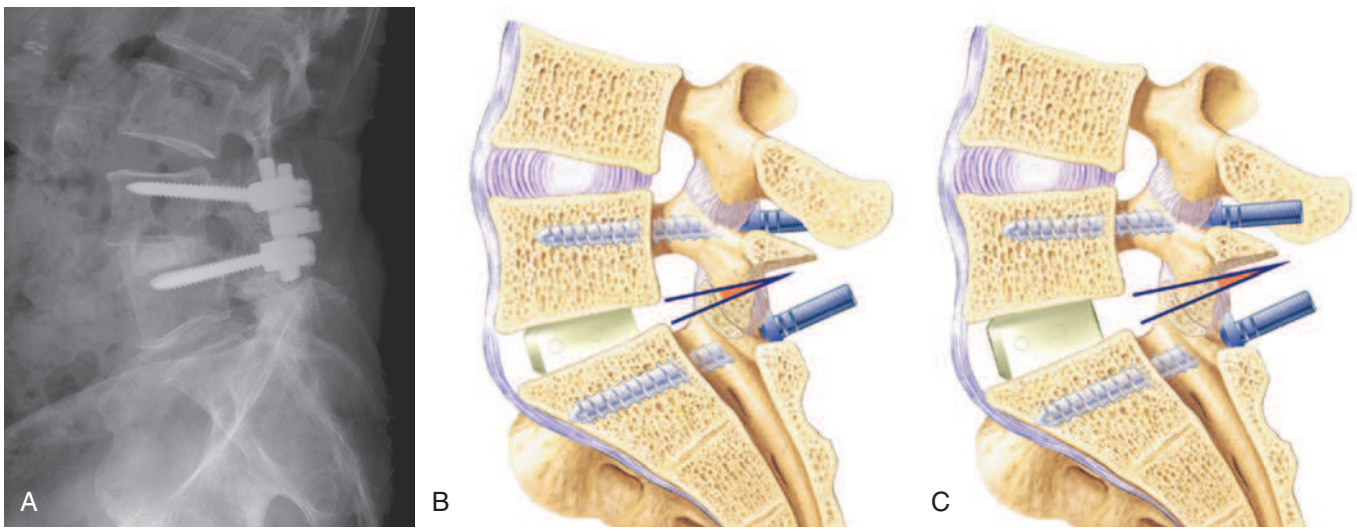

FIG. 50.5 Using a tapered cage or spacer is the best way to achieve lordosis. Facet resection is sometimes needed to allow the back of the disc space to narrow adequately. An advantage of allograft bone is the ease with which it can be sculpted intraoperatively to achieve the desired shape. (A) In this case, more lordosis was achieved than would be typically possible using commercially prepared devices by using a burr to increase the taper of the graft. (B–C) Using larger grafts and distracting the disc space more does not increase lordosis; it only increases the amount of dural retraction needed and increases the difficulty of the surgery. (B–C, Courtesy Depuy Synthes Spine, West Chester, PA.)

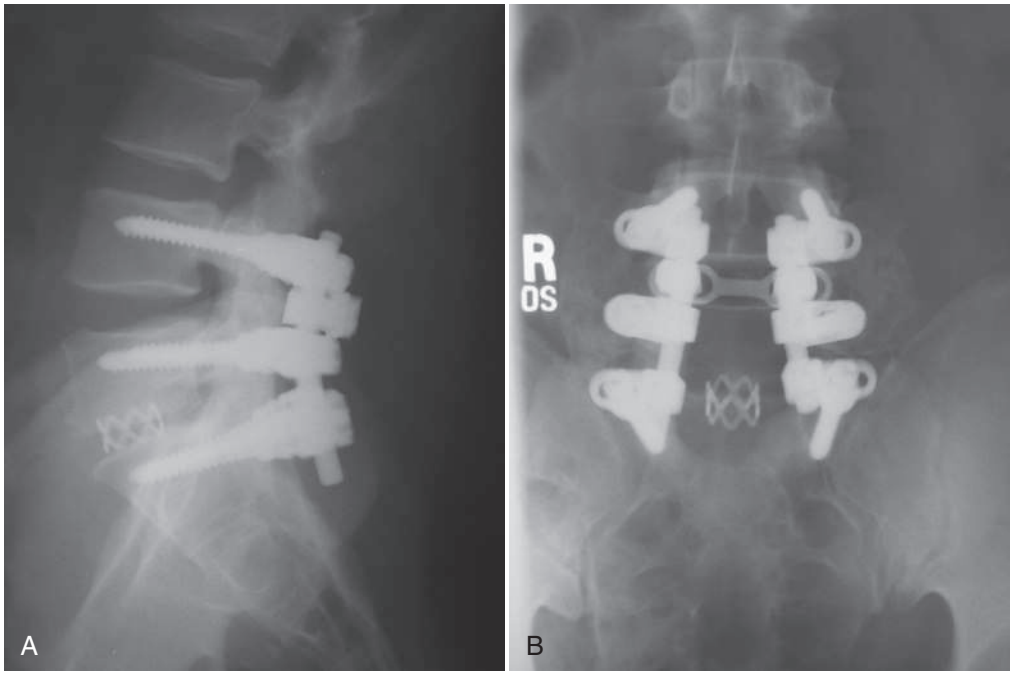

FIG. 50.6 Obvious subsidence of the cage into the inferior endplate of L5. Technical factors that may have predisposed to subsidence include the use of a single small cage placed centrally. Endcaps were not used, which would have increased the surface area of metal supporting the endplate. Inadequate grafting of the interspace around the cage may also have been a factor, suggested by the absence of bone in the disc space. Fortunately, a solid posterolateral fusion was achieved.

that would be necessary to place such an implant. Lordotic cages placed laterally also achieve near-optimal endplate contact. The surface area of the endplate that needs to be in contact with the graft is unknown, but is commonly stated to be 30%. This percentage is based on a study of thoracic vertebrae subjected to a physiologic load of 600 N. Failure of the endplate occurred in 80% of specimens subjected to that load when the grafts were 25% or less of the endplate surface area. When the grafts exceeded 30% of the endplate surface, 88% of the specimens remained intact (Fig. 50.6).[59]

Preservation of the endplate is important to maintain the structural integrity of the vertebra. Oxland and colleagues[60] removed slightly less than 1 mm of cortical endplate with a power burr to expose trabecular bone; this resulted in a 33% reduction in compressive resistance of the vertebra. If the endplate is decorticated where it is not in contact with the cage, the strength of the remaining endplate is preserved.[61] Consequently, it is recommended that the endplates be carefully preserved during preparation of the disc space wherever they are in contact with the implant, but that areas of the endplate that are not load bearing can be decorticated to increase contact of graft placed outside the cage with trabecular bone.

Our Preferred Technique

Our experience with PLIF dates back to 1994; the method of interbody fusion described here has been used without modification since 1999. Early results were reported in 2000 with an interbody fusion rate of 92%.[62] It is our practice always to perform a posterolateral fusion simultaneously with the PLIF to ensure the highest chance of achieving an arthrodesis. The technique for PLIF evolved from that described by Steffee and Biscup (personal communication, October 1994) for insertion of trapezoidal "ramps" made of carbon fiber–reinforced polymer. Their method was to insert the ramps sideways and rotate them into their final position, minimizing the amount of root retraction needed and simplifying placement of a lordotic graft.

We prefer to use a commercially prepared trapezoidal allograft wedge for two reasons. First is that its size and shape can be easily customized intraoperatively with a power burr to match the individual patient's anatomy. The second is that, in contrast to titanium and polymer cages, this structural device has the potential to incorporate in the fusion. Although the graft is placed primarily as a spacer and it is the autologous bone placed around the graft that is relied on to achieve arthrodesis, incorporation of the allograft generally occurs, resulting in a more robust fusion. There is no potential for polymer or metal to incorporate and contribute to the fusion; thus, a smaller area of the endplate is available to participate in healing when using devices made of those materials. Ceramic blocks have been used in Asia because of the potential for bone ingrowth, but there is no experience with that material in the United States, and it does not share the ability to be easily sculpted intraoperatively. Currently, several manufacturers produce allograft implants of this design.

The technique described here for preparation of the intervertebral space is applicable to any intervertebral cage or graft,

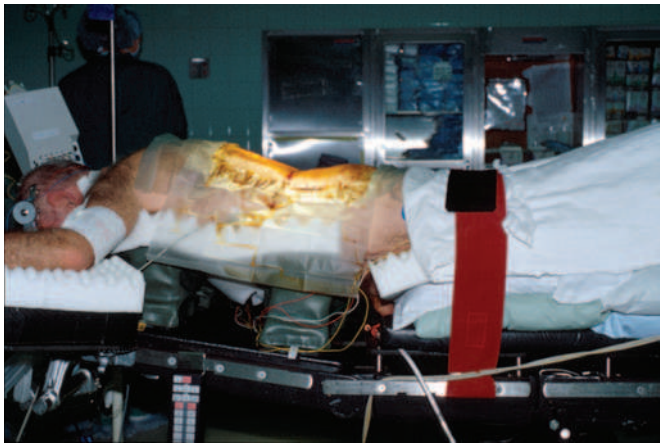

FIG. 50.7 The patient is positioned in hyperextension, with pillows under the thighs and the head of the bed elevated to help achieve maximum lordosis. The abdomen hangs free to allow unimpeded venous return. Electromyelographic monitoring is used to help prevent nerve injury due to excessive traction.

and the principles outlined help prevent neural injury and other complications that have been associated with this operation. The procedure begins with proper positioning, which is essential to achieve a good outcome. The patient is positioned in hyperextension to help create lumbar lordosis. The abdomen should hang free for unimpeded venous return; this decompresses the epidural venous plexus and helps reduce bleeding. A radiolucent positioning frame is useful so that intraoperative fluoroscopic images can be obtained to confirm correct placement of screws and grafts (Fig. 50.7). Pedicle screws should be placed before beginning the interbody fusion. PLIF destabilizes the motion segment and should not be done unless adequate pedicle fixation can be achieved.

A wide laminectomy and resection of the medial portion of the facet joints is essential to minimize retraction of the dura and nerve roots. The wide exposure helps avoid traction injury to the lumbar roots, which can cause neuropathic pain and weakness. Generally, the exposure of the disc space should extend lateral to the medial border of the pedicle below. Adequate exposure may require sacrifice of the facet joints, especially in the upper lumbar spine. This sacrifice is of little consequence because stability is restored by pedicle screw fixation. The facets should always be excised when correcting deformity because this helps loosen the spine and facilitates correction. The superior edge of the upper lamina should be preserved to maintain the posterior ligamentous attachments to the vertebra above the fusion.

An abundant epidural plexus is usually encountered at the lateral border of the spinal canal. Bipolar electrocautery and packing with cottonoid patties can prevent the excessive bleeding that sometimes accompanies interbody fusion procedures. A paste made from absorbable gelatin foam powder and saline is very helpful in controlling bleeding. The venous plexus should be sharply divided to facilitate mobilization of the nerve roots and dura. A nerve root retractor is used to protect the dura, and a rectangular opening is cut in the anulus with a scalpel. When extending the annular opening laterally, care is taken to protect the exiting nerve root. This is easily done by sweeping any soft tissue toward the root with a No. 1 Penfield elevator and leaving the elevator in place to protect the root while working laterally.

The anulus is opened bilaterally, and the disc space is distracted with intervertebral spreaders. These are bars of increasing width with rounded edges. They are inserted into the disc space horizontally and rotated 90 degrees, distracting the disc space. If the disc space is initially very narrow, it is sometimes helpful to use a smaller instrument first, such as a No. 4 Penfield elevator, to identify the path. It is important not to use force in order to avoid inadvertent penetration into the vertebral body. Lateral fluoroscopy can be helpful to confirm that the starting tools are correctly placed in the interspace. The disc is gradually distracted, working from side to side with increasingly large spreaders until resistance is met. The interspace should not be overdistracted, or the endplates may collapse. It is not necessary to maximize distraction to achieve lordosis, and decompression of the nerve roots should be accomplished by aggressive foraminotomy, not aggressive distraction. Placing a maximally tapered graft is the best way to increase lordosis. Trying to place a tall graft has many negative effects. It increases the amount of dural retraction necessary, it increases the volume of bone graft needed to fill the interspace, and it increases the distance over which the fusion must occur (Fig. 50.8).

After distracting the space to a comfortable working distance, usually 11 or 12 mm, one of the spreaders is removed, and a four-sided Collis curette 1 or 2 mm smaller than the largest spreader used is inserted horizontally, then rotated clockwise and counterclockwise to separate the cartilage from the bony endplate. This step is repeated at various depths and angles to clean as much of the endplate as possible. These curettes can be very aggressive, and it is important to be careful not to cut into the endplate. A Kerrison rongeur is used to resect loosened anulus flush with the vertebral endplates; this allows better visualization of the disc space so that a more complete discectomy can be done.

The discectomy is completed with standard curettes and pituitary rongeurs. A reverse curette is very effective in removing any remaining cartilage from the endplates. It is helpful to mark the curettes so that they are not inserted past a depth of 30 mm. In most cases, the anterior anulus prevents protrusion anterior to the vertebra, but the anulus is sometimes deficient, especially in patients with spondylolisthesis. Thus, it is important to avoid anterior protrusion of the instruments and visceral injury. After cleaning the interspace, the intervertebral spreader is reinserted, usually one size larger than was possible before removing the disc and cartilaginous endplate. Next, the opposite side of the disc is prepared in the same fashion.

It now is obvious that the interspace has been grossly destabilized. If a rotational deformity is present, it can be corrected by rotating the bilateral intervertebral spreaders simultaneously and "walking" the displaced vertebra into alignment. If no rotational deformity is present, the spreaders should be turned in opposite directions so that a rotational deformity is not induced. A graft is chosen to fit into the

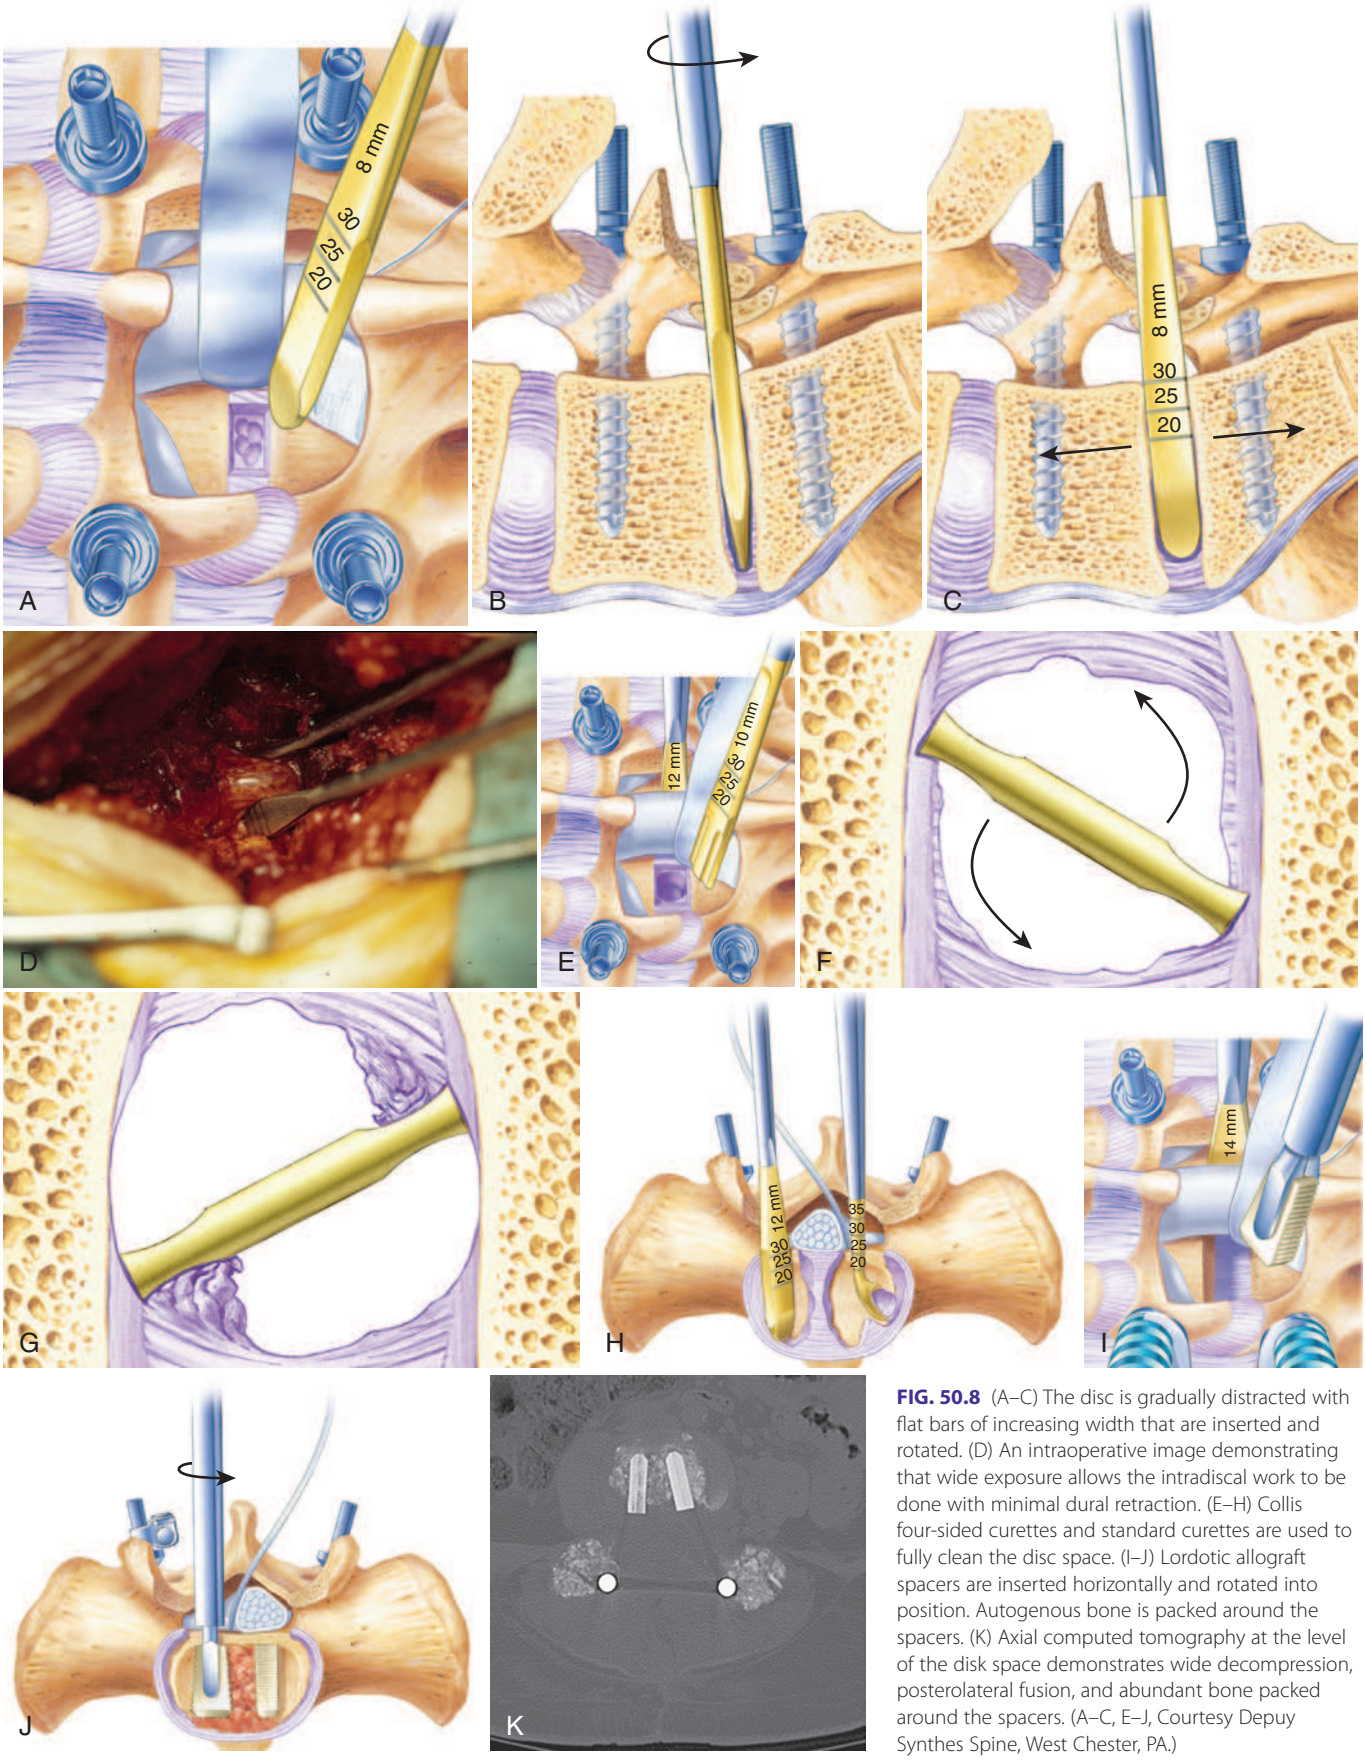

FIG. 50.8 (A–C) The disc is gradually distracted with flat bars of increasing width that are inserted and rotated. (D) An intraoperative image demonstrating that wide exposure allows the intradiscal work to be done with minimal dural retraction. (E–H) Collis four-sided curettes and standard curettes are used to fully clean the disc space. (I–J) Lordotic allograft spacers are inserted horizontally and rotated into position. Autogenous bone is packed around the spacers. (K) Axial computed tomography at the level of the disk space demonstrates wide decompression, posterolateral fusion, and abundant bone packed around the spacers. (A–C, E–J, Courtesy Depuy Synthes Spine, West Chester, PA.)

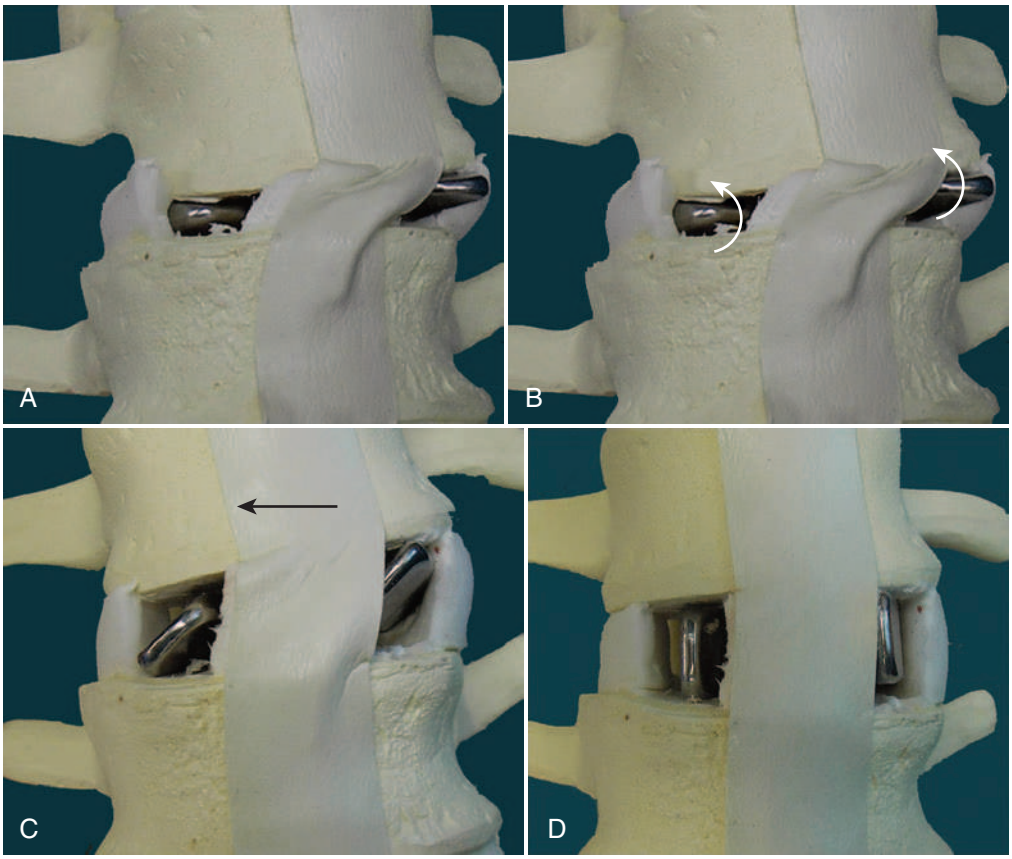

FIG. 50.9 Lateral listhesis and rotational deformity can be corrected efficiently with posterior lumbar interbody fusion. The spine is destabilized by bilateral facet excision and complete discectomy. The distraction paddles can now be used to translate the vertebra laterally, correcting axial rotation, lateral listhesis, and asymmetric disc space collapse.

interspace. The graft should not be taller than the widest spreader used. It can be tapered to achieve the desired lordosis. After ensuring that the dura and exiting nerve root are protected, the trapezoidal allograft is inserted horizontally into the disc space and then rotated into its final lordotic position. The intervertebral spreader is removed from the opposite side of the disc space.

Cancellous graft is packed from the opposite side into the middle of the interspace; a syringe with the end cut off is useful for this step. Finally, the second trapezoidal allograft is inserted into position. Additional graft is packed around the allograft wedges to fill the disc space maximally with bone. The foramina and the midline under the dura are inspected to ensure that no cancellous bone or disc material was displaced into the spinal canal or neural foramen. Last, the instrumentation is tightened in gentle compression to secure the grafts and achieve lordosis (Figs. 50.9 through 50.11).

Optimal Graft Material

The gold standard for achieving a solid fusion is cancellous autograft bone, regardless of which cage device or intervertebral spacer is chosen. Brantigan[63] reported a 97.7% fusion rate when using autologous cancellous graft in the cage that he designed. Numerous authors have reported similar fusion rates using bone harvested from the lamina, spinous processes, and facet joints, without using iliac graft.[64] Miura and colleagues[65] reported a 100% fusion rate at 12 months in 32 patients treated with carbon fiber–reinforced polymer cages. Kim and colleagues[66] reported a 95% rate using local bone in titanium vertical mesh cages in a prospective study of 50 patients. Kasis and colleagues[67] reported improved clinical outcomes in a prospective comparison when using local bone, attributing at least some of the benefit to avoiding the pain and complications of iliac graft harvest. McAfee and colleagues[68] reported a 98% fusion rate in 120 patients using local bone in carbon fiber–reinforced polymer cages placed via a unilateral transforaminal approach.

These reports of fusion rates determined radiographically must be interpreted in light of previous studies that suggested that radiographic methods have limited reliability for the determination of fusion success.[69,70] Other authors have cautioned that the use of local bone may be associated with pseudarthrosis, and if local bone is used, careful preparation and cleaning is necessary to avoid incorporation of soft tissue with the graft material.[63,71] Synthetic ceramic bone graft substitutes combined with iliac crest aspirate have also been reported to be highly effective for achieving interbody fusion,[72] but experience is limited.

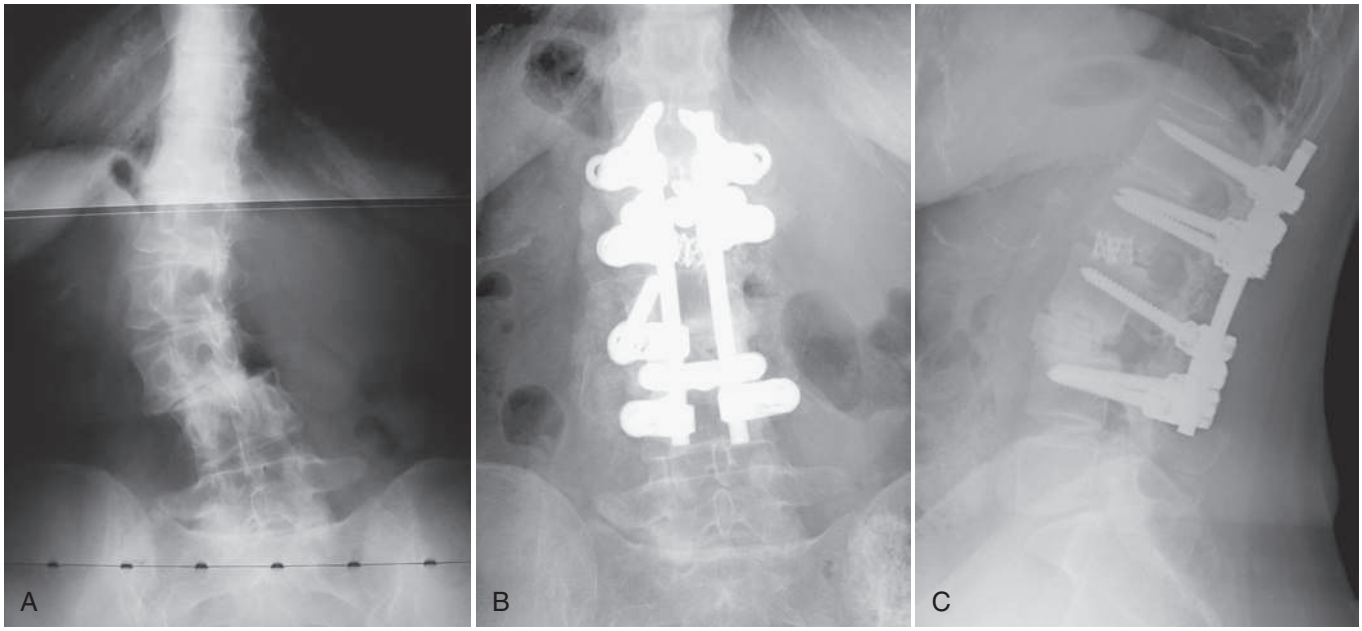

FIG. 50.10 Acute rotational deformity causing degenerative scoliosis is corrected by posterior lumbar interbody fusion. Note that the deformity at L4–L5 was flexible and resolved spontaneously with correction of the structural deformity at L3–L4.

More recently, there has been a surge of enthusiasm for the use of bone morphogenetic protein to achieve spinal fusion.[73] Recombinant human bone morphogenetic protein (rhBMP-2) was shown to be highly effective in achieving spinal fusion when used inside a titanium-threaded cage placed anteriorly in the intervertebral space. In a 2-year prospective randomized trial of 279 patients, fusion was achieved in 94.5% of patients compared with 88.7% in the control group in whom iliac autograft was used.[74] Although not approved by the US Food and Drug Administration (FDA) for posterior use, many surgeons have extrapolated the outcomes documented in the anterior clinical trial to posterior intervertebral applications. Review of the published data on outcomes of posterior interbody use of this material reveals conflicting results. Although some authors report universal fusion with few complications,[75] others have reported a worrisome list of unexpected outcomes.

A clinical trial of rhBMP-2 used in posterior threaded fusion cages was stopped by the FDA because of a high rate of new bone formation (28 of 34 patients) in the spinal canal or neuroforamina, although the authors of the study were enthusiastic about the fusion results and believed that there was no clinical significance to the new bone formation.[76] Radiculopathy and neurologic deficit associated with ectopic bone have been reported by other authors,[77,78] and radiculitis has been reported with the use of rhBMP-2 even when no ectopic bone has formed. The use of a barrier between rhBMP-2 and the neural elements has been reported to eliminate this complication.[79,80] Osteolysis and endplate resorption resulting in subsidence and cage migration have also been reported as a complication of using rhBMP-2. Reports regarding the clinical significance of these radiographic findings vary significantly, and many surgeons continue to advocate for the use of rhBMP-2 in posterior interbody applications.[81-84] Optimal dosing and methods of application of this recombinant protein are unclear at this time. Although fusion rates seem to be high with the use of rhBMP-2, questions remain regarding safety, superiority, and cost effectiveness.

Posterior Lumbar Interbody Fusion Versus Transforaminal Lumbar Interbody Fusion

Although Cloward, Stefee, Branch, and others emphasized the importance of a wide exposure to minimize dural retraction and nerve root injuries during PLIF, other authors described a more medial approach, which was often associated with a high incidence of nerve root injuries. This association was especially true before the advent of posterior instrumentation, when it was often recommended that the facet joints be preserved to avoid destabilizing the motion segment.[85] Dural and root injuries were particularly prevalent when threaded fusion cages were used posteriorly because of the emphasis on using large devices to achieve stability through annular distraction.[86] Because the cylinders were designed to cut into the endplates, the diameter needed was sometimes 50% greater than the height of the interspace achieved.[39] Even when using smaller devices, rates of neurologic complications of 17% were reported.[87]

In 1997, Harms and colleagues[88] reported a technique for performing a posterior interbody fusion through a more lateral approach than previously described.[89] These investigators advocated a unilateral approach to the disc space through the neural foramen by removing the facet joint. This approach allowed access to the disc space through the triangular "safe zone" between the exiting nerve root and the lateral dural

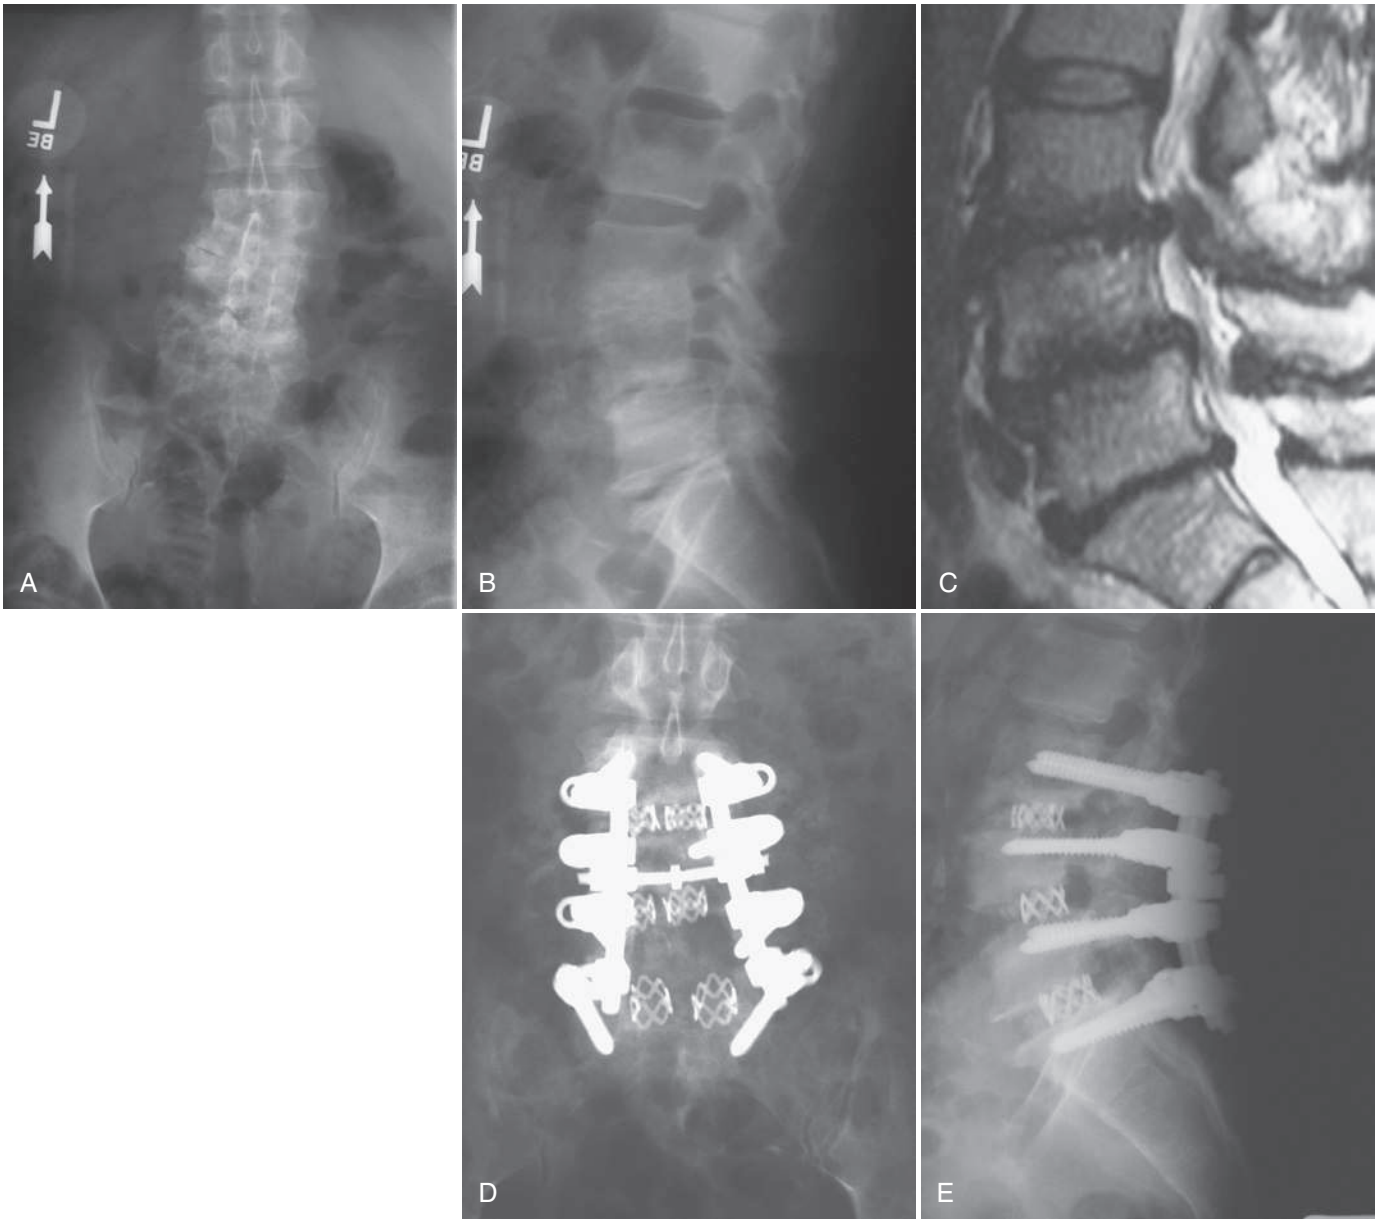

FIG. 50.11 In this patient, severe degenerative disease of the lumbar spine has resulted in spinal stenosis, degenerative spondylolisthesis, and asymmetric disc space collapse. Because a posterior decompression is needed to treat the patient's stenosis and pseudoclaudication, posterior lumbar interbody fusion is the most efficient way to simultaneously correct the patient's deformity and achieve fusion.

edge.[90] In this way, an interbody fusion could be performed with minimal or no retraction of the dura. The transforaminal technique has been enthusiastically adopted by many surgeons; a number of studies have shown a reduction of nerve root injuries when comparing PLIF and TLIF in their hands.[91,92] The increased incidence of iatrogenic nerve root injuries, reported by some authors, during a PLIF versus a TLIF may be due to the technical aspects of the PLIF technique, which requires a more complete exposure of the thecal sac as well as dural retraction. Surgeons who favor the TLIF also report decreased blood loss, operative time, dural tears, and need for reoperation. Although these differences are quoted in the literature, this has not been our experience.[91-93]

One theoretical disadvantage of the TLIF technique is that, because only a unilateral approach to the disc space is done, it is impossible to remove the disc material completely. Javernick and colleagues[94] showed that, on average, 31% more disc material could be removed when a bilateral approach was done. This finding leads to concern that the fusion rate might not be satisfactory with a unilateral approach. McAfee and colleagues[95] showed that, for anterior interbody fusions, 100% of patients who underwent complete discectomies achieved a solid arthrodesis, whereas only 86% of patients with incomplete discectomies achieved solid fusion. In an animal model, the inclusion of disc material with autologous bone in cages led to a significant impairment of fusion.[96] Despite these

concerns, although no prospective randomized comparison has been done, the unilateral approach to the disc space seems to result in adequate fusion rates.

In our experience, the unilateral transforaminal approach is useful when extensive postoperative scar makes mobilization of the dura or exposure of one side of the disc difficult. When trying to correct deformity, the greater laxity of the motion segment achieved by a bilateral approach makes PLIF the preferred technique, however. The technique of PLIF described in this chapter involves extensive or complete facet resection, eliminating any differences in risk of nerve root or dural injury between PLIF and TLIF.

Outcome and Complications of Posterior Lumbar Interbody Fusion

The outcome of PLIF surgery depends on many factors. Probably the most important, as with any operation on the lumbar spine, is proper patient selection. Lumbar fusion done for the wrong reasons or on the wrong patient uniformly yields bad results. Review of the published outcomes of PLIF surgery makes it clear that PLIF is a technically demanding procedure. Variations in technique, care, and skill have significant influence on the rate of fusion and the frequency with which complications occur.

In large series, fusion rates greater than 95% have routinely been reported with PLIF, regardless of whether carbon fiber–reinforced cages, polymer cages, vertical titanium mesh cages, allograft bone spacers, or stand-alone cylindrical threaded cages have been used.[19,96–99] In contrast, only 77% of the patients reported by Rivet and colleagues[100] achieved solid arthrodesis, despite the use of cancellous iliac graft and supplementary pedicle fixation. Fuji and colleagues[101] reported a nonunion rate of 72% in their series of threaded cages placed posteriorly without supplementary fixation. It is unclear whether poor technique or other factors are responsible for the poor fusion results reported in those series.

Probably the most devastating complication that can occur with PLIF procedures is a nerve root injury.[102] The reported incidence of this complication varies widely, suggesting that surgical technique is an important factor affecting the frequency with which this complication occurs. Hosono and colleagues, in their review of 240 patients operated on by four surgeons, correlated complication rates with the experience of the surgeon.[87] In that series, 41 patients had some kind of nerve injury, mostly transient. In Brantigan's series,[63] despite previous failed discectomy and the associated epidural scar in 83% of his patients, postoperative radiculitis was reported in only 2 of 100 patients, and one patient experienced a footdrop.

In the larger series of carbon fiber–reinforced polymer cages submitted to the FDA in which 221 patients were operated on by 15 surgeons, 3 cases of reflex sympathetic dystrophy and 3 cases of motor deficit, 1 of which was permanent, were reported.[97] Davne and Myers[103] reported only a 0.4% rate of traction root injury in their series of 384 PLIF procedures.

Krishna and colleagues[104] reported postoperative neuralgia in 7.1% of their patients, but they were able to reduce the incidence of this complication by half by modifying their technique and removing the superior facet to widen the exposure. Barnes and colleagues[86] reported a 13.6% incidence of permanent nerve root injury when using threaded fusion cages but no nerve root injury when using much smaller allograft wedges. These results reinforce the principle that wide exposure, careful technique, and avoiding oversized grafts can minimize the risk of neurologic injury in PLIF.

Graft displacement and loosening is another complication that was associated with PLIF when the technique was first described. This is a rare complication, however, with the addition of posterior pedicle screw stabilization. Subsidence of the implants can occur with PLIF. Most authors have not carefully documented this phenomenon. Factors predisposing to subsidence include inadequate graft technique and sizing, and endplate injury during preparation. Patient factors such as weight and osteoporosis are likely important.[105] Implant type may be a factor, but convincing evidence of this has not been presented.[106,107] Pedicle screws alone do not prevent subsidence after PLIF.[108]

Vertebral compression fractures at the adjacent proximal or distal level to the interbody fusion have also been reported. Osteopenia/osteoporosis, short segment fusions, female gender, and age older than 65 years were cited to increase the risk of compression fractures at the nonfused vertebrae after interbody fusion.[109]

Other complications of PLIF are similar to the complications encountered in all lumbar spine surgery. Epidural hematoma, wound infections, and other non–implant-related complications seem to occur with similar frequency in PLIF as in other reconstructive operations on the lumbar spine.

Summary

PLIF is a technically demanding operation that has an important role in the modern management of lumbar spine problems. Careful surgical technique emphasizing wide exposure and avoiding oversized implants can lead to excellent results with a low rate of complications and high fusion rates. Many different types of implants and grafts are available, without a clear-cut advantage of one type of device over another. Excellent results have been reported with most commercially available cages and grafts. PLIF is a useful way to provide anterior column support without the need for an anterior incision. PLIF is especially helpful to avoid failure of posterior instrumentation in patients who have undergone realignment of high-grade spondylolisthesis and to prevent distal instrumentation failure in long fusions to the sacrum.[110]

Although PLIF with supplementary fixation creates a very stiff motion segment, the PLIF operation by itself destabilizes the motion segment. This destabilization is useful for correcting spinal deformity but makes the addition of posterior fixation, such as pedicle screw fixation, important to ensure successful healing of the fusion. In the treatment of degenerative conditions of the lumbar spine and back pain, PLIF offers

some theoretical advantages over traditional posterolateral fusion techniques. Clinical studies generally have failed to show superiority of PLIF convincingly over other techniques, however. In clinical situations involving degenerative conditions of the lumbar spine and back pain, the role of PLIF as part of the surgical treatment of the patient has more to do with the experience of the surgeon than with any other factor.

CHAPTER 51

Posterolateral and Lateral Corpectomies

SECTION VI

Raghav Badrinath
T. Barrett Sullivan
Steven R. Garfin
R. Todd Allen

Posterolateral and lateral approaches to disc disease in the thoracic spine developed as a consequence of poor outcomes after traditional posterior laminectomies, generally due to the approach morbidity and inadequacy of ventral decompression achieved by these procedures in surgical management of central and paramedian herniated discs. Posterolateral approaches to the thoracic spine are varied and include costotransversectomy, transforaminal, transpedicular, transfacet pedicle sparing, and transverse arthropediculectomy. Variations among these approaches largely hinge on the amount of bone resected to achieve decompression. These may be seen as in a continuum with the lateral approaches, namely the lateral rhachotomy, the lateral extracavitary approach, and the lateral parascapular extrapleural approach. Improved exposure offered by these approaches facilitates better decompression of centrally located, larger, or highly calcified disc herniations, among many other pathologies. However, these techniques come at a cost of being technically demanding and require significant soft tissue manipulation and dissection.

In the lumbar spine, posterolateral corpectomy and arthrodesis is a fairly common procedure performed for pathologies such as spinal deformity, degenerative disease, trauma, tumor and infection. In many patients corpectomy can serve as a workhorse for more complex disorders requiring effective interbody fusion, and use of a less-invasive lateral approach to perform lateral corpectomy and arthrodesis is increasingly common and used for more complex disorders of the spine. Interest in the procedure has exponentially increased after its introduction.

Although the focus of this section is thoracic and lumbar disc disease, posterolateral and lateral approaches to corpectomy are among the most versatile of approaches for vertebral body resections and have been adapted for use in spinal deformity and scoliosis, thoracic and thoracolumbar vertebral body trauma, vertebral neoplasm, and vertebral osteomyelitis.

Posterolateral and Lateral Corpectomy in the Thoracic Spine

Historical Perspective

Spinal cord decompression for thoracic disc herniation traditionally involved simple laminectomies. Adson performed the first laminectomy and decompression for thoracic disc herniation in 1922.[1] Mixter and Barr reported on laminectomies for 19 disc herniations in 1934, of which 4 were in the thoracic spine.[2] Two of these patients developed transverse myelopathy postoperatively, and another recurrence of symptoms was noted shortly thereafter. Similar results were noted by multiple other series, with significant morbidity and mortality associated with the procedure.[3-8] Perot and Munro in 1969 reviewed 91 cases of thoracic disc herniations treated with dorsal laminectomy and noted persistence of symptoms or paralysis in 40 of these patients.[9] Importantly, they were able to demonstrate improved outcomes with lateral disc herniations compared with centrally located protrusions.

Costotransversectomy was introduced by Menard in 1895, as with many approaches to the spine, for the treatment of Pott disease.[10,11] Variations were developed by Seddon (1935) and Capener (1954).[12,13] Hulme (1960) is believed to have been the first to perform the procedure for thoracic disc herniation, although his technique was a modification of the original and involved a more extensive transverse arthropediculectomy.[5] The lateral extracavitary approach (LECA) was originally developed by Alexander[14] and a modified version by Capener[15] in the treatment of tuberculous spondylitis. The procedure was later introduced by Larson[16] in 1976, allowing for wide exposure using a fully extrapleural approach, which gave surgeons the ability to span the thorax and abdomen without taking down the diaphragm.[17,18] Several authors have subsequently, and in recent decades, used modified versions of the procedure to access and treat all types of anterior spinal pathology while allowing for the placement of posterior

instrumentation. Patterson and Arbit[19] described the transpedicular approach in 1978, which involved removal of the entire pedicle and facet, affording a more direct exposure of ventral disc space. This approach offers the advantage of not placing radicular vessels at risk but still provides reasonable access to central and calcified discs.

The development of these approaches was driven out of goals to improve the management of degenerative disease and disc pathology via decreased morbidity with improved decompression and *partial* corpectomy. These techniques, however, have been modernized to facilitate greater degrees of corpectomy and even vertebrectomy in the management of more diverse pathologies, including vertebral body fractures, neoplasms, vertebral osteomyelitis, and spinal deformity (e.g. kyphosis, kyphoscoliosis) to generate greater sagittal and coronal plane corrections.

Indications and Choice of Approach

Absolute indications for surgical management of thoracic disc disease, and cord compression from a variety of pathologies, remain poorly defined. The natural history of the disease is not well captured, and thus is relatively unknown, and symptoms do not always correlate with the extent of disease noted on imaging.[20-23] In general, patients with severe, intractable radicular pain, progressive myelopathy, lower extremity weakness, or bowel and bladder dysfunction with evidence of cord compression on magnetic resonance imaging are considered to be good candidates for surgical treatment, not uncommonly requiring partial corpectomy for decompression. Indications for more extensive corpectomy or vertebrectomy via posterolateral and lateral approaches are outlined in separate sections, but this chapter is focused on cord compression, progressive neurologic deficits, or spinal column instability resulting from degenerative, deformity, traumatic, infectious, or neoplastic processes leading to destruction of the vertebral body that causes anterior column instability or direct cord compression via mass effect.

Surgeon opinion regarding choice of approach is also inconsistent. Each approach carries with it unique benefits and risks. Choice of approach requires careful evaluation of patient-specific pathology and overall medical status as well as a consideration of surgeon experience with a particular technique. In all cases, the most important goal during treatment is to minimize manipulation of a damaged/compressed spinal cord while ensuring complete decompression and stabilization. Transpedicular and pedicle-sparing transfacet approaches are often cited as technically simpler than other approaches, allowing for minimal bone removal and decreased operative time.[21,22,24,25] Costotransversectomy requires more extensive soft tissue dissection and rib removal and comes with increased risk of blood loss.[24,26,27] There also exists the potential for vascular compromise due to poor visualization of the radicular vessels, especially when operating between T7 and L2 due to possible disruption of the artery of Adamkiewicz.[28,29] The extrapleural nature of these approaches usually eliminates the need for a chest tube. Posterior and posterolateral approaches, particularly when made via a central midline incision, also allow for posterior instrumentation without the need for an additional incision.

Transpedicular and pedicle-sparing approaches are suited for more laterally located pathologies or in the treatment patients with multiple medical comorbidities, who require less anesthesia and historically a more expedient procedure.[19,25,30] Densely calcified discs or centrally located pathologies have been suggested to be better managed with a more direct transthoracic or thoracoscopic approach.[9,31] However, some authors continue to prefer a costotransversectomy approach with an interbody fusion after removal of more ventral disc, then impacting the calcified compressive disc away from the dural sac and spine. Lateral and costotransversectomy approaches tend to offer advantages in exposure with paramedian pathology or lateral disc herniations with calcification,[21,25,32-34] although it has been suggested that a direct lateral approach can achieve decompressions in a variety of ventral pathologies. As mentioned, vascular compromise must be guarded against in these approaches, and some recommend routine angiography in cases where the planned procedure places multiple radicular vessels at risk.[10,24,35] New modifications of and indications for these approaches continue to be described.[21,36] Beyond thoracic disc herniations, many of these techniques have been used extensively for neoplasm, trauma, deformity, and infection with good results.[33,37-41] The extent of corpectomy varies with the burden of disease. Vertebrectomy is more commonly indicated in cases of extensive vertebral osteomyelitis, fracture, or neoplasm but also facilitates improved decompression or deformity correction in kyphosis/kyphoscoliosis. These approaches often require anterior interbody fusion devices and posterior instrumentation and arthrodesis depending on the amount of bone removed and subsequent instability.

Surgical Technique

Posterolateral Approaches

In posterior/posterolateral approaches, the patient is prone or in a modified prone/laterally tilted position. The approach side is based on the laterality of the pathology, and a right-sided approach is often preferred in central pathology to avoid the descending aorta. Special consideration must also be given to the artery of Adamkiewicz with left-sided approaches in the lower thoracic spine.[5,42,43] Care must be taken intraoperatively to accurately identify and mark the correct surgical level, and intraoperative fluoroscopic images should be compared with preoperative radiographs to account for vertebral level anomalies.[22,24] With a costotransversectomy, the incision is typically midline and vertical rather than curving out over the rib. Dissection is carried through the fascia, and subperiosteal dissection proceeds for optimal spine exposure. The costotransverse articulation is an important landmark. It approaches medially and ends just at and above the pedicle, to articulate with the vertebral body and disc space, crossing along the undersurface of the transverse process. The trapezius and nondissected erector spinae muscles are further exposed and dissection proceeds through the rib periosteum as laterally as

needed prior to rib removal. The intercostal neurovascular bundle is identified on the rib undersurface and separated from the rib, and the rib is then cut and disarticulated from the vertebral body. A periosteal tissue plane can protect the pleura during dissection. The pleura is mobilized (preferably behind a subperiosteal tissue plane of the vertebra) and reflected anterolaterally, protected with malleable retractors and moistened sponges. The intercostal nerve can be followed medially to identify the intervertebral foramen. Visualization is improved several ways, including laminectomy and by partial removal of the pedicles, and the dural sac is exposed. Having achieved visualization of the neural elements and remaining bony landmarks, the surgeon can subsequently proceed with partial or near complete corpectomy without manipulation of the dura. If circumferential decompression is desired, bilateral costotransversectomy can be performed.[27,43] When this is performed, a temporary rod should be placed contralateral to the side of decompression to maintain spinal stability, optimize complete decompression, and reduce risk of iatrogenic injury to the spinal cord.[27] An interbody cage can be placed posterolaterally to fill either the discectomy or corpectomy defect. For larger defects, the spinal root often may need to be tied and resection, allowing greater exposure for placement of larger interbody devices, such as titanium mesh cages, expandable cages, or structural bony grafts (e.g., femoral and humeral allografts).

The transpedicle and transfacet approaches use a posterior midline incision. Paraspinal musculature is reflected from the spinous processes and laminae via subperiosteal dissection, facilitating access to the posterior aspect of the spinal for facet and/or pedicle removal and subsequent partial discectomy or corpectomy. In the case of central pathology, bilateral facetectomies may be performed for improved access.[19,31,44,45] Once again a central cavity allows for anterior decompression. Posterior instrumentation can be accomplished from the same incision, and excised bone can be used if an arthrodesis is desired in addition to the decompression.

Lateral Approaches

LECA has historically used a curvilinear incision extending from the midline to approximately 7 to 12 cm lateral at its apex (e.g., "hockey stick" incision). A thick cutaneous flap down to the thoracodorsal fascia is mobilized and retracted. A vertical incision is made in the latissimus dorsi parallel to its fibers at the lateral extent of the incision down to the ribs, and is mobilized. This mobile mass of latissimus and paraspinal musculature can be mobilized medially for rib resection and laterally for access to the central pathology. The rib at the inferior level of the pathology is isolated from the neurovascular bundle and intercostal muscles, cut laterally, and disarticulated.[16,46-48] A LECA can, in practicality, be performed via a midline incision if extensile enough. The key difference between the costotransversectomy and the LECA is not only the central midline versus a more hockey stick–like incision in LECA, but also in the amount of rib resection, with the LECA generally resecting greater than 6 cm of rib. At this point, the ipsilateral facet complex, transverse process, and laminae can be resected for exposure of the dural sac and posterior spine. A partial or complete corpectomy and complete decompression can then be accomplished. As with posterolateral approaches, interbody fusion and posterior instrumentation and arthrodesis can be accomplished with the same incision.

With upper thoracic disc herniations (T1–T4), additional challenges are encountered, including a narrowed thoracic cage, accentuated kyphosis, greater proximity to the brachial plexus and mediastinal structures, and scapular bone and surrounding musculature.[49] A proximal approach, or lateral parascapular extrapleural approach, involves a curvilinear midline incision around the scapula. The trapezius and rhomboids are transected, mobilized, and reflected as a myocutaneous flap, allowing the scapula to retract laterally. At this point, the paraspinal musculature can be elevated subperiosteally off the spinous processes and dissection proceeds as for the LECA.

The direct lateral thoracic approach for the thoracic spine is a modification of a standard thoracotomy; the direct lateral lumbar spine approach is detailed later in this chapter. During the direct lateral thoracic approach, the patient is placed in the lateral decubitus position (typically with sticky rolls), with the torso, pelvis, and legs secured. We prefer not to "break" the table or bend open the disc space for thoracic discs. However, during the approach to the thoracolumbar spine, gently opening this space can be beneficial to pull the ribs proximally and with little morbidity or concern for plexus injuries. Obtaining an anteroposterior (AP) fluoroscopy image, followed by an orthogonal view directly lateral (perpendicular to the floor and parallel to the disc space endplates), centered at the disc space of interest to minimize parallax, is crucial to decrease the risk of surgical injury during discectomy and corpectomy, as well as during cage and instrumentation placement. The table should be adjusted to provide true AP and lateral images when the C-arm is horizontal and vertical, respectively. Once identified, disc spaces of interest are marked on the lateral skin parallel to the ribs, then sterile prep and drape is performed. Entry into the thoracic cavity can then be performed via partial rib resection or in between ribs for single-level disc access. We prefer a partial rib resection to decrease the risk of postoperative radiculitis or rib pain due to retractor pressure at the rib undersurface. Care should be taken to avoid the neurovascular bundle that lies on the inferior surface of each rib. An oblique incision is made and the rib dissected through the periosteum. Depending on the segments of interest and size of the incision, multiple ribs can be exposed. The rib is dissected circumferentially with the direct undersurface protecting the pleura from being breached, and the rib is cut at the desired interval. Recall that one can work in between ribs if single-level disc pathology is approached. Once the portion of the rib is cut and removed, dissection ensues around the posterior wall in a preferably retropleural tissue plane on the undersurface of the thoracic cage. This proceeds to the disc of interest via blunt dissection, often following a rib head to the disc space, prior to localization. Discectomy ensues after ensuring the retractor blades are centered around the desired area in the lateral and then AP planes. Alternatively, the index finger can

be used to enter the pleural space and digitally displace the lung and pleural structures anteriorly. Posteriorly introducing the inner dilator behind this and onto the disc, at the junction of the rib head and vertebral body, can be performed. The lung does not need to be deflated. Some authors prefer variations of this approach, which typically requires a chest tube. If the surgeon remains in a plane mostly behind the parietal pleura, and discectomy/corpectomy performed, a malleable tube or red rubber catheter can be placed during closure and removed prior to sealing the cavity without chest tube placement. Once the dilator is positioned (preferably in the posterior third of the disc) and lateral fluoroscopic imaging is performed, an inner wire and serial dilation ensues until the retractor is docked in the appropriate trajectory (e.g., parallel to the disc space) and stabilized via the retractor arm to the bed. For corpectomy, thorough discectomies can be performed above and below the vertebra of interest, followed by expansion of the retractor over the vertebral body, using the prior discectomies, proximal pedicle, and posterior vertebral body as a guide to placement. Once placed and expanded to the appropriate size, orthogonal lateral and AP fluoroscopic imaging should be obtained, followed by corpectomy and thorough canal decompression. A key anatomic structure to identify is the pedicle, in reference to its relationship to the posterior vertebral body, rib, and disc. Several interbody options can be used to span the corpectomy site, and instrumentation can be applied via the same approach.

Outcomes

Disc Herniation

In general, outcomes are comparable between the posterolateral, lateral and transthoracic approaches when used for disc herniation. However, studies do not specifically identify the extent of corpectomy performed in addition to the disc excision and decompression. Mulier et al reviewed 331 cases of thoracic disc herniation and noted improved outcomes in 93% of patients treated with the transthoracic approach, 87% of patients treated with posterolateral approaches, and 80% of patients treated with lateral approaches.[21] Worse outcomes were noted with the presence and degree of preoperative paresis, absence of radiculopathy, duration of symptoms, and a history of previous surgery. Outcome does not appear to be related to level of herniation, multiplicity, or the presence of calcification or intradural penetration. Fessler et al, in their meta-analysis comparing approaches to thoracic disc herniation, noted a 10% morbidity rate with the transthoracic and LECA approaches.[26] They noted lower morbidity rates with costotransversectomy (2%) and transpedicular approaches (1%), although relatively few patients underwent these procedures in their analysis. Although the transthoracic approach appears to cause the most reliable symptom relief, it poses a greater risk. McCormick et al performed a meta-analysis of complications after various approaches between 1934 and 1998.[24] They noted a 13.4% rate of complications with the transthoracic approach compared with 5.4% with costotransversectomy, 2.8% with LECA, and 4.6% with the transfacet pedicle-sparing approach. They noted no complications associated with the transpedicle approach in their review. However, postoperative infections, pneumonia, and cerebrospinal fluid leak were specifically excluded from their analysis due to a relative lack of data in the literature.[24] Common complications noted were neurologic compromise, misidentification of the surgical level, postoperative instability, cerebrospinal fluid leak, pulmonary complications, surgical infection, intercostal neuralgia and general surgical complications such as deep venous thrombosis and pulmonary embolus.

A more recent review by Lubelski et al compared thoracotomy, costotransversectomy, and LECA, analyzing 774 cases in the literature between 1991 and 2011.[27,32] The thoracotomy approach had the highest rate of complications (39%), reoperations (3.5%), and death (1.5%) among the three approaches. LECA had a complication rate of 17%, with the need for a thoracostomy tube (9.6%) and wound infections (5.7%) being the most common complications. Costotransversectomy had a 15% complication rate. Wound infection (3.7%) and deep vein thrombosis/pulmonary embolism (DVT/PE) (3.7%) were the most common complications. Reoperation rate (1.3% with LECA vs. 1.2% with costotransversectomy) and mortality rate (0.6% for LECA vs. 1.2% with costotransversectomy) were similar between the two approaches. Average operating time with LECA was 544 minutes, and average estimated blood loss was 3.3 L. With costotransversectomy, average operating time was 405 minutes, average estimated blood loss was 2.0 L, and average postoperative length of hospital stay was 6.7 days.

Results of operative management of traumatic, neoplastic, infectious, or degenerative deformity pathologies with corpectomy or vertebrectomy in the thoracic spine are addressed in their respective chapters in this text.

Posterolateral and Lateral Corpectomy in the Lumbar Spine

Historical Perspective

Spinal fusion surgery was first introduced by Hibbs and Albee in 1911 for the treatment of Pott disease.[50,51] Following Chandler's description of lumbar fusion for low back pain, corpectomy and arthrodesis gained in popularity as surgeons recognized that disc excision alone did not alleviate symptoms of discogenic back pain.[2,52] Watkins later introduced the technique of posterolateral fusion with the aim of reducing high rates of pseudarthrosis encountered in posterior fusion surgery.[53] Partial corpectomy with interbody fusion was subsequently proposed by Cloward[54] in 1953, and this technique quickly gained favor as a means by which to increase fusion and graft compression surface area.[55] Although reports of poor outcomes in arthrodesis in the 1970s led the technique to briefly fall out of favor, focus on the technique was reinvigorated by development of the pedicle screw, fusion cages, and modern biologics seen in the 1990s.[56-59]

More recently, interest in reducing postoperative hospitalization time and operative morbidity through minimizing exposure and soft tissue trauma has been a driving force in

the development of minimally invasive techniques for spinal decompression and fusion. Although approaches for percutaneous posterior instrumentation are relatively straightforward, addressing the anterior aspect of the spinal column through minimally invasive methods is limited by the abdominal and thoracic viscera in the lumbar and thoracic regions of the spine. Historically, approaches to the anterior aspect of the spinal column required violation of the peritoneum or pleura, frequently necessitating the involvement of access surgeons. As minimally invasive techniques evolved with the development and implementation of laparoscopic and thoracoscopic instrumentation, limitations in postoperative visceral complications, a steep learning curve, and access surgeon support persisted. It was, at least in part, in the interest of developing an extracavitary approach to the anterior aspect of the spinal column via tissue planes not requiring violation of the pleura or peritoneum that the lateral transpsoas approach was developed.

Initially reported as an endoscopic retroperitoneal technique in 2001, the direct lateral approach was quickly adapted into an open, minimally invasive, psoas-splitting technique.[60] Developed for treatment of degenerative disc disease, indications for the approach grew to predominantly mirror those for anterior and posterior approaches to spinal fusion: unstable degenerative disc disease, degenerative spondylolisthesis, degenerative scoliosis, disc herniation, and even trauma, infection, or neoplastic processes.[60-64] As with other posterolateral approaches, the transpsoas approach (or direct lateral in the thoracolumbar or thoracic spines) can be combined with partial corpectomy or vertebrectomy to facilitate desired deformity correction, decompression, or preparation for interposition constructs.

Indications

Absolute indications stem from preservation of neurologic function due to severe retrovertebral compression and/or spinal instability, with many contributing diagnoses such as trauma, tumor, deformity, infection/spondylodiscitis, and advanced degenerative disease. Precise indications for posterolateral and lateral corpectomies in cases of degenerative disc disease are ill defined, yet roughly 51% of lumbar spinal fusion surgery is performed for a diagnosis of degenerative disc disease.[58,65-68] As expected in cases of chronic low back pain associated with degenerative disease, initial nonoperative measures including rest, activity modification, physical therapy, antiinflammatory medications, and often epidural steroid or other injections focused on the pathology.[70-79] As with many cases of lumbar degenerative disease, symptoms nonresponsive to aggressive nonoperative management are indications for surgery, with clear priority given to progressive neurologic deficits, saddle anesthesia, or bowel and bladder dysfunction. Although specific indications for partial corpectomy or vertebrectomy and fusion in the setting of trauma, neoplasm, infection, or degenerative deformity are discussed in their respective chapters, intervention in each of these conditions is recommended in the presence of progressive neurologic deficits or spinal column instability.

Technique

Posterolateral

After induction of anesthesia and intubation, the patient is placed in a prone position typically on a Jackson table. Care is taken to pad all prominences and fluoroscopy is utilized to identify appropriate spinal levels. Posterolateral extracavitary corpectomy is typically performed through a posterior midline approach. Open approaches, even in fairly good bone, typically require 2 levels of instrumented stabilization above and below the corpectomy site, though 3 levels should be considered with larger deformity corrections and/or poor bone quality. Once incision is made, subperiosteal dissection proceeds to expose spinal lamina, pars and facets, then spinous processes are removed and laminectomy is performed using a high-speed burr and Kerrison punches/rongeurs. Transverse processes, pars and facets are decorticated to stimulate fusion. This allows access to the pedicles and lateral vertebral body, and pedicle resection and corpectomy may be performed using the curettes and pituitary rongeur if desired.[69] Autograft or allograft graft material is placed over the decorticated areas. Fusion may be augmented with various osteoconductive or osteoinductive materials. Stabilization may be enhanced by the addition of posterior pedicle screws from the same approach.

Lateral Transpsoas Approach (Extreme or Direct Lateral Approach)

This procedure was first reported in the literature by Ozgur et al in 2006.[60] The following procedural description is based on their work, with slight modification. After induction of anesthesia, the patient is typically placed in the left side up, right side down lateral decubitus position using anterior and posterior sticky rolls, with an axillary roll in place. Tape is used to secure the patient to the bed, at the torso and between the ilium and greater trochanter. The break in the table is placed just above the greater trochanter, and the table is often gently flexed to pull the iliac wing caudal and the ribs proximally. We strongly prefer, however, to use angled instruments rather than break or bend the table. When required, it is broken *as little as possible* and only if access to the spine needs to be improved or optimized. Attempts should be made to minimize table break so that little, if any, significant stretching the lumbar plexus or psoas occurs. Mild forward flexion of the patient may assist to distract the posterior elements and may increase working room between the iliac wing and the twelfth rib. Intraoperative fluoroscopy is then used, first obtaining a perfect AP image with spinous process splitting the pedicles symmetrically, then obtaining a later image in which the caudal vertebral body has a flat endplate and the pedicles overlap. Once fluoroscopic confirmation is achieved by using orthogonal views that the patient is in the true 90-degree lateral orientation, discs of interest are marked on the lateral abdominal wall using a radiopaque marker, and sterile prep and drape is performed. A 1.5- to 2-cm posterolateral incision can be made overlying the border between the abdominal obliques and the erector spinae as an access portal to the

retroperitoneal space via a Kocher clamp and then blunt finger dissection. The posterolateral incision also allows for gentle retraction of the peritoneum during passage of dilators through the lateral approach.

After gaining access to the retroperitoneal space the surgeon's finger can be used to gently lift the peritoneum anteriorly in a sweeping fashion, thereby facilitating palpation down to the psoas muscle and transverse process. After separating these tissue planes the surgeon's finger can then be redirected superficially to directly under the lateral approach marking, further facilitating anterior retraction of the peritoneum from the abdominal wall. A surgical blade is then used to make a skin incision overlying the direct lateral mark, and an initial dilator (with attached free-run electromyographic neuromonitoring) is then passed through this incision and the surgeon's index finger, passed into the retroperitoneal space via the posterolateral incision, is used to gently guide the soft tissue dilator to the psoas muscle with care taken to protect the peritoneum by lifting it anteriorly during passage. Once the dilator has reached the psoas muscle, it is used to split the psoas fibers at the middle to anterior third of the muscle to reduce risk to more posteriorly located nerve roots and the lumbar plexus. Neurologic monitoring cannot be overemphasized as a means to reduce risk of injury to the lumbar plexus and roots during this process. After the initial dilator has reached the disc space, intraoperative lateral fluoroscopy is used to confirm appropriate positioning. Once confirmed, an inner wire is placed into the disc space. After confirmation, sequential dilators are used until a retractor can be inserted over the final dilator and secured to a retractor arm. Gentle, controlled distraction can then be used to generate the desired exposure. At this point, we prefer to confirm neural elements are out of the field using a neuromonitoring probe in all quadrants of the disc space and retractor bed. Once lateral and AP fluoroscopy is used to verify appropriate retractor positioning, the surgeon proceeds with discectomy. Care should be taken of all opposite-side structures, particularly if the annulus is released via a cobb or other method. Our preference for lateral corpectomy is to perform discectomy at the proximal disc space, identify the pedicle and posterior body wall, and then perform caudal interbody space discectomy. Once caudal discectomy is performed, the posterior vertebral wall and pedicle are identified once again, and the retractor is opened to access the vertebral body for corpectomy. At the onset, a lateral fluoroscopic image is crucial to ensure one is not overlying the canal and that the retractor is in an optimal position. Once confirmed, and the pedicle and posterior vertebral body are identified, the segmental artery is transected using a bipolar and/or clips and a bovie. We then proceed with corpectomy, or vertebrectomy and subsequent interposition construct insertion.[70] In addition to placement of static or expandable interbody devices of titanium, polyetheretherketone, or bone, one can consider lateral fixation options such as a plate or screw-rod constructs, the latter being our preference when required. After completion of instrumentation, copious irrigation, and optimization of hemostasis, the retractor is slowly removed with direct visualization used to confirm closure of the psoas and ensure excellent hemostasis. Incision sites are then closed in a layered fashion and dressed with sterile dressings.

Outcomes

In general, and as may be expected, outcome studies specifically analyzing corpectomy for degenerative disease are not readily available. The following data help to define some of the roles for which the LECA and minimally invasive direct lateral approach have been used in a variety of pathologies.

Lateral Extracavitary Approach

The versatility of the LECA allows for its use for a wide range of spinal pathologies, including tumor, trauma, and infection in addition to disc disease. However, good-quality, larger scale studies specifically evaluating approach as the variable are difficult to come by.

Resnick et al performed a retrospective review of 33 patients with thoracic and thoracolumbar fractures treated by LECA in an effort to outline complications from the approach.[33] Patients were overwhelmingly male (91%), with a mean age of 32.5 years. Fractures were largely at the thoracolumbar junction. Mean blood loss was 3.1 L, and mean operative time was 7.74 hours. Complications were observed in 55% of patients. The most common complication (33%) was a hemothorax or pleural effusion requiring chest tube placement. Pneumonia occurred in 21% of patients, and wound complications were observed in 12% of patients. Other complications included incisional hernias, sepsis, gastrointestinal bleeding secondary to anticoagulation, and implant malposition. There were no cases of neurologic worsening or death. Arnold and colleagues reviewed 33 patients undergoing LECA for nontuberculous thoracic and lumbar osteomyelitis.[71] Of these, 22 patients with extensive disease required fusion. Graft material used included the rib in the thoracic spine and iliac crest in the lumbar spine. They noted good neurologic recovery after the procedure. Three of seven paraplegic patients improved, with one patient regaining ambulation. All 11 patients with mild weakness became neurologically intact, and 10 of 11 patients with severe preoperative weakness achieved good functional recovery. Although details on specific complications were not provided, the authors reported on two reoperations, and no deaths. McCormick et al. studied 12 patients with dumbbell or paraspinal tumors treated with LECA.[72] They noted gross total removal of tumor, confirmed by computed tomography or magnetic resonance imaging, in 10 patients. At mean follow-up of 34 months, nine patients showed no evidence of residual tumor. There were two deaths from systemic tumor dissemination and recurrence in one patient. The study notes no significant perioperative complications, although two patients did require chest tube placement for pleural entry. Lubelski et al compared LECA to costotransversectomy performed for any indication, including disc herniation, trauma, osteomyelitis, scoliosis, and kyphosis.[32] Overall, 54 patients were included in the study, 19 of whom underwent LECA. The average age was 53.7 years, and 74% were male. Mean blood loss was 2.1 L, and average length of stay was 17.2 days.

Complications were noted in 68% of patients. Approximately half of these were classified as intraoperative complications. The common intraoperative complications included need for transfusion, need for a thoracostomy, and DVT/PE. The most common postoperative complications were pleural effusion, infection, and reoperation. Of note, complications were not found to be different between the two approaches studied. Similarly, Graham et al. looked at 29 patients with significant medical comorbidities and anterior spinal cord compression secondary to a variety of diagnoses who underwent LECA.[73] The average age was 53 years, and the population was 34% male. They noted death secondary to pneumonia in one patient, and two patients had postoperative infections. Overall, they concluded that LECA offered a useful one-stage treatment in medically complex patients for whom a two-stage procedure may not be preferable.

Summarizing these and other studies, Foreman et al. performed a meta-analysis of the literature examining the use of LECA for any indication.[48] They included 11 studies covering 278 patients in addition to their own series of 65 patients. They noted improved neurologic outcomes in 75% of patients and improved pain outcomes in 85%. Thirty-two percent of patients were noted to have at least one complication.

Costotransversectomy

Costotransversectomy has perhaps been most studied in its application to address tumors in the thoracolumbar spine. Sciubba and colleagues noted the utility of the surgery in addressing spinal cord compression secondary to metastatic lesions, effectively improving neurologic outcomes.[74] One of the earlier studies, by Cybulski et al., reported on performing corpectomy and decompression in 15 patients with metastatic tumors of the thoracic spine, 10 of whom also underwent posterior instrumentation.[75] They noted neurologic improvement in 75% of patients and, importantly, no neurologic deterioration. More recently, Chong and colleagues retrospectively analyzed 105 patients undergoing single-stage posterior decompression with or without corpectomy for thoracic vertebral metastases.[76] Twenty percent of patients noted an improvement in Frankel grade, and 10 of 21 Frankel grade C patients became ambulatory. Pain improvement was especially pronounced in patients with anterior column reconstruction and more than four fixation levels. Wiggins and colleagues performed a retrospective review of their prospective database and compared outcomes of 29 patients undergoing costotransversectomy with 18 patients undergoing anterior procedures for neoplasms.[77] They found a complication rate of 38% in the costotransversectomy group and noted that it was similar between the two groups. However, they did note two cases of neurologic deterioration and one death in the costotransversectomy group compared with none in the anterior group. Lu et al. similarly compared outcomes after thoracolumbar corpectomy with the transpedicular approach in 34 patients with the anterior approach in 46 patients, noting similar rates of complications, blood loss, and operative time between groups.[78] Good results have been noted using the approach for large intradural ventral neoplastic lesions, as noted in the series by Ito et al.[79] and Kim et al.[80] Thorat and colleagues reported on their series of 11 patients with dumbbell tumors of the thoracic spine treated with single-stage corpectomy using the costotransversectomy approach.[81] They noted the ability to obtain total excision in 10 of the 11 patients. No significant neurologic worsening was noted postoperatively, and two patients required thoracostomy tube placement. Similar results were also noted by Ando et al. in their series of 16 patients undergoing a modified costotransversectomy for thoracic dumbbell tumors.[82]

Besides applications in tumor, the approach is fairly versatile and also allows for more extensive decompression, circumferential arthrodesis, and multilevel corpectomies for any indication.[83-86] In their meta-analysis, Lubelski et al. looked at 13 papers in the literature that detailed a costotransversectomy approach for a variety of spinal disorders.[27] They noted an overall complication rate of 15%, with wound infection (3.7%) and DVT/PE (3.7%) being the most common complications. They also noted a mortality rate of 1.2% and a reoperation rate of 4.3%.

Lateral/Posterolateral/Posterior Minimally Invasive Surgical Thoracic and Lumbar Corpectomy

Increasing familiarity of lateral access anatomy, instrumentation, and implants has led to advanced applications of lateral surgery for all types of spine disorders. Kim et al[87] were among the first to describe minimally invasive posterolateral corpectomy in a combined cadaver and case series, including two burst fractures, one plasmacytoma, and one metastatic lesion. In their clinical cases a mean 79.2% of corpectomy procedures were facilitated via the approach, with all patients achieving satisfactory neural decompression, though they did report difficulty with contralateral decompression. Average estimated blood loss was 495 mL, with a mean operating room time of 5.8 hours. In 2010, Smith et al.[88] treated 52 patients with unstable thoracic or lumbar burst fractures with mini-open lateral corpectomy. All patients received supplemental fixation with anterolateral plating or transpedicular fixation, and titanium cages were used in 35% of patients. Average operative time was 128 minutes, estimated blood loss was 300 mL, and the complication rate was 13.5%. No patients had neurologic deterioration, and postoperative American Spinal Injury Association (ASIA) score significantly improved. Khan et al.[89] reported on the use of a minimally invasive extreme lateral approach to the thoracolumbar spine for corpectomy and reconstruction in 25 patients with varying pathology, which included tumor, infection, and fracture. Thirteen patients underwent anterior-only fixation, and the remaining 12 had a staged posterior procedure. Mean operative time was 188.5 minutes, and average blood loss was 423 mL. Although mean follow-up was only 5.1 months, these authors observed no implant failures or wound complications at final follow-up, and patients reported a 62% decrease in visual analog scale score. Gandhoke and colleagues[90] used a minimally invasive extreme lateral approach to treat thoracolumbar burst fractures in two patients with incomplete spinal cord injury. Estimated blood loss was less than 500 mL in both patients,

with an operating room time of 4 hours in one case and 4.5 hours in the second case. Both patients were neurologically intact without pain at roughly 1 year follow-up, and both patients had maintained their restored lordosis.

In addition to direct lateral approaches, posterolateral and posterior transpedicular modifications using less-invasive retractors and paramedian incisions have been used for vertebral corpectomy. Deutsch et al.[91] reported their results of a minimally invasive transpedicular corpectomy without instrumentation in eight patients with metastatic disease. Operations were planned as palliative procedures, but the authors reported a 75% decompression of the canal with a unilateral approach. They also described an average blood loss of 227 mL and mean operating room time of 2.2 hours, a marked improvement over traditionally reported operative times and estimated blood loss. Sixty-three percent (63%) of patients had a postoperative improvement of at least one Nurick grade.[91] Smith and colleagues[92] reported the results of a cadaveric feasibility study for a minimally invasive LECA for corpectomy. They performed the procedure in three human cadavers and achieved a circumferential volume decompression of 48% and mean vertebral body resection of 72%. Average anterior height expansion was 47 mm and posterior height expansion was 61 mm. No dural or pleural tears were encountered, and of 24 screws placed there was only one lateral breach. In the three clinic cases (a T11 burst fracture, a T7 plasmacytoma, and a T4–T5 tuberculosis lesion), estimated blood loss was 517 mL and average operating room time was 4.75 hours. Patients were all determined to have excellent outcomes, and the authors concluded that the procedure was safe and associated with reduced blood loss and minimal morbidity. Chou and Lu performed a case series analysis consisting of minimally invasive transpedicular corpectomy and cage reconstruction in eight patients compared with a similar cohort treated with an open procedure. They reported similar findings.[93,94] In a comparative study, Lau and Lou[95] compared mini-open versus open posterior thoracic corpectomy with cage reconstruction in oncology patients with metastatic disease. Twenty-one patients underwent mini-open surgery and 28 patients had open surgery, with mean operative times similar at approximately 4 hours. In the mini-open group, however, significantly reduced blood loss and shorter length of hospital stay were observed. No differences were found in complication rate, revision rate, or postoperative ASIA change. There was a nonsignificant trend toward reduced infection rate in the mini-open technique.[95]

Summary

From the time of tuberculous pathology, deformity, and disc disease, successful treatment of this and more advanced pathologies has been made possible by the versatility of extracavitary, costotransversectomy, and now lateral approaches to the spine. Although several reports allow conclusions to be drawn regarding exceptional surgical utility, high-level outcome studies remain elusive. Future investigation will likely require prospective, multicenter study designs to determine how truly impactful these approaches are toward removing offending pathology and improving patient quality of life.

52 CHAPTER Dynamic Stabilization: What's Current and What's the Potential

Dilip K. Sengupta

Dynamic stabilization in the treatment of activity-related mechanical low back pain was introduced nearly three decades ago (Graf ligament in 1989[1] and Dynesys in 1994[2]).

The need for dynamic stabilization originated from the limitations of spinal fusion, which may not always result in successful clinical outcome,[3,4] and may lead to accelerated degeneration of the adjacent segments.[5,6] Nearly every possible flexible design of dynamic stabilization devices has been introduced for clinical application without proper biomechanical evaluation or design rationale. During the turn of the 21st century, the use of dynamic stabilization devices gained momentum, but the enthusiasm has declined recently, as the mechanical failure of the devices and failure of clinical success were increasingly recognized. Dynamic stabilization is broadly classified into pedicle screw–based posterior dynamic stabilization (PDS) devices and interspinous/interlaminar distraction (IPD) devices.

Understanding Spinal Instability

When abnormal increased motion—in particular, translation—is present on flexion-extension radiographs, especially in the setting of spondylolisthesis, fusion is accepted as a reasonable option.[7] By this standard, however, relatively few patients with low back pain have clear subjective or objective evidence of instability. Biomechanical and radiologic studies using open magnetic resonance imaging in flexion and extension have shown that segmental motion either does not change significantly with lumbar disc degeneration,[8–10] or may decrease, except during early stages of disc degeneration.[11]

Panjabi redefined spinal instability as an abnormal-quality motion, often accompanied by an increased neutral zone (NZ) motion caused by ligament laxity, even when range of motion (ROM) is diminished.[12] Panjabi uses the analogy of a marble rolling in a soup bowl (Fig. 52.1).

Mulholland and Sengupta[13] hypothesize that spinal instability does not mean "increased motion" as commonly misunderstood,[14,15] but it indicates abnormal load distribution across the vertebral endplate. The normal disc is isotropic; it consists of a homogeneous gel of collagen and proteoglycan, and behaves like a fluid-filled bag that allows distribution of load uniformly across the vertebral endplates.[13] Disc degeneration alters the isotropic properties of the disc. The disc becomes nonhomogeneous, with areas of fragmented and condensed collagen, cartilage fragments, fluid, and gas.[16] The nucleus becomes depressurized and an increasingly larger load is transmitted through the anulus, which leads to splitting and inward folding of the anulus.[17] Load transmission over the endplates, therefore, becomes uneven.[18,19] Focal loading of the endplate cartilage and subchondral bony trabeculae can occur with certain positions, leading to a sharp increase in back pain, analogous to a stone in the shoe, a concept proposed by Mulholland and Sengupta.[13] This explains the clinical sign of *instability catch* in mechanical back pain. Mulholland's hypothesis of abnormal loading as the primary cause of mechanical back pain was supported by a close association of abnormal disc pressure profiles to positive discography with pain provocation.[20] This was established by a pressure profilometry study by McNally and Adams.[21]

There is no real conflict between Panjabi's abnormal motion theory and Mulholland's abnormal load distribution theory of spinal instability. These two factors may be interrelated. An abnormal motion may cause abnormal load distribution, which, in turn, may cause pain. On the other hand, it may be anticipated that, if an abnormal motion does not cause abnormal load distribution, it may not be associated with pain production, and explains why many dark discs do not hurt.

Biomechanical Goals of a Posterior Dynamic Stabilization Device

Survival of a PDS device against fatigue failure in the long term and its clinical success depend on how closely its design adheres to the biomechanical goals.

Motion Preservation

The primary goal of dynamic stabilization is to preserve as much normal motion as possible and limit any abnormal motion. Since clinical instability occurs mostly during the

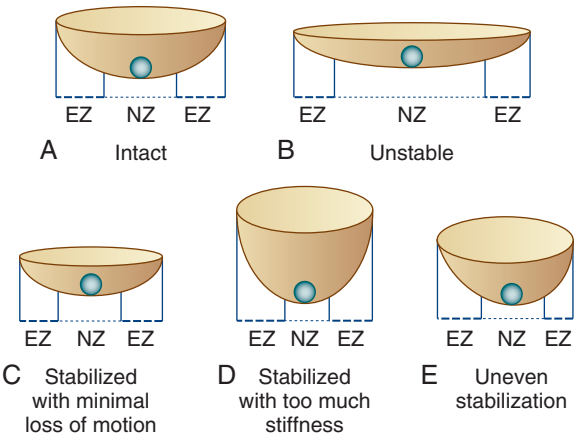

FIG. 52.1 Panjabi's analogy of a marble in a soup bowl, explaining the relationship between spinal instability and change in range of motion. (A) In an intact spine, the marble can move with little resistance across the neutral zone (NZ) but faces increasing resistance toward the elastic zone (EZ). (B) With an unstable motion segment the bowl is flat, allowing the marble to move to and fro with little resistance; that is, increased NZ with no increase in EZ. (C) A stabilized segment has a smaller cup that reduces primarily the NZ, with minimal reduction of EZ movement. (D) A stabilized segment, but with too much loss of motion, which is undesirable. (E) Uneven stabilization, which has different stiffness in two directions, which is again undesirable. (Modified from Sengupta DK. Use of posterior motion-sparing instrumentation and interspinous devices for the treatment of degenerative disorders of the lumbar spine. In: Shen FH, Shaffrey CL, eds. *Arthritis and Arthroplasty: The Spine*. Philadelphia: Elsevier; 2010:349–356.)

NZ motion secondary to ligament laxity, the key to stabilization should be restriction of the NZ while preserving the elastic zone (EZ) motion as much as possible. All PDS systems, regardless of their mechanism of action, can reduce NZ motion, which explains their short-term clinical success. In postlaminectomy instability, the ROMs may be increased with abnormal translation and the goal of the PDS device should be to restore a normal range and quality of motion. Normally, it is unlikely that a dynamic stabilization device will increase the ROM of a degenerated segment unless it induces a favorable biologic reaction to the facet joint and disc, such as restoring the height of a collapsed disc by offloading these structures.

Load Transmission

The mechanism of pain relief with dynamic stabilization may be unloading the disc and the facet joints by load sharing, thereby preventing abnormal load distribution and high spot loading.[13] How much load should be shared by the device is not clear, but it should alleviate any elevated intradiscal pressure.

Resistance to Fatigue Failure

The most important challenge for dynamic stabilization devices is to survive against fatigue failure despite allowing continued motion. The key to survival against fatigue of a PDS device, which is structurally weaker than a fusion rod, is appropriate quality and quantity of motion restriction and load sharing so that the device is never exposed to an abnormal load.

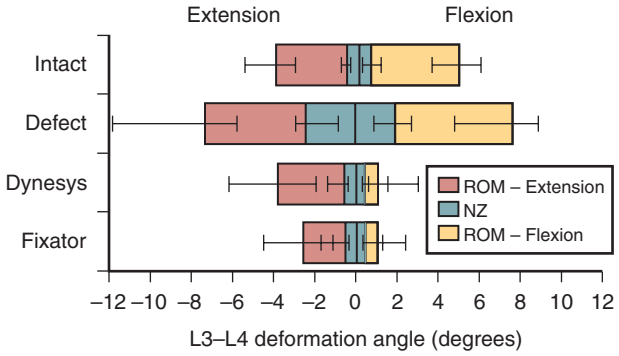

FIG. 52.2 Dynesys restricts flexion too much, equivalent to rigid fixation, but permits near-normal extension in the cadaver spine. NZ, neutral zone. (Modified from Schmoelz W, et al. Dynamic stabilization of the lumbar spine and its effects on adjacent segments: an in vitro experiment. *J Spinal Disord Tech*. 2003;16[4]:418–423.)

There are two important biomechanical principles to ensure that the device or the device-bone junction is not exposed to a failure load. Motion restriction should be uniform throughout the ROM. Should the device cause too much restriction at any phase of motion—for example, Dynesys controlling flexion smoothly, but acting as an extension block—the device may be exposed to unusually high stress in extension repeatedly and may fail eventually (Fig. 52.2). The second biomechanical principle is that load-sharing should be uniform throughout the ROM. If the device may unload the disc too much in one phase of motion, often in extension, the device has to bear an unusually high load during that motion and becomes likely to fail (Fig. 52.3).

The fatigue property of a fusion device is normally tested in an ASTM standard spine model consisting of two plastic cubes as vertebral bodies, but there is nothing available to represent anatomic structures such as the disc or the facet joints. Dynamic stabilization devices are expected to share load with the disc and facet joints. Therefore, unfortunately, the fatigue property of a dynamic stabilization device cannot be tested directly in a spine model. A crude estimation of the fatigue load that a PDS device may encounter can be assessed indirectly by studying the changes in the kinetic and kinematic properties of the motion segment before and after application of the PDS device. These may include the instantaneous axis of rotation (IAR), intradiscal pressure changes, and pedicle-to-pedicle distance excursion before and after application of the device in a cadaver spine or model.

Normally, the disc pressure increases both in flexion and extension and is lowest in neutral position. A PDS device should ideally permit the rise in disc pressure in both flexion and extension but to a smaller magnitude due to load sharing (see Fig. 52.3). If the disc pressure does not rise at all, particularly in extension, it may indicate that the device is acting like a total load-bearing structure during extension rather than as a load-sharing structure in extension. Similarly, a mismatch in the location of the IAR of the device and the motion segment is a predictor of the device encountering a higher load and being more likely to undergo fatigue failure.

A normal pedicle-to-pedicle excursion during flexion-extension may be as large as 6 to 9 mm, less in lateral bending,

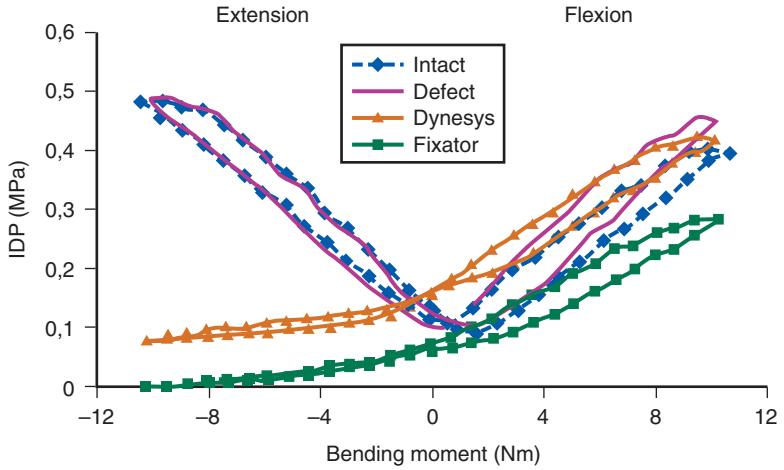

FIG. 52.3 Intradiscal pressure (IDP) changes with flexion-extension motion. Normally, the pressure at the center of the disc rises both in flexion and extension. Stabilization with Dynesys restores disc pressure in flexion to normal but unloads the disc completely and behaves like a total load-bearing structure, without sharing any load with the disc. (From Schmoelz W, Huber JF, Nydegger T, Claes L, Wilke HJ. Influence of a dynamic stabilisation system on load bearing of a bridged disc: an in vitro study of intradiscal pressure. *Eur Spine J.* 2006;15[8]:1276–1285.)

and minimal in rotation (Fig. 52.4). The device should permit a normal pedicle-to-pedicle distance excursion to permit normal ROM and ensure that the device does not act as a motion stopper in any direction or phase of motion. Unfortunately, only a few dynamic stabilization devices can accommodate such a large degree of flexibility.

Nonmetallic devices may deform, soften, and creep to adapt to the kinematics of the motion segment and survive fatigue better at the cost of reduced efficacy over time. Is creep and softening of a nonmetallic device a disadvantage? One may argue that dynamic stabilization may stimulate a favorable biologic response to repair the motion segment, and its subsequent creep or softening is truly an advantage, when its function is over. Conversely, metallic spring devices may retain their mechanical property over a long period but are more subject to fatigue failure should there be any mismatch in kinematics. It is important to note that fatigue failure of a nonmetallic device may not be recognized radiologically unless there is screw loosening or breakage, but failure of a metallic device cannot hide!

The following are design rationales for PDS devices:

1. Motion preservation with uniform effect throughout ROM
2. Load sharing uniformly throughout ROM
3. Minimum conflict with the IAR, intradiscal pressure, and pedicle-to-pedicle distance excursion of the motion segment

Other design-related factors are as follows:

1. Safe and easy salvage—conversion to fusion in case of failure
2. Ease of implantation—top-loading screws
3. Compatibility with minimally invasive procedures
4. Restoration of normal sagittal alignment, for example, lordosis
5. Biomaterial—metallic versus nonmetallic
6. Easy salvage procedure to address failure of the device, such as conversion to fusion with a rod (Fig. 52.5).

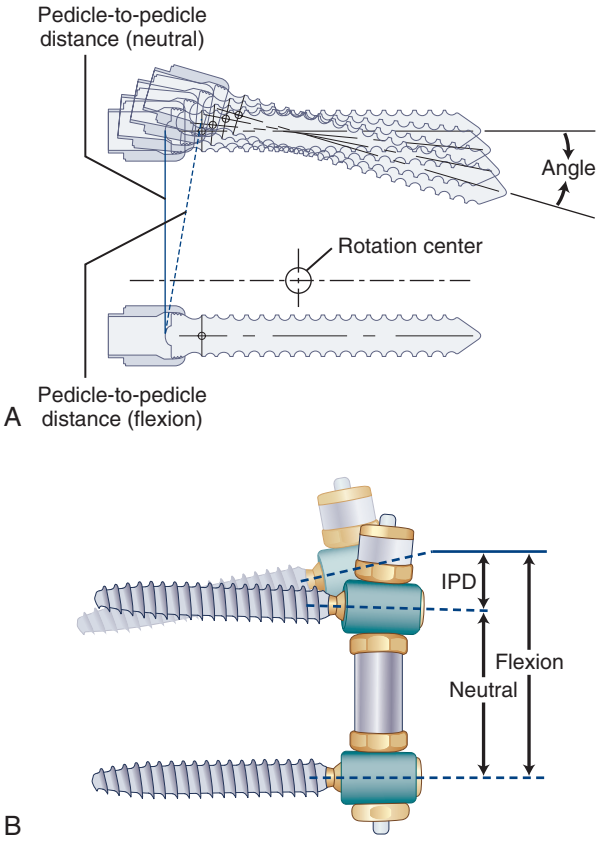

FIG. 52.4 (A) The pedicle-to-pedicle distance from flexion to extension may be as large as 8 to 9 mm to preserve normal motion. (B) Dynamic stabilization (e.g., Transition; Globus Medical) may need to permit an excursion of the pedicle screw heads by the same magnitude. IPD, interspinous/interlaminar distraction. (From Sengupta DK. Use of posterior motion-sparing instrumentation and interspinous devices for the treatment of degenerative disorders of the lumbar spine. In: Shen FH, Shaffrey CL, eds. *Arthritis and Arthroplasty: The Spine*. Philadelphia: Elsevier; 2010:349–356.)

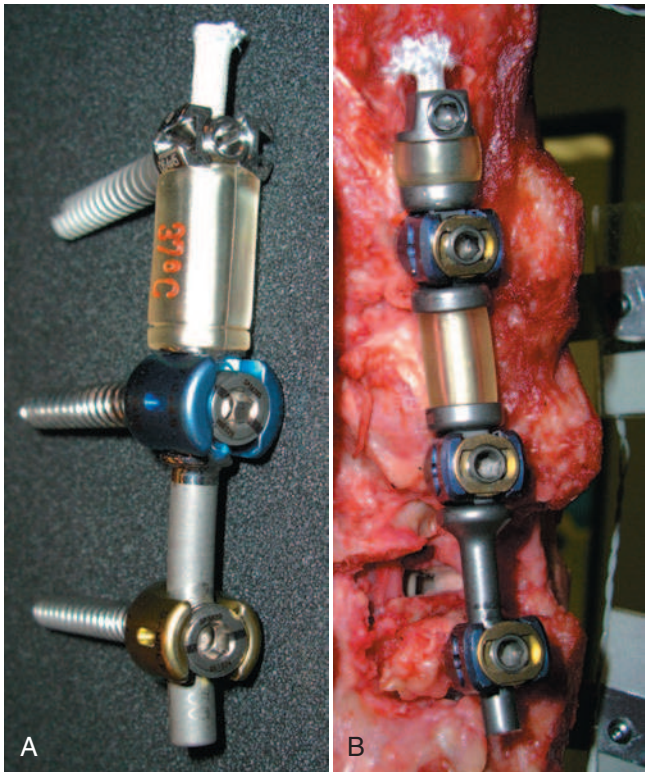

FIG. 52.5 Design rationale between second- versus third-generation posterior dynamic stabilization devices. (A) Dynesys uses a side-loading screw, which is not suitable for rod insertion. A recent design adaptation, Dynesys DTO, makes it suitable for use in conjunction with fusion at an adjacent segment and requires three different types of screws. It needs in situ assembly and tensioning. (B) Transition has been designed to accommodate implantation in isolation and in conjunction with adjacent-segment fusion using the same pedicle screw design. It uses top-loading screws for all the segments, lordosis is built in, the bumper at the end offers larger pedicle-to-pedicle excursion, and it comes preassembled or can be assembled on the back table.

Dynamic Stabilization Devices

The classification of dynamic stabilization devices is a moving target; new devices are being introduced and some devices are being withdrawn. A broad classification, as presented in the earlier edition of this publication, includes pedicle-screw–based PDS devices, and interspinous distraction devices (Box 52.1).

Indications for Pedicle Screw–Based Posterior Dynamic Stabilization

The primary indication of dynamic stabilization is treatment of mechanical back pain due to spinal instability. Radicular pain or claudication pain can be adequately treated by decompression alone; the role of additional dynamic stabilization here is only to prevent instability and back pain. Application of a dynamic stabilization device with concomitant decompression to address radicular or claudication leg pain may not be accepted as evidence in support of their efficacy to relieve back pain. Such efficacy can only be established by application of the device to treat mechanical back pain in the absence of decompression. Once that is established, application in conjunction with decompression procedures could be justified. Dynamic stabilization to supplement total disc replacement is still in the experimental stage and may be considered as a future indication.

Indications for Interspinous Process Distraction

- Primary indication: central spinal canal and/or foraminal stenosis with neurogenic claudication
- Secondary indication: Axial mechanical back pain

IPD devices are ideally suited for indirect, less invasive decompression of the spinal canal or the foramen causing claudication pain. Direct decompression by conventional laminectomy may achieve a more definitive and longer-lasting relief of symptoms. Intuitively, interspinous distraction may produce less postoperative morbidity. Its use may only be justified in elderly patients with multiple comorbidities. Osteoporosis and scoliosis may be relative contraindications for IPD because of high incidence of device failure. Proponents and enthusiasts of interspinous distraction sometimes recommend its use in the treatment of axial back pain. This is a questionable indication. IPD devices can reduce the laxity of the motion segment and secondarily reduce the unstable motion in the NZ. This action may also address mechanical back pain to some extent. Currently, a sound rationale, justification, or evidence in favor of such indication is lacking.

Clinical Experience With Dynamic Stabilization

Pedicle Screw–Based Posterior Dynamic Stabilization Devices

One of the earliest dynamic stabilization devices is the *Graf ligament*, described by Henry Graf in 1992.[1] This is the first-generation PDS device, and forms the basis of many other devices introduced subsequently. The mechanism of action or the design rationale has never been published in the English literature. The monograph from the inventor in French describes that the device locks the facet joints to reduce painful motions.

The Graf ligament consists of braided polypropylene bands that span between flanges at the titanium pedicle screw heads under tension, locking the facet joints. The surgical procedure is simple and, unlike fusion, it avoids exposure of the transverse processes or the need to harvest bone graft. Unfortunately, as a result of compression applied to the screws, there is a high incidence of radicular symptoms secondary to either disc herniation or foraminal narrowing.[22,23] Increased facet loading may lead to back pain.

The clinical outcome during short-term follow-up (up to 2 years) is reported to be as good as with conventional fusion.[23] However, the long-term outcome with Graf ligament stabilization has conflicting reports in the literature. Gardner[24] and Markwalder and Wenger[25] reported reasonably good results with

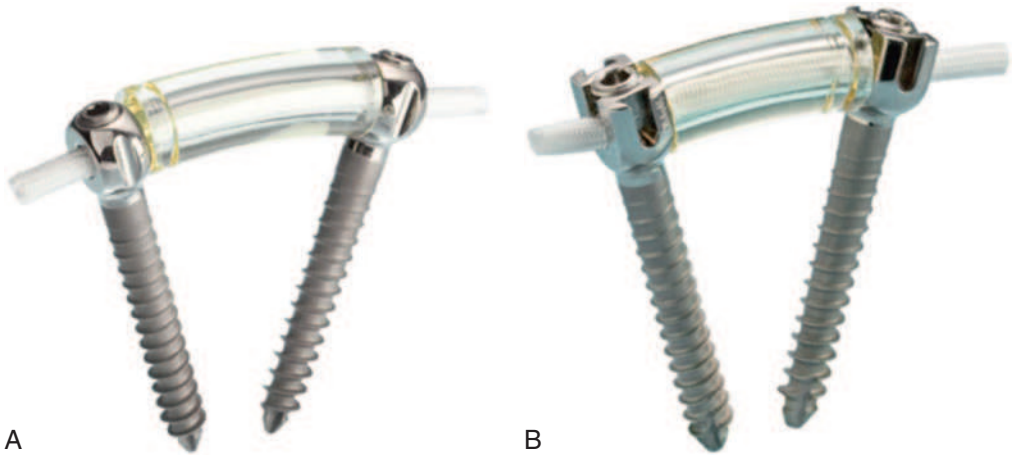

FIG. 52.6 (A) Original Dynesys, now presented as Dynesys LIS. (B) Dynesys top-loading device.

BOX 52.1 Classification of Dynamic Stabilization Devices

Pedicle Screw–Based Posterior Dynamic Stabilization (PDS) Devices

Nonmetallic Devices

Dynesys LIS and Dynesys top-loading system (Zimmer-Biomet)
Transition (Globus Medical)

Metallic Devices

DSS-II Dynamic Stabilization System (Abbott Spine)
BioFlex (Bio-Spine
Stabilimax NZ (Applied Spine Technologies)
Cosmic Posterior Dynamic System (Ulrich GmbH)

Hybrid Devices (Metallic Component With Plastic Bumper)

CD Horizon Agile (Medtronic Sofamor Danek)

NFlex (Synthes GmbH)
Transition (Globus Medical)

Interspinous Distraction (IPD) Devices

Rigid Devices With Free Flexion

X-Stop interspinous process decompression device (Medtronic Sofamor Danek)
Flexus (Globus Medical)
Superion (VertiFlex)

Rigid Devices With Restricted Flexion

Wallis system (Zimmer-Biomet)
Interspinous Locker (NHS)

Flexible Devices

Nonmetallic: DIAM (Medtronic Sofamor Danek)
Metallic: Coflex (Paradigm Spine)

Indications for IPD Devices

Primary: spinal stenosis with neurogenic claudication
Secondary: axial-mechanical back pain

the Graf ligament even at 5- to 10-year follow-up. On the other hand, from a retrospective case control study, Hadlow et al[22] reported that the Graf ligament produces a worse outcome at 1 year and a significantly higher revision rate at 2 years compared to the fusion group. The Graf ligament is still used in a few centers in both Europe and Asia, but its use has declined.[24,26]

Dynesys Dynamic Stabilization System

The most extensively used pedicle screw–based PDS system to date is Dynesys (Zimmer-Biomet).[2,27] This was introduced in Europe as a true dynamic stabilization device, to be used without fusion. In 2004, Dynesys was introduced in the US market as a fusion device under 510(k) US Food and Drug Administration (FDA) approval.

The design incorporates a plastic cylinder (Sulene-polycarbonate urethane) around the cord to apply a distraction force unloading the facet joints, which is thought to be the cause of back pain with the Graf ligament. This is a design improvement over the Graf ligament and may be considered as a second-generation PDS device (Fig. 52.6). A review of the literature provides the best resource for understanding the mechanism of PDS systems in general.

The design rationale or the mechanism of action of Dynesys has never been presented in the English literature. The current designs of Dynesys are the original lateral side-loading system, Dynesys LIS, and an alternative Dynesys top-loading system. In biomechanical testing on a cadaver spine, the Dynesys device is shown to reduce range of flexion more than extension,[28] (see Fig. 52.2), apparently because the device holds the segment in close to full flexion. The extension is produced by an abnormal distraction of the disc space, with the plastic cylinder acting like a fulcrum. This is evidenced by an abnormal negative disc pressure during extension.[29] Conversely, in vivo, Dynesys limits extension more than flexion,[30] as expected, because the device acts like an extension stop. In flexion, Dynesys acts as an ideal load-sharing device. However, in extension, Dynesys acts as an extension stop, and becomes totally load-bearing, allowing no load transmission through the disc[29] (see Fig. 52.3). Because of uneven restriction of motion and uneven load-sharing properties, Dynesys may be subjected to high stress at the pedicle screws.[31] This may explain why screw loosening and breakage had been so rare with the Graf ligament but fairly common with Dynesys, as high as 17% in some clinical series[27,32] (Fig. 52.7).

The clinical outcome with Dynesys used as a dynamic stabilization device, as reported by the inventor group in Europe, was comparable to spinal fusion but without the need

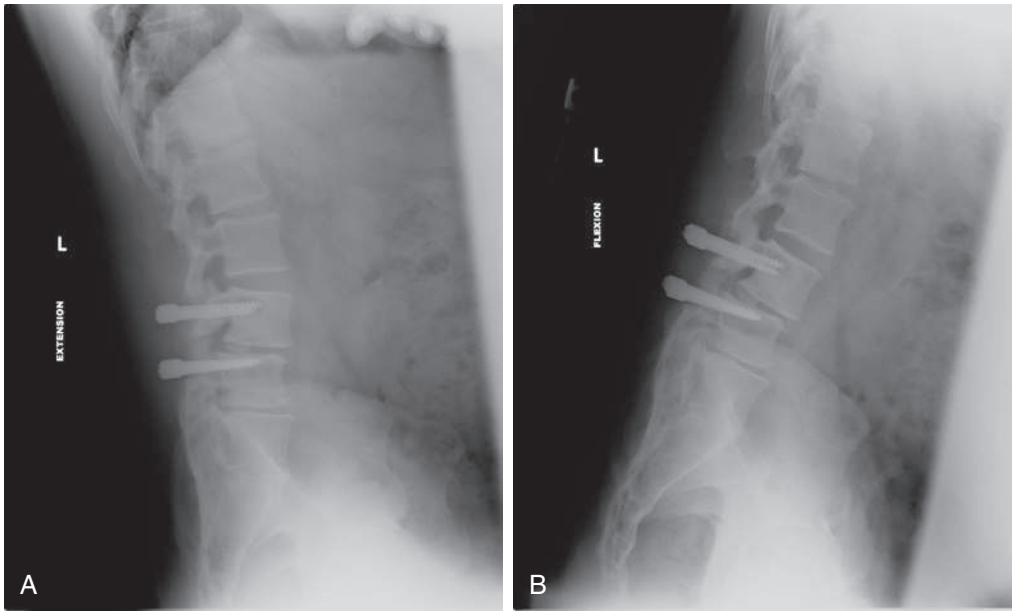

FIG. 52.7 Dynesys LIS stabilization at L4–L5 segment in (A) extension and (B) flexion. The segment is held in the flexed position and does not permit extension of the index segment. The screws are loose in both L4 and L5.

for fusion.[2] Over 60% of their cases had spinal stenosis and Dynesys was used in conjunction with decompression. This made it difficult to evaluate whether the good outcome was secondary to Dynesys or decompression. Subsequent studies by Grob et al.[27] found that stand-alone Dynesys produced a good outcome in only 39% of cases compared to 69% when combined with decompression. A similar experience was reported by other independent researchers.[33]

Most clinical outcome studies with Dynesys were reported from outside of the United States. Dynesys was introduced in the United States as a fusion device. The initial clinical outcome reported from the United States involved Dynesys as a fusion device, used with posterolateral bone graft.[34]

Dynesys has been used in the United States since 2004, when it was approved by the FDA for stabilization of spinal segments as an adjunct to fusion.[35] In 2009, an FDA-controlled investigations device exemption (IDE) clinical trial was completed for use of Dynesys as a stand-alone PDS device. The Orthopaedic and Rehabilitation Devices Panel of the FDA released an Executive Summary available on their website.[36]

The objective of this FDA IDE study was to assess the safety and efficacy of the Dynesys system for patients requiring one-level or contiguous two-level posterior spinal stabilization of the lumbar and/or sacral spine following decompression for degenerative back and leg pain. The outcome with the Dynesys system was compared to a posterolateral spinal fusion procedure using autogenous bone graft with a rigid posterior instrumentation (Silhouette Spinal Fixation System).

The IDE study database was initially closed on September 20, 2007, but was reopened for additional data entry on November 6, 2008, in order to respond to deficiencies pointed out by the FDA. It was closed again on March 13, 2009. The original study design was approved for 399 patients at 30 sites (266 Dynesys, 133 Silhouette). The final study design involved a total of 367 patients, randomized in 2:1 ratio (253 Dynesys, 114 Silhouette) at 26 sites. A total of 28 patients were nonrandomized and are referred to as the Dynesys training cohort.

The inclusion criteria emphasized predominant leg pain, with a leg pain visual analog scale (VAS) score greater than 4 out of 10. Patients with predominant axial mechanical back pain and back pain more than leg pain were excluded. A total of 74.6% of Dynesys patients and 70% of Silhouette patients have reached the 24-month primary endpoint, but only 57.3% and 56%, respectively, completed data entry within the protocol-defined study window. The study reported 52.1% overall clinical success rate in Dynesys patients compared with 40.4% in Silhouette patients. The overall clinical success rates drop to 47.0% for Dynesys and 37.5% for Silhouette if only patients in the protocol-defined windows are considered.

The Dynesys and Silhouette patients experienced differential results depending on primary indication, instability versus stenosis, and one versus two levels. For instability, Dynesys patients performed notably better; 64.6% achieved success criteria with Dynesys as opposed to 41.5% with Silhouette. However, for central canal stenosis, the outcome was reversed, with Silhouette patients (54.5%) performing better than Dynesys patients (37.3%) in achieving success criteria. Single-level disease had better outcome compared to two-level disease in both the groups.

The FDA panel pointed out several deficiencies in this study. The study was not blinded, which may have led to reporting bias among patients and investigators, potentially in favor of the investigational treatment. The study design was noninferiority in nature, and the follow-up rate in both the groups was very low. At the end, the FDA did not approve Dynesys for use as a nonfusion device.

The failure of Dynesys as a stand-alone nonfusion stabilization device by the FDA resulted in a sharp decline of its use

in the United States. Most of the recent clinical outcome studies are reported from Europe and Asia.[37–43]

Hoppe et al.,[37] in a review of 39 cases treated with Dynesys for monosegmental (L4–L5) instability with a mean 7-year follow-up, reported high success rates (>85% of patients) in long-term, low adjacent-segment disease (ASD). They concluded that Dynesys stabilization is a possible alternative to other stabilization devices. Zhang et al.[43] from China reported a review of 46 cases treated with the Dynesys system compared to 50 cases with posterior lumbar interbody fusion (PLIF) with a greater than 4-year follow-up. The authors concluded that both Dynesys and PLIF can improve the clinical outcomes for lumbar degenerative disease. Compared to PLIF, Dynesys stabilization partially preserves the ROM of the stabilized segments, limits hypermobility in the upper adjacent segment, and may prevent the occurrence of ASD. Conversely, St. Pierre et al.[41] reviewed their 52 cases treated with the Dynesys system in Canada with 5-year follow-up and concluded that Dynesys was associated with a high rate of ASD over long-term follow-up, despite maintaining a low fusion rate. Prior ASD was the strongest predictor of progressive ASD. In a recent meta-analysis, Lee et al.[39] reported that spinal fusion still remains the method of choice for advanced degeneration and gross instability; however, spinal degenerative disease with or without grade 1 spondylolisthesis, particularly in patients who require a quicker recovery, will likely constitute the main indication for PDS using the Dynesys system.

The Transition Stabilization System (Globus Medical) evolved from Dynesys, addressing several limitations in implant design. This system uses a regular top-loading pedicle screw, actively creates lordosis, and permits increased pedicle-to-pedicle distance excursion, and is preassembled. It may therefore be considered as a third-generation PDS device. It consists of a cylindrical polycarbonate urethane spacer around a polyethylene tetraphthalate (PET) cord similar to Dynesys. The system comes preassembled or can be assembled in the back table and does not require in situ tensioning. It is implanted between regular, top-loading pedicle screws, making insertion and conversion to fusion as a salvage procedure simple (see Fig. 52.5B). It incorporates a soft bumper at the end, which allows adequate pedicle-to-pedicle excursion in flexion-extension (see Fig. 52.5B). The length of the spacer defines the unloading of the facet joint. The capability of creating an active lordosis is built into the metal spools that connect the soft section of the device to the pedicle screws. Lordosis ensures unloading of the disc. These two important mechanical properties permit uniform motion restriction in all directions and uniform load sharing throughout the ROM, which is important to increase resistance to fatigue. Although this device has made several design improvements compared to Dynesys, its advantages remain to be established. The device has only been approved by the FDA under 510(k) as a fusion device, but no clinical outcome has been reported yet. The failure rate of the device in terms of screw loosening or breakage are found to be not superior compared to Dynesys (Fig. 52.8).

The DSS-II dynamic stabilization system[44] was developed by the author and is one of the earliest titanium metallic springs used for dynamic stabilization. Its predecessor, the

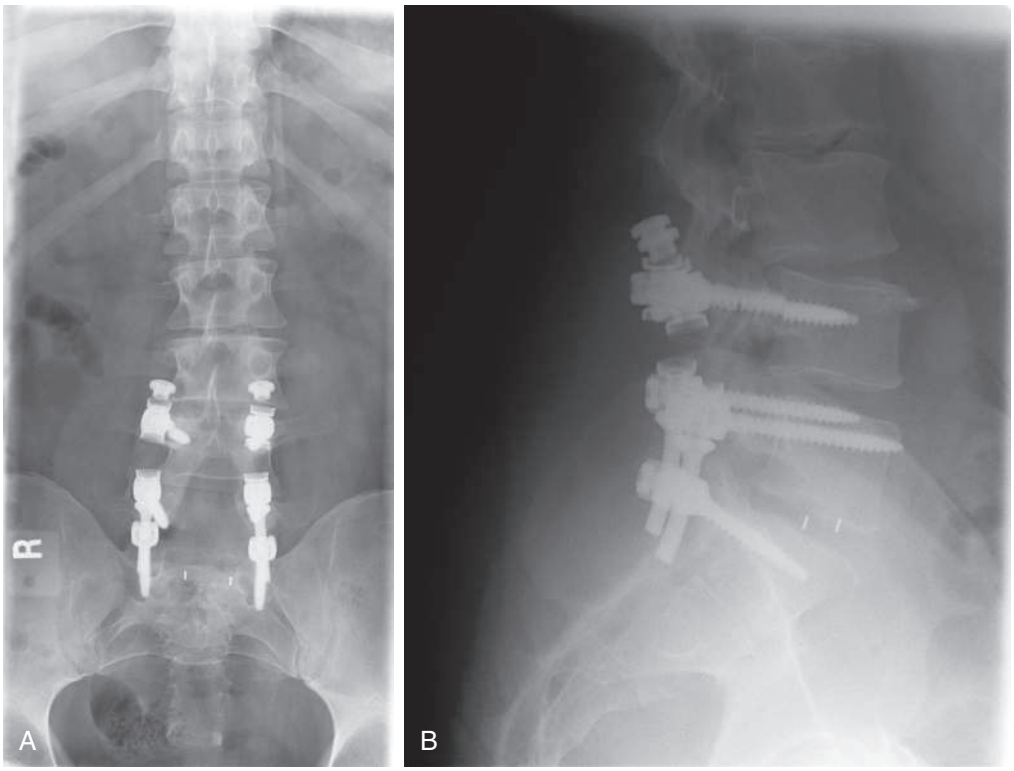

FIG. 52.8 Transition system used for rigid fusion at the L5–S1 segment (S1 is lumbarized) and dynamic stabilization at L4–L5. Note screw breakage at L4 at 18-month follow-up.

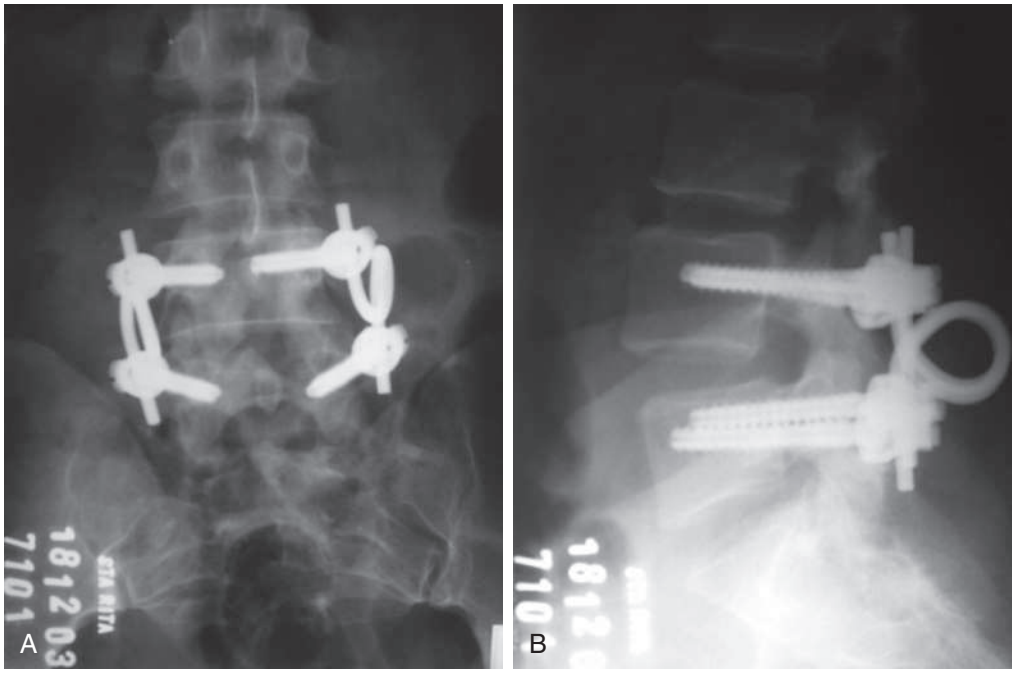

FIG. 52.9 DSS-II system for stabilization of L4–L5 motion segment: (A) anteroposterior and (B) lateral radiographs.

DSS-I, was a C-shaped titanium spring which, on biomechanical testing, showed uneven restriction to extension and excessive unloading of the disc in extension, indicating possibility of fatigue failure. It was therefore never used clinically. The second-generation DSS-II is an α-shaped titanium spring implanted between the pedicle screws. This design improvement produces active lordosis and permits adequate pedicle-to-pedicle excursion and physiologic translation of the IAR of the motion segment. The system allows uniform motion restriction and uniform load sharing throughout the ROM, the two essential biomechanical characteristics for survival of the implant against fatigue failure. The device has never been introduced for general use, but a pilot clinical trial in a small group of patients (n = 19) was completed in Sao Paulo, Brazil for patients with mechanical back pain without needing decompression (Fig. 52.9). The clinical outcome was encouraging, but, more important, no implant failure was observed in 2 to 3 years of follow-up.[44]

The BioFlex (Bio-Spine Corporation),[45] a coil spring made of nitinol 4 mm in diameter for increased flexibility, has been used extensively in Seoul, Korea. This device has been used most commonly in conjunction with interbody cages to achieve fusion, although it has also been used alone as a nonfusion device.[46] Recently, a titanium version of the device has been approved by the FDA under 510(k) as a fusion device, but no clinical use in the United States has been reported yet. In a retrospective study, Yang et al.[47] reported a review of 28 cases treated with BioFlex stabilization for L4–L5 degenerative spondylolisthesis, with 82% of cases experiencing good or excellent clinical outcome. Park et al.[48] reported encouraging clinical outcomes in 27 cases but cautioned against hardware-related complications that they encountered in five cases at 1-year follow-up (Fig. 52.10).

Stabilimax NZ (Applied Spine Technologies),[49] a dual-core spring device developed by Panjabi, is designed to apply soft resistance against both compression and distraction. The design rationale is to limit the NZ motion but leave the elastic zone unaffected. Currently, the device is undergoing an FDA-controlled IDE trial to assess whether it is at least as safe and effective as fusion in patients receiving decompression surgery for the treatment of clinically symptomatic spinal stenosis at one or two contiguous vertebral levels from L1–S1.[49,50]

The Cosmic Posterior Dynamic System (Ulrich GmbH)[51] has a unique design that incorporates a rigid rod connected to the pedicle screws with a hinged screw head, which is expected to permit motion. No biomechanical data are available in the peer-reviewed literature. There are some clinical reports of its use in journals that are not peer reviewed.[52] In a retrospective study, Yang et al.[47] reported a review of 23 cases treated with Cosmic stabilization for L4–L5 degenerative spondylolisthesis, with 78% of cases experiencing good or excellent clinical outcome. Kaner et al.[53] reported only one case with screw loosening, but no screw breakage, at 2- to 5-year follow-up in a review of 30 cases treated with Cosmic stabilization following decompression.

The AccuFlex (Globus Medical) titanium rod has a spiral cut to make the rod flexible and can be inserted between regular pedicle screws. This device has been used clinically for fusion[54] but not for nonfusion dynamic stabilization as yet. This metallic device offers some flexibility but does not permit any significant pedicle-to-pedicle excursion.

Hybrid devices incorporate a metallic rod connected to a flexible segment, with a nonmetallic bumper to allow shock absorption as well as some degree of pedicle-to-pedicle excursion. The primary clinical indication is to address

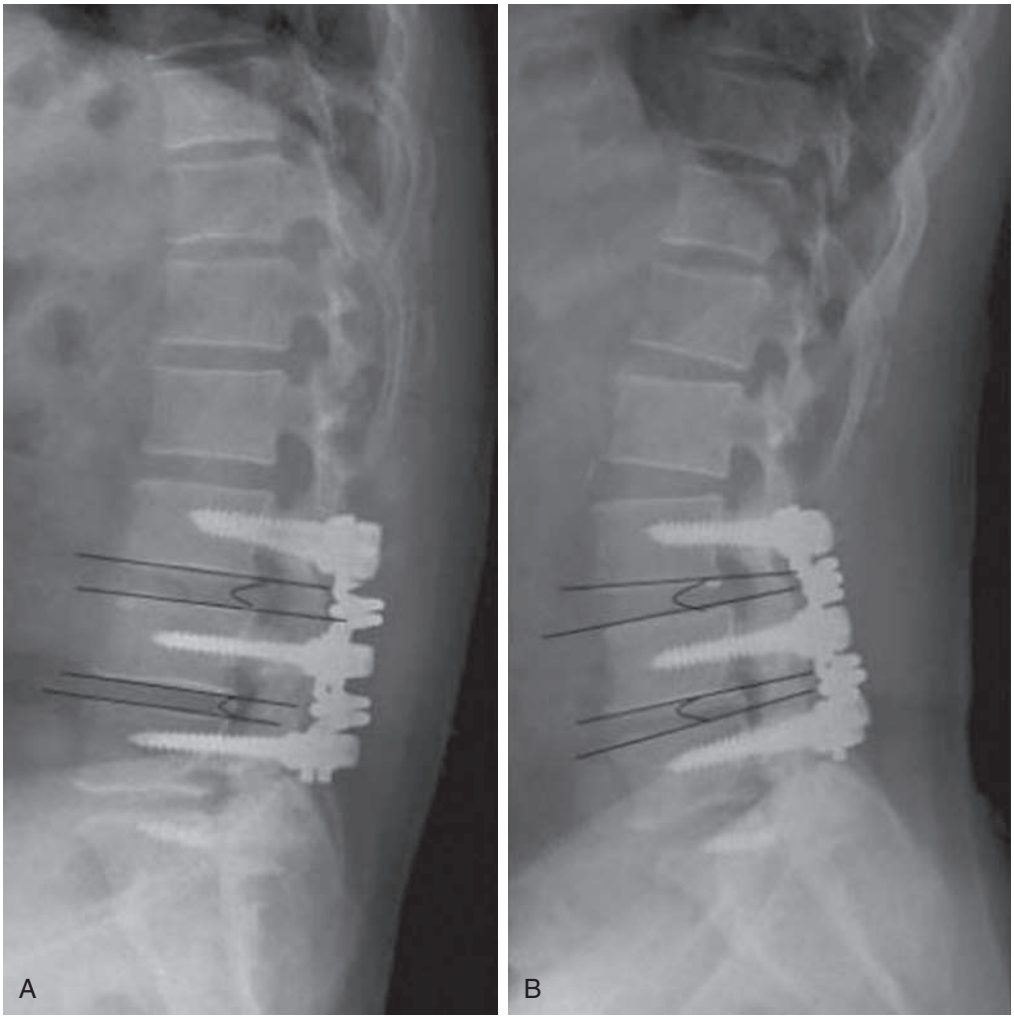

FIG. 52.10 BioFlex system for stabilization of L3–L4 and L4–L5 segments in (A) flexion and (B) extension.

advanced degenerated segments with rigid fusion and address moderately degenerated adjacent segments by stabilizing with a flexible device without fusion in order to prevent progression of degeneration. The Transition system described earlier is an example that can be used as a dynamic stabilization system only as well as a rigid to flexible hybrid system.

The CD Horizon Agile (Medtronic Sofamor Danek) system incorporates a soft cylindrical bumper at the end of a fusion rod, held by a metallic cable in its center, similar to the fabric cord as used in the Dynesys system described earlier. Following initial clinical use, the device was recalled by the company for reported fatigue failure of the cable.

The Dynesys Transition Optima (DTO) implant (Zimmer-Biomet) is a modification of the original Dynesys system that combines a hybrid rigid to dynamic stabilization. This transition system allows for arthrodesis of critically unstable vertebrae in combination with the dynamic stabilization of adjacent moderately degenerated segments. In a recent study, Lee et al.[55] reported their small experience using this hybrid system in 15 cases. They reported better outcome and greater preservation of posterior disc height with the use of the hybrid system compared to rigid fusion (see Fig. 52.5).

NFlex (Synthes GmbH) has a similar design, in which a 6.0-mm titanium fusion rod is connected to a flexible end made of 3.25-mm titanium core and a polycarbonate urethane sleeve. The sleeve allows soft resistance to both flexion and extension, permitting the essential pedicle-to-pedicle excursion. Although the device may permit compression and elongation, its ability to permit anteroposterior translation remains a concern. The device has been used clinically since the fall of 2006.[56] In 2012, Coe et al.[57] reported 2-year outcomes in 65 of 72 cases treated in five centers. They concluded that the NFlex system was effective in improving pain and functional scores at 2 years and may be considered an effective alternative to rigid fusion with appropriate patient selection (Fig. 52.11).

Interspinous Distraction Devices

One of the earliest and most frequently used IPDs was the X-Stop device (Medtronic). This titanium spacer can be inserted with a minimally invasive approach under local anesthesia; therefore, elderly patients with medical comorbidities are considered ideal candidates. Biomechanical studies in

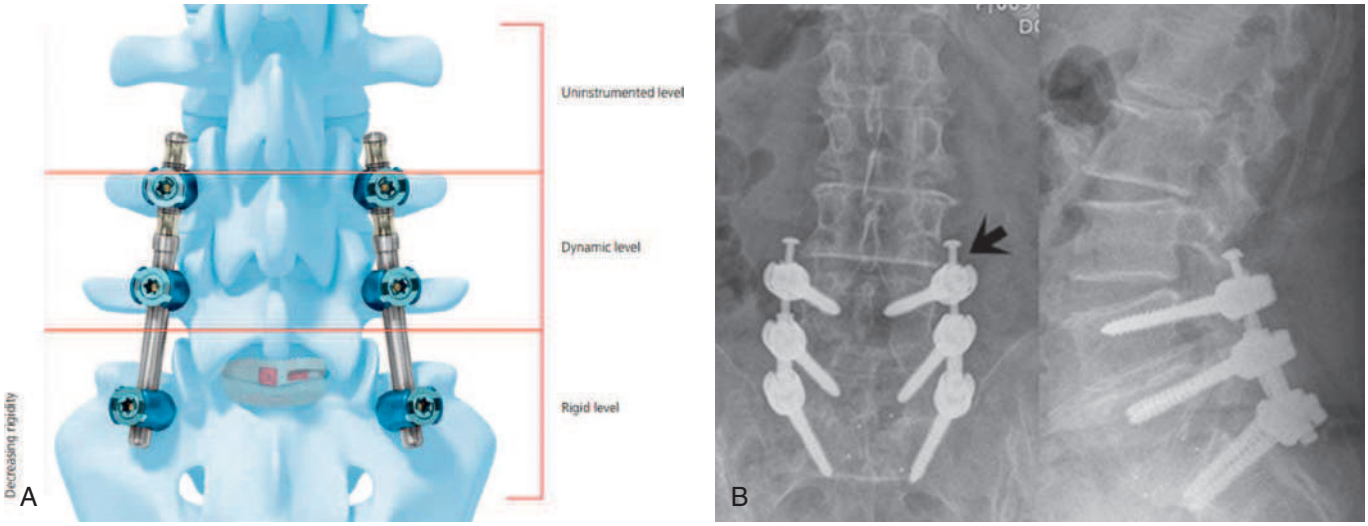

FIG. 52.11 (A) NFlex system schematic indicating the rigid and dynamic levels. (B) Clinical application at the L4–L5 and L5–S1 segments.

cadaver spines have demonstrated that X-Stop significantly decreases posterior intradiscal pressure[58,59] and reduces facet pressures; it decreases the contact area at the facets as well.[60] An in vivo study with MRI scan also demonstrated that X-Stop increases the spinal canal and foramen diameter during extension.[61] This device holds the spine into a position of flexion, a position of relief from claudication pain. Because it is not tied with Dacron ligament to the adjacent spinous process, it can permit further flexion.

In a prospective randomized, multicenter study on 191 patients with neurogenic intermittent claudication, the efficacy of X-Stop was compared to nonoperative treatment.[62] At 2-year follow-up, the X-Stop group had improved symptom severity, physical function, and patient satisfaction scores at all of the time points compared to the nonoperative group. The reoperation rate was 6% at 2 years for the X-Stop group, which is comparable to the reoperation rate for lumbar decompression procedures. There were some limitations to this study, including a lack of blinding and loss to follow-up. But the major limitation of the study was failure to compare the efficacy of X-Stop to a conventional surgical treatment for spinal stenosis, that is, decompressive laminectomy. The device received FDA approval for use in one- or two-level stenosis in patients over 50 years with significant neurogenic claudication with or without back pain after failed conservative treatment for at least 6 months.

The main complication of this device is dislodgement of the spacer with or without breakage of the spinous process. This is because the device is not flexible and does not permit extension movement of the spine. In a randomized control trial, Anderson et al.[63] reported that the X-Stop device was more effective than nonoperative treatment in the management of neurogenic claudication secondary to degenerative lumbar spondylolisthesis. However, in another study, Verhoof et al.[64] reported failure of X-Stop in seven of 15 (58%) consecutive cases within 2 years when the device was used for degenerative spondylolisthesis. A similar experience was reported by other authors as well.[65]

The Superion device (Vertiflex) is another metallic device similar to X-Stop, but with a smaller profile, and can be inserted through a minimally invasive approach without disrupting the interspinous ligament. This device is also metallic and not flexible, permitting flexion but no extension. Patel et al.[66] reported 3-year clinical outcomes of a randomized, controlled FDA IDE trial of Superion (190 cases) compared to a control group with X-Stop (201 cases) for the treatment of moderate degenerative lumbar spinal stenosis. They reported better outcomes with Superion, achieving a success rate of 80% for each of the individual components of the primary endpoint (Fig. 52.12).

The Wallis device (Zimmer Spine) is an example of a rigid nonmetallic polyetheretherketone spacer, retained between the spinous processes by a Dacron tape, which prevents its accidental dislodgement.[67] This device holds the spine into flexion and stops extension. In addition, the holding ligaments also restrict further flexion. As a result, its manufacturers and inventors have recommended its use for indications beyond spinal stenosis, for example, mechanical back pain with early disc degeneration.[68,69]

An FDA IDE trial is currently comparing the Wallis system to total disc replacement for the treatment of mild to moderate degenerative disc disease of the lumbar spine at the L4–L5 level.[70] An updated report of this trial is not available, but a prospective randomized controlled trial to assess the efficacy of the Wallis system has been reported from Europe.[71] Sixty patients with an average age of 58 years (range, 34–81 years) with spinal stenosis were randomly assigned to two groups with an equal number of patients: decompression alone or decompression with Wallis implant. The Wallis group had better improvement of symptoms, but it was not statistically significant. Korovessis et al[72] reported a prospective controlled study, designed to investigate if the implantation of Wallis implant cephalad to short segment instrumented fusion in 25 cases, and a control group without; they found that the adjacent segments with Wallis implant stabilization resisted degeneration more than in the control group. Floman et al[68]

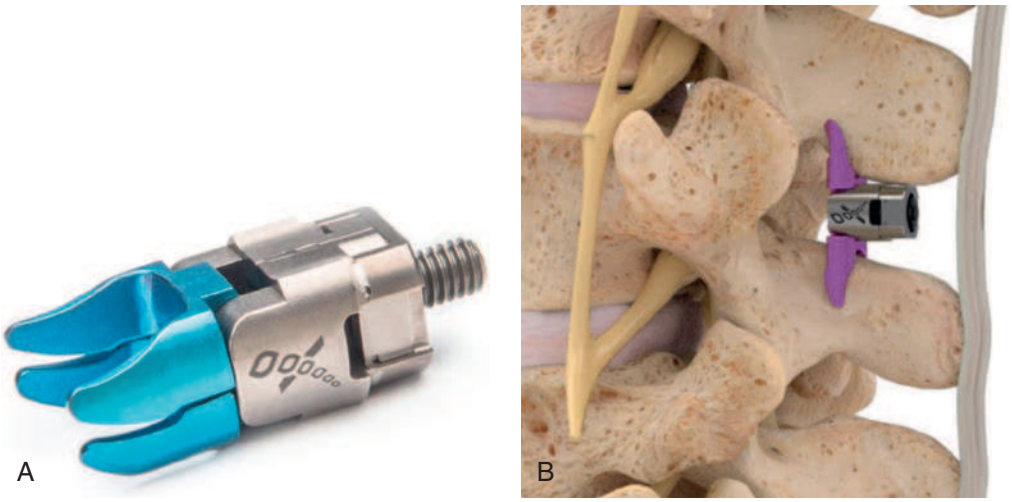

FIG. 52.12 Superion system (A) collapsed and (B) expanded after insertion between the spinous processes.

reported failure of the Wallis interspinous implant to lower the incidence of recurrent lumbar disc herniation in patients undergoing primary disc excision.

The DIAM system (Medtronic Sofamor Danek) is an H-shaped, polyester-covered, silicone bumper that is placed between the spinous processes with a suture to hold it in place. The device has been used in Europe for a few years. A recent clinical study failed to establish efficacy of DIAM in improving back pain when compared to decompression alone.[73] An FDA-regulated clinical trial for DIAM was initiated in late 2006 for patients with lumbar spinal stenosis. The FDA also granted another IDE trial to study DIAM in patients with low back pain caused by degenerative disc disease.[74] In February of 2016, the Orthopaedic and Rehabilitation Devices Panel of the FDA Medical Devices Advisory Committee presented its report on the DIAM Spine Stabilization Trial.[75] This was a prospective, randomized, controlled pivotal clinical trial, with nonoperative control, randomized at a 2:1 ratio, no blinding, and the primary endpoint to be determined at the 12-month time point. Inclusion criteria were degenerative disc disease, in the 18 to 70 years age group, with Oswestry Disability Index score greater than 30 and visual analog scale (VAS) score for back pain greater than or equal to 8 out of 10. Study success was defined as superiority in the treatment group at 12 months. The DIAM subjects reported better outcomes (64%) as compared to the control group (24.5%) in the primary and secondary effectiveness assessments. Spinous process erosions and spinous process fractures were observed in DIAM subjects throughout the course of this clinical trial. Despite significantly superior clinical outcome in the DIAM group, the panel suggested a postapproval study to provide long-term safety and effectiveness data with the device with 5-year follow-up.

The Coflex device (Paradigm Spine), is a U-shaped titanium device, retained in place by clamping its wings around the adjacent spinous processes (Fig. 52.13). In contrast to other IPD devices, it allows both flexion and extension and does not act as an extension stop. Biomechanical studies report that it restores normal flexion-extension in a destabilized spine rather

than holding the spine in flexion.[76] Kong et al. reported a comparable outcome at 1-year follow-up with Coflex versus PLIF for degenerative back pain.[77] However, the Coflex group had preserved motion and the PLIF group had an adverse effect on the adjacent segment. Bae et al.[78] recently reported the 3-year follow-up of the prospective randomized controlled trial (FDA IDE study) of Coflex interlaminar stabilization (n = 196) versus instrumented fusion (n = 94) in patients with lumbar stenosis. Both groups showed improvement, but the percentage with a clinically significant improvement (≥15) in the Oswestry Disability Index seemed larger for the Coflex group. In addition, ROM was maintained with the Coflex device in the index and adjacent segment compared to increased ROM in the superior adjacent segment in the fusion group. Five-year follow-up data of the same study showed a similar outcome.[79]

Device slippage due to loosening, bony erosions in osteoporotic bones, and/or progression of instability are the main concerns with the Coflex device.[80] Because of the smaller size of the S1 spinous process, there is a concern of failure of the Coflex device at the L5–S1 level. However, in a retrospective study, Xu et al.[81] reported a consecutive series of 33 patients with degenerative lumbar spinal stenosis or lumbar disc herniation at the L5–S1 level, stabilized successfully with Coflex, and observed no significant implant failure.

Many other spinous process distraction devices are being developed or are beginning an FDA trial. A comprehensive review is beyond the scope of this chapter. A systematic review comparing four different commonly used IPD devices (DIAM, Wallis, Coflex, and X-Stop) was reported by Lee et al.[82] Out of a total of 286 articles, 20 were included in the final assessment. Two assessors independently extracted data. The authors found that the complication rate of combined interspinous dynamic stabilization and decompression treatment (32.3%) was greater than that of decompression alone (6.5%), but no complication that significantly affected treatment results was found. Interspinous dynamic stabilization produced slightly better clinical outcomes than conservative treatments for spinal stenosis. No significant difference in treatment outcomes was found in the studies that compared interspinous dynamic stabilization with decompression or fusion alone. The authors concluded that clinical outcomes with the IPD devices were similar to those of conventional techniques and that no additional clinical advantage could be attributed to interspinous dynamic stabilization. However, few studies have been conducted on the long-term efficacy of interspinous dynamic stabilization.

Summary

PDS evolved from failure of fusion to address mechanical back pain due to spinal instability. IPD devices have been primarily introduced to treat spinal stenosis with claudication or radicular pain by indirect decompression. Spinal instability is poorly defined, but the current understanding is abnormal quality of motion, leading to uneven load transmission. This occurs mostly during NZ motion. The biomechanical goals of PDS devices are to preserve motion as much as possible but prevent any abnormal motion and to unload the disc and facet joints by load sharing. The biggest challenge for PDS devices is to survive fatigue failure despite allowing continued motion. The key to this survival is uniform load sharing and uniform restriction of motion throughout ROM. Unfortunately, many PDS devices have been introduced without any biomechanical basis, and their clinical success was confounded by combining the effect of a concomitant decompression for leg pain. It is essential that efficacy of PDS devices to treat back pain be established before they are recommended for secondary indications, such as preventing instability after decompression or preventing adjacent-segment degeneration. IPD devices are primarily indicated for treatment of neurogenic claudication in the elderly with comorbidities by minimal intervention and indirect decompression. Clinical studies to establish their efficacy against open and direct decompression is lacking. Their recommendation in the treatment of mechanical back pain does not have any scientific basis. Product development and marketing is expensive; therefore, most clinical trials are aimed at establishing clinical success rather than a proper scientific evaluation of their clinical efficacy. Most of the new PDS devices are introduced in the US market with FDA approval under 510(k) as a fusion device. The clinical use for dynamic stabilization without an attempt of fusion has become an off-label use in the United States. This has led to the concept of soft fusion, which indicates intertransverse fusion only, using a PDS device. Expectation is that resultant fusion would be less stiff than conventional fusion with rigid instrumentation and therefore less likely to produce adjacent-segment disease. There is no clinical evidence to support this concept yet. Dynamic stabilization has raised a great deal of enthusiasm, theoretical promises, and many expectations. Like any new technology, these procedures are apt to breed clinical failures. The need for detailed consideration of design rationale and proper clinical evaluation without confounding factors to prove safety and efficacy cannot be overemphasized. Fusion remains the method of choice for advanced disc/facet degeneration and gross instability. However, disc degeneration in multiple segments—particularly in young patients with concerns about adjacent-segment disease following fusion—will likely constitute the main indication for PDS. Future applications of dynamic stabilization may include salvage of failed disc prosthesis or nuclear replacement. In the future, PDS may be considered to provide temporary mechanical support for any pharmacologic treatment aiming for repair or regeneration of the intervertebral disc.

PEARLS

1. Clinical instability causing mechanical back pain may be defined as abnormal quality of motion leading to uneven load distribution in the motion segment.
2. The goals of PDS are motion preservation and to prevent abnormal motion in the NZ.
3. The mechanism of pain relief by PDS is load sharing with the disc and the facet joints.
4. The goal of interspinous distraction is indirect decompression for the spinal stenosis, with minimal intervention.
5. The primary indication for PDS is activity-related mechanical back pain.

6. The secondary indications for PDS are prevention of instability, prevention of iatrogenic instability after decompression, and stabilization of the adjacent motion segment.
7. The primary indication for IPD is spinal stenosis with claudication.
8. The secondary indication for IPD is mechanical back pain.
9. Contraindications for dynamic stabilization are osteoporosis, advanced disc degeneration with complete collapse of disc height, scoliosis, and spondylolisthesis greater than grade 1.

PITFALLS

1. The biggest challenge for dynamic stabilization devices is survival against fatigue, despite allowing continued motion.
2. Avoid too much distraction and kyphosis with a PDS device, which increases the poor outcome and device failure.
3. Avoid using any dynamic stabilization device in the presence of osteoporosis to prevent implant loosening.
4. For advanced disc degeneration, fusion remains the gold standard of surgical treatment.

53 CHAPTER Rationale of Minimally Invasive Spine Surgery

Choll W. Kim
Steven R. Garfin

Introduction

The goal of minimally invasive spine (MIS) surgery is to accomplish the intended goals of treatment, whether they be decompression, fusion, and/or realignment. The key concepts that guide MIS approaches are to (1) decrease muscle crush injuries during retraction; (2) avoid detachment of tendons to the posterior bony elements, especially the multifidus attachments to the spinous process and superior articular processes; (3) maintain the integrity of the dorsolumbar fascia; (4) limit bony resection; (5) utilize known neurovascular planes; and (6) decrease the size of the surgical corridor to coincide with the area of the surgical target site. Recent advances in instrumentation, combined with refinement of surgical techniques, have allowed treatment of an ever increasing number of spinal disorders.

Anatomy of the Posterior Paraspinal Muscles

The posterior lumbar paraspinal muscles are part of a larger biomechanical system that includes the abdominal muscles and their fibrous attachment to the spine through the dorsolumbar fascia. This network of muscles is responsible for generating movements of the spine while maintaining its stability.[1,2] In addition to maintaining spinal posture in its neutral position, the paraspinal muscles guard the spine from excessive bending that would otherwise endanger the integrity of the intervertebral discs and ligaments.[3] Panjabi et al. have proposed that the paraspinal muscles apply minimal resistance inside the neutral zone, but increase their stiffness exponentially once the range of motion falls outside this neutral zone.[4,5] This dynamic stabilizing system is controlled by an interconnected chain of mechanoreceptors imbedded in the muscle fascicles, disc anulus, and spinal ligaments.[6] Functional electromyelography (EMG) studies reveal that spinal stability is achieved by the simultaneous contraction of several agonist-antagonist muscles.[3,7,8] Architectural studies suggest that the individual paraspinal muscles may have different primary roles as either movers or stabilizers of the spinal column.[9] The anatomic position of the intermuscular planes vary from level to level and may affect the proper location of the incisions.[10,11] In general, the intermuscular plane at the L1–L2 level is closer to the midline than at the L5–S1. Placement of the paramedian incisions should take into consideration this finding along with other characteristics unique to the individual patient, including the depth of the surgical target site from the skin and the trajectory of the pedicles in cases in which the same incision will be used for pedicle screw insertion.

Multifidus Muscle

The posterior paraspinal muscles are composed of two muscle groups: the deep paramedian transversospinalis muscle group, which includes the multifidus, interspinales, intertransversarii and short rotators, and the more superficial and lateral erector spinae muscles, which include the longissimus and iliocostalis (Fig. 53.1). These muscles run along the thoracolumbar spine and attach caudally to the sacrum, sacroiliac joint, and iliac wing. The multifidus is the most medial of the major posterior paraspinal muscles and is the largest muscle that spans the lumbosacral junction. It is believed to be the major posterior stabilizing muscle of the spine.[3,9,12] Compared to other paraspinal muscles, the multifidus muscle is short and stout. It has a large physiologic cross-sectional area (PCSA) but short fiber lengths. This unique architectural anatomy is designed to create large forces over relatively short distances (Fig. 53.2A).[9] Furthermore, the multifidus sarcomere length is positioned on the ascending portion of the length-tension curve (Fig. 53.2B). When our posture changes from standing erect to bending forward, the multifidus is able to produce more force as the spine flexes forward. This serves to protect the spine at its most vulnerable position. Not only is the multifidus muscle designed for maximal active force generation during spinal flexion and extension maneuvers, passive stability is created through increased stiffness of the extracellular matrix surrounding the multifidus muscle at the muscle bundle level.[13]

The multifidus is the only muscle that is attached to both posterior parts of the L5 and S1 vertebrae and is, therefore, the sole posterior stabilizer that both originates and inserts to this segment. The morphology of the lumbar multifidus is complex.[14] Unlike the other paraspinal muscles that have

specific origins and insertions, the multifidus muscle is formed by five separate bands, each having its own origin and several different insertion sites. Each band consists of several fascicles arising from the tip of the spinous process and the lateral surface of the vertebral lamina. Caudally, the different fascicles diverge to separate attachments into the mammillary processes of the caudal vertebrae 2 to 5 levels below their origin and downward through each vertebra to the sacrum. For example, fibers from the L1 band insert into the mammillary processes of the L3, L4, and L5 vertebrae; to the dorsal part of S1; and to the posterior superior iliac spine. Biomechanical analyses, based on the multifidus muscle anatomy, show that it produces posterior sagittal rotation of the vertebra, which opposes a counter-rotation generated by the abdominal muscles. The multifidus can further increase lumbar spine stability through a "bowstring" mechanism in which the muscle, positioned posterior to the lumbar lordosis, produces compressive forces on the vertebrae interposed between its attachments.[15]

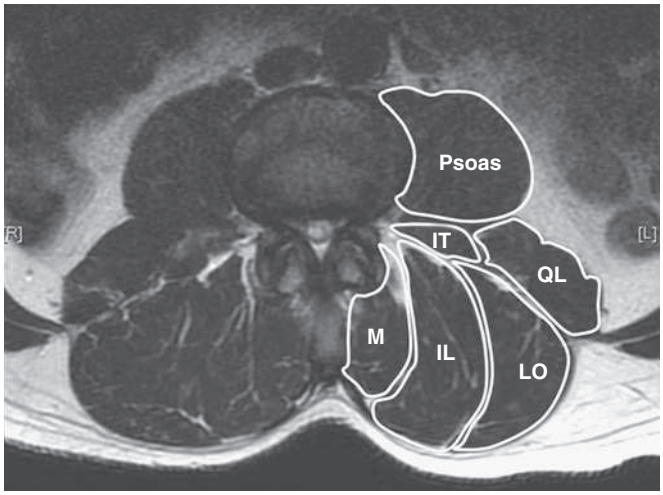

FIG. 53.1 Magnetic resonance cross-sectional image through the L4–L5 disk space showing the multifidus (M), iliocostalis (IL), longissimus (LO), quadratus lumborum (QL), intertransversarii (IT), and psoas muscles.

Erector Spinae Muscles

The erector spinae muscles are composed of the longissimus, iliocostalis, and spinalis (in the thoracic area).[14,16] In the lumbar spine, the longissimus is positioned medially and arises from the transverse and accessory processes; it inserts caudally into the ventral surface of the posterior superior iliac spine. The laterally positioned iliocostalis arises from the tip of the transverse processes and the adjacent middle layer of the thoracolumbar fascia; it inserts into the ventral edge of the iliac crest caudally.[17] Unilateral contraction of the lumbar erector spinae laterally flexes the vertebral column; bilateral contraction produces extension and posterior rotation of the vertebrae in the sagittal plane. In addition to their role as the major extensor muscles of the trunk, the iliocostalis and longissimus also exert large compressive loads as well as lateral and posterior shear forces at the L4 and L5 segments. While these forces increase the stiffness and stability of the normal vertebral column, the shearing forces may also exacerbate instability and deformity in a malaligned spine.[18] In contrast to the multifidus muscle, microarchitectural studies reveal that these muscles are designed as long muscle fascicles with relatively small PCSA. This anatomic morphology suggests that they serve to move the trunk to extension, lateral bending, and rotation. With this type of design, they are less likely to act as primary stabilizers of the vertebral column.[19]

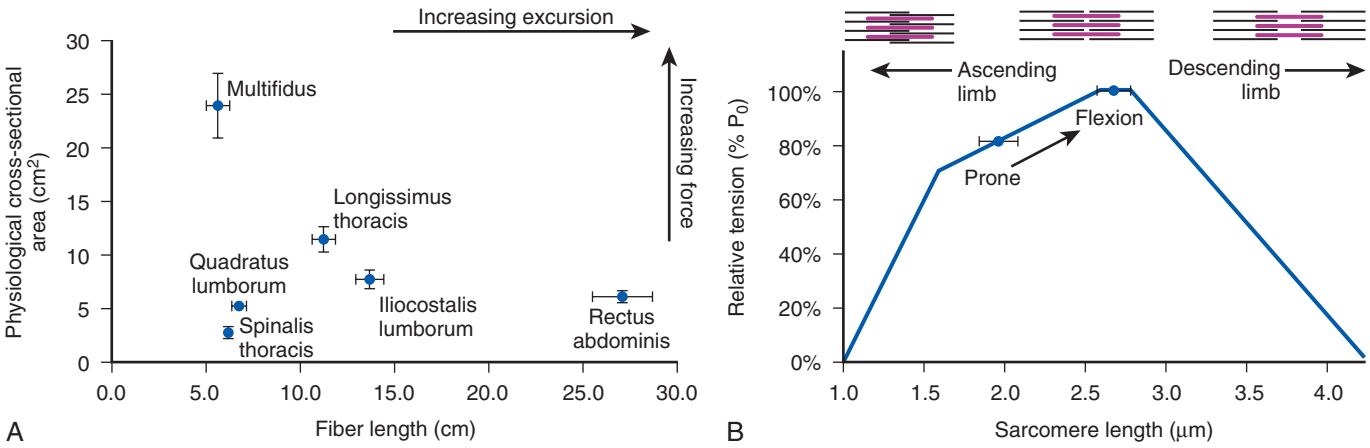

FIG. 53.2 (A) Scatter plot of physiologic cross-sectional area (PCSA) versus fiber length. Since PCSA is proportional to muscle force and fiber length is proportional to muscle excursion, this type of plot illustrates the functional design of a muscle. These data illustrate that the multifidus has the largest force-generating capacity in the lumbar spine and is designed for stability. (B) Sarcomere length operating range of the multifidus plotted on the human skeletal muscle sarcomere length-tension curve (*black line*). These data demonstrate that the multifidus muscle operates on the ascending limb of the length-tension curve and becomes intrinsically stronger as the spine is flexed (*arrow*). Schematic sarcomeres are shown on the ascending and descending limb to scale based on the quantification of actin and myosin filament lengths. (From Ward SR, Kim CW, Eng CM, et al. Architectural analysis and intraoperative measurements demonstrate the unique design of the multifidus muscle for lumbar spine stability. *J Bone Joint Surg Am.* 2009;91:176-185.)

Interspinales, Intertransversarii, and Short Rotator Muscles

The interspinales, intertransversarii, and short rotator muscles are short, flat muscles that lie dorsal to the intertransverse ligament (see Fig. 53.1). The intertransversarii and interspinales run along the intertransverse and the interspinous ligaments of each segment. The short rotators originate from the posterior-superior edge of the lower vertebra and attach to the lateral side of the upper vertebral lamina. Because of their small PCSA, they are not able to generate the forces needed for movement or stability of the spinal column. More likely, they act as proprioceptive sensors, rather than force-generating structures.[20]

Innervation of the Posterior Paraspinal Muscles

The innervation of all of the posterior paraspinal muscles is derived from the dorsal rami. The iliocostalis is innervated by the lateral branch, while the lumbar fibers of the longissimus receive innervation from the intermediate branch. The multifidus is innervated by the medial branch of the dorsal rami (Fig. 53.3). The medial branch curves around the root of the superior articular process and passes between the mammillary and accessory processes to the vertebral lamina, where it branches to supply the multifidus muscle, the intertransversarii and interspinales muscles, and the zygapophyseal joints.[21]

During its extramuscular course, the medial branch is strongly attached to the vertebral body in two locations. The first attachment is to the periosteum lateral to the zygapophyseal joints by fibers of the intertransverse ligament. The mammilloaccessory ligament provides the second attachment in the lumbar spine. This strong ligament covers the medial branch and is often calcified.[22] These attachments to the vertebra are of clinical importance, as they expose the medial branch to possible damage during a midline posterior surgical approach.[23]

Direct damage to the nerve is also possible during insertion of pedicle screws.[13] Insertion of a pedicle screw in the area of the mammillary process can injure the medial branch arising from the cephalad-level nerve root, causing denervation injury and consequent atrophy to the multifidus fascicles that arise from the adjacent cephalad level.[24–26] For instance, pedicle screws placed at L2 may damage the L1 nerve, which denervates the multifidus bands that originate at L1 and insert into the vertebrae caudally. Moreover, the monosegmental innervation of the multifidus makes it particularly susceptible to atrophy, as it lacks a collateral nerve supply from adjacent muscle segments.[14] It is intriguing to consider that dysfunction of this muscle could contribute to adjacent-level disc degeneration.

Fiber Type Characteristics of the Paraspinal Muscles

Fiber type analysis can provide important information about the use pattern of a muscle.[27,28] There are two major fiber types in skeletal muscles: type I, also known as a "slow twitch," and type II, or "fast twitch." The type I fibers possess low adenosine triphosphatase (ATPase) activity, prolonged twitch duration (hence, "slow twitch"), and a low maximal velocity. In addition, type I fibers contain higher mitochondrial content and greater oxidative enzyme complements than type II fibers. Type II fibers are characterized by higher ATPase activities and correspondingly shorter isometric twitch durations. With this design, they are better suited to support the regeneration of adenosine triphosphate through anaerobic mechanisms. Type II fibers can be further subdivided into type IIa and IIx fibers. Type IIx fibers are generally more extreme in each of these respects than the type IIa fibers.[28–30]

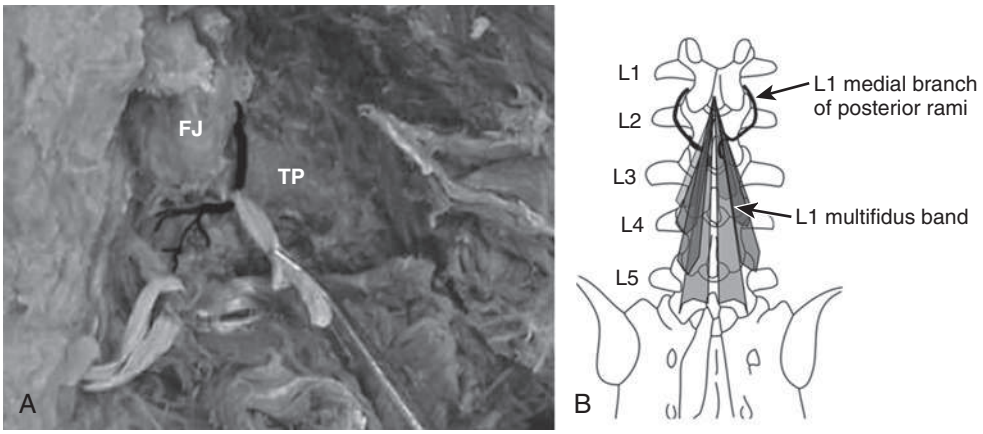

FIG. 53.3 (A) Anatomic specimen showing the spatial relationship of the medial branch of the posterior rami (MBPR) nerve (*highlighted in black and retracted with a rubber vessel loop*), the facet joint (FJ), and transverse process (TP). (B) Path of the L1 medial branch of posterior rami nerve to the L1 multifidus muscle. The L1 MBPR traverses the L2 transverse process and rises posteriorly to innervate the multifidus muscle that originates from the L1 spinous process. The L1 multifidus then separates into four bands that insert into the lamina and superior articular processes of the L3, L4, L5, and S1. (From Regev GJ, Lee YP, Taylor WR, Garfin SR, Kim CW. Nerve injury to the posterior rami medial branch during the insertion of pedicle screws: comparison of mini-open versus percutaneous pedicle screw insertion techniques. *Spine (Phila Pa 1976).* 2009;34:1239-1242.)

One of the most striking features of the lumbar paraspinal muscles is the predominance of type I muscle fibers compared with other skeletal muscles. Polgar and Johnson studied the distribution of fiber types in 36 human muscles.[31] A significantly larger type I to type II fiber ratio was observed in the multifidus, longissimus, and iliocostalis muscles compared to muscles of the extremities. The predominance of type I fibers and selective type II atrophy has been found in other studies that analyzed fiber type distribution and size in normal paraspinal muscles. It is presumed that, along with the adaptation to their stabilizing tonic work characteristics, the phenomenon of type II atrophy can be explained by the sedentary modern lifestyle that deprives these muscles of stimulation from exercise.[32] The relatively larger size of type II fibers in professional athletes further supports this assumption.[33,34]

The morphology of fiber type distribution between the different paraspinal muscles and in different areas inside the muscle is well known. Jorgensen et al. reported a higher proportion of type I fibers in the longissimus than in the multifidus or iliocostalis muscles.[35] Furthermore, the multifidus muscle is composed of a relatively high percentage of type I fibers, consistent with a postural function. The psoas muscle, on the other hand, is composed of a higher percentage of type II fibers, such as in the appendicular muscles.[36] Mannion et al. showed that, in women, the mean size of the type I fiber is significantly greater than that of either the type IIA or the type IIx, while men have relatively larger-sized type II fibers.[37] In the older population, a loss of muscle mass leads to a decrease in both fiber type sizes with slightly more effect in type II fibers.[38–40] The most profound changes in fiber size and fiber type distribution occur in patients with degenerative conditions of the spine.[29] Compared with the control, the muscle of low back pain patients had a significantly higher proportion of type IIx fibers than type I fibers. They proposed that the relatively low proportion of type I fibers in patients with low back pain render them less resistant to fatigue and more susceptible to injury.

Paraspinal Muscle Injury

Characteristics of Paraspinal Muscles in the Postsurgical Spine

Spine surgery inherently causes damage to surrounding muscles.[41] This injury can be followed by atrophy of the muscles and subsequent loss of function. Among the different surgical approaches to the spine, injury to the muscle is greatest when using the midline posterior approach.[42] The multifidus muscle is most injured when using this approach. Muscle atrophy coincides with decreased muscle cross-sectional area (CSA), which, in turn, correlates with decreased force production capacity of the muscle.[41,43–49]

Muscle biopsies obtained from patients undergoing revision spinal surgery exhibit an array of pathologic features that include selective type II fiber atrophy, widespread fiber type grouping (a sign of reinnervation), and "moth eaten" appearance of muscle fibers.[40] Although these pathologic changes can occasionally be found in biopsies from normal individuals, the pathologic changes are more prevalent after surgery.[50] Atrophy of the paraspinal muscles can readily be seen in postsurgical back patients.[51] Reductions in the CSA of the paraspinal muscles are greatest following a midline approach for a posterolateral fusion.[42,47,52] Using electromyography, paraspinal muscle function adjacent to instrumented fusions was significantly diminished after traditional midline open transforaminal lumbar interbody fusion (TLIF).[53] In contrast, electromyography evidence of muscle function was well maintained after minimally invasive transforaminal lumbar interbody fusion (MIS TLIF).[53]

Mechanism of Paraspinal Muscle Injury During Surgery

The factors responsible for muscle injury during surgery have been well studied in both animals and humans. Muscle damage can be caused by several different mechanisms. Direct injury to the muscle is caused by dissection and stripping of tendinous attachments from the posterior elements of the spine. Additionally, extensive use of electrocautery causes localized thermal injury and necrosis to the tissues. The most significant factor responsible for muscle injury is likely the use of forceful self-retaining retractors. Kawaguchi and co-workers quantified the factors responsible for muscle necrosis following a standard open midline posterior approach.[54–56] They proposed that injury is induced by a crush mechanism similar to that caused by a pneumatic tourniquet during surgery of the limbs. During the application of self-retaining retractors, elevated pressures lead to decreased intramuscular perfusion.[57–60] The severity of the muscle injury is closely correlated to the degree of intramuscular pressure and length of retraction time. A pressure-time parameter can be calculated by multiplying the intramuscular pressure and the length of time of the surgery. A high pressure-time product was shown to be tightly correlated to muscle necrosis. They concluded that muscle damage can be reduced by intermittent release of the retractors during prolonged surgery combined with a relatively longer incision that allows reduced retraction pressures.

Denervation is yet another mechanism that leads to muscle degeneration and atrophy following surgery. Muscle denervation can occur in a discrete location along the supplying nerve or can be located in several points along the nerve and the neuromuscular junction. As previously described, nerve supply to the multifidus is especially vulnerable to injury because of its monosegmental innervation pattern.[14] Muscle denervation is also possible through damage to the neuromuscular junction following long muscle retraction and necrosis. Shorter retraction time or an intermittent release of muscle retraction has been shown to significantly decrease degeneration and denervation of the muscles.[59] Gejo et al. examined the relationship between retraction time and postoperative damage to the paraspinal muscle by measuring postoperation signal intensity of the multifidus muscle using T2-weighted MRI.[61] Long retraction time during surgery was found to correlate with high signal intensity in the multifidus muscle even at 6 months after surgery. They proposed that these findings

reflect chronic denervation of the muscle caused by damage to the neuromuscular synapses.

Correlation of Muscle Injury With Clinical Outcomes

There appears to be a correlation between muscle damage and long-term postoperative pain. Sihvonen et al. found signs of severe denervation of the multifidus muscle in patients with failed back syndrome.[62] Muscle biopsies showed signs of advanced chronic denervation consisting of group atrophy, marked fibrosis, and fatty infiltration. Moreover, fiber type grouping, a histologic sign of reinnervation, was rare. They hypothesized that the denervation injury resulted from direct damage to the medial branch of the posterior rami during muscle retraction associated with the posterior midline approach. The lack of reinnervation was thought to result from the absence of intersegmental nerve supply to the multifidus. Signs of severe denervation of the paraspinal muscles correlate with poor outcome of postsurgical patients. They also showed that poor clinical outcomes are associated with abnormal EMG patterns 2 to 5 years after surgery.

Changes in multifidus CSA and T2 signal intensity vary significantly depending on the surgical approach. There is significantly less atrophy after MIS TLIF compared with open TLIF. These changes are correlated with improved pain scores, disability, and creatine kinase levels.[63] Changes in the paraspinal atrophy were significant in the multifidus muscle but not in the longissimus muscle between open TLIF and MIS TLIF groups.[64] Other parameters of surgical success seem to favor a minimally invasive approach.

The integrity of the paraspinal muscles may have an effect on fusion rates.[65] Patients with less atrophy of the paraspinal muscle group had higher rates of solid fusion than patients with more significant paraspinal atrophy.[65] The most clinically obvious and pronounced benefit of minimally invasive posterior techniques over the conventional midline open approaches is the decreased postoperative infections. The Scoliosis Research Society Morbidity and Mortality studies show a nearly 5-fold decrease in rates of deep surgical site infections when a TLIF is performed using MIS techniques. This has been shown in several other studies, with a wide range of significant differences.[66] In a more direct comparison of open TLIF versus MIS TLIF, Ee et al. showed that the relative risk of deep surgical site infections.[67]

Preservation of Muscle Function and Integrity

MIS surgery techniques strive to minimize muscle injury during surgery. By minimizing the use of self-retaining retractors, intramuscular retraction pressure is reduced, leading to less crush injury. Furthermore, focusing the surgical corridor directly over the surgical target site allows for less muscle stripping that may otherwise disrupt its tendinous attachments or damage their neurovascular supply. Kim et al. compared trunk muscle strength between patients treated with open posterior instrumentation versus percutaneous instrumentation.[68] Tests were performed isometrically at multiple flexion positions. Patients undergoing percutaneous instrumentation displayed over 50% improvement in extension strength, while patients undergoing traditional midline open surgery had no significant improvement in lumbar extension strength. Extension strength correlated with preservation of multifidus CSA as measured on MRI. In a similar study, Stevens et al. assessed the postsurgical appearance of the multifidus muscle using a high-definition MRI sequence.[69] In patients treated via an open posterior TLIF technique, marked intermuscular and intramuscular edema was observed on postsurgical MRI at 6 months after surgery. In contrast, patients in the MIS TLIF group had a normal appearance on MRI following surgery.

Hyun et al. retrospectively assessed a group of patients who underwent unilateral TLIF with ipsilateral instrumented posterior spinal fusion via an open technique.[45] Contralateral instrumented posterior spinal fusion was performed at the same level employing a paramedian, intermuscular (Wiltse) minimally invasive approach. Postoperatively, there was a significant decrease in the CSA of the multifidus on the side of the open approach while no reduction in the multifidus CSA on the contralateral side was observed.

Decreases in tissue trauma not only have local effects but alter overall systemic physiology. Kim et al. studied circulating markers of tissue injury in patients undergoing open versus MIS fusions.[69,70] Markers of skeletal muscle injury (creatinine kinase, aldolase), proinflammatory cytokines (interleukin 6 [IL-6], IL-8), and antiinflammatory cytokines (IL-10, IL-1 receptor antagonist) were analyzed with enzyme-linked immunosorbent assay techniques. Twofold to sevenfold increases in all markers were observed in the open surgery group. The greatest difference between the groups occurred on the first postoperative day. Most markers returned to baseline in 3 days for the MIS group, whereas the open surgery group required 7 days. IL-6 and IL-8 are known cytokines that participate in various systemic inflammatory reactions.[71–73] It is possible that such elevations in inflammatory cytokines have direct effects beyond the surgical site. As such, persistently elevated levels of proinflammatory cytokines have been associated with organ failure in postsurgical patients.[74]

Preservation of the Bone-Ligament Complex

It is well accepted that excessive facet resection leads to altered motion and spinal instability.[75–78] Furthermore, a laminectomy leads to loss of the midline supraspinous/interspinous ligament complex, which can contribute to flexion instability.[79,80] In cases in which significant bony resection is required, or when there is an underlying relative instability (such as in spondylolisthesis), concomitant fusion is often recommended following a decompressive laminectomy.[79–82] Efforts to limit such potentially destabilizing surgery have been pursued via unilateral laminotomies in which the spinous processes and corresponding tendinous attachments of the multifidus muscle and the supraspinous/interspinous ligaments are preserved (Fig. 53.4). When this technique is combined with minimally invasive tubular retractors, bilateral decompression

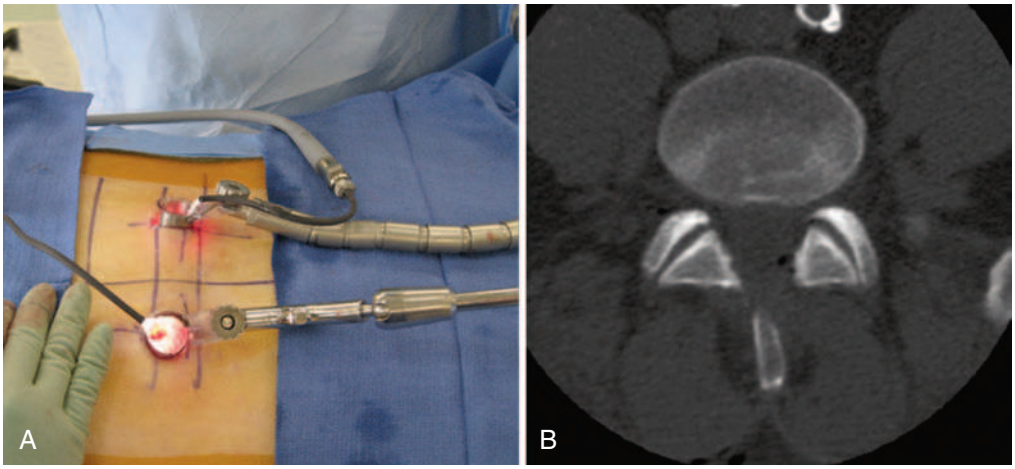

FIG. 53.4 (A) A minimally invasive decompression procedure for the treatment of L4–L5 spinal stenosis. The strategy is to use a bilateral paramedian approach that spares the tendinous attachment of the multifidus muscle at the spinous process. (B) Postoperative computed tomographic scan demonstrating good decompression of the spinal canal without noticeable damage to the posterior paraspinal muscles. Decompression of the left lateral recess via the right paramedian approach (and vice versa) allows minimal facet resection during decompression of the lateral recess.

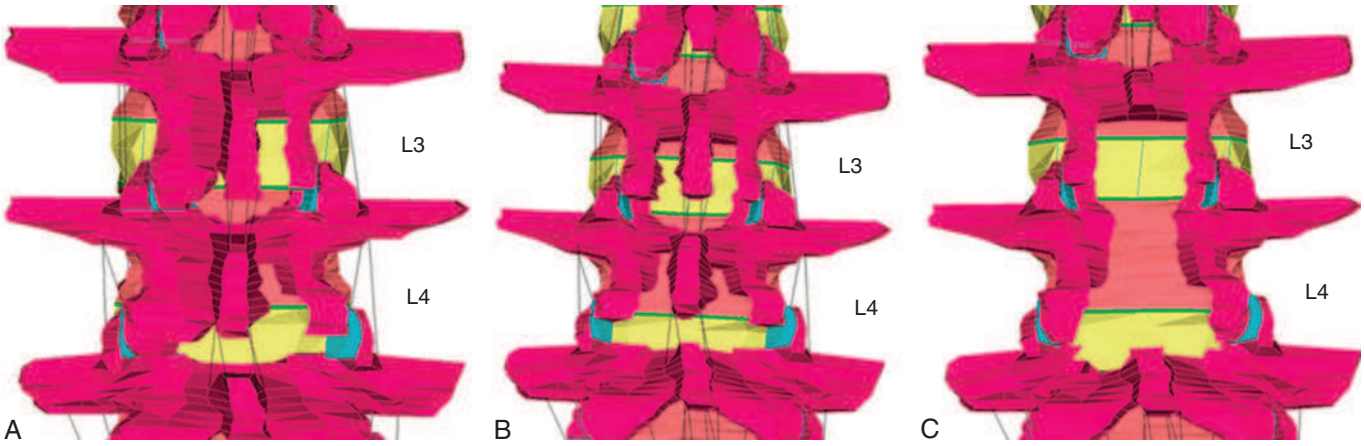

FIG. 53.5 Posterior view illustrating three different decompression methods tested by finite element analysis: (A) minimally invasive unilateral laminotomies; (B) midline interlaminar decompression, which retains the spinous process but sacrifices the interspinous/supraspinous ligaments; and (C) midline open laminectomies with resection of the spinous processes. (From Bresnahan L, Ogden AT, Natarajan RN, Fessler RG. A biomechanical evaluation of graded posterior element removal for treatment of lumbar stenosis: comparison of a minimally invasive approach with two standard laminectomy techniques. *Spine (Phila Pa 1976).* 2009;34:17-23.)

for stenosis can be achieved with good clinical results.[83–85] The long-term outcome of such MIS procedures and their effect on spinal stability have yet to be shown clinically. However, biomechanical studies suggest that such MIS techniques have significant effects on spinal stability.

Biomechanical and finite element analyses have been used to assess the consequences of various lumbar decompressive procedures on spinal motion.[86,87] Bresnahan et al. compared three decompressive techniques to treat two-level spinal stenosis: open laminectomies versus interlaminar midline decompression (which retains the spinous process but sacrifices the interspinous/supraspinous ligaments) versus MIS unilateral laminotomies (Fig. 53.5).[87] These studies show that open laminectomy produces marked increases in flexion, extension, and axial rotation. For flexion-extension, there is a greater than twofold increase in motion, which leads to increased stress on the anulus. No changes in flexion were noted when the interlaminar or MIS models were studied. Axial rotation increased by 2.5-fold in the open and interlaminar groups but only 1.3-fold in the MIS group. Similar findings have been shown in biomechanical studies in human lumbar cadaveric specimens.[86] These findings lend further support to the concept that MIS techniques have relevant effects on spinal motion and stability.

Summary

Preservation of normal spinal motion and stability constitutes the best means for ensuring improved long-term outcomes

following the surgical treatment of spinal disorders. In the living organism, stability and motion are controlled by active and passive means. The lumbar spine is surrounded by powerful muscles that actively control movement and confer dynamic stability. Concurrently, the ligaments, bones, cartilage, and discs provide for passive stability. Emerging MIS surgery techniques seek to minimize surgical damage and thereby preserve normal function. The rationale of this approach relies on limiting the surgical corridor to the minimum necessary to safely expose the surgical target site. This minimizes the destruction of anatomic structures necessary for normal function, namely, the relevant osseoligamentous, neurovascular, and musculotendinous anatomy. In addition, the traditional use of larger self-retaining retractors, which can induce crush injuries to adjacent tissues, have been supplanted by table mounted, tubular-type retractors that minimize pressure on muscles, vessels, and nerves. Continued development of minimally invasive techniques remains a vital effort in the advancement of spinal surgery.

54 CHAPTER Minimally Invasive Posterior Approaches to the Spine

Choll W. Kim

The term *minimally invasive spine* (MIS) *surgery* describes a variety of surgical techniques that employ key concepts in spinal surgery. The guiding principles of MIS are to (1) decrease muscle crush injuries during retraction, (2) avoid injury of osseotendinous attachments important for spinal stability, (3) maintain the integrity of the dorsolumbar fascia, (4) limit bony resection, (5) avoid injury to the neurovascular supply of muscle compartments by using known anatomic planes, and (6) decrease the size of the surgical corridor to coincide with the area of the surgical target site. These principles can be used in a variety of settings. In the lumbar spine, the most significant application of these principles has been for posterior approaches to the lumbar spine.

Surgical Anatomy of the Posterior Paraspinal Muscles

The posterior lumbar paraspinal muscles are responsible for maintaining spinal posture in its neutral position. Furthermore, the paraspinal muscles guard the spine from excessive bending that would otherwise endanger the integrity of the intervertebral discs, facet joints, and ligaments.[1] It is the body's dynamic stabilizing system that prevents pain and injury to the spinal column due to repetitive loads during the course of daily activities. The posterior paraspinal muscles are composed of several muscle groups that run along the thoracolumbar spine and attach caudally to the sacrum, sacroiliac joint, and iliac wing.

Posterior spine surgery using midline approaches inherently causes damage to surrounding muscles.[2,3] Muscle injury leads to long-term muscle atrophy, which, in turn, leads to decreased force production capacity of the muscle.[2,4–12] The multifidus muscle is most severely injured when using this approach for several reasons. First, its medial location inherently requires that it be displaced most during retraction. This predisposes the muscle to greater retraction pressures and makes it more vulnerable to disruption of its neurovascular supply.[2,7] Of equal importance, the midline posterior approach inevitably leads to disruption of the multifidus tendon attachment to the spinous process and the integrity of the dorsolumbar fascia.

Key Concepts for Minimally Invasive Spine Retraction Systems

A key advance in minimally invasive surgery came from Perez-Cruet and colleagues[13] with the development of the tubular retractor. A cylindrical retractor allows the surgical corridor to be opened via serial dilation using sequentially larger concentric tubes. This decreases the need for muscle stripping during the exposure. Furthermore, a tubular retractor maximizes the surface contact area, which, in turn, minimizes the pressure per unit area. Another key concept in MIS is use of a retractor holder mounted to the table instead of using a "self-retaining" mechanism. In a self-retaining retractor system, constant pressure on the tissues must be exerted to hold the retractor in place. Studies show that the maximum intermuscular pressure around a tubular retractor decreases by 50% within 3 seconds.[14] Thereafter, the pressure is undetectable. With self-retaining retractors, the pressure remains unchanged.

Minimally Invasive Spine Surgical Corridor

The guiding principles of MIS posterior lumbar surgery are to avoid injury to the multifidus tendon attachment to the spinous process and to maintain dorsolumbar fascia integrity. This is accomplished by using paramedian approaches rather than midline approaches. Decompression, microdiscectomy, interbody fusion, posterolateral fusion, and pedicle screw instrumentation can be accomplished through this surgical corridor. Emerging techniques for advanced reconstruction—including posterior corpectomies and strut fusion for burst fractures, tumors, and infections—are also possible.

Posterior Lumbar Approaches

Tubular Microdiscectomy

The treatment of herniated discs via MIS tubular microdiscectomy is the most common technique currently used in the United States. This system, developed by Foley and Smith, consists of a series of concentric dilators and thin-walled

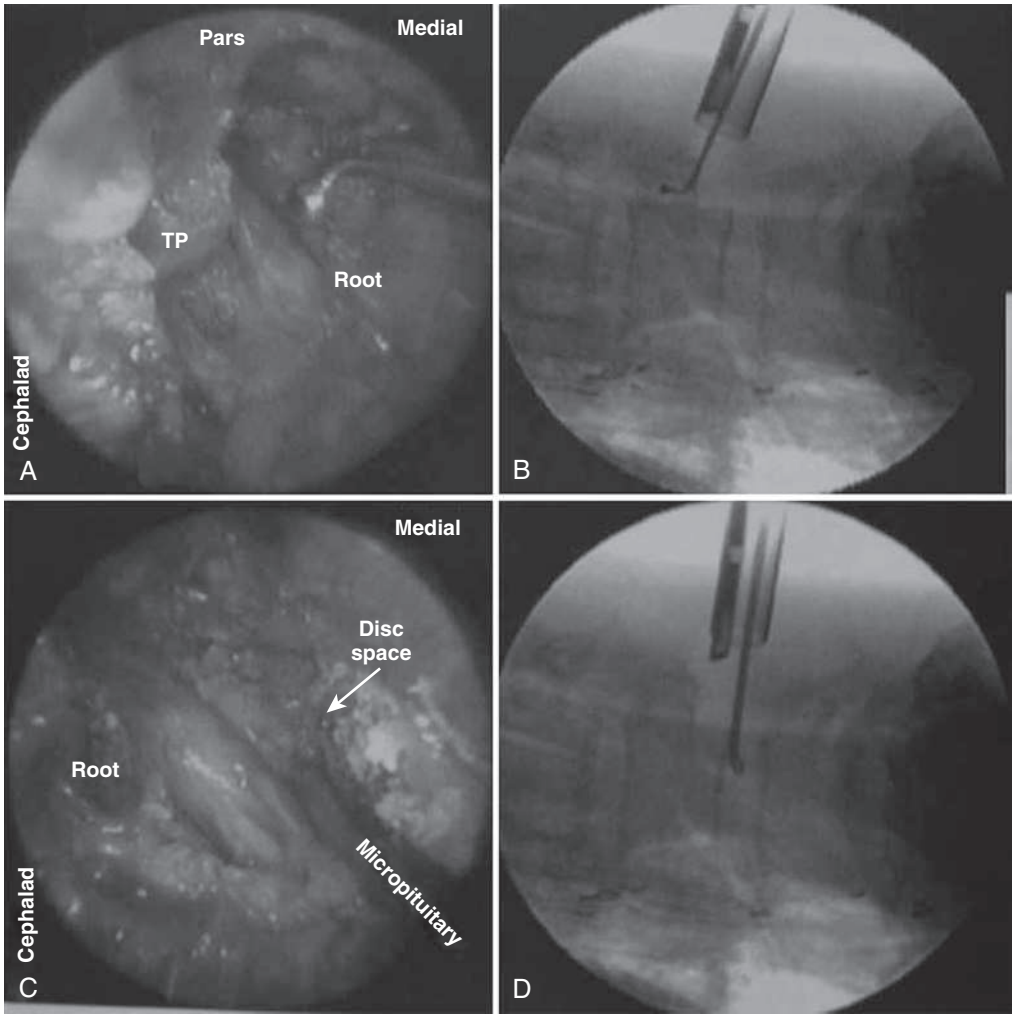

FIG. 54.1 Intraoperative and fluoroscopic images of the tubular microdiscectomy technique. (A, C) Intraoperative image and (B, D) corresponding to the lateral fluoroscopic image of the surgical target site showing the lateral pars and inferomedial transverse process (TP) after removal with a fine Kerrison rongeur. This maneuver allows for palpation of the pedicle and assists identification of the exiting nerve root adjacent to the ball-tip probe.

tubular retractors of variable length. The use of the tubular retractor rather than blades allows the retractor itself to be thin walled (0.9 mm). The tube circumferentially defines a surgical corridor through the erector spinae muscles. The appropriate depth of retractor prevents the muscle from intruding into the field of view. The retractor allows for the appropriately sized working channel to permit spinal decompression. The typical retractor size is approximately 18 mm for microdiscectomy (Fig. 54.1). Surgery is typically performed using an operating microscope. Several randomized controlled trials have been performed to compare traditional open microdiscectomy with minimally invasive tubular microdiscectomy.[15–17] These studies all show that tubular microdiscectomy is safe and efficacious compared with well-established traditional techniques. However, clinically significant superiority was not shown, likely reflecting the difficulty in demonstrating differences between the two already successful procedures. In a meta-analysis of 6 trials comprising 837 patients, clinical improvements in pain and function were similar in both the minimally invasive and traditional open groups, but there were higher risks of incidental durotomies and reoperations for recurrent disc herniations.[17a]

Lumbar Decompression

An important goal of minimally invasive posterior surgery is maintaining the tendinous attachment of the multifidus to the spinous process. During a traditional laminectomy, the spinous process is removed and the multifidus muscle is retracted laterally. Upon wound closure, the multifidus origin can no longer be repaired to the spinous process. The midline approach affords a symmetrical view of the posterior elements, which allows for safe resection of the lamina, ligamentum flavum, and medial facets. The symmetrical view allows the surgeon to readily identify and orient the surgical corridor. However, a thorough decompression can be achieved without need for removal of the spinous process. In a technique originally described by Weiner and colleagues,[18] the spinal canal can be approached through a unilateral portal via a hemilaminectomy technique. Decompression of the central canal and

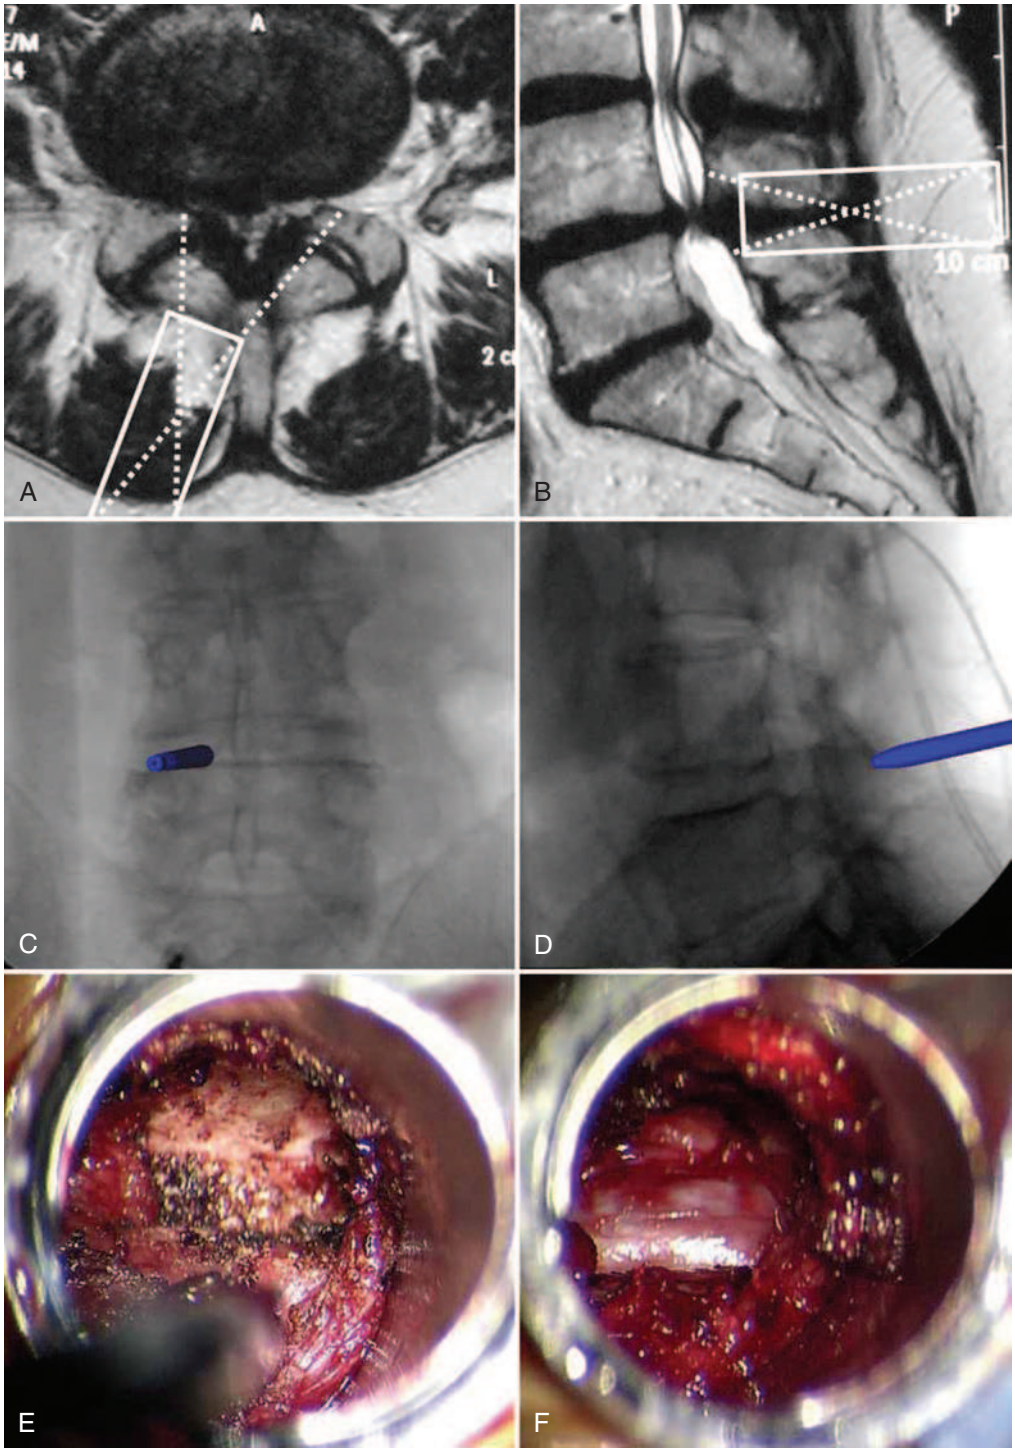

FIG. 54.2 Magnetic resonance (A) axial and (B) sagittal images in a patient with spinal stenosis. The surgical corridor is overlaid with the tubular retractor in *solid white* and surgical target sites in *dashed lines*. (E–F) Intraoperative photomicrographs of the surgical target site. (E) Initial bony exposure of the base of the spinous process and facet joint line; top is medial. (F) Visualization of the dural tube to the contralateral side using a unilateral approach.

contralateral recess can be achieved by angling the tubular retractor dorsally to view the undersurface of the spinous process and contralateral lamina (Fig. 54.2). The dural tube can be gently pushed down and the ligamentum flavum and contralateral superior articular process resected to achieve a bilateral decompression.

The efficacy and safety of minimally invasive posterior lumbar decompression have been assessed in multiple studies.[18–24] In a review by Asgarzadie and Khoo,[25] this technique provides long-term symptomatic relief equivalent to traditional open surgery but with significant reductions in operative blood loss, postoperative pain, hospital stay, and

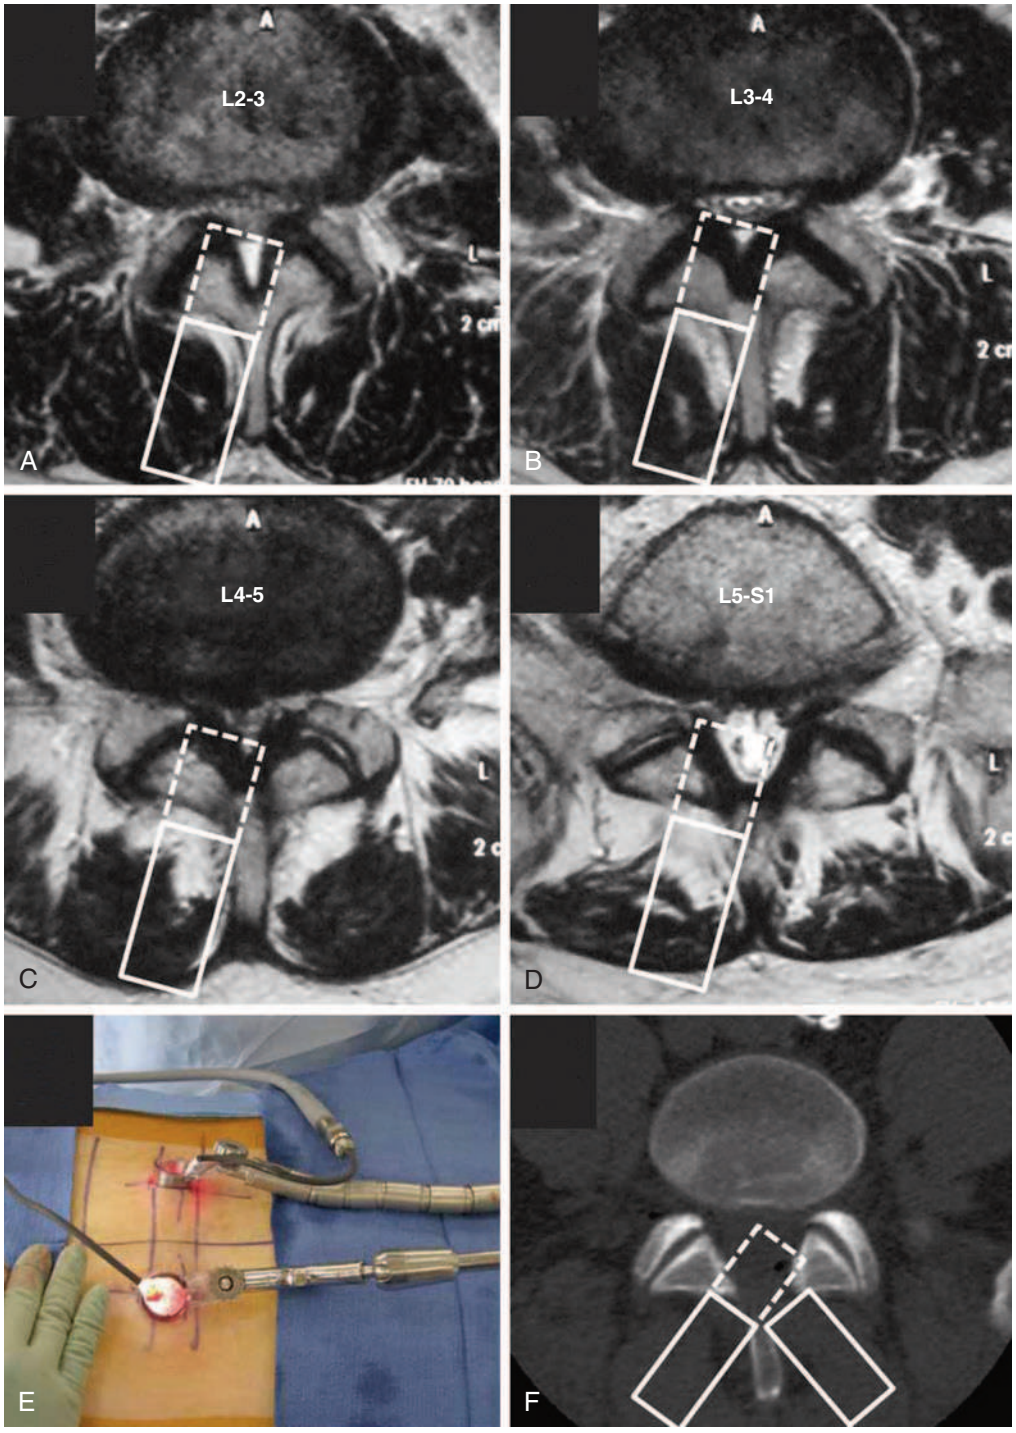

FIG. 54.3 Magnetic resonance cross-sectional image through disc space of (A) L2–L3, (B) L3–L4, (C) L4–L5, and (D) L5–S1. The outline of the tubular retractor is overlaid on each image. Note the proximity of the ipsilateral facet joint at the higher lumbar levels. At L3–L4 and above, care must be exercised to avoid inadvertent injury to the ipsilateral facet joint. (E) A bilateral approach can be used to decompress the lateral recess from the contralateral sides (F).

narcotic usage. The effect of the MIS learning curve remains a significant concern, as increased complication rates are seen during the initial series of patients.[26] Despite the learning curve, the overall complication rates remain low, even in patients who are elderly or medically frail.[27–29]

It is important to consider the anatomic variation of the lower lumbar spine with the upper lumbar spine with this particular technique. At L3 and above, the lamina between the spinous process and facet joint can be narrow (Fig. 54.3). With a unilateral approach, it may be difficult to reach the ipsilateral recess without excessively removing the ipsilateral inferior articular process. An option is to use a bilateral crossover technique to reach the right lateral recess from a left-sided hemilaminectomy and vice versa.[2] Anatomically, the lateral

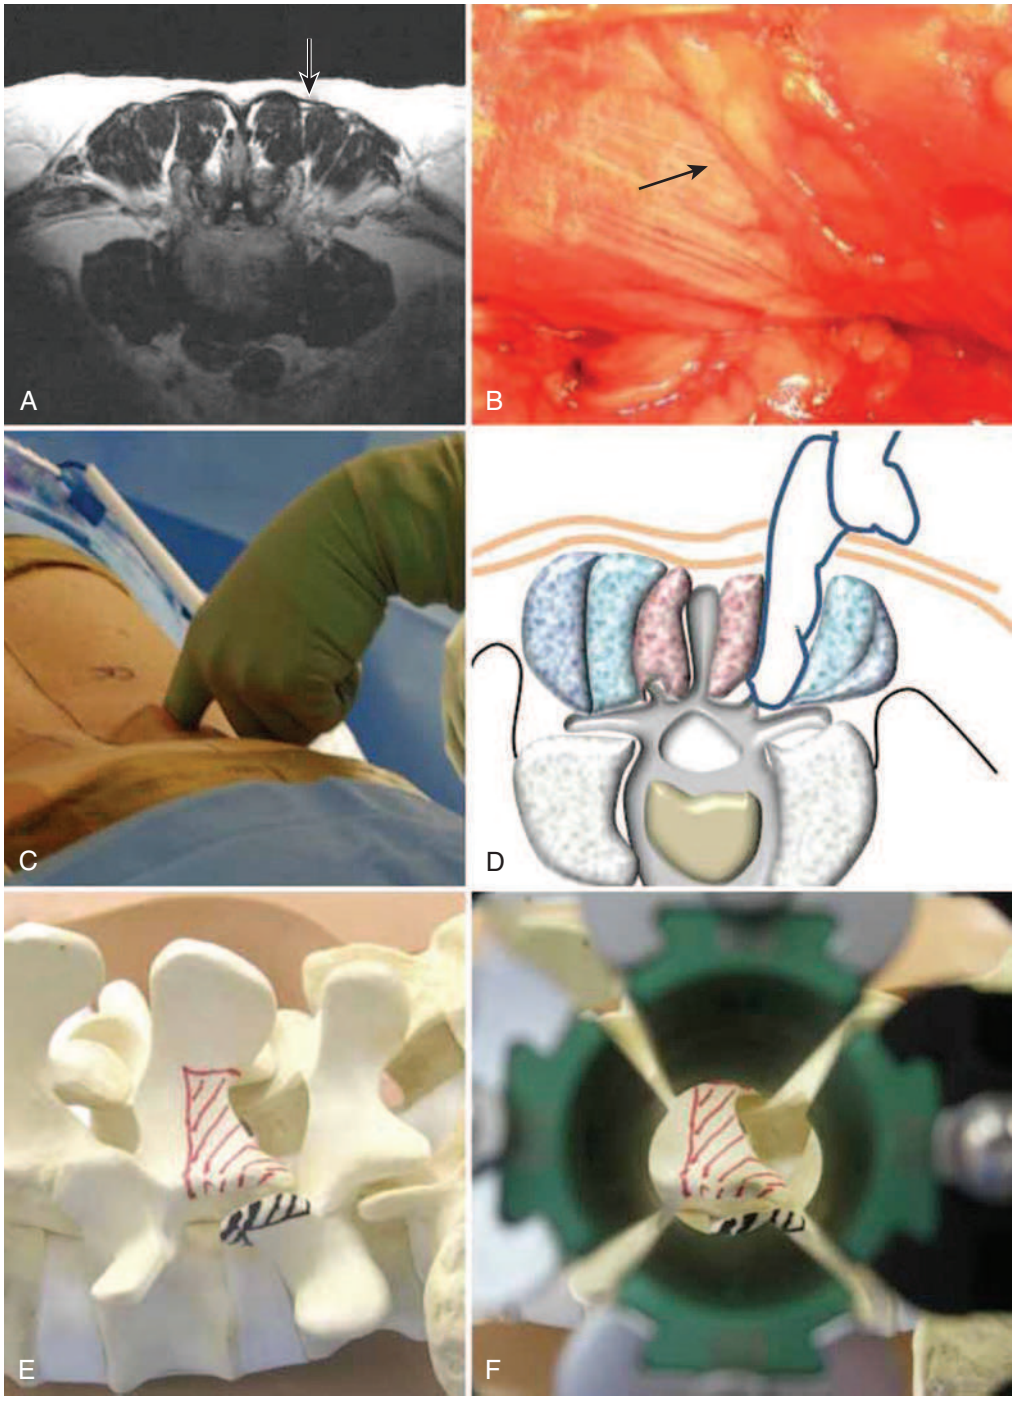

FIG. 54.4 Minimally invasive spine transforaminal lumbar interbody fusion surgical corridor is shown. (B) Intraoperative photomicrograph showing the lateral aspect of the multifidus muscle and the neurovascular bundle (*arrow*). (C) Intraoperative image and (D) corresponding illustration showing the technique of manual blunt dissection to the surgical target site. (E) Image of a spine model with the surgical target site noted (*red and black lines*). (F) View of the surgical target site through a minimally invasive retractor.

recess is more accessible through a contralateral approach when using the unilateral approach. In a preliminary study of four patients and seven levels of decompression, the total operating time was 32 minutes per level and the estimated blood loss was 75 mL. The average postoperative stay was 1.2 days. All patients had resolution of neurogenic claudication and there were no complications.[30]

Posterior Lumbar Interbody Fusion

An extension of the minimally invasive hemilaminectomy technique is transforaminal lumbar interbody fusion (MIS TLIF). The unilateral approach is used to perform the analogous decompression and is combined with a complete facetectomy. The surgical corridor is in the neurovascular plane between the multifidus and longissimus muscles (Fig. 54.4). A

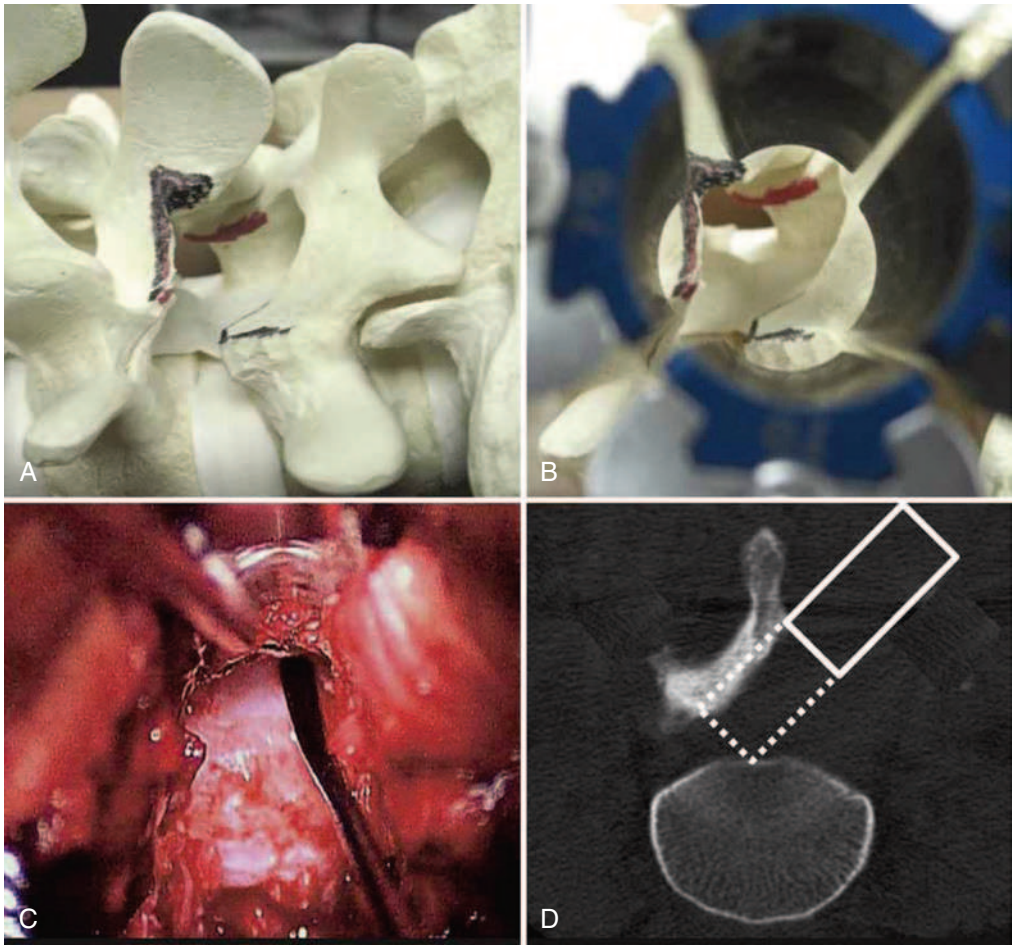

FIG. 54.5 Minimally invasive spine transforaminal lumbar interbody fusion decompression is shown. (A) Image of a spine model with removal of the inferior articular process of the cephalad level and overhang of the superior articular process of the caudad level. (B) Corresponding view through a minimally invasive retractor. (C) Intraoperative photomicrograph of the dural tube with a Penfield probe reaching to the contralateral side. (D) Postoperative computed tomographic scan with overlay of the surgical corridor.

complete facetectomy allows for decompression of the spinal canal from the ipsilateral to the contralateral side (Fig. 54.5). Access to the disc space is through a window bordered medially by the dural tube, proximally by the exiting nerve root, and distally by the pedicle and superior endplate of the caudad vertebra, thus forming within the Kambin triangle (Fig. 54.6). Angled curettes are used to perform a subtotal discectomy from a unilateral approach. If necessary, an osteotome is used to remove the overhanging rim of the posterior vertebral endplate during discectomy. Fusion is performed using interbody spacers that can be placed anteriorly for maximum lordosis correction. A second cage may be inserted by using the smooth trials to push the first cages to the far side of the disc space. Dual cage constructs may be desirable when there is significant osteoporosis or at L5–S1 in a multilevel fusion.

The clinical safety and efficacy of this technique has been well established. Schwender and colleagues[31] reported on 49 patients who underwent MIS TLIF through a paramedian, muscle-sparing approach using an expandable tubular retractor system. Of these patients, 26 patients had degenerative disc disease with herniated nucleus pulposus, 22 had spondylolisthesis, and 1 had a Chance-type fracture as their primary diagnosis. The minimum follow-up was 18 months with a mean follow-up of 22.6 months. Operative time averaged 240 minutes (range, 110–310 minutes), and average estimated blood loss was 140 mL (range, 50–450 mL). No patients required a blood transfusion, and there were no intraoperative complications. Length of hospital stay was 1.9 days on average (range, 1–4 days). All 45 patients who had preoperative radicular symptoms had resolution of their symptoms. All patients with mechanical low back pain had postoperative improvement of their pain. Four complications were noted postoperatively (two from malpositioned screws, one from graft dislodgement causing new radiculopathy, and the last from radiculopathy caused by contralateral neuroforaminal stenosis). Visual Analog Scale pain scores improved from 7.2 to 2.1, and Oswestry Disability Index scores improved from 46% to 14% at last follow-up.

Numerous studies have since confirmed the safety and efficacy of this technique.[32–40] These studies show that MIS TLIF can achieve results comparable with traditional open techniques but with less postoperative pain, decreased blood

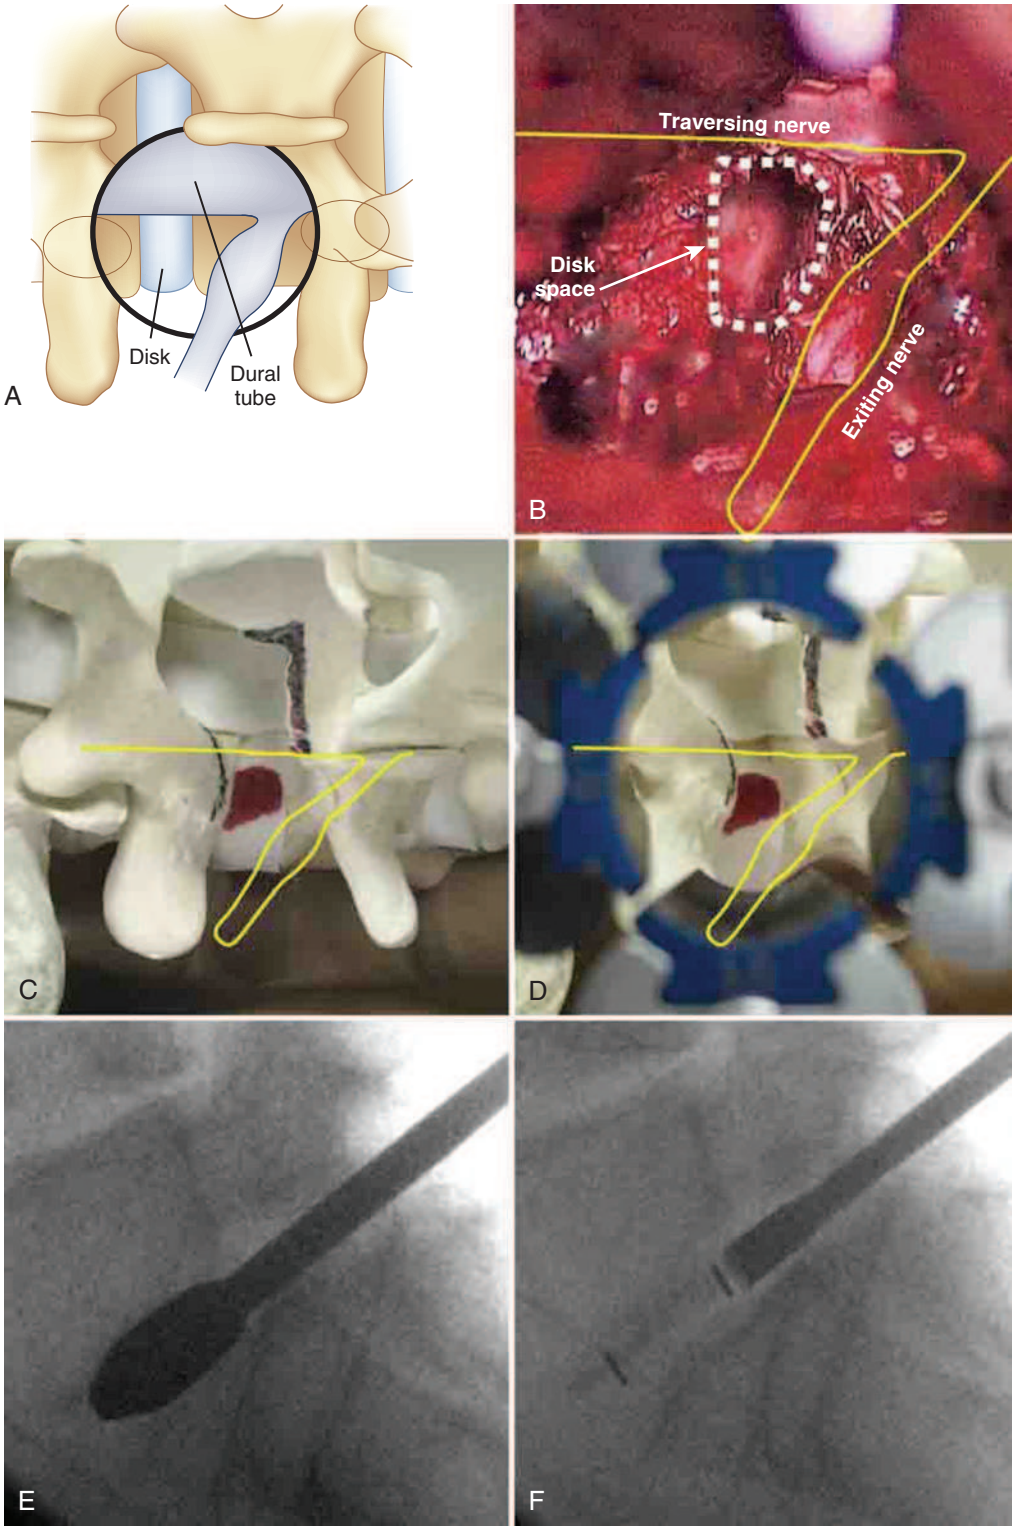

FIG. 54.6 Minimally invasive spine transforaminal lumbar interbody fusion discectomy is shown. (A) Illustration and (B) corresponding photomicrograph of the surgical target site after facetectomy to expose the Kambin triangle, which is bounded medially by the dural tube, proximally by the exiting nerve root, and distally by the pedicle and superior endplate of the caudad vertebra. (C) Image of a spine model after facetectomy. The Kambin triangle is in red. (D) Corresponding view through a minimally invasive retractor. (E) Intraoperative image during discectomy showing a paddle distractor and sizer and (F) during cage insertion.

loss, and shorter hospital stays, particularly when compared with anteroposterior circumferential fusion.[41] Another significant advantage of MIS is the marked decrease in rates of surgical site infections. Several studies show several-fold decreases in deep infection rates with MIS posterior lumbar fusions.[41a-41d] Shorter hospital stay, faster return to work, and decreased rates of reoperations due to infections lead to decreased overall cost of care.[41d-41h] The long-term benefits of minimally invasive fusion techniques have yet to be elucidated. It is intriguing to consider that preservation of the osseomusculotendinous complex may provide dynamic stability to the adjacent segments and provide some degree of protection from adjacent-segment disease.[41i,41j]

Percutaneous Pedicle Screw Instrumentation

Insertion of pedicle screws through a midline approach requires massive retraction of the multifidus muscle, subjecting the muscle to high retraction pressures and disruption of its osseotendinous attachments and neurovascular supply. The rationale for MIS pedicle screw insertion lies in the preservation of multifidus muscle function. Pedicle screw insertion can be performed percutaneously or via a paramedian mini-open technique. With the percutaneous technique, the pedicle is entered using a Jamshidi-type trocar needle under fluoroscopic control (Fig. 54.7). Once the needles are within the pedicle, the stylets are removed and guidewires inserted. The guidewire is then used to direct cannulated taps and screws into the pedicle (Fig. 54.8). Sequential soft tissue dilators are used to create a path for the tap and screw. The outermost dilator can be used as a protective sleeve during pedicle tapping. A cannulated pedicle screw is then placed over the guidewire. Rods are inserted percutaneously to minimize soft tissue trauma.

In the mini-open technique, a longitudinal, paramedian incision is placed slightly lateral to the lateral edge of the pedicles. Dissection is performed through the intermuscular plane between the multifidus and longissimus muscles. A tubular retractor system is subsequently deployed after tissue dilation is performed. The pars interarticularis and the mammillary processes of the cephalad and caudal levels are exposed with gentle electrocautery. A high-speed burr to create a starting point and pedicle probes are used to enter the pedicle. Cannulated or noncannulated pedicle screws can be used with this technique. The exposure allows for decortication of the pars, facet joint, and transverse processes for bone grafting and fusion. A standard rod and end caps can then be placed.

The mini-open technique offers several advantages over the percutaneous method. It allows for direct visualization of the anatomy and the choice of using either cannulated or noncannulated pedicle screw systems. The mini-open technique also allows for greater access for bone grafting posteriorly. On the other hand, the mini-open technique threatens the medial branch of the dorsal rami, which extends downward to the transverse process of the caudal level, where it passes between the mammillary and accessory processes. It then curves posteriorly, where it branches to supply the multifidus muscle, the intertransverse muscles and ligaments, and the facet joint of the cephalad level. As a result, insertion of a pedicle screw through the mammillary process at one level can cause injury to the medial branch nerve of the dorsal rami that supplies the adjacent cephalad level. In a cadaveric study comparing these MIS techniques, Regev and colleagues found that the mini-open technique causes injury to the medial branch of the dorsal rami more frequently than the percutaneous technique.[42] They recommend that pedicle screw insertion at the cephalad level be performed percutaneously if one desires to minimize denervation of the multifidus complex at the cephalad adjacent level.

The overall safety and accuracy of minimally invasive pedicle screw insertion has been shown in several studies. Ringel and colleagues[43] assessed a total of 488 pedicle screws implanted in 103 patients via a percutaneous technique. They found that only 3% of screws were rated as unacceptable, leading to nine screw revision surgeries. These results mirror a growing body of evidence that reflects the safety and efficacy of minimally invasive posterior spinal instrumentation.[31,44,45] These results are comparable with pedicle screws inserted via a traditional open approach. In a meta-analysis of 130 studies and 37,337 pedicle screws placed, the overall screw accuracy was 91.3%.[46]

Limitations and Drawbacks

Radiation Exposure

Several techniques for minimally invasive posterior screw insertion exist, but the percutaneous pedicle screw technique is the least tissue disruptive and is currently adapted for single or multilevel fusions. Its use, however, depends on intraoperative fluoroscopy. In the past, fluoroscopy was mainly used for lateral fluoroscopic pedicle screw guidance in open surgery. However, multiplanar fluoroscopic techniques are necessary for minimally invasive spinal instrumentation. Obtaining multiple views in several planes increases accuracy but increases operating times. The operative time for two screws on the same vertebra level reaches 10 minutes or longer using advanced fluoroscopic techniques, whereas lateral-only fluoroscopic methods require less than 5 minutes per level.[47–49] With increased insertion times associated with advanced fluoroscopic guidance, the cumulative exposure to radiation increased concomitantly.

Studies have shown that fluoroscopically guided pedicle screw placement exposes surgeons to 10 to 12 times the dose of radiation required when compared with nonspinal musculoskeletal procedures.[50] Despite these concerns, the convenience of the C-arm, combined with a high degree of accuracy, has made intraoperative fluoroscopy an increasingly necessary part of advanced spinal surgery. The addition of navigation technology is a promising means of decreasing radiation exposure to the surgical team. Kim and colleagues[51] showed that the use of navigation-assisted fluoroscopy for MIS TLIF markedly decreases direct exposure to radiation. In addition to reducing radiation exposure, navigation eliminates the need for cumbersome protective lead gear and clears the surgical field by removing the C-arm during surgery.

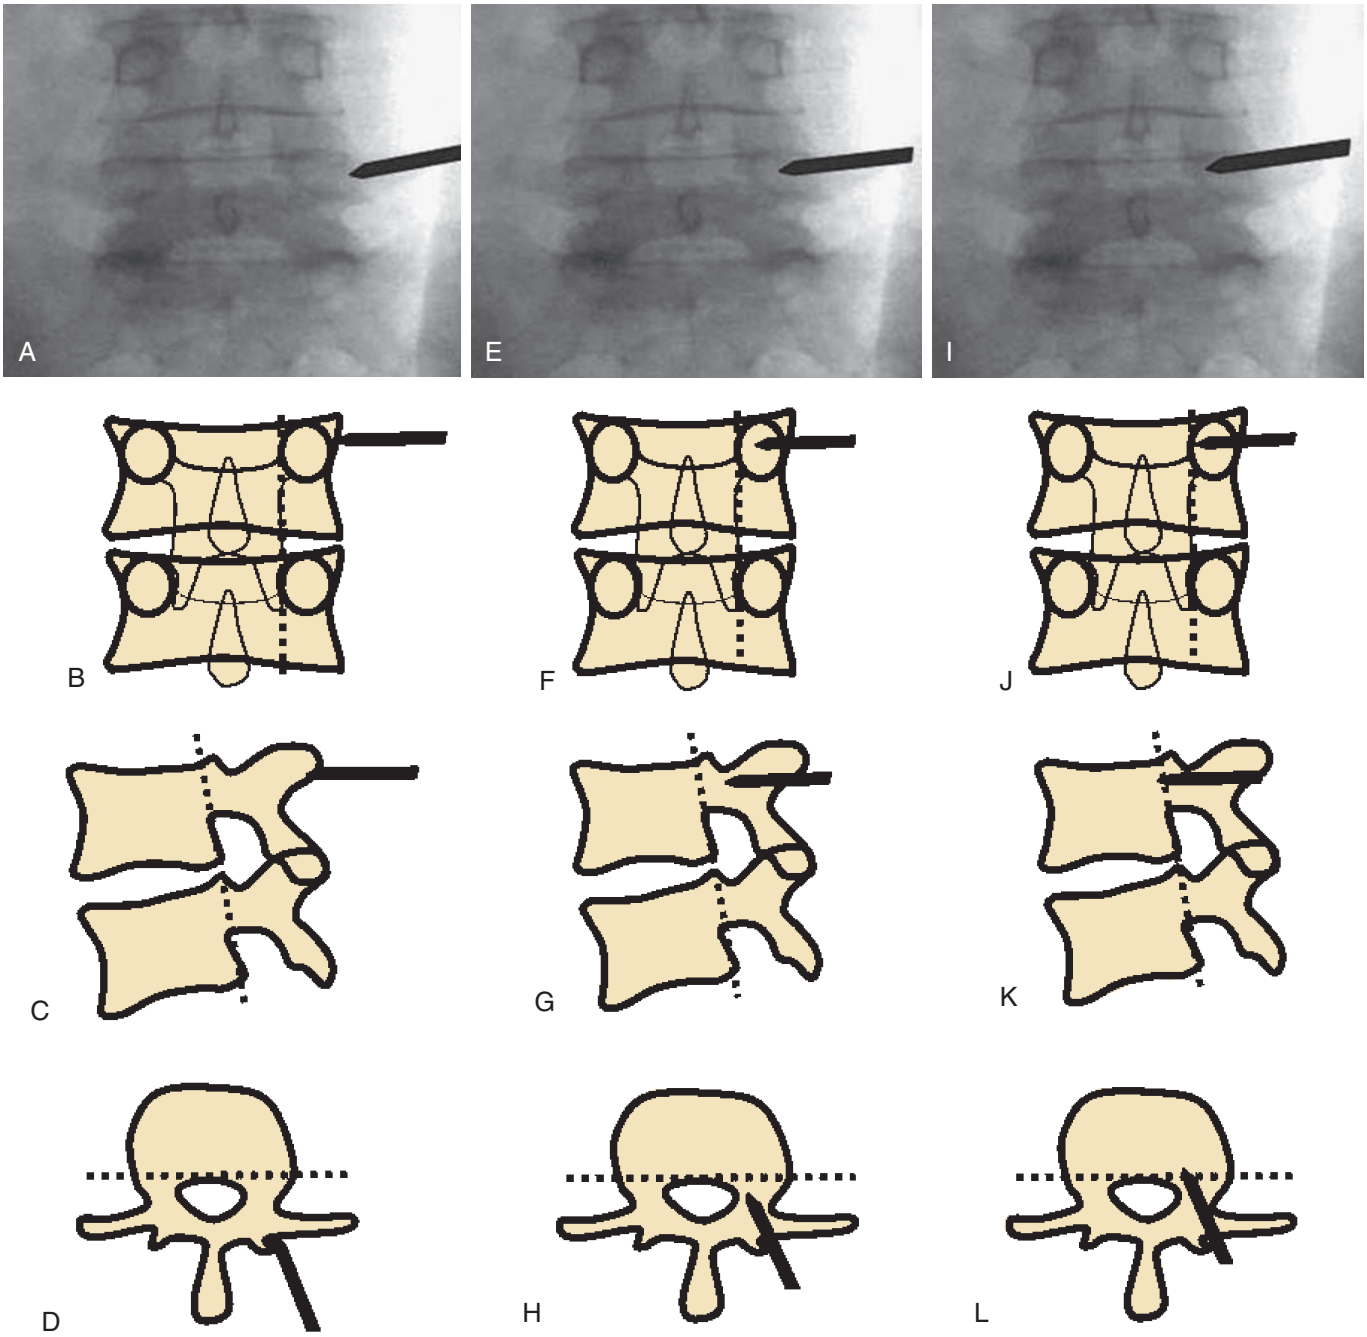

FIG. 54.7 Percutaneous pedicle screw insertion requires scrupulous intraoperative imaging. (A, E, I) The trocar needle is inserted using a perfect en face anteroposterior image of the pedicle. The endplates should be flat and the top of the pedicle is in line with the superior endplate. The needle is inserted from a lateral to medial direction until the tip reaches the medial border of the pedicle (I and J). The C-arm is then brought under the table for a lateral view (B, F, J). If the needle is correctly inserted into the pedicle, the tip should be past the posterior vertebral body line (K and L). (A–D) Initial position of the needle in the anteroposterior, lateral, and axial planes, respectively. (E–H) Needle halfway across the pedicle. (I–L) Needle at the medial border of the pedicle. Once past the posterior vertebral body line, the needle can be inserted another 5 mm in preparation for insertion of the guidewire.

Learning Curve for Minimally Invasive Spinal Surgery

The barriers to widespread adoption of minimally invasive techniques appear to be related to technical difficulties of the procedures and a lack of adequate training opportunities. In a survey of spinal surgeons, Webb and colleagues[52] showed that most surgeons perceive MIS to be efficacious and want to perform more MIS procedures. However, most have not pursued MIS surgery because of concerns with technical difficulties of the procedure and a lack of adequate training opportunities. The technical difficulty of the procedure, combined with inadequate training, is evident in initial studies of MIS surgery. Nowitzke evaluated the learning curve for tubular decompression and

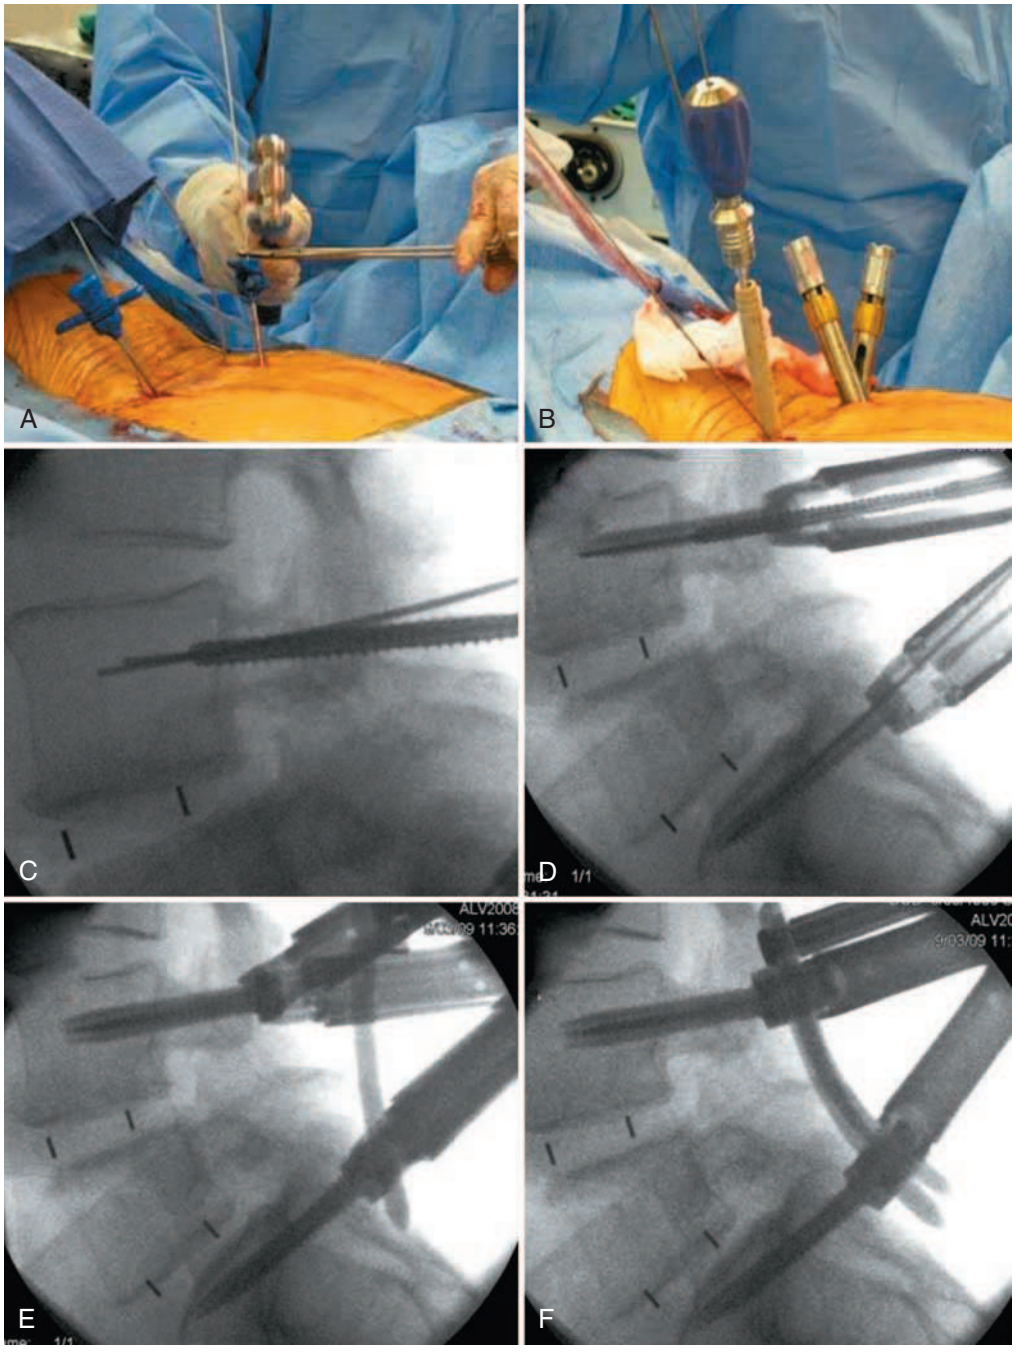

FIG. 54.8 Percutaneous pedicle screw insertion uses guidewires to guide the taps and screws through the pedicle and into the vertebral body in a reliable manner. (A) Once the Jamshidi needle is safely passed through the pedicle and into the vertebral body, the inner stylet is removed and the guidewire inserted. (B) The cannula is then removed and soft tissues opened with serial dilators. (C) The tap is then passed over the guidewire and into the dilator sleeves, which is monitored on a lateral fluoroscopic image. It is critical to maintain control of the guidewire to avoid inadvertent advancement into the abdominal cavity. (D) After tapping, cannulated pedicle screws with extension sleeves are inserted over the guidewire. Again, a lateral image is used to monitor the guidewire and to insert the tulips to a consistent depth. (E) Once all the screws are in place, a contoured rod is inserted under the dorsolumbar fascia and through the rod sleeves. (F) The rod sleeves are then used to reduce the rod to the tulips and insert the locking caps.

noted that 3 of the first 7 but none of the subsequent 28 cases required conversion to open surgery.[53] Villavicencio and colleagues[41] noted a higher rate of overall perioperative complications, Dhall and colleagues[54] found a higher rate of instrumentation complications, and Peng and colleagues[55] noted longer operative times when comparing MIS TLIF versus open TLIF. However, it is important to note that a better understanding of the learning curve may decrease the complication rates associated with initial adoption of MIS techniques.[56]

Summary

The posterior spine is dynamically stabilized by a diverse group of muscles that lie in close proximity to the vertebral column. These muscles possess a single tendon origin at the spine process and multiple tendon insertion sites distally along the superior articular processes. Each of these muscles possesses unique anatomic and structural characteristics that reflect their primary role. The multifidus muscles are made up of short and powerful fibers that enable them to produce large forces over short distances, making them a powerful stabilizer. Traditional posterior midline open approaches disrupt the function of these muscles through tendon detachment, devascularization, and crush injury. Currently, minimally invasive techniques use surgical approaches in which these events are minimized. Paramedian incisions avoid detachment of the multifidus tendon origin. Table-mounted, tubular retractors minimize retraction pressure. Specialized surgical instruments and implants accommodate narrow surgical corridors. The short-term results of these techniques are well demonstrated in multiple studies. The long-term effects of minimally invasive posterior spinal surgery are not yet known, but it is anticipated that maintaining muscle function will have effects on future events such as adjacent-level degeneration and level of function.

PEARLS

1. Ensure adequate preparation and training for all MIS procedures by performing the entire procedure, skin to skin, on a cadaveric specimen.
2. Use intraoperative imaging to precisely position the retractor directly in line with the intended surgical corridor.
3. Avoid the temptation to excessively open the retractor because this leads to additional muscle creep that further obscures the surgical target site.
4. Use instruments specifically designed for MIS procedures that are properly angled and bayoneted for use down a long, narrow surgical corridor.
5. Consider the use of expandable tubular retractors that contain a gap between the blades to allow increased angulation of instruments.

PITFALLS

1. MIS procedures are reliant on fluoroscopic imaging, which can lead to excessive radiation exposure to the surgical team. Proper protective wear should include not only a lead gown but also a thyroid shield and protective eyewear. Strong consideration should be given to use of protective gloves.
2. Unintentional durotomies more often occur in patients with severe stenosis and facet cysts. Meticulous release of the tissue adherent to the dural tube before use of the Kerrison rongeur decreases this risk.
3. Insertion of an interbody cage during MIS TLIF procedures endangers the exiting nerve root. Care should be taken to maintain the pars interarticularis, which serves to protect the nerve during cage insertion. Similarly, the dural tube should be adequately released and decompressed to allow the traversing nerve root to move out of the path of the cage during insertion.

KEY POINTS

1. The posterior paraspinal musculature, particularly the multifidus muscle, provides a critical dynamic stabilizing function.
2. Prevention of multifidus muscle injury is the main concept in minimally invasive posterior lumbar surgery.
3. Multifidus muscle injury can occur by detachment of the tendon origin at the spinous process.
4. Table-mounted, tubular retractors minimize muscle crush injury by maximizing the surface area of the retractor and avoiding the prolonged elevated retraction pressures associated with self-retaining retractors.
5. Minimally invasive posterior lumbar techniques remain technically demanding, leading to higher complication rates and longer operative times during the early period of the learning curve.
6. A difficult learning curve demands that surgeons have sufficient preclinical training and that education is obtained before the application of MIS surgery in clinical practice.
7. Meticulous use of fluoroscopic imaging is required to prevent instrumentation-related complications.

CHAPTER 55

Minimally Invasive Posterior Lumbar Instrumentation

SECTION VII

Eiman Shafa
James D. Schwender

Overview

Various surgical fields have been revolutionized by expansion of minimally invasive techniques in the recent past. In spine surgery, minimally invasive surgical (MIS) techniques have evolved to safely allow access to the spine with less collateral damage compared to traditional open surgical approaches. The basic principles and treatment goals are unchanged. The most basic tenet of minimally invasive spine surgery is to perform the same surgery as has traditionally been done open but with less approach-related morbidity and equal or better outcomes. MIS techniques have demonstrated less blood loss, decreased postoperative pain and narcotic demand, shorter hospital stays, earlier mobilization and return to work, lower disability index at 2 years postoperatively, and lower infection rates as compared with open surgical techniques.[1–5,6] However, adoption of minimally invasive lumbar surgery techniques is associated with a prolonged learning curve, initially longer operative times, and higher initial rate of complications.[7] Nonetheless, with increasing popularization of MIS techniques and incorporation in surgical training programs, these practices are progressively utilized successfully in patient care.

The concept of percutaneous spinal fixation was first introduced by Magerl in 1982 for management of thoracolumbar trauma.[8] To decrease the related high risk of pin tract infection and screw loosening, in 1995, Matthews and Long described a technique for percutaneous transpedicular screw fixation connected by a subcutaneous plate.[9] This was both poorly tolerated by the patient due to prominent instrumentation and associated with a high nonunion rate. Today, a variety of different instrumentation systems may be used in posterior-based minimally invasive lumbar spine surgery. These primarily include traditional pedicle screws, percutaneous pedicle screws, facet screws, and cortical screws. Each type of instrumentation has been shown to be safely and effectively used in minimally invasive surgery.

Indications and Contraindications

The indications for minimally invasive posterior spinal instrumentation are similar to traditional open surgery. Minimally invasive posterior spinal fusion with instrumentation has been used safely and effectively to treat instability associated with spondylolisthesis, degenerative disc disease, large or recurrent disc herniations, postlaminectomy instability, degenerative scoliosis, and trauma. Minimally invasive fusion with instrumentation can be performed safely in the revision setting and is often advantageous, as it allows the surgeon to access the spine through a native surgical corridor free of scar tissue.

A number of high-quality studies have shown the harmful effect of open exposure related to muscle detachment, ligamentous disruption, denervation, adjacent facet joint disruption, and prolonged muscle retraction. In all, these events can lead to increased risk of local instability and adjacent-level disease, requiring further surgery. Kim et al.[10] compared open versus percutaneous posterior pedicle screw fixation and found significantly greater cross-sectional area of the multifidus muscle and greater trunk extension strength in the percutaneous posterior fixation cohort. Kim et al.[11] compared conventional open versus mini-open posterior spinal fusion and instrumentation. They reported increased postoperative serum levels of proinflammatory cytokines interleukin (IL)-6 and IL-8 as well as increased serum creatinine kinase and aldolase in cohort undergoing open procedure. Hu et al.[12] have shown the accuracy of postoperative MRI in evaluating multifidus injury and atrophy.

Though there are no absolute contraindications to minimally invasive posterior spinal instrumentation, relative contraindications include high-grade spondylolisthesis (grade 3 or 4) and previous posterior fixation requiring an open approach for removal or extension of instrumentation.

Obesity poses an interesting case for minimally invasive surgical techniques. Obesity (body mass index [BMI] >30) remains a national epidemic, with a prevalence of 35.7% in the United States.[13] Complication rates as high as 36% to 50% have been reported for obese patients undergoing lumbar fusion.[14] Although obesity certainly makes minimally invasive surgery more challenging, it can be done safely and effectively in this population. In obese patients, we have found it helpful to measure the distance from the dorsal aspect of the facet at the level of the intended procedure on the preoperative magnetic resonance imaging (MRI) to help determine the length of retractor needed (Fig. 55.1). This measurement is often a lower

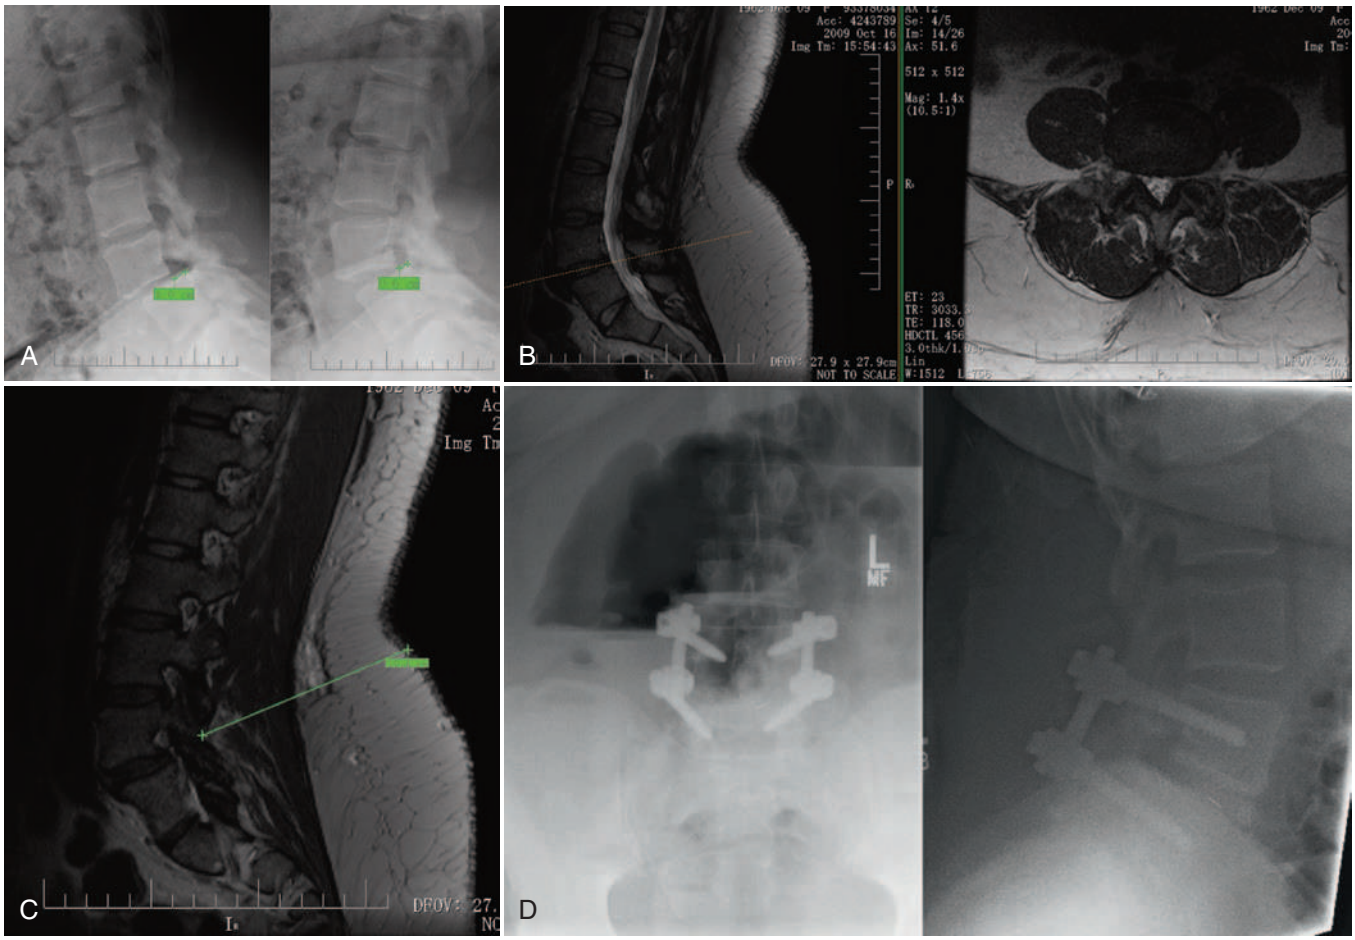

FIG. 55.1 Degenerative spondylolisthesis with body mass index (BMI) >40. A 43-year-old woman (BMI = 41) presented with neurogenic claudication. (A) Flexion-extension radiographs show unstable degenerative spondylolisthesis. (B) Magnetic resonance imaging (MRI) shows bilateral subarticular stenosis and facet arthropathy. (C) The expected length of tubular retractor is measured from the skin edge to the facet joint on axial and sagittal MRI. (D) Postoperative radiographs after minimally invasive transforaminal lumbar interbody fusion, posterior spinal fusion, and decompression at L4–L5. Visual analog scale score: preoperative = 10, postoperative = 1.

estimate, as the patient is lying supine during MRI yet positioned prone for surgery. The surgeon should consider the technical challenges of performing MIS procedures that become progressively demanding as the working depth increases. This is particularly true for fusion surgery. During a surgeon's initial experience with minimally invasive lumbar fusion surgery, patients with an expected retractor length greater than 80 mm are a relative contraindication, particularly early in the learning stages. However, with experience, obesity becomes a relative indication for minimally invasive fusion and instrumentation rather than a contraindication, as tubular retractors and percutaneous techniques drastically minimize surgical exposure in obese patients where adipose tissue and the deep (often thick) musculature make traditional open techniques difficult. Our personal experience has found that pedicle screws often can be placed more easily through a minimally invasive Wiltse-type approach as compared with midline approaches because there is much less muscle, fat, and soft tissue retraction necessary to obtain the correct screw trajectory.

Minimally invasive lumbar surgery in obese patients also creates less postoperative dead space, which may lead to lower infection rates. O'Toole and colleagues[15] reviewed surgical site infections in MIS decompressions, discectomy, and fusion cases. A total of 1338 cases were included for the review. Three postoperative surgical site infections were identified. Two patients developed superficial cellulitis after minimally invasive fusions and one patient developed discitis after a microendoscopic discectomy. The reported surgical site infection rate for simple decompressive procedures was 0.1% and 0.74% for fusion with internal fixation. The overall infection rate for the entire cohort was 0.22%. The reported infection rate for minimally invasive fusion compares favorably with open fusion infection rates. Importantly, there were no cases of postoperative deep wound infection in O'Toole and colleagues' cohort. The one patient with discitis developed symptoms 1 month after developing a lower extremity cellulitis. The disc space biopsy grew the same organism as the cellulitis. No patient in their series required reoperation for a deep wound infection. In contrast, Picada and colleagues[16] reported a 3.2%

deep wound infection after reviewing 817 patients who underwent an open lumbosacral fusion.

Technical Outcomes of Transpedicular Lumbar Instrumentation

The goal of lumbar instrumentation is to provide stability required to improve the rate of spinal fusion. Pedicle screws engage all three anatomic columns of the vertebra as defined by Denis.[17] This biomechanical advantage allows the need for fewer instrumented levels, early postoperative mobilization, and obviates the need for casting or rigid orthoses.

Lonstein et al. reviewed their experience with pedicle screw instrumentation over a 10-year period.[18] Of the 4790 pedicle screws reviewed, 94.9% were placed fully within the pedicle and vertebral body. Only 0.2% were associated with nerve root irritation due to improper screw placement. Overall, they concluded that with attention to technical details of the operative technique, there were few complications with use of pedicle screws. In a more recent review, Parker et al.[19] revisited pedicle screw placement accuracy. In a review of 6816 consecutively placed pedicle screws, they found a 0.9% rate of pedicle breach. These findings suggest pedicle screw placement to be a safe procedure with low rates of complications due to misplacement, which can certainly still occur even with experience and routine use.

Traditional ("Mini-Open") Pedicle Screws

Minimally invasive fusions use the surgical corridor as described by Wiltse[20] between the multifidus and longissimus paraspinal muscles (Fig. 55.2). This trajectory is ideal for pedicle screw placement as well as decompression and disc space preparation if required for fusion. Anatomic localization can be done using standard fluoroscopy and a radiographic marker placed on the skin.

After the appropriate trajectory is localized with fluoroscopy, sequential dilators are passed through the fascia and docked onto the facet joint. A tubular retractor (typically 20 or 22 mm) is then docked and secured over the dilators. The use of an expandable retractor allows the blades to expand cephalad or caudad, creating a corridor for pedicle screw placement (Fig. 55.3). Soft tissue is cleared to expose the standard pedicle screw entry points (Fig. 55.4). Screws can be placed using a variety of methods—including freehand, under C-arm guidance, or using navigation—depending on surgeon preference. In addition, both posted- and tulip-style screws can be used if working through the tubular retractor systems that are available.

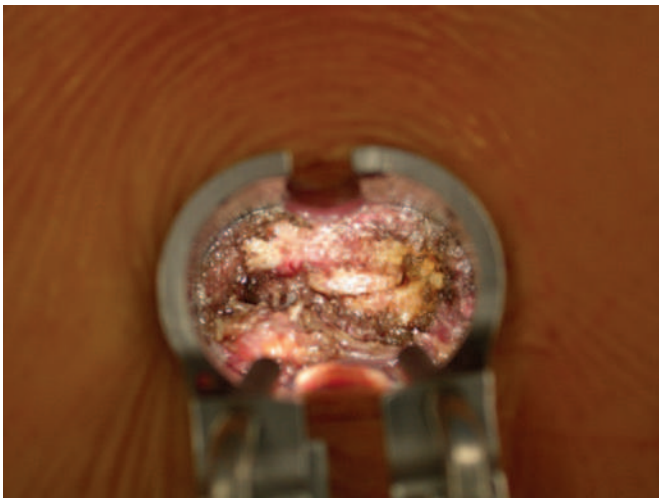

FIG. 55.3 Tubular retractor docked on desired facet and expanded.

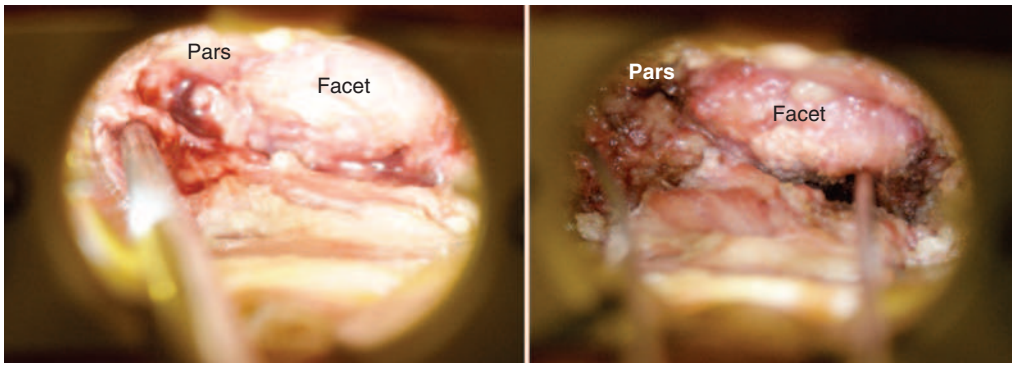

FIG. 55.4 Pedicle screw entry sites visualized through a tubular retractor.

Surgeon preference dictates the sequence of steps when planning for minimally invasive fusion. Early on in a surgeon's experience, it may be easiest to place the pedicle screw tracts first, before the decompression or facetectomy. This will preserve "normal" anatomy to help orient the surgeon to the anatomic starting points. However, our experience has shown that it is more efficient to perform the decompression and interbody spacer placement before screw tract preparation if required. This minimizes the surgical exposure during the portion of the procedure that requires the most medial angulation of the retractor and thereby helps to limit muscle creep (Fig. 55.5).

Percutaneous Pedicle Screws

Pedicle screws can be safely and effectively placed percutaneously to avoid the additional dissection required for the placement of traditional pedicle screws. Percutaneous pedicle screw placement has the advantage of less muscle injury and less potential damage to the medial branch nerve (innervation of the multifidus), and it can be used effectively over long segment fusions.[10,21] The placement of percutaneous pedicle screws can require more operative time and more radiation exposure for accurate placement.

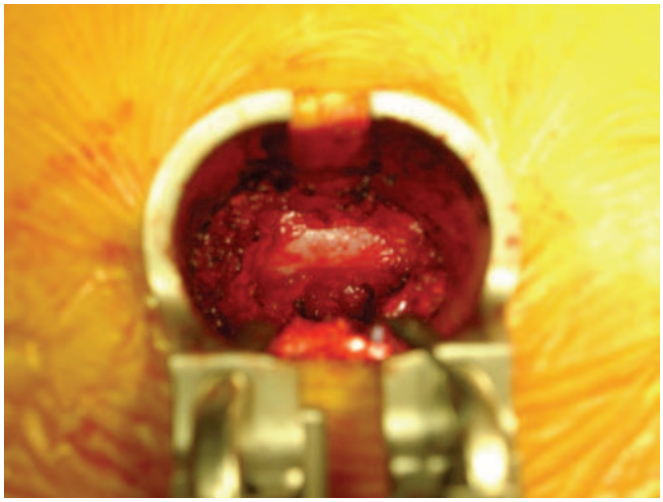

FIG. 55.5 Visualization of dura and transforaminal lumbar interbody fusion discectomy through a tubular retractor.

Technique of Percutaneous Pedicle Screw Placement

We prefer to place percutaneous pedicle screws using fluoroscopy as it is readily available, though navigation technology is becoming more widely accessible. The orientation of the C-arm beam is of critical importance. The anteroposterior (AP) images must be true AP images of each pedicle for which the surgeon is planning screw placement (Fig. 55.6). The spinous process should be in the midline of the vertebral body, equally spaced between both pedicles. The superior and inferior endplates should be parallel, and the pedicles should be appropriately located at the caudal end of the ascending articular process. On the lateral view, the superior endplate should appear as one line and the pedicles should overlap and thus appear as one. True AP and lateral radiographs are of critical importance because a small variance can produce a large degree of error.

The pedicle of interest is localized using the AP fluoroscopic image. The skin is incised just lateral to the lateral pedicle border. The thoracolumbar dorsal fascia and muscle fascia are incised in line with the skin incision. A Jamshidi trocar is used to cannulate the pedicle. The ideal starting point is at the 10 and 2 o'clock positions on the left and right pedicles, respectively. The Jamshidi trocar is slowly advanced a few millimeters to gain purchase in bone. A lateral fluoroscopic image is obtained and should confirm that the trocar is placed within the center of the pedicle. Under AP fluoroscopic imaging, the trocar is advanced approximately 20 mm. The tip should

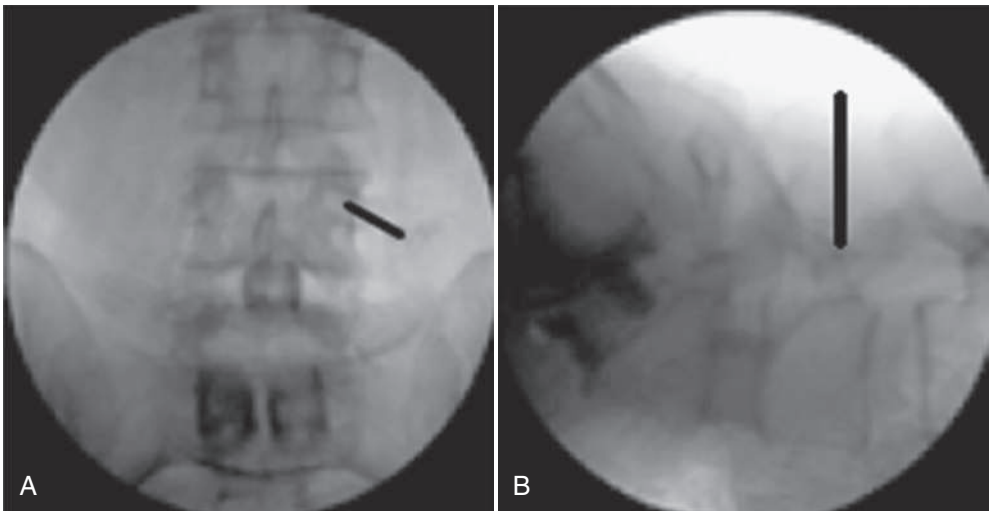

FIG. 55.6 Fluoroscopic imaging for percutaneous pedicle screw placement. (A) "True AP": pedicles are located just below the ascending articular process, and the superior endplate is parallel to the x-ray beam. The spinous process is in the middle of both pedicles. (B) "True lateral": both pedicles appear as one. The superior endplate is parallel to the x-ray beam.

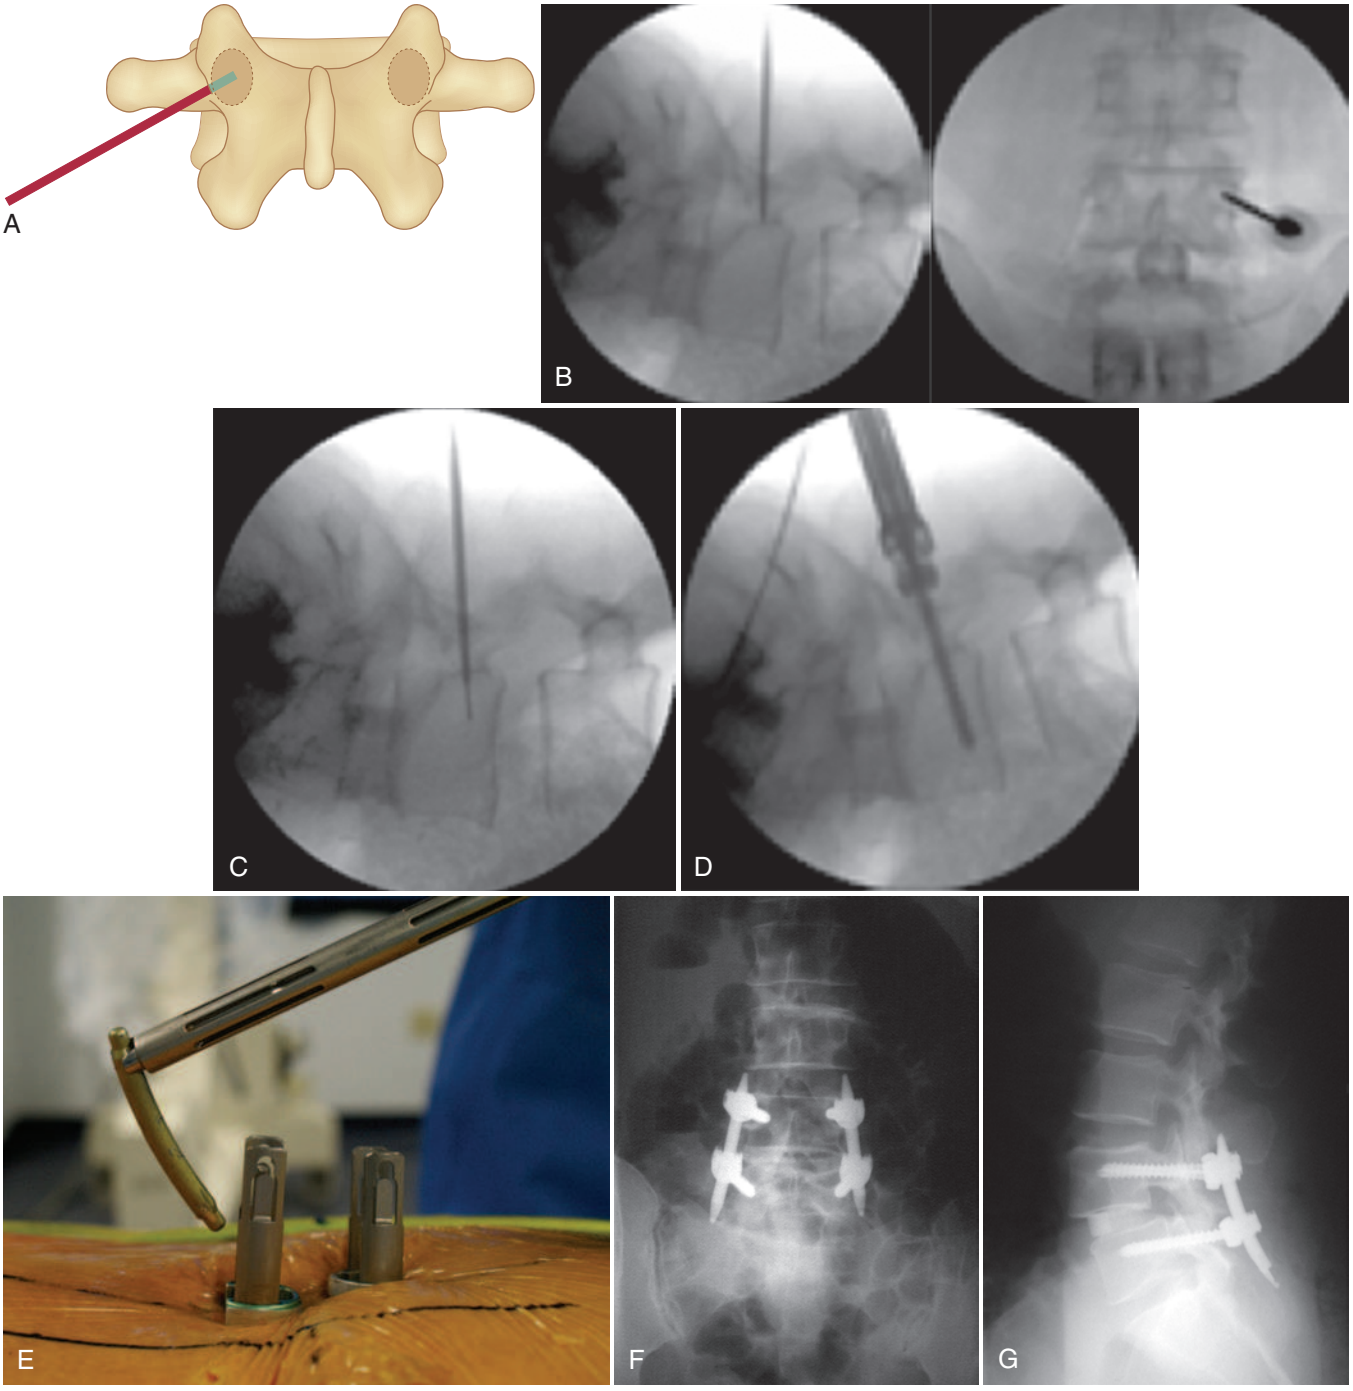

FIG. 55.7 Pedicle cannulation. (A) The ideal anteroposterior starting point. (B) The Jamshidi trocar has been advanced until it sits within the center of the pedicle. A lateral view is obtained. If the Jamshidi tip is at the neurocentral junction, then it may be safely advanced under lateral fluoroscopy. (C) Once the trocar is placed past the neurocentral junction in a satisfactory position, the guidewire may be inserted and advanced into the cancellous bone. (D) Screw holes are tapped, and screws are passed over the guidewires. Intermittent fluoroscopy is recommended to identify potential guidewire migration. (E) The appropriately sized rod is passed. Use direct visualization and palpation to avoid trapping muscle beneath the rod, which can lead to severe postoperative pain. (F–G) Final images.

remain lateral to the medial border of the pedicle. A lateral image is obtained and should show the tip of the trocar at or past the neurocentral junction. If so, the trocar can be safely advanced to its desired depth. If the tip of the trocar is at or medial to the medial border of the pedicle on the AP view and has not yet passed the neurocentral junction on the lateral, the pedicle screw tract has breached the medial border of the pedicle (Fig. 55.7).

After appropriate placement of the Jamshidi trocar is confirmed radiographically on orthogonal views, a guidewire is passed. These steps are repeated at each pedicle. The Kirschner wires (K-wires) are secured out of the field, and the

[a]Not statistically significant.

decompressive and interbody work are performed. A cannulated pedicle screw is then placed over each K-wire and the appropriately sized rod is passed. It is critical to continue lateral C-arm visualization to ensure that the K-wire is not advanced anteriorly during this process. When first performing this procedure, we encourage the liberal use of fluoroscopy. With experience, radiographic exposure and operative time will diminish.

Studies Comparing Mini-Open and Percutaneous Pedicle Screws

The decision regarding which minimally invasive instrumentation technique to use is largely surgeon dependent. Regev and colleagues[21] compared mini-open pedicle screw placement with percutaneous pedicle screw insertion in cadavers. After screw placement, the authors dissected out the medial branch nerve, which originates from the dorsal rami of each spinal nerve and innervates the multifidus muscle. In this study, percutaneous pedicle screw placement better preserved the segmental innervation of the multifidus, with only 20% of cases causing disruption of this innervation compared with 84% medial branch nerve transection using the mini-open pedicle screw insertion technique. The clinical significance of this difference is unknown.

To date, no clinical studies have directly compared the use of traditional pedicle screws placed through a tubular retractor (mini-open) to percutaneous pedicle screws. However, multiple studies have reported perioperative data regarding percutaneous versus open screw insertion (Table 55.1). Schizas and colleagues[4] reported their experience with 18 minimally invasive transforaminal lumbar interbody fusions (TLIFs) using percutaneous pedicle screw fixation and compared this with 18 open TLIFs. The percutaneous pedicle screw patients used 2.7 cGy/cm^2 of radiation as compared with 1.8 cGy/cm^2 in the open TLIF group. The minimally invasive TLIF operative time averaged 4.3 hours in the last third of their experience. Their estimated blood loss was 456 mL. Peng and colleagues[3] also reviewed the results of minimally invasive TLIFs. They used an average 105 seconds of fluoroscopy, estimated blood loss (EBL) of 150 mL, and operative time of 216 minutes. Neither of these studies reported any technical complications with minimally invasive TLIFs performed by percutaneous screws. Foley's[22] initial experience was similar, with an average operative time of 290 minutes and EBL of 25 mL. He reported one technical complication of a loose locking plug that required revision. Dhall and colleagues[1] compared minimally invasive TLIFs with traditional pedicle screws with open TLIFs. Their average EBL was 194 mL, and their average operating room time was 199 minutes. There were two technical complications in the minimally invasive group with one misplaced pedicle screw and one case of interbody cage migration. The open group also had one misplaced screw. Schwender and colleagues[5] reported on their initial experience with minimally invasive TLIFs and

percutaneous screw insertion. Their average operative time was 240 minutes and EBL of 140 mL. In this series there were two misplaced screws and interbody cage dislodgement. Park and Ha[2] compared 32 minimally invasive posterior lumbar interbody fusions (PLIFs) with 29 open PLIFs. All minimally invasive cases were stabilized with percutaneous screws. The average operating room time was longer for the minimally invasive cases compared with open cases, 191 minutes and 150 minutes, respectively. The average EBL in the minimally invasive cases was 432 mL compared with 737 mL. There were two technical complications, one screw malposition and one interbody cage migration, reported in the minimally invasive group and none in the open group. These differences were not statistically significant.

In 2005, Kim and colleagues[10] compared longitudinal changes in multifidus cross-sectional area and trunk extension strength in both open and percutaneous pedicle screw constructs. The T2 cross-sectional area of the multifidus muscle was recorded on preoperative and postoperative MRIs. Trunk extension strength was measured using a MedX lumbar extension machine. Multifidus cross-sectional area decreased from 1140 to 800 mm^2 in open pedicle screw constructs as compared with percutaneous pedicle screw constructs in which multifidus area decreased from 1320 to 1270 mm^2. Trunk extension strength increased in both open and percutaneous pedicle screw constructs, but the improvements in strength were only statistically significant in the percutaneous pedicle screw cohort.

Overall, there are not enough comparative data to make any evidence-based decisions between the use of traditional pedicle screws through tubular retractors and percutaneous pedicle screws. More clinical data are necessary.

Consideration for Radiation Exposure

As discussed, minimally invasive spine surgery, particularly percutaneous techniques for which no exposed anatomy is available for guidance, requires greater use of fluoroscopy. The clear concern with the use of fluoroscopy is exposure to ionizing radiation to the surgeon, the operative room staff, and the patient. Rampersaud et al.[23] performed a cadaveric study to determine occupational radiation exposure during lumbar fluoroscopy. They noted 10 to 12 times greater radiation exposure to the surgeon during thoracolumbar pedicle screw placement than other, nonspinal musculoskeletal procedures that use fluoroscopy. Exposure was greatest to the torso and hand when the surgeon was positioned ipsilateral to the beam source and increased with cadavers with larger dorsal body surface. Kim and colleagues[24] performed a two-phased cadaveric and prospective clinical review comparing navigation-assisted fluoroscopy and standard fluoroscopy use in minimally invasive TLIFs. In the cadaveric study, they noted a longer setup time for navigation (9.7 minutes) compared with fluoroscopy (4.8 minutes). The mean fluoroscopic time was 42 seconds in the fluoroscopy group and 29 seconds in the navigation group. The average radiation exposure to the surgeon was undetectable in the navigation group and was 12.4 mrem in the fluoroscopic group. Clinically, minimally invasive TLIFs with navigation used 57 seconds of fluoroscopy and minimally invasive TLIFs with fluoroscopy used 147 seconds. They found that total fluoroscopy time was statistically greater with standard fluoroscopy and that radiation exposure to the surgeon was undetectable with the navigation-assisted technique. Kim and colleagues reported no cases of screw malposition in either group and blood loss, operating time, and hospital stay were similar in both groups.[25] In a 2014 prospective randomized study, Villard et al.[26] showed that the use of intraoperative three-dimensional, fluoroscopy-based navigation reduced surgeon exposure to ionizing radiation almost 10-fold compared to the freehand, nonnavigated technique; radiation exposure to the patient was decreased in the navigated group but did not reach statistical significance. Bindal et al. prospectively recorded radiation exposure in 24 consecutive minimally invasive TLIF procedures.[27] The mean fluoroscopy time was 1.69 minutes (101 seconds). The mean exposure was 76 mrem at the surgeon's dominant hand, 27 mrem under a lead apron, and 32 mrem at an unprotected thyroid level. The mean exposure to the patient's skin was between 59 mrem and 78 mrem depending on the orientation to the x-ray beam. According to Bindal and colleagues,[27] the radiation exposure to both surgeon and patient was relatively low. They extrapolated that it would take 194 cases to exceed the acceptable torso radiation limits. The radiation levels that they observed also compared favorably with other fluoroscopic procedures, such as percutaneous coronary interventions. Nonetheless, all surgeons should be judicious with the use of intraoperative radiation. Computer-assisted navigation has been proposed as one means to reduce the need for fluoroscopy.

Fluoroscopic Versus Navigation-Assisted Spinal Instrumentation

Fluoroscopically guided percutaneous posterior lumbar instrumentation is considered an accurate and safe procedure.[28,29] However, the AP and lateral images are limited in assessing the screw in the axial plane that best demonstrates the position of the intended screw in relation to the neural elements.

Navigation-assisted pedicle screw placement is gaining popularity around the United States and worldwide. These techniques are designed to improve intraoperative orientation and hence the accuracy and precision of instrumentation. Additionally, navigated procedures significantly reduce or eliminate radiation exposure. This technology pairs preoperative or intraoperatively obtained imaging of the spine to corresponding intraoperative anatomy. Currently, four types of navigation guidance are available: fluoroscopic navigation, intraoperative isocentric fluoroscopic navigation, preoperative computed tomography (CT), and intraoperative CT. To achieve the goal of providing real-time three-dimensional guidance, algorithms establish a spatial relationship between image data and surgical anatomy. There are three distinct ways to achieve this: "surface matching," paired point registration,

and automated registration. The specifics of navigation technology are beyond the scope of this chapter. Data suggest that navigation can be used safely for percutaneous pedicle screw placement and there is evidence that its use improves accuracy rate. However, caution is warranted when known identifiable landmarks are not visualized and great care must be taken to avoid dislodgement of the positioning arrays, which can cause the navigation to err.

Waschke et al.[30] reviewed their experience with CT navigation and fluoroscopically guided 4500 pedicle screw placements. They did find a statistically significant improvement in accuracy when utilizing CT navigation and 3D reconstruction and intraoperative CT control of the screw position. This difference was most pronounced in the thoracic spine. Gelalis and colleagues[31] performed a systematic review of prospective in vivo studies comparing freehand, fluoroscopy-guided, and navigation techniques; 26 studies and 6617 screws were included in their analysis. They concluded that all techniques were considered safe; however, navigation did exhibit the greatest accuracy and increased safety. The percentage of pedicle screws fully confined within bony anatomy ranged from 69% to 94% in the freehand group, 28% to 85% in the fluoroscopy-guided group, 81% to 92% for the fluoroscopy-based navigation group, and 89% to 100% in the CT-based navigation group.

Intraoperative Electrophysiological Monitoring

Calcancie and colleagues first described intraoperative electromyographic monitoring as a nonimaging modality for assessment of pedicle screw placement.[32] This can be used in conjunction with techniques described earlier or independently. Dermal or subdermal needle electrodes are placed in given muscles of the lower extremities and a monopolar probe is used by the surgeon to touch the exposed pedicle screw head, delivering progressively increased current intensities. Recordings from distal electrodes identify motor function of individual nerve roots. The pedicle wall provides an anatomic barrier without breach of the bony wall. A stimulation threshold of 10 to 20 mA strongly suggests that the screw does not breach the medial pedicle wall. An elicited action potential with a current intensity of 8 mA or less should prompt inspection and repositioning of the screw. A stimulation threshold above 15 mA is associated with a 98% likelihood for accurate screw placement when postoperative CT scan was obtained.[33] Raynor et al. retrospectively analyzed their experience with 4857 pedicle screws using evoked electromyography in addition to intraoperative imaging and direct palpation of the pedicle border and found improved accuracy of screw placement.[34]

PEARLS AND PITFALLS

1. When working through a tubular retractor, remember to move the retractor to see what you want to see and to allow you to position instrumentation in the direction you want to direct it. Do not let the retractor dictate what you see and do.
2. When first placing screws through a tubular retractor, expose the pars and the medial portion of the transverse process well.
3. Pedicle screw tracks may be easier to prepare before performing the decompression and facetectomy when more bony landmarks are present.
4. When placing percutaneous screws, fluoroscopic images must be "perfect" AP and lateral views. Otherwise, percutaneous screw placement may be aberrant.
5. Start simple. Surgeons should build confidence and skill beginning with less technically demanding procedures and anatomy.

KEY POINTS

1. Minimally invasive pedicle screw instrumentation is associated with less blood loss and shorter hospital stays but longer initial operative times.
2. Minimally invasive instrumentation has a lower infection rate than open instrumentation.
3. Obesity is an initial contraindication to minimally invasive instrumentation and fusion, but as a surgeon gains experience, obesity is a relative indication.
4. Technical complications have been comparable in minimally invasive instrumentation and open instrumentation.

CHAPTER 56

Minimally Invasive Posterior Lumbar Fusion Techniques

SECTION VII

D. Greg Anderson
Jonathan D. Krystal

Introduction

Lumbar spinal fusion has long been used in the treatment of a wide variety of spinal pathologies causing spinal instability and pain. Various spinal fusion techniques are the subject of ongoing clinical investigations, with the goal of improving surgical technique, graft biomaterials, and implant designs in order to achieve a stable symptom-free spinal column with the least chance of patient morbidity.

Surgical morbidity after spinal fusion remains significant, despite multiple advances in technique and implant design. The standard open paraspinal approach involves extensive stripping of the paraspinal musculature, which has been shown to lead to denervation and atrophy.[1,2] Additionally, the large dissection may be associated with prolonged recovery and in-hospital complications.[3–7]

The development of less invasive surgical techniques has allowed surgeons to accomplish their treatment goals without utilizing the traditional open dissection. This approach may lead to lower surgical blood loss, lower transfusion rates, and shorter hospital stays for similar outcomes.[8–13] Additional benefits have been shown in regard to total cost and utility, with decreasing perioperative costs and less utilization of hospital resources and operative time.[14–16]

Minimally invasive spinal surgery (MIS) is a rapidly evolving field that is supported by a number of technological innovations. These include the operative microscope, C-arm fluoroscopy, tubular retractor systems, cannulated pedicle screws, and, for some, image guidance systems. The basic hand instruments used during a minimally invasive spinal procedure are similar to those used during a traditional spinal case, but are often longer and bayoneted to improve visualization through a tubular retraction system. A high-speed burr or drill, with a long and thin shaft, is useful in decorticating or thinning the bony elements of the spine. To be successful with MIS, a surgeon must be familiar with the microscopic anatomy of the spine. The surgeon must gain the skills necessary to work safely and efficiently despite a limited field of view and must become facile with the use of MIS equipment. Numerous surgeons have evaluated the learning curve needed to become proficient with minimally invasive techniques. With increasing experience, operative time, blood loss, and outcomes improve.[17,18] Care should be taken when first introducing MIS lumbar fusion techniques, as the overall complication rate has been shown to be significantly higher during a surgeon's first 20 to 30 cases.[19] The learning process is best accomplished in a slow, stepwise fashion, mastering basic skills with simple cases before attempting to approach the more challenging spinal pathologies in an MIS fashion. This chapter will provide an overview to the field of MIS as it applies to lumbar fusion techniques for common conditions of the lumbar spine.

Principles of Minimally Invasive Spinal Surgery

Whether using traditional open approaches or a minimally invasive technique, the goal is to treat and correct the underlying spinal pathology. MIS has the additional goal of doing this while minimizing damage to the paraspinal muscle envelope. As with any spinal surgery, careful analysis of preoperative imaging and patient symptomatology are important to correctly localize the pathology and devise an effective treatment plan. Localizing fluoroscopy is used to localize the pathologic levels and plan the skin incision to offer the most direct access to the necessary structures. It is important to note that the paraspinal musculature should not be cut or resected, but rather should be split inline with the muscle fibers using serial tubular dilators (Fig. 56.1). Exposure should be limited only to those areas of the spine that are necessary for the procedure, and electrocautery should be limited.

There are two distinct paraspinal muscle compartments that need to be considered when planning the surgical approach. Overlying the midline spinal structures is the multifidus compartment. This midline compartment contains the large multifidus muscle, which surrounds the spinous process, lamina, and facet joints. The multifidus is innervated by the medial branches of the dorsal rami and receives its vasculature from the segmental vessels, which course along the base of the transverse process and enter the lateral margin of the muscle in the region of the pars interarticularis. Overlying the transverse processes is the lateral compartment (Fig. 56.2). Within the lateral compartment, the erector spinae muscle group lies with its longitudinally oriented fibers. The starting point for lumbar pedicle screws lies within the lateral

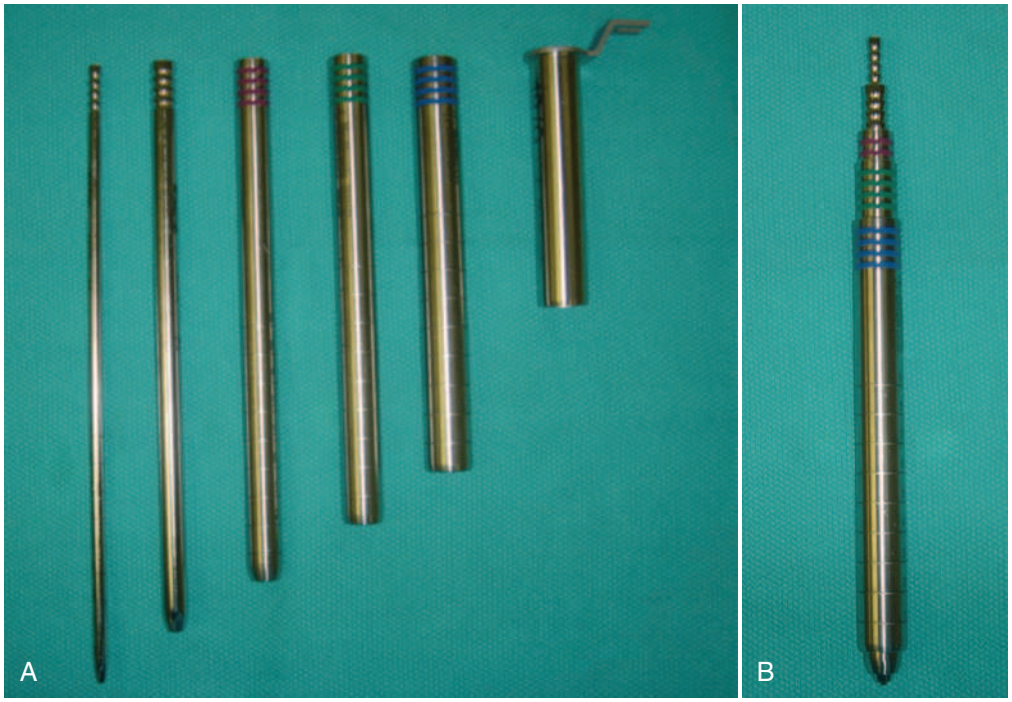

FIG. 56.1 (A) Individual and (B) assembled serial tubular dilators are used to gain access to the spine through muscle splitting rather than cutting through the paraspinal muscles.

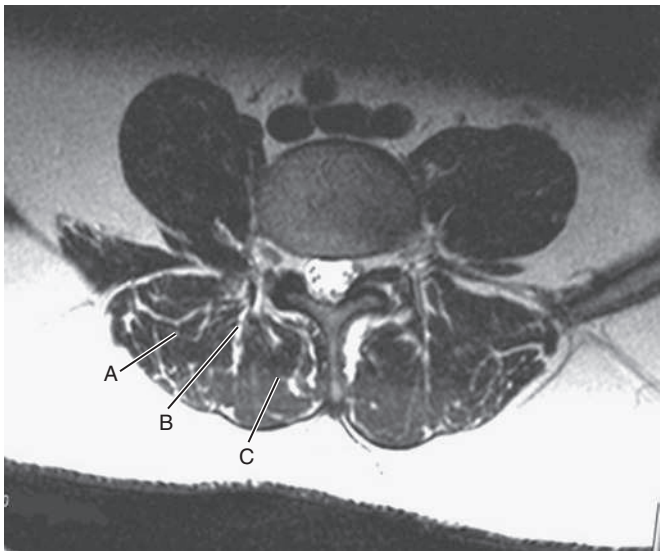

FIG. 56.2 Deep paraspinal muscle compartment: The multifidus muscle *(C)* overlies the midline, and the lateral compartment *(A, B)* contains the longissimus and iliocostalis muscles, overlying the transverse processes.

compartment, as do the transverse processes, which provide a fusion surface for a posterolateral onlay fusion.

Many procedures will require access to both compartments. In the multifidus compartment, the midline structures will be accessible, and the lateral compartment will need to be utilized for the placement of pedicle screws and posterolateral fusion. Operating in a paraspinal compartment requires a fascial incision over each individual compartment. The underlying muscle should be split or dilated in order to reach the desired structure below. Care should be taken not to divide the fascial barrier between compartments, which can disrupt the blood supply to the multifidus muscle. Separate fascial incisions should be made to access the two compartments separately; however, a well-placed single skin incision can be made to access both regions.

Both the surgeon and patient must understand the benefits and limitations of MIS compared with other options, including open surgery. The surgeon and patient should discuss the goal of surgery and treatment of the underlying spinal pathology, and it should be made clear to the patient that the approach is a secondary issue. Surgical consent should always include the possibility that the less invasive procedure may have to be aborted in favor of an open procedure if the pathology proves too difficult to treat though an MIS approach.

Surgical Setup for a Posterior Fusion Procedure

Setup and Imaging

Following placement of surgical monitoring equipment and the induction of general anesthesia, the patient should be positioned prone on a radiolucent spinal frame (Fig. 56.3). The abdomen should be free of compression and free access to the lumbar region for fluoroscopy should be confirmed. The preoperative imaging studies should be available in the room, with the operative plan clearly marked. The surgeon should ensure the availability of the proper implants and instruments prior to commencing with the operative procedure.

After a sterile skin preparation and draping, the C-arm mobile fluoroscopy unit is used to demarcate the location of

bony landmarks, which are drawn on the skin. A critical step is to ensure that the skin incisions are localized in an optimal position to allow access to the underlying spinal pathology. In some cases, it may be useful to introduce a spinal needle along the proposed trajectory of the surgical incision and check the position of the needle on both anteroposterior (AP) and lateral fluoroscopic views to ensure that an optimal path to the pathology is achieved.

Care should be taken in positioning and planning for C-arm use in order to minimize intraoperative radiation exposure. On average, a surgeon performing an MIS procedure is likely to receive about 10 to 20 times the radiation exposure compared with an open technique. Additionally, operating on patients with a body mass index greater than 35 kg/m^2 has been shown to significantly increase the radiation exposure to the patient, physician, and nursing staff.[20,21] While the clinical significance of this increased exposure is unclear, planning and judicious use of fluoroscopy to limit radiation exposure is recommended.

FIG. 56.3 The patient is positioned prone on a radiolucent spinal frame.

Surgical Incisions and Approach

The number and length of skin incisions should correspond to the surgical plan, which must be more thoroughly planned compared to a traditional open surgery. A single skin incision may be used during different phases of the surgical procedure to reach different areas of the spine. For instance, one incision may initially be used to decompress the neural elements in the multifidus compartment. Subsequently, the same skin incision may be used to perform a posterolateral fusion and place pedicle screw instrumentation in the lateral compartment. Although a single skin incision is used, separate fascial incisions should be used to reach each individual compartment.

When working through perimedian incisions, two distinct fascial layers will be encountered. The superficial layer corresponds to the thoracodorsal fascia, while the deeper layer is a thin fascia that overlies the muscle of the compartment. Both fascial incisions should be a little longer than the corresponding skin incision to allow the subsequently placed tubular retractors to be maneuvered and angulated freely as needed to reach the various areas of the spine necessary to perform the operation. The muscles of the compartment can be split with the surgeon's digit or with an instrument such as a Cobb elevator. It is often helpful to palpate bony landmarks, such as the facet joint or transverse processes, to assist with placement of the initial instruments through the skin and muscle portal to the vertebral column.

When operating through a tubular retractor, the smallest dilator is then docked at the appropriate bony site and serial dilation is used to expand the operative corridor. Care should be taken when bringing each subsequent dilator into contact with the bony vertebra. The correct length of the tubular retractor can then be selected, inserted, and secured using an operating table–mounted retractor holder. Once the tubular retractor is in place, the position of the retractor should be verified using fluoroscopy (Fig. 56.4).

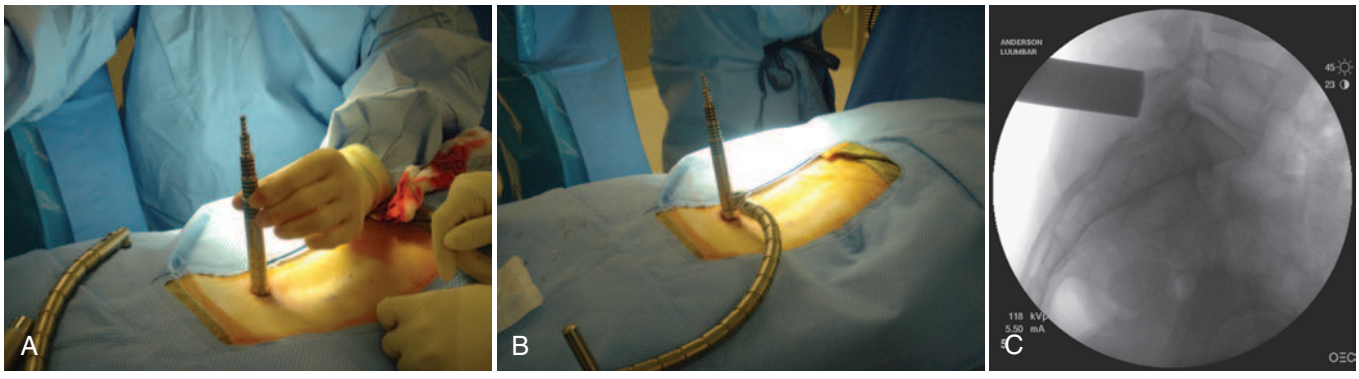

FIG. 56.4 (A) Following insertion of the tubular dilator system, (B) the tubular retractor is secured in place using an operating table–mounted rigid retractor holder. (C) Fluoroscopy is used to verify correct positioning of the tubular retractor.

Spinal Decompression

The topic of spinal decompression is substantial and exceeds the goals of this chapter; however, a few points deserve mention. Our preference is to perform the decompression first when performing both a decompression and fusion of the lumbar spine. This allows the surgeon to obtain local autologous bone from the decompression site that may be used for the spine fusion and exposes important bony landmarks, such as the pedicle, that will be useful in subsequent stages of the procedure. The decompression will be done by entering and traversing the multifidus compartment. Thus, it is useful to perform a facet fusion during this phase of the procedure before exiting the multifidus compartment.

Posterior Interbody and Transforaminal Interbody Fusion

When performing a posterior lumbar interbody fusion (PLIF) or transforaminal lumbar interbody fusion (TLIF) via a minimally invasive approach, it is important to align the tubular retractor collinear with the disc space on the lateral view (see Fig. 56.5). When performing a TLIF procedure, the tubular retractor must be aligned with enough lateral to medial angulation to allow the surgeon to reach the contralateral side of the disc space for preparation of an adequate fusion bed (Fig. 56.6). During the exposure, an adequate amount of facet joint must be removed to minimize retraction of the neural elements and provide working access to the disc space.[22]

The detrimental effects of overretraction of the neural elements with the PLIF procedure have been well documented in the literature.[23] Facet removals for a PLIF or TLIF can be achieved with either osteotomes or a high-speed burr. It is helpful to skeletonize the upper and medial portions of the caudal pedicle (e.g., L5 pedicle for an L4–L5 TLIF) to gain adequate access to the disc space and allow safe retraction/protection of the dural/neural elements.

Once the disc space has been adequately exposed, the posterolateral anulus is incised with a scalpel and the posterior margin of the disc is removed. The posterior "lip" of the vertebral body should be resected so that the opening is flush with the most concaved portions of the disc space. Disc material and cartilaginous endplate are thoroughly debrided from the interbody space using curettes, shavers, and/or pituitary rongeurs until the interspace is clean, leaving intact only bony endplates to support the interbody cage. If the disc space is collapsed, the endplates should be dilated to restore the foraminal height and improve the sagittal contour of the spine.

After disc space preparation, the interspace should be packed with autologous bone graft or an adequate fusion substrate. An appropriately sized interbody fusion cage is selected and packed with the graft material before impacting the cage into the disc space. The optimal position of the cage is toward the anterior portion of the disc space.[24,25] This produces better reconstruction of the sagittal contour of the spine and allows ample bone graft material to be packed around and behind the cage. With correct placement of interbody fusion cages, similar improvements in sagittal contour have been seen with both MIS and open surgery.[26]

Instrumentation, most commonly with pedicle screws, is a standard component of both the modern PLIF and TLIF procedures. Following the insertion of pedicle screws and rods, compression of the interbody construct is performed to restore the lumbar lordosis and ensure compressive loading of the interbody grafts.

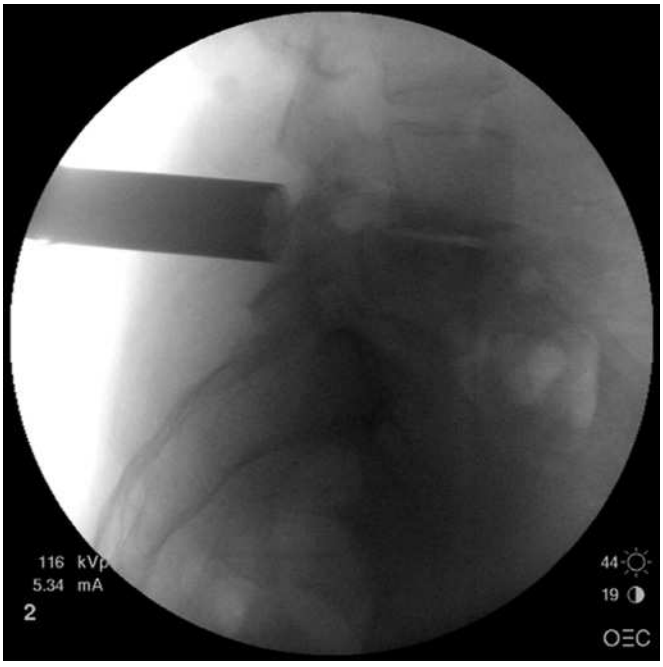

FIG. 56.5 Lateral fluoroscopic view shows the tubular retractor positioned in a proper alignment (i.e., collinear with the disc space).

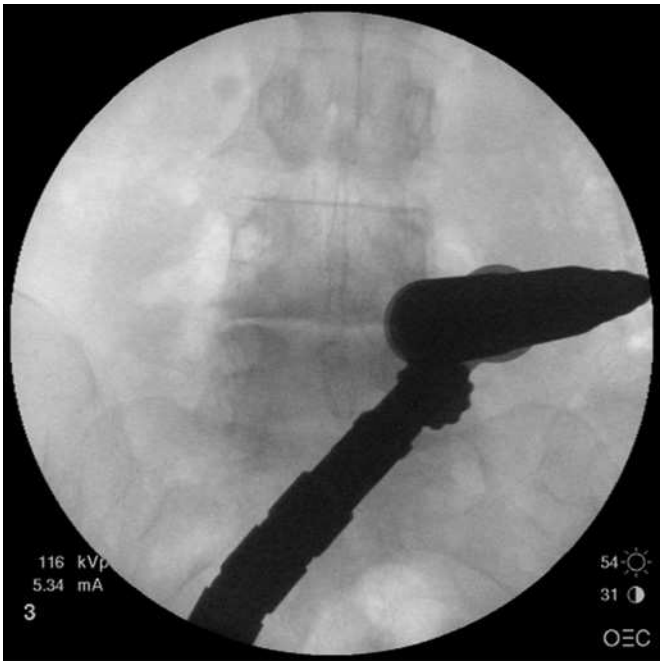

FIG. 56.6 Angulation of the tubular retractor system allows access to the contralateral side of the disc space and therefore preparation of the fusion bed.

Posterolateral Fusion (Intertransverse Onlay Fusion)

From the traditional midline approach, access to the intertransverse region for onlay fusion requires complete stripping of the paraspinal muscles to the tips of the transverse processes, an act that causes destruction of the multifidus muscle and significant postoperative scarring.[2] Using the paraspinal muscle–splitting approach (Wiltse approach), exposure of the intertransverse region is simple to achieve without major muscle stripping. This provides direct access to the intertransverse region for fusion.

The skin incision for a paraspinal approach with intertransverse fusion is made at least 3.5 to 4 cm lateral to the midline. The fascia is divided in line with the skin incision and the paraspinal muscles are split in line with their fibers to expose the transverse processes. For fusion purposes, the entire transverse process at both levels should be exposed. Either a tubular retractor (preferably an expandable tubular retractor) or side-to-side retractor (e.g., McCullough retractor) can be utilized to visualize the intertransverse interval. We prefer to use an expandable tubular retractor, which allows both transverse processes to be simultaneously exposed (Fig. 56.7).

Once the intertransverse region has been exposed, the soft tissues are meticulously cleaned away from the transverse processes and intertransverse membrane. The transverse processes are decorticated using a high-speed burr. Then, the interval is packed with autologous bone graft or a suitable graft material. Care should be taken when withdrawing the retractors in order not to displace the graft materials from the fusion bed.

Facet Fusion

Fusion of the facet joints is a useful adjunct to interbody or intertransverse fusion, but has not been well accepted as stand-alone fusion due to the relatively small surface area of the facet joints. However, the facet joint offers a number of theoretical advantages as a fusion site, including the ease of access to the joint, the small gap across which the fusion must heal, and the compression of the fusion site that is achieved during normal upright posture of the patient. In addition, a facet fusion is a quick, simple, and low-morbidity procedure.

To perform a facet fusion, the retractor should be docked on the facet that resides in the lateral portion of the multifidus compartment. If decompression of the spinal canal is required, facet fusion can easily be performed during the exposure through the multifidus compartment. Once the facet is exposed, the capsule is removed with electrocautery, and the articular surfaces of the inferior and superior articular processes are identified. A high-speed burr is used to decorticate the facet joint along its entire length, and the joint space is packed with fragments of autologous bone or a suitable bone substitute. In some cases, osteophytic bone material may overlie the true facet joint, which should be removed to expose the native joint surfaces. The surgeon should be cognizant of the normal anatomy of the facet joint, with the superior articular process lying lateral and deep to the inferior articular process. The specific topography of the facet joint can also be defined preoperatively by analyzing imaging studies, either magnetic resonance imaging (MRI) or computed tomography (CT).

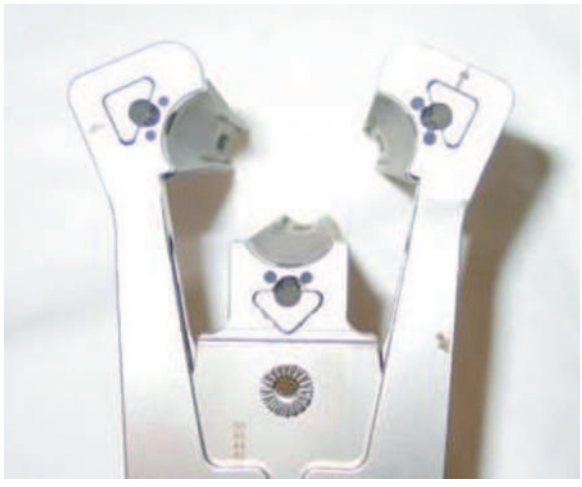

FIG. 56.7 Use of an expandable tubular retractor allows simultaneous exposure of both transverse processes.

Pedicle Screw Instrumentation

Pedicle screw instrumentation has emerged as the most common form of internal fixation used for thoracolumbar arthrodesis. Pedicle screws offer numerous advantages compared with hooks or wires, which are less rigid. Pedicle screws can be used when posterior spinal elements are deficient due to prior surgery and provide rigid segmental immobilization, minimizing the need for postoperative brace immobilization. Because of the three-column support provided by the transpedicular fixation, these implants are effectively used in various complex spinal pathologies, including deformities, where corrective forces must be employed.[27]

With the advent of cannulated pedicle screw systems, these implants can be placed through the same skin incisions used for the decompression or fusion portions of the spinal operation. Our preference is to place instrumentation as the final stage of surgery so that the bulk of the implants will not physically interfere with other stages of the operation.

Some surgeons prefer to use noncannulated pedicle screws, placed with direct visualization of the spinal anatomy, using an expandable tubular retractor system. This approach is best used for short procedures (one or two levels), in the lower lumbar spine, where the natural spinal lordosis brings the trajectory of the pedicles into close proximity. In such a situation, it is not difficult to place pedicle screws at adjacent levels using a small, paramedian incision and appropriate expandable retractor system. Placement of pedicle screws in an MIS fashion offers significant advantages compared to traditional pedicle screw instrumentation, which requires full exposure of the spine and major paraspinal muscle stripping.

Cannulated Pedicle Screw Insertion

The first step in placing cannulated pedicle screws involves obtaining a true AP image of each vertebra to be instrumented (Fig. 56.8). Because of the natural sagittal contour of the spine, the C-arm must be angulated to the specific sagittal profile of each individual vertebra in order to obtain the true AP view. It is helpful to have the radiology technician mark the exact angle of the C-arm where the true AP image can be obtained to facilitate rapid return to the proper image (Fig. 56.9). A properly aligned AP C-arm image will demonstrate the superior vertebral endplate as a single, dense line and the pedicles will be localized just below the upper endplate. Correct rotation of the vertebra is ensured when the spinous process shadow is centered between the pedicles. The true AP view is most useful when cannulating the pedicle during pedicle screw insertion.

True lateral fluoroscopic images are also used during pedicle screw instrumentation, particularly during assembly of the construct. The true lateral image will demonstrate the superior endplate as a single, dense line (Fig. 56.10). The pedicles will be superimposed. The posterior cortex of the vertebral body should also appear to be a single radiopaque line, confirming that no rotation of the vertebra is present. The true lateral view is useful during pedicle tapping, placement of pedicle screws, and assembly of the construct. In cases in which scoliosis is present, the C-arm may need to be angled ("wig-wagged") to obtain a true lateral view of each individual vertebra.

When performing percutaneous instrumentation, obtaining properly aligned C-arm images is, by far, the most important step in the procedure. Thus, it cannot be overemphasized that good images should be obtained prior to attempting to implant percutaneous pedicle screws. If adequate C-arm images cannot be obtained due to severe osteopenia, obesity, intraabdominal contrast or any other reason, placement of percutaneous pedicle screw implants should not be attempted.

After obtaining a true AP fluoroscopic image of a given level, a Kirschner wire (K-wire) should be aligned over the skin of the back so that it appears to bisect the pedicles (Fig. 56.11). Next, a horizontal line is drawn along the skin using the K-wire (Fig. 56.12). This step should be repeated using a true AP image for each of the vertebrae in the construct. Vertical lines are then drawn (using a K-wire placed over the skin of the back) along the lateral pedicle shadow (Fig. 56.13). Skin incisions for percutaneous pedicle screw insertion should be placed about 1 cm lateral to the vertical line (Fig. 56.14).

Once the skin and fascia have been divided, the surgeon can digitally palpate the transverse process of the vertebra whose pedicles are to be cannulated. A Jamshidi needle is then placed at the base of the transverse process (at the junction of the transverse process and superior articular process) and a true AP image is obtained (Fig. 56.15). The goal is to position the tip of the needle directly over the lateral margin of the pedicle shadow (at the 3 and 9 o'clock positions) on the true AP view (Fig. 56.16). The tip of the needle should be adjusted until it lies directly at the lateral border of the pedicle. The

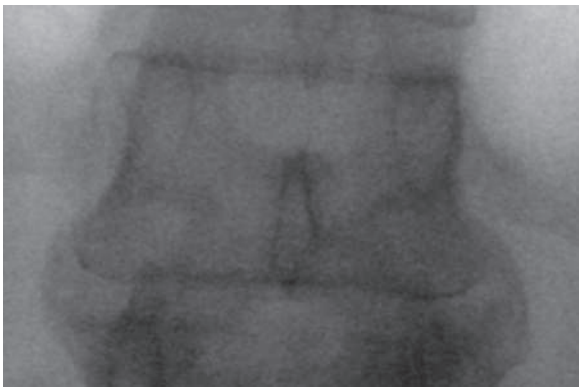

FIG. 56.8 True anteroposterior imaging of each vertebra to be instrumented is crucial for safe pedicle screw placement.

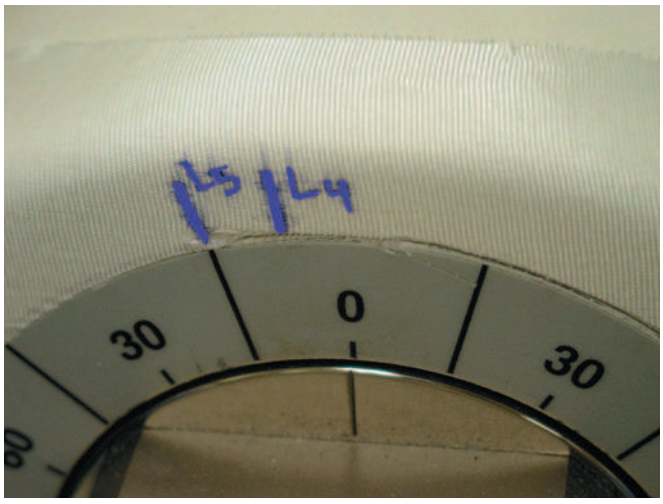

FIG. 56.9 Marking of the exact C-arm angle where the true anteroposterior image can be obtained helps the radiology technician and assists rapid return to the proper image.

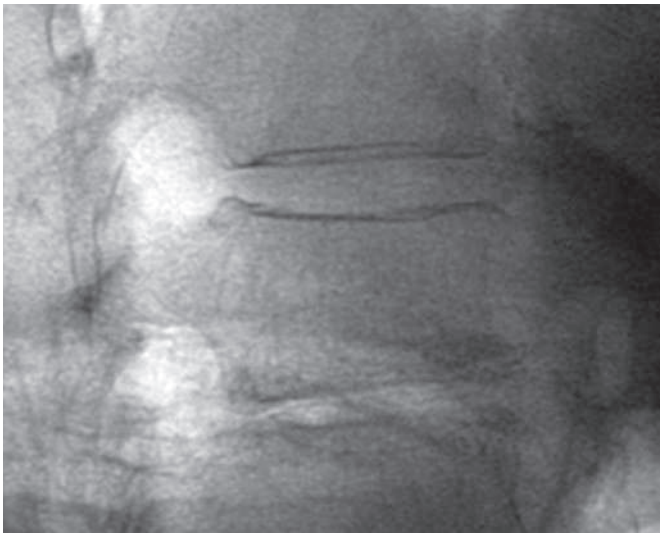

FIG. 56.10 True lateral images are also necessary for proper pedicle screw instrumentation.

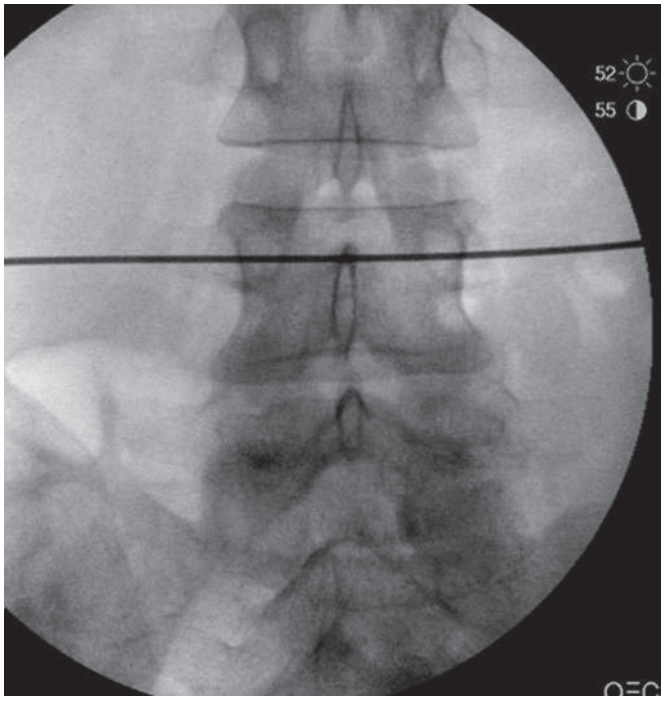

FIG. 56.11 Marking the skin (horizontally): With fluoroscopic assistance, a K-wire is placed horizontally over the skin of the back, bisecting the pedicles of the level to be addressed.

FIG. 56.12 The skin is marked using the K-wire to draw a horizontal line.

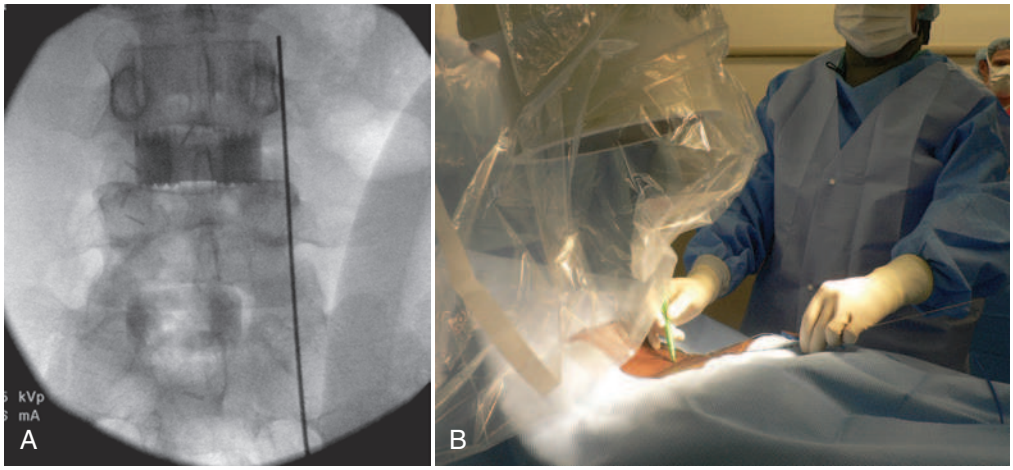

FIG. 56.13 (A) Marking the skin (vertically). Under fluoroscopy, the K-wire is vertically placed over the skin of the back and positioned along the lateral pedicle shadow. (B) The skin is then marked using the K-wire as a reference to draw a vertical line.

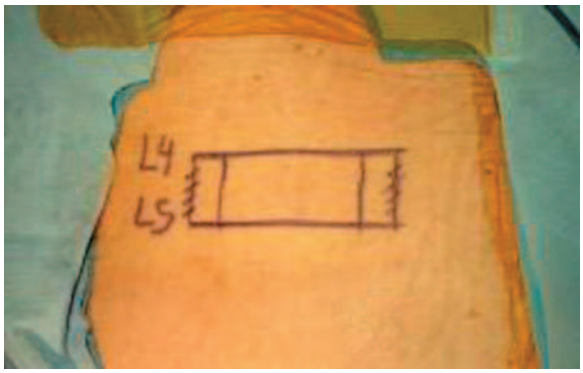

FIG. 56.14 Skin incisions, for percutaneous pedicle screw instrumentation, are placed 1 cm lateral to the marked vertical lines.

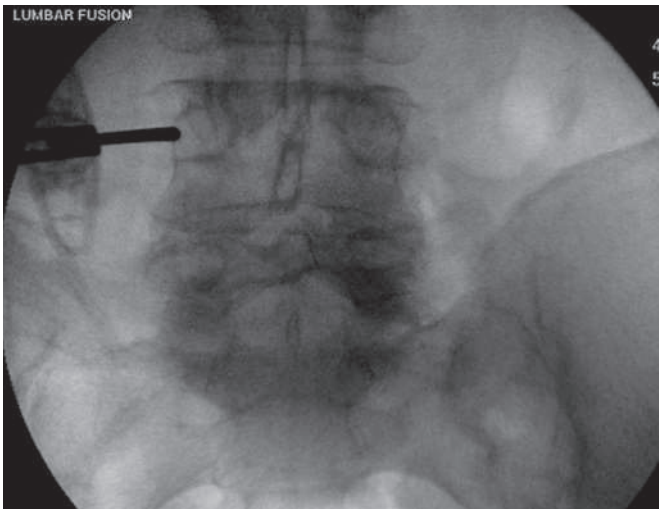

FIG. 56.15 The Jamshidi needle is placed, with fluoroscopic assistance, at the base of the transverse process.

needle shaft is then aligned parallel to the endplate (or transverse process) on the AP image, which ensures a needle trajectory parallel to the central axis of the pedicle (Fig. 56.17). The shaft of the needle should also be held with a lateral to medial trajectory of approximately 10 to 15 degrees, depending on the level to approximate the normal divergence of the pedicles anatomically. Then, the needle is tapped gently a few times to seat the needle tip into the bone and ensure that slippage of the needle tip does not occur as the needle is driven through the pedicle. A final true AP image is checked to be sure that the needle is properly positioned and aligned.

Next, a line is drawn on the shaft of the Jamshidi needle, 20 mm above the skin edge (Fig. 56.18). Because the average length of the pedicle is 20 mm from the starting point, this line is used to determine the depth of the needle tip as it is driven through the pedicle. With the Jamshidi needle properly aligned, the needle is tapped with a mallet to drive the needle through the bone of the central pedicle. When this line on the needle shaft reaches the skin edge, the needle tip has traversed the pedicle isthmus and is at approximately the depth of the base of the pedicle. At this point, another true AP fluoroscopic image is obtained to ensure that the needle tip lies well within the pedicle shadow, no more than three-fourths of the distance (from lateral to medial) across the pedicle (Fig. 56.19). This true AP image should be critically analyzed—if the needle tip

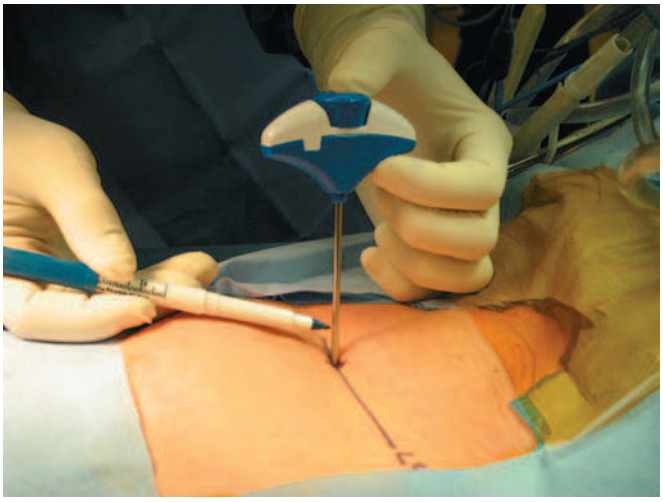

FIG. 56.18 The Jamshidi needle is marked 20 mm above the skin edge, an estimate of the depth of the pedicle.

FIG. 56.16 True anteroposterior view illustrates the recommended positioning of the needle tip over the lateral margin of the pedicle shadow at the 3 and 9 o'clock positions.

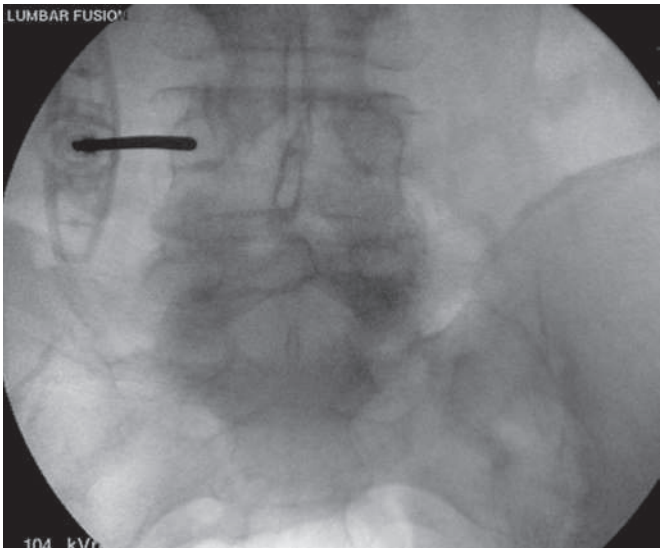

FIG. 56.19 On true anteroposterior fluoroscopy, the needle tip should be located within the pedicle shadow, no more than three-fourths of the distance across the pedicle.

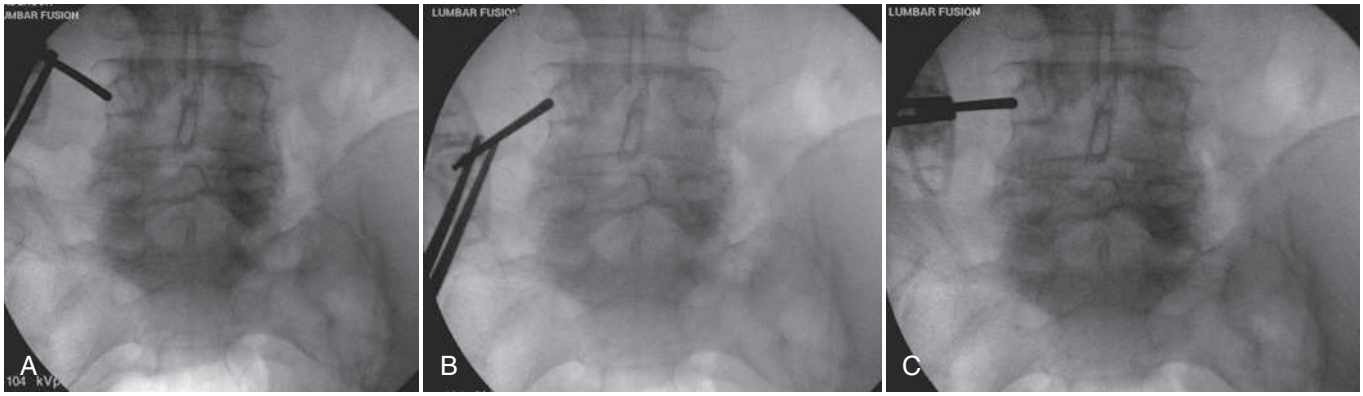

FIG. 56.17 Fluoroscopy is valuable in localizing the needle tip at the (A–B) lateral border of the pedicle and (**C**) the needle shaft parallel to the endplate.

is in proper position, then it is deemed acceptable for pedicle screw insertion.

Subsequently, the Jamshidi needle is driven 5 to 10 mm deeper into the vertebral body and a guidewire is inserted through the Jamshidi needle into the cancellous bone of the vertebral body. The surgeon should feel "crunchy" cancellous bone at the base of the needle and will generally be able to insert the guidewire 10 to 15 mm beyond the needle tip into the vertebral body with manual pressure. If the bone is too hard for manual insertion, a Kocher clamp can be placed on the guidewire 10 mm above the top of the Jamshidi needle and tapped with a mallet to achieve the positioning of the guidewire into the vertebral body. The same procedure is repeated for all the pedicles in the surgical construct. Our preference is to cannulate all pedicles in the construct using AP fluoroscopy before adjusting the C-arm into the lateral position.

Once all of the pedicles in the construct have been cannulated and guidewires have been placed, the C-arm is adjusted to obtain true lateral images of the spine (Fig. 56.20). The position of the guidewires on the lateral fluoroscopic view is verified prior to proceeding with pedicle preparation. Pedicle preparation and pedicle screw placement are then carried starting from one end of the construct in an "assembly line" fashion. Each pedicle is tapped using a cannulated tap. We prefer to stimulate the tap using stimulus-evoked electromyelography (EMG) to ensure that no low-voltage activity is present that might indicate a breach of the pedicle. Then, cannulated pedicle screws are placed over the guidewires at each level and threaded into the pedicles. The pedicle screws are adjusted in height as needed to maintain polyaxial motion of the screw crowns and to achieve a smooth contour of the screws at adjacent levels (necessary for rod seating). It is also our preference to stimulate each pedicle screw, after insertion with stimulus-evoked EMG, using an insulated port over the screws (Fig. 56.21).

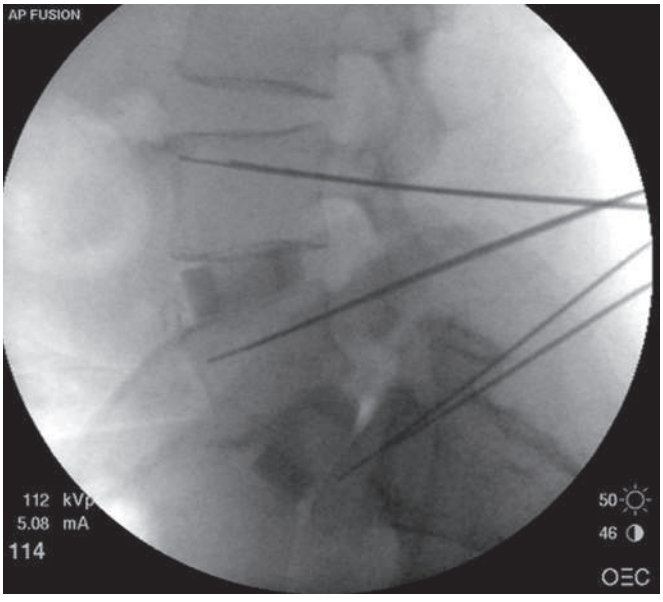

FIG. 56.20 True lateral fluoroscopic image showing the guidewires properly placed within the pedicles.

Once the screws are positioned, the proper rod length is measured and rods are inserted through the screw extensions and into the screw crowns. The details of rod insertion differ slightly between different manufacturers of cannulated screw systems. The surgeon should be familiar with the details of the specific system selected. After the rods are placed, screw caps are inserted into each screw to capture the rod. Compression or distraction of the construct can be performed as needed, followed by final tightening of the construct. At the conclusion of the procedure, AP and lateral imaging of the entire construct should be obtained (Fig. 56.22).

Technical Tips

A few technical points are worth mentioning. First, the advancement of the Jamshidi needle across the pedicle should proceed smoothly with light to moderate taps of the mallet. If the surgeon encounters very hard bone, it generally indicates that the needle tip is displaced medially into the facet joint (the needle tip is striking the hard cortical surface of the superior articular facet). In this instance, the surgeon should withdraw the needle tip and begin with a slightly more lateral starting point to prevent the needle tip from slipping into the facet joint. Another useful tip is to consider the en face view if the AP view fails to clearly show the outline of the pedicle. This is most commonly a concern at the L5 level. To obtain an en face view, start with a true AP view and then angulate the C-arm 10 to 15 degrees in the axial plane to line up the beam with the pedicle axis (Fig. 56.23). Using the en face view, the center of the pedicle should be targeted, keeping the shaft of the needle in line with the C-arm beam. Another useful tip is to consider making minor adjustments to a cannulated pedicle screw trajectory. In such a case, the pedicle can be tapped (with a cannulated tap) to the base of the pedicle. Then, leaving the tap in place, the guidewire can be withdrawn into the tap, allowing the trajectory of the tap to be adjusted as desired with the assistance of fluoroscopy. Once the new trajectory is achieved, the guidewire is reinserted into the vertebral body

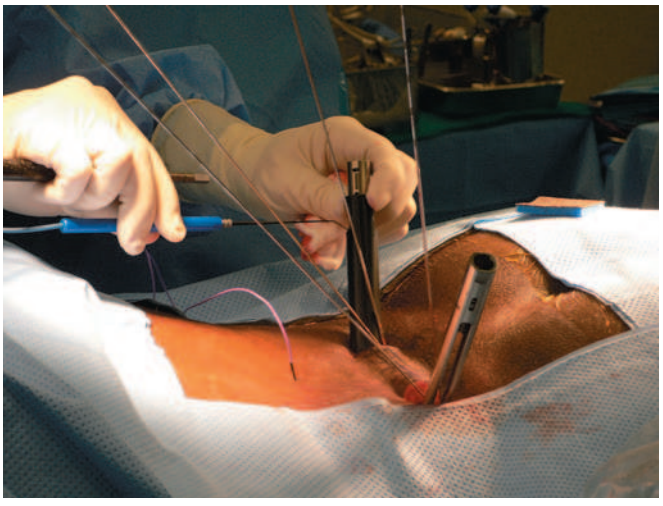

FIG. 56.21 Following their insertion, pedicle screws are tested with stimulus-evoked electromyography using an insulated port.

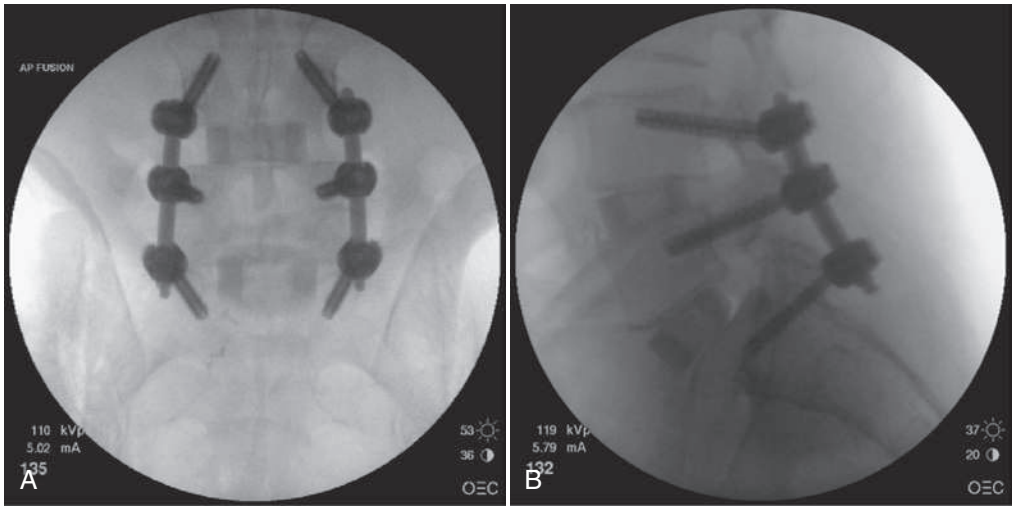

FIG. 56.22 (A) Anteroposterior and (B) lateral fluoroscopic views of the construct at the conclusion of the procedure.

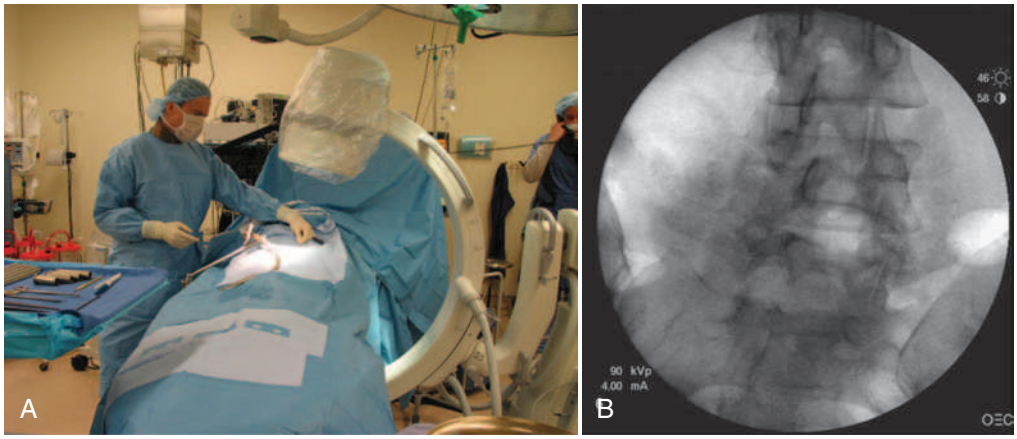

FIG. 56.23 (A) En face view obtained through angulating the C-arm 10 to 15 degrees in the axial plane to (B) line up the beam with the pedicle axis.

along the new trajectory. Finally, stimulus-evoked EMG testing of the taps and screws has proven to be a useful adjuvant to the placement of percutaneous pedicle screws. Any low-voltage activity (<8 mV) should alert the surgeon to the need to pursue additional measures to ensure correct placement of the implant.

Direct Pedicle Screw Insertion via a Paramedian Approach

Some surgeons prefer direct insertion of pedicle screws, using an expandable tubular retractor system to directly visualize the anatomic landmarks for pedicle screw insertion. This approach is especially useful when performing a minimally invasive TLIF procedure. In performing this technique, an expandable tubular retractor is positioned to visualize the junction between the base of the transverse process and the superior articular process. Any overlying soft tissue is cleared away using electrocautery to expose the bony landmarks. A starting hole for the pedicle screw insertion is then made using the normal anatomic landmarks as with traditional open pedicle screw insertion. C-arm fluoroscopy can be utilized to document the location of the starting point and trajectory for the pedicle cannulation. A "gear shift" or similar type blunt instrument is inserted into the starting hole and passed through the pedicle, using fluoroscopic guidance as needed. The walls of the pedicle are palpated to ensure the absence of a breach. Next, the site is tapped and the walls of the pedicle are again palpated for integrity. Pedicle screws are inserted using a technique analogous to open pedicle screw placement. Electrical testing of the screw can be used if desired, followed by the introduction of a rod and caps.

Facet Screw Instrumentation

Although pedicle screws are the workhorse for most spinal fixation strategies, facet screws offer certain advantages in selected cases. Facet screws are quick and relatively easy to place. They are generally less expensive compared with pedicle screw implants and yet offer comparable initial stiffness for

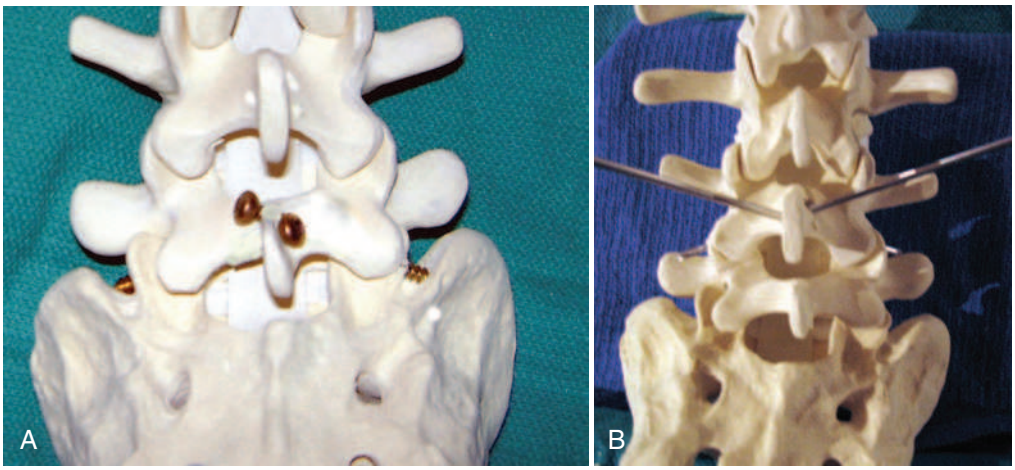

FIG. 56.24 Facet screw instrumentation. (A) The screw path begins at the base of the spinous process on one side and then (B) advances across the contralateral lamina and facet joint.

short constructs.[28] In certain clinical situations, such as following anterior lumbar interbody fusion, facet screw instrumentation has been shown to produce favorable clinical results.[29,30] Additionally, recent studies have suggested similar results with lower costs for patients undergoing minimally invasive TLIF surgery who have unilateral pedicle screws and contralateral facet screws compared to traditional bilateral pedicle screw fixation.[31]

Magerl et al. described a technique using large fragment (4.5-mm) cortical bone screws to perform a translaminar fixation of the facet joint.[32] The screw path begins at the base of the spinous process on one side and is then advanced across the contralateral lamina and facet joint (Fig. 56.24). Two screws are placed to immobilize the facet joints bilaterally using a mini-open or percutaneous technique.[33,34]

To insert translaminar facet screws, using the mini-open technique, a midline incision is performed and the spinous processes, bilateral laminae, and facet joints are exposed. The facet joint capsules may be removed and the joint decorticated and packed with bone graft to promote local fusion following instrumentation. When placing translaminar facet screws, pilot holes are made on each side of the spinous process in line with the anticipated screw trajectories. The pilot holes should be slightly staggered to prevent the two screws from contacting one another as they cross through the base of the spinous process.

Next, the trajectory for each screw is defined, using fluoroscopy if desired. Some surgeons prefer to make a small laminotomy and palpate the medial wall of the pedicle as a landmark and to ensure direct visualization of the dura while drilling the screw trajectory. Additionally, decompressions of the lateral recess using fenestration can be performed if necessary.

Next, a line connecting the mid-facet (or medial border of the pedicle) and the pilot hole is marked on the skin. This trajectory can be extended superiorly and laterally to the midline incision. A small, percutaneous incision is made along this line, about 10 to 12 cm from the midline such that the drill trajectory will be in line with the contralateral lamina.

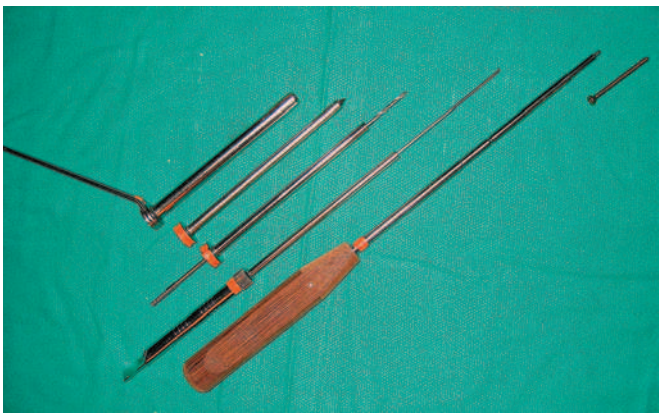

FIG. 56.25 Various instruments (e.g., drill guides, depth gauge, screws) are used during percutaneous facet screw placement.

A drill guide is inserted into the percutaneous incision and advanced into the midline exposure (Fig. 56.25). The drill is inserted and seated into the pilot hole at the base of the spinous process. The drill is adjusted as necessary so that it will traverse the lamina and then the facet joint. As the drill is advanced, the surgeon should feel uniform resistance until the facet joint has been breached. A momentary change in resistance may be noted as the facet joint space is traversed, but the cortical bone of the superior articular process will then be encountered. After drilling, the length of the screw path is measured. Then, a 4.5-mm, fully threaded cortical screw is placed to secure the position of the facet joint. A similar percutaneous technique has been described, relying only on fluoroscopic images to ensure adequate placement of the translaminar facet screw implants.[30]

Patient Selection

Patient selection remains the most crucial outcome variable for any spinal procedure. The same selection criteria that have been shown to produce success in traditional spinal surgery

apply to patient selection for an MIS approach. In addition, patients being considered for an MIS approach have some additional selection criteria that should be considered.[35]

In the early learning curve of an individual surgeon, only simple cases should be considered for an MIS approach. Experience can be gained working with MIS equipment, such as tubular retractors and microscopes, by performing straightforward cases (e.g., microdiscectomy). As a surgeon gains experience with minimally invasive spinal procedures, progressively more complex cases may be tackled in a minimally invasive fashion. Other aspects should be considered as well, including the size of the patient (obese patients will be more difficult), severity of the pathologies, and history of any prior spinal surgery.

Summary

It appears likely that MIS will become an increasingly important component of the spinal surgical armamentarium in the future. With the advances in MIS techniques, spinal fusions and instrumentations are now being achieved with less morbidity and faster recovery compared to traditional open surgical approaches. However, surgical expertise in MIS can be reached only by ascending a learning curve. Thus, surgeons interested in this innovative field must be willing to spend the time and effort necessary to become proficient in MIS techniques.

In skilled hands, the benefits of MIS procedures appear to outweigh the risks. Additional long-term outcome data are still needed to define the efficacy of these approaches compared to traditional open spinal fusion approaches. However, early data suggest that surgeons willing to spend the time and energy necessary to gain proficiency in MIS can expect to be rewarded through the benefits provided to their surgical patient population, especially with regard to reduced blood loss and a shorter recovery period.

CHAPTER 57

Posterolateral Endoscopic Lumbar Discectomy

SECTION VII

Christopher A. Yeung
Anthony T. Yeung

Posterolateral endoscopic lumbar surgery is a less invasive surgical procedure to address lumbar pathology in the disc and bony foramen. Like any surgical procedure, it is based on visual identification and exposure of the target pathology and adequate surgical tools to address the offending pathology. Modern endoscopic technology allows for discectomy and decompression of the traversing and exiting nerve roots from a percutaneous posterolateral/transforaminal approach under continuous direct visualization. This is safe and equally efficacious to microscopic discectomy in properly selected patients.[1–4] Recent advances also allow for bony decompression of foraminal stenosis.[5,6]

Advances in the ability to perform endoscopic discectomy have paralleled other specialties, yet endoscopic spinal surgery has not met with the same peer recognition as the other fields. This is due in part to the high success rate and relative low morbidity of the current gold standard, posterior microscopic lumbar discectomy. However, this approach still requires a 1-inch midline incision, muscle and ligament stripping, prolonged muscle retraction, partial facet and lamina resection, and both nerve root and dura retraction. This can weaken the muscular lumbar stabilizers, create instability and facet arthrosis, cause traction neurapraxia, promote epidural scarring, and make revision surgery more difficult.

Another barrier for more widespread adoption was the relative paucity of peer-reviewed literature, and critics noted that only a few authors were contributing to this body of literature. Recently, there have been many more published results of posterolateral endoscopic discectomy from around the world; the preponderance of evidence supports its efficacy.

Numerous other nonvisualized, percutaneous techniques often get categorized and confused with posterolateral endoscopic lumbar discectomy. These include automated percutaneous lumbar discectomy, percutaneous laser discectomy, and percutaneous discectomy with the Dekompressor or Arthrocare wand (Coblation). These are all fluoroscopically guided, nonvisualized procedures that access the disc via the same posterolateral approach as endoscopic lumbar surgery. The underlying principle of these procedures is that, through central nucleus removal or ablation, intradiscal pressure can be substantially lowered. This was based on the work of Hirsh and his postulated relationship between intradiscal pressure, disc herniation, and low back pain.[7] He hypothesized that lowering this pressure in an injured disc could be efficacious in the relief of sciatica. Multiple studies described decreases in intradiscal pressures of 50% or greater.[8–10]

The results of these types of indirect decompressive procedures have been similar, with initial favorable reports. However, subsequent studies have shown varying degrees of success. The inability to consistently see the decompressed nerve or the targeted pathoanatomy has limited the use of these nonvisualized decompressive procedures.[11–14] It is unfortunate that these interventional procedures and their results are mistaken for posterolateral endoscopic discectomy surgery.

History

The basis for percutaneous lumbar disc procedures came from accepted posterolateral percutaneous biopsy techniques of the lumbar vertebrae. These procedures were initially performed with the use of a Craig needle to perform a posterolateral biopsy for neoplastic conditions.[15,16]

Minimally invasive surgery for lumbar disc herniation was first independently reported by Kambin and colleagues[17] and Hijikata[18] in 1975. A posterolateral approach was used to position a small cannula in the foraminal zone of the disc bordered by the traversing nerve dorsally, the exiting nerve ventrally, and the endplate of the inferior vertebra caudally. Mechanical instruments were used to remove disc tissue. The early efforts were limited to a nonvisualized central discectomy to achieve an indirect decompression of the nerve roots.[17–19] The goal was to decompress nerve roots secondary to lumbar disc herniation by the inside-out technique of central and posterior nuclectomy and fragmentectomy.

The addition of an endoscope to help with the decompression developed in stages. Initially, an arthroscope was used to inspect the disc and anulus intermittently through the cannula while the mechanical nuclectomy was done under fluoroscopic guidance. The introduction of a biportal approach allowed for direct visualization of instruments introduced through a cannula inserted into the disc from the opposite

posterolateral portal. The later development of an operating spine scope with a working channel for instruments allowed for surgical removal of disc material and visualization of foraminal anatomy under direct visualization via a uniportal approach.

Kambin performed the first true endoscopic lumbar procedures. The arthroscope was at first used intermittently through the working cannula. At certain stages of the procedure, such as perforating the disc in the triangular working zone, the arthroscope would be placed in the cannula. The nonworking-channel scope was used for identification of the anulus and periannular structures. The basis was to see that the nerve was not in the way before advancing the cannula. Once the cannula was safely within the disc, the nucleotome, an arthroscopic shaver, and pituitary rongeurs were passed through the cannula to perform mechanical disc removal. The majority of the procedure was only fluoroscopically visualized.[17] Kambin reported an 88% success rate in his first 100 patients.[20,21]

The early endoscopic procedures were limited by the absence of a working-channel arthroscope. This led Kambin to the development of a biportal technique in which the scope was inserted on one side and the working cannula on the opposite side. Kambin's indications for a biportal approach included large subligamentous herniations, extraligamentous herniations, and arthroscopic interbody fusion.[22] In later studies, Kambin reports results from both uniportal and biportal procedures together. Overall results ranged from 85% to 92% satisfactory results at a minimum 2-year follow-up. There was no differentiation made between the results of uniportal versus biportal approaches.[23–25]

Kambin's first prototype of the working-channel scope was not fully developed and was not successfully marketed. The problems with the initial scope included fragility, limited degree of angulation for the working instruments, and the inability to establish sufficient inflow or outflow for adequate visualization.[26] Yeung developed the first working-channel endoscope to become widely available. The scope was developed in 1997 and was approved for use by the US Food and Drug Administration in March 1998. The Yeung Endoscopic Spine Surgery system (Richard Wolf Surgical Instruments) modified the scope by adding multichannel integrated irrigation, specialized beveled cannulas, a two-hole obturator, and newly designed discectomy tools that allowed for constant real-time visualization with a uniportal technique[27] (Fig. 57.1).

Another major change, which allowed for advancement in the field of endoscopic spinal surgery, was Yeung and Mathews' emphasis on placement of the cannula closer to the epidural space and the base of the targeted disc herniation leading to the so-called targeted technique. They promoted routine visualization of the epidural space and greater access to the traversing nerve root.[28] This enabled surgeons to target extruded herniations in addition to contained herniations. Previous percutaneous modalities all focused on entry through Kambin's triangle and working within the center of the disc with the cannula anchored inside the anulus. The cannula was advanced past the anulus and remained intradiscal for the procedure.

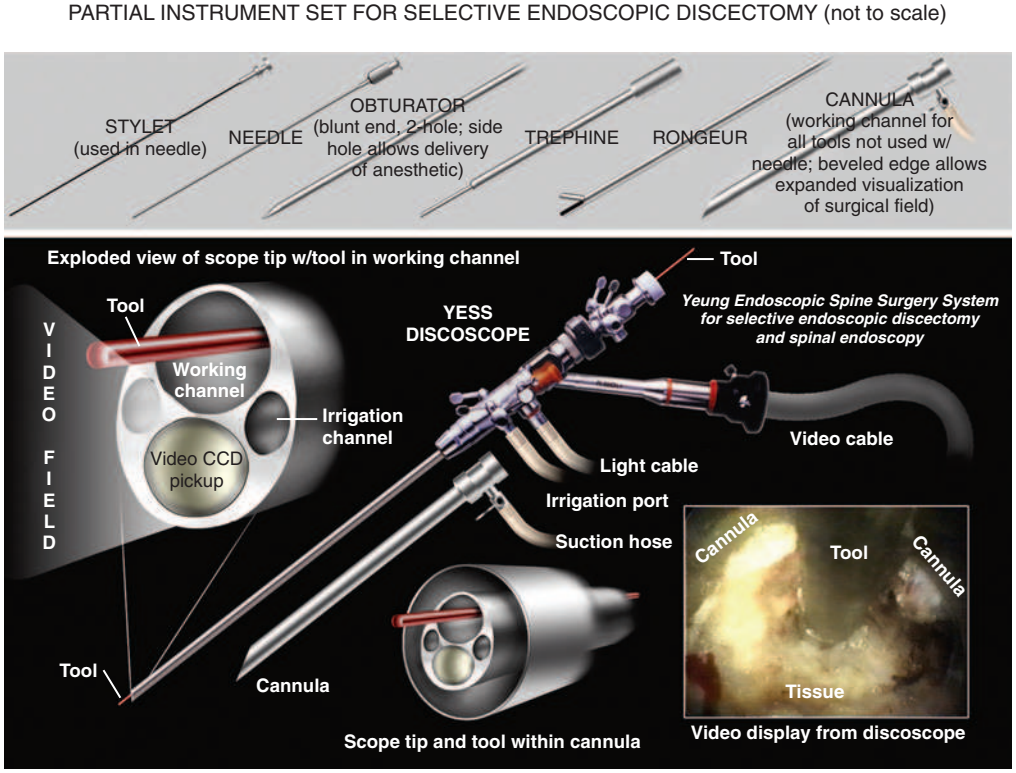

FIG. 57.1 The Yeung Endoscopic Spine Surgery system. (Courtesy Richard Wolf Surgical Instruments, Vernon Hills, IL.)

The development of a working-channel scope and use of the transforaminal approach using beveled and slotted cannulas enhanced endoscopic lumbar surgery. Using this approach, surgeons could operate under full visualization throughout most of the procedure and follow the neural structures into the epidural space. The specialized cannulas provide greater access to pathology and help protect and retract sensitive anatomy, such as the exiting nerve and dorsal root ganglion. The working channel also allows the passage of high-speed burrs for bone removal and direct foraminal enlargement and decompression of foraminal stenosis (foraminoplasty). This facet decompression also allows the surgeon to access the midline of the disc and the epidural space. Thus, it is feasible to treat the full spectrum of disc herniations with advanced endoscopic instrumentation and techniques that can either target the extruded fragment directly or with a combination of the inside-out technique.[29]

Improvements in surgical equipment and technique have evolved gradually since 1975. A systematic fluoroscopically guided approach method introduced by Yeung and reported by Tsou[30–32] outlined a consistent and safe technique for entry into all lumbar posterior disc spaces, including the L5–S1 level. This specific technique has been termed selective endoscopic discectomy but can be classified under the more general descriptive term of posterolateral endoscopic lumbar discectomy (PELD) that other authors describe. In the past 15 years, the important major equipment improvements have included various-sized high-resolution rod lens operating endoscopes with variable-sized working channels, more variety of beveled and slotted cannulas, flexible shavers and pituitary forceps, a bipolar flexible high-frequency/low-temperature radiofrequency electrode, multidirectional holmium yttrium-aluminum-garnet (YAG) lasers, and high-speed diamond burrs and motorized shavers to decompress the foramen.[29] These refinements have enhanced the capabilities of foraminal endoscopic discectomy to deliver surgical results similar to the results obtainable by traditional transcanal approaches for treating common lumbar disc herniations.[1–4]

Recent development of expandable and cannulated interbody fusion devices has allowed truly minimally invasive interbody fusion procedures to become feasible. The RISE IntraLIF (Globus Medical) expandable interbody device can fit down an 8.5-mm access cannula after endoscopic discectomy and endplate preparation. The OptiMesh (Spineology) expandable polyetheretherketone mesh cage is another example. Early studies are just starting to get reported.[33]

Anatomy

Posterolateral endoscopic lumbar surgery is performed through what has been named the *triangular working zone*, or *Kambin's triangle* (Fig. 57.2). This triangular zone is defined as a safe zone in the posterolateral anulus between the exiting and traversing nerve roots. The exiting nerve root forms the anterior border of the triangular zone as it exits under the cephalad pedicle. The superior endplate of the caudal vertebral body forms the inferior border and the articular process and

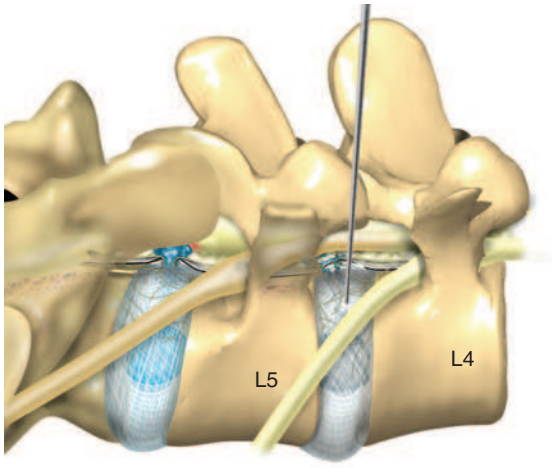

FIG. 57.2 Triangular working zone at L4–L5 (Kambin triangle). This is the access point for posterolateral disc access. The exiting nerve root is the hypotenuse of the triangle, the superior endplate of the caudal vertebral body/sacrum is the base (width), and the traversing nerve root/dura is the height of the triangle.

superior articulating facet of the caudal vertebra form the posterior border. The working zone is bordered medially by the traversing nerve root and dura. From cadaveric measurements, it was determined that cannulas ranging from 4 to 10 mm could be safely used in the triangular working zone.[22,34–37] A thorough understanding of the three-dimensional anatomy is necessary to understand and perform posterior percutaneous lumbar surgery.

Indications and Contraindications

Current indications for the use of an endoscopic posterolateral approach to the lumbar spine include foraminal and far-lateral disc herniations, contained central and paracentral disc herniations, small nonsequestered extruded disc herniations, recurrent herniations, symptomatic annular tears, synovial cysts, biopsy and debridement of discitis, decompression of foraminal stenosis with or without spondylolisthesis, visualized total nuclectomy (before nucleus replacement), and visualized discectomy with endplate preparation before interbody fusion.

Perhaps the ideal lesions for posterolateral selective endoscopic discectomy are the foraminal and extraforaminal disc herniations. The cannula inserts directly at the herniation site, and the exiting nerve is routinely visualized and protected (Fig. 57.3). This approach requires less manipulation of the exiting nerve root than the paramedian posterior approach.

Any herniation contiguous with the disc space not sequestered and migrated is amenable to endoscopic disc excision if the bony anatomy permits an unobstructed approach. A targeted technique can be utilized or the inside-out technique, in which the herniation is grasped from its base within the disc, pulled back into the working intradiscal cavity, and removed via the cannula. The size and types of herniations chosen by the surgeon for endoscopic excision will depend on the skill and experience of the surgeon. Certainly, all contained disc

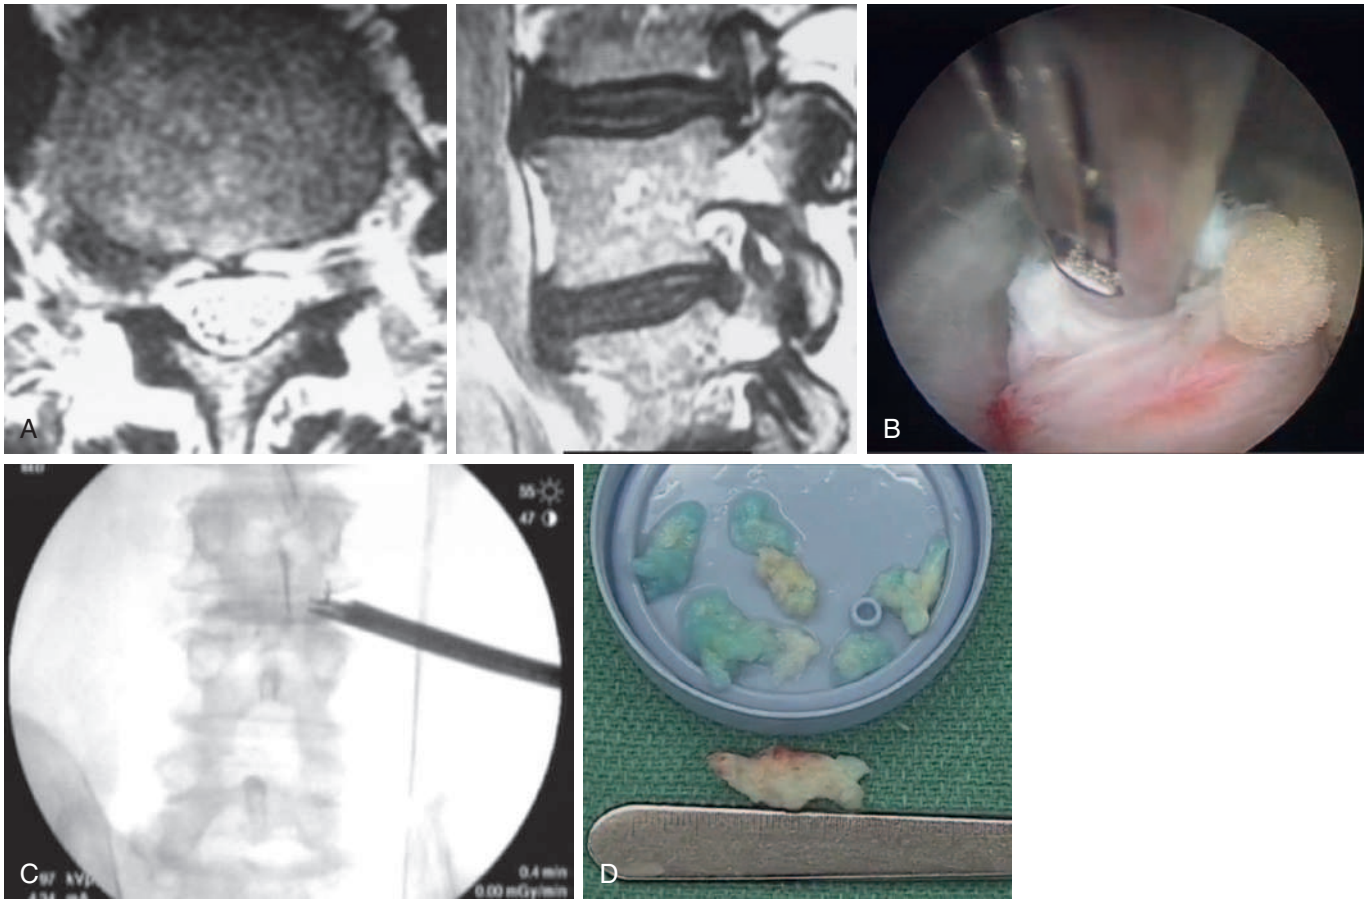

FIG. 57.3 Treatment of a foraminal herniated disc. (A) Magnetic resonance image of an extruded right L3–L4 foraminal herniation with some cephalad migration. (B) Fluoroscopic anteroposterior image shows the pituitary forceps positioned to grab the herniation in the epidural space in the axilla of the exiting nerve root. The forceps are within the working channel of the scope and the herniation is removed under direct endoscopic visualization. (C) Endoscopic picture of the extruded herniation abutting the axilla of the exiting right L3 nerve root. (D) The large extruded fragment that was removed. Note the red, white, and blue stained portions of the fragment. The red portion is the part that was extruded and has some inflammatory tissue, the white portion is the part trapped within the anulus, and the blue part is the intradiscal portion that is stained by the injected indigo carmine dye.

herniations are appropriate for endoscopic decompression. With experience, extruded herniations can be routinely addressed. This approach is especially attractive for recurrent herniations after a traditional posterior approach because the surgeon can avoid the scar tissue from the previous surgery.

Extruded herniations with limited cephalad/caudal migration can be removed with the outside-in technique. If the herniation is sequestered and a free fragment, then posterolateral endoscopic discectomy is relatively contraindicated.

Radiofrequency energy can be applied to the annular tears under direct visualization to contract the collagen and ablate ingrown granulation tissue, neoangiogenesis, and sensitized nociceptors.[38] Frequently, interpositional nuclear tissue is seen within the fibers of the annular tear, preventing the tear from healing. This tissue can then be removed to allow the tear to heal.

Endoscopic foraminoplasty can be readily achieved with bone trephines/rasps, the side-firing holmium-YAG laser, and endoscopic high-speed drills.[5,6] The roof of the foramen is formed by the undersurface of the superior articular facet. This is easily visualized and accessed via the endoscope, and the previously mentioned tools are used to remove bone and enlarge the foraminal opening. Synovial cysts can sometimes be visualized and removed as well, depending on their location.

In cases of discitis, the posterolateral endoscopic approach will provide a robust biopsy for culture diagnosis, and the infected/necrotic disc tissue can be thoroughly debrided to reduce the bacterial load and accelerate healing and potential in situ fusion.[39] This approach also limits the spread of the infection since no approach-related dead space is created.

Contraindications include any pathology not accessible from the posterolateral endoscopic approach. This may include some extruded sequestered disc herniations, extruded migrated disc herniations (migrated extent greater than the measured height of the posterior marginal disc space on T2 sagittal magnetic resonance imaging [MRI]), larger herniations occupying greater than 50% of the spinal canal,[4] moderate to severe central canal stenosis, and hard calcified herniations. These contraindications are considered relative contraindications dependent on the surgeon's technical

experience and comfort level. More experienced endoscopic surgeons can gain greater access to pathology using advanced techniques for bone removal of osteophytes, stenosis, and the posterolateral corner of the vertebral body before addressing the pathology. Other relative contraindications include inadequate support staff or equipment to successfully perform procedure and uncooperative patients.

Posterolateral Endoscopic Lumbar Discectomy

Different styles of posterolateral endoscopic discectomy have been described in the literature. The inside-out technique initially positions the cannula within the disc near the base of the herniation as a safe starting point. The cannula is gradually backed out and the surgeon works toward the base of the herniation and epidural space to directly remove the herniated fragment in addition to some of the underlying unstable nucleus. The outside-in technique positions the cannula immediately in the epidural space where the herniated fragment is. The fragment is removed and the surgeon only minimally enters the disc space or does not enter it at all, thus performing more of a fragmentectomy. This is especially useful for extruded migrated disc herniations. The targeted technique is a blend of these two techniques, in which the initial cannula placement is at the site of the herniation. The herniated fragment is removed and the surgeon enters the disc space to then remove any loose unstable nucleus. All of these techniques are effective; the main difference is simply the starting point of the cannula position in relation to the disc. After that initial starting point, the surgery progresses to attempt removal of the offending disc herniation completely by using the same instruments.

The different types and locations of herniations also dictate the location of the skin incision (skin window). The approach trajectory gets shallower if you start farther away from the midline. Foraminal herniations are more easily removed with a more steep approach trajectory into the disc, about 45 to 55 degrees. It is better to have a shallower 20- to 40-degree approach trajectory for paracentral herniations in order to fully access them. Central or large paracentral herniations may utilize an extreme lateral approach with a 0- to 20-degree approach trajectory, but care must be taken to avoid breaching the retroperitoneal or peritoneal space.

Most surgeons operate with the patient placed in a prone position, but some prefer the patient to be in a lateral decubitus position. It is more ergonomic to operate with the patient prone, which is our preferred position.

The basic inside-out technique for a typical paracentral herniation is described in detail next.

Step-by-Step Operative Technique

Patient Positioning

The patient is prone on a hyperkyphotic frame with a radiolucent table. The endoscope is on one side and the fluoroscopic unit is on the opposite side of the patient.

Anesthesia

Although some experienced international endoscopic surgeons prefer general anesthesia, we recommend mild sedation and local anesthesia so that the patient is awake and responsive throughout the procedure. The patient can then provide real-time feedback in case of nerve irritation from instrument pressure or retraction, adding a layer of safety and allowing the surgeon to adjust the instruments accordingly. We use midazolam (Versed) and fentanyl for sedation and recommend against using general anesthetics like propofol, which can produce temporary total analgesia, eliminating the patient's responsiveness to any nerve stimuli. The skin, needle tract, and anulus are anesthetized with 0.5% lidocaine. This allows anesthesia without motor block of the nerve roots.

Needle Placement

Optimal needle placement is the most crucial step of the procedure and is based on the type of pathology being addressed.[30] The skin window (needle insertion site) is determined using this protocol. This will typically be about 12 to 15 cm lateral to the midline aligned parallel to the disc inclination (Fig. 57.4). The starting point can be adjusted based on the location of the targeted herniation. You would start closer to the midline for foraminal/extraforaminal herniations and more lateral for central herniations.

Once the starting point is determined, the skin window and subcutaneous tissue are infiltrated with 0.5% lidocaine. A 6-inch, 18-gauge needle is then inserted from the skin window at the desired trajectory, typically at a 30-degree angle to the floor (coronal plane) and passed anteromedially toward the anatomic disc center. Infiltrating the needle tract with 0.5% lidocaine as you advance the needle will anesthetize the tissue tract, avoiding pain when the dilator is passed later in the procedure.

In order to avoid puncturing the dura with a trajectory that is too shallow, we advance the needle with the C-arm in the posteroanterior view and never advance the needle tip medial to the medial border of the pedicle without checking a lateral view first. The C-arm lateral projection should confirm the needle tip's correct annular location at the annular window (annular entry point). In the posteroanterior view, the needle tip should be at the disc between the pedicles. In the lateral view, the correct needle tip position should be just touching the posterior anulus surface. These two views of the C-arm confirm that the needle tip has engaged the safe zone, the center of the foraminal annular window.

While monitoring the posteroanterior view, advance the needle tip through the anulus to the midline (anatomic disc center). Then, check the lateral view. If the needle tip is in the center of the disc on the lateral view, you have a central needle placement, which is good for a central nucleotomy and foraminal herniations. Ideally the needle tip will be in the posterior third of the disc, indicating posterior needle placement if you are attempting to access paracentral herniations.

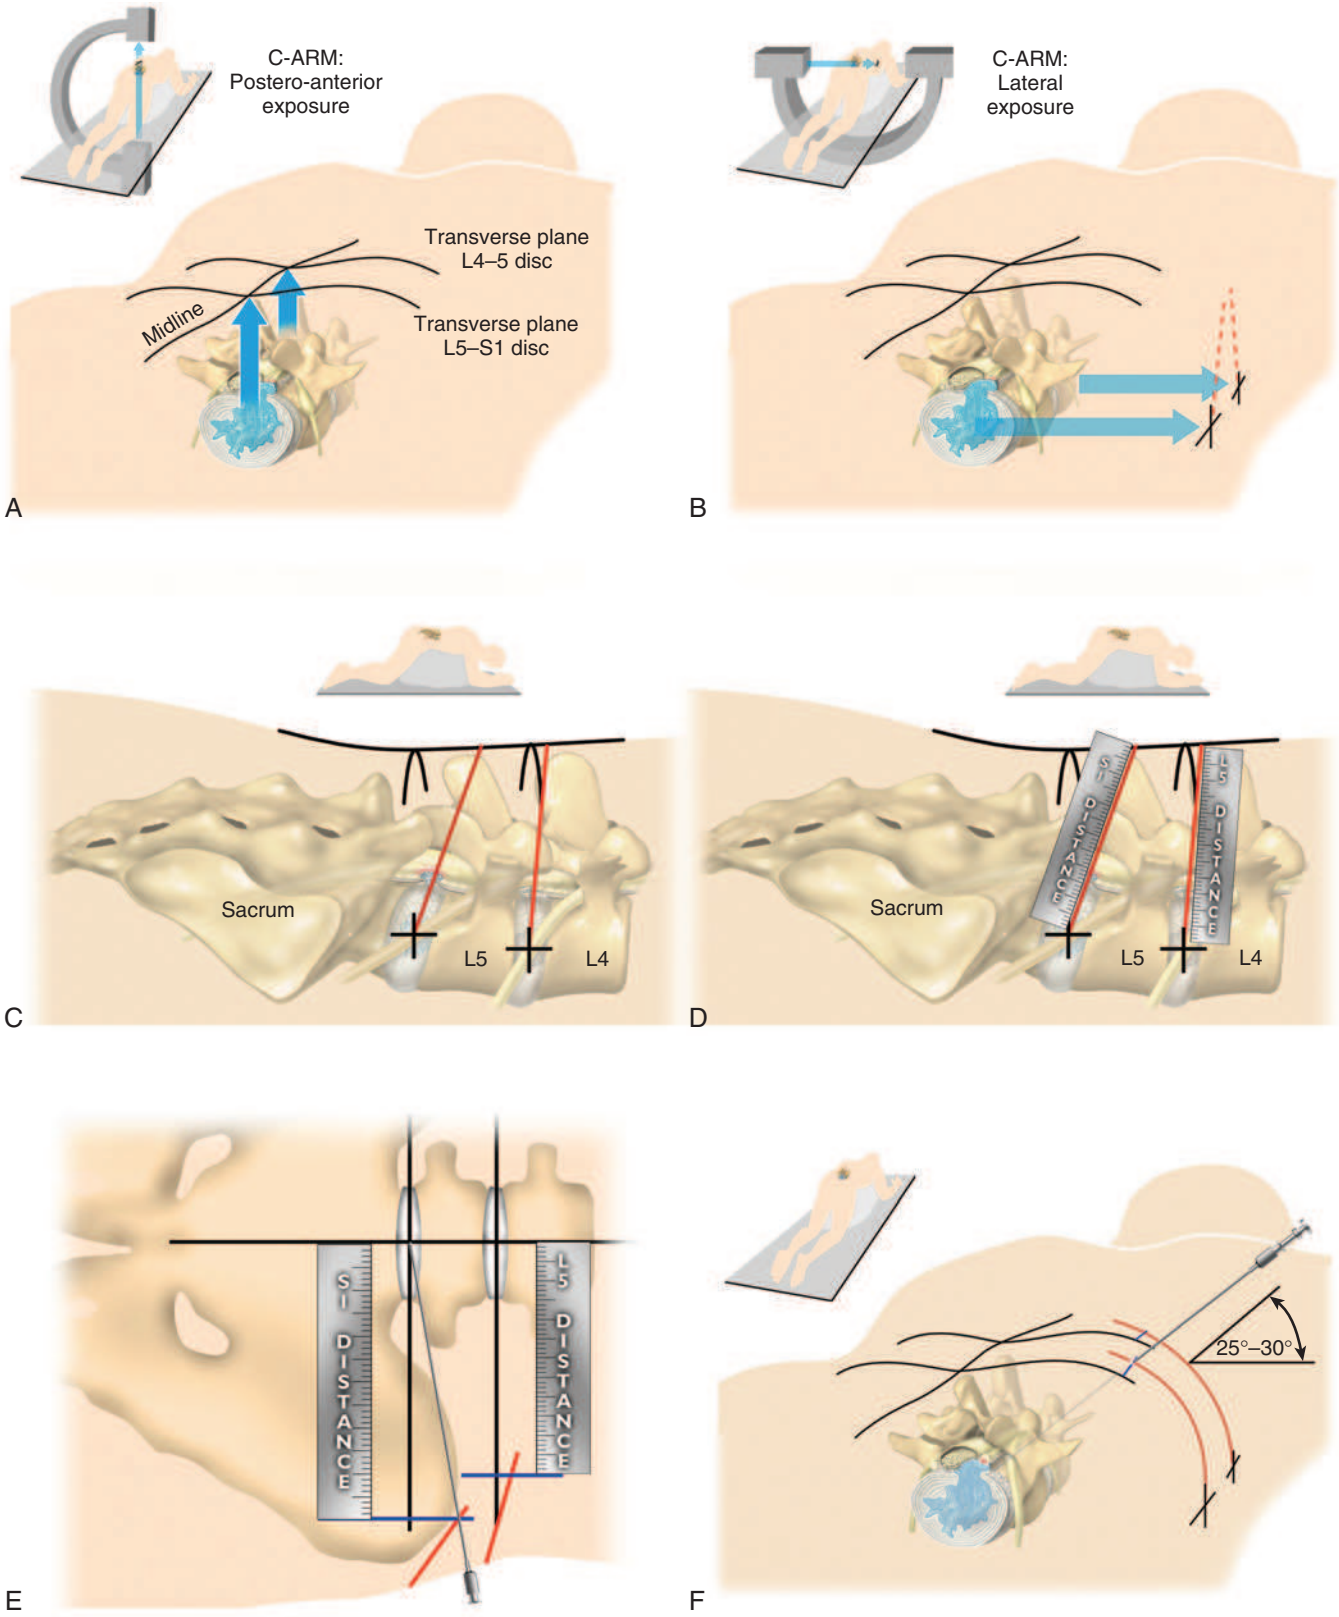

FIG. 57.4 Protocol for optimal needle placement. (A) Posteroanterior (PA) fluoroscopic view enables topographic location of the midline and the transverse disc plane. The intersection of these lines is the PA anatomic disc center. (B) Lateral fluoroscopic view enables topographic location of the disc inclination plane. (C) The inclination plane of each target disc is drawn on the skin from the lateral disc center. (D) The distance from the lateral disc center to the posterior skin plane is measured along the inclination plane. (E–F) This same distance is measured from the midline along the transverse disc plane for each target disc. At the end of this measure, a line parallel to the midline is drawn to intersect the disc inclination line. This is the skin entry point or skin window for the needle.

Evocative Chromodiscography

Perform confirmatory contrast discography at this time. Historically, the following contrast mixture was used: 9 mL of Isovue 300 (iopamidol injection) with 1 mL of indigo carmine dye. This combination of contrast ratio gives readily visible radiopacity on the discography images and intraoperative light blue chromatization of pathologic nucleus and annular fissures, which help guide the targeted fragmentectomy. Indigo carmine was recently discontinued; substitution with methylene blue dye is now used.

Instrument Placement

Insert a guidewire through the 18-gauge needle channel. Advance the guidewire tip, 1 to 2 cm deep into the anulus; then, remove the needle. Slide the bluntly tapered tissue-dilating obturator over the guidewire until the tip of the obturator is firmly engaged in the annular window. An eccentric parallel channel in the obturator allows for four-quadrant annular infiltration using small incremental volumes of 0.5% lidocaine in each quadrant, enough to anesthetize the anulus but not the nerves. If the patient has some radicular nerve pain while placing the needle in one of these quadrants, the surgeon is alerted to the nerve's close proximity to the obturator. Hold the obturator firmly against the annular window surface and remove the guidewire.

The next step is the through-and-through fenestration of the annular window by advancing the bluntly tapered obturator with a mallet. Annular fenestration is the most painful step of the entire procedure. Advise the anesthesiologist to heighten the sedation level just before annular fenestration. Advance the obturator tip deep into the anulus and confirm on the C-arm views. Now, slide the beveled access cannula over the obturator toward the disc. Advance the cannula until the beveled tip is deep in the annular window, with the beveled opening facing dorsally. Remove the obturator and insert the endoscope to get a view of the disc nucleus and anulus (Fig. 57.5). If the targeting has been ideal and the cannula is within the base of the herniation, the surgeon will be looking right at the herniated disc material that requires removal. The subsequent steps depend on the goal of the procedure and pathology being addressed. The basic endoscopic method to excise a noncontained paramedian extruded lumbar herniated disc via a uniportal technique is described here. Different steps are used for other pathology and are beyond the scope of this chapter.

Performing the Discectomy

Oftentimes, there are some annular fibers at the base of the herniation that need to be resected in order to remove the herniation easily. In this situation, enlarge the annulotomy medially to the base of the herniation with cutting forceps. The side-firing holmium-YAG laser can also be used to enlarge and widen the annulotomy. This is performed to release the annular fibers at the herniation site that may pinch off or prevent the extruded portion of the herniation from being

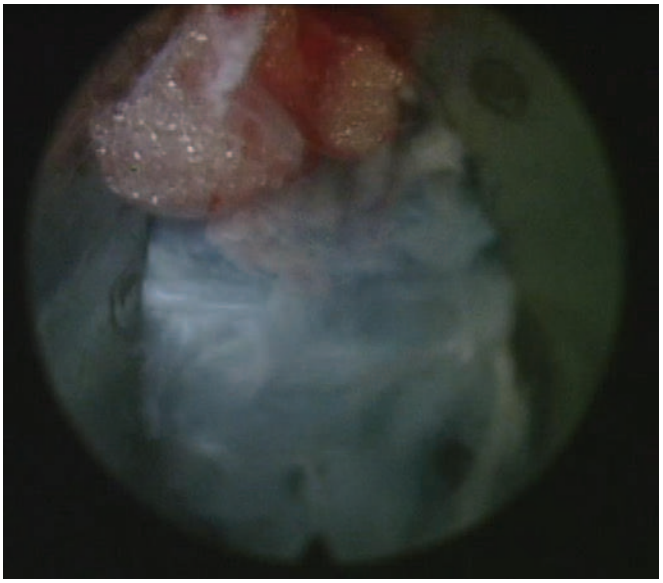

FIG. 57.5 Uniportal endoscopy for paracentral herniation. The cannula is positioned near the base of the herniation. The epidural fat can be seen at the top of the image. The extruded herniation is stained blue with indigo carmine dye and is seen here extruding through the thinned-out annular fibers seen coursing horizontally in this image. At this point, the annular fibers are cut to enlarge the annulotomy with the cutting forceps and the side-firing laser to allow the apex of the herniation to be pulled back into the disc and out the cannula with pituitary rongeurs.

extracted. Directly under the herniation apex, a large amount of blue-stained nucleus is usually present, likened to the submerged portion of an iceberg. The nucleus here represents a migrated and unstable nucleus. The endoscopic rongeurs are used to extract the blue-stained nucleus pulposus under direct visualization. The larger straight and hinged rongeurs are used directly through the cannula after the endoscope is removed. Fluoroscopy and surgeon feel guide this step. By grabbing the base of the herniated fragment, one can usually extract the extruded portion of the herniation. Initial medialization and widening of the annulotomy reduce the prospect of breaking off the herniated nucleus and retaining the apex of the herniation in the spinal canal. The traversing nerve root is readily visualized after removal of the extruded herniation (Fig. 57.6).

Next, perform a minimal bulk decompression by using a straight and flexible suction-irrigation shaver. This step requires shaver head C-arm localization before power is activated to avoid nerve/dura injury and anterior annular penetration. The cavity thus created is called the *working cavity*. The debulking removes the loose, unstable nucleus material to prevent future reherniation.

Inspect the working cavity. If a noncontained extruded disc fragment is still present by finding blue-stained nucleus material posteriorly, then these fragments are teased into the working cavity with the endoscopic rongeurs, curved nerve hooks, and the flexible radiofrequency trigger-flex bipolar probe (Elliquence) and removed. Creation of the working cavity allows the herniated disc tissue to follow the path of least resistance into the cavity. The flexible radiofrequency bipolar probe is used to contract and thicken the annular

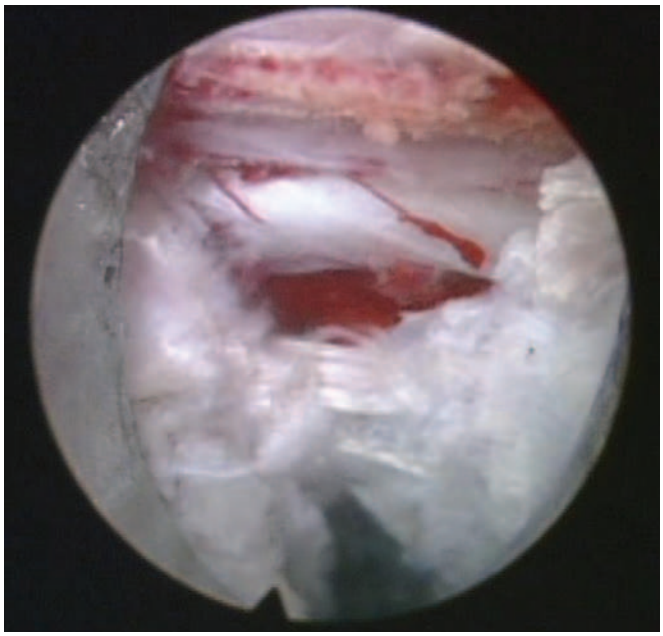

FIG. 57.6 Inspection of the freed traversing nerve root. After successful removal of an extruded paracentral herniation, the traversing nerve root is visualized, confirming complete decompression of the nerve. This is routine in extruded herniations. If the herniation is a contained herniation, the surgeon would visualize the undersurface of the thinned-out posterior annular fibers rather than the traversing nerve root because the herniation did not extrude past the posterior anulus.

collagen at the herniation site. It is also used for hemostasis throughout the case.

The vast majority of herniations can be treated via the uniportal technique. Sometimes for large central herniations and herniations at L5–S1, the disc needs to be approached from both sides, a biportal technique. This allows the use of larger articulating instruments that fit through the contralateral 7-mm access cannula and can reach more posteriorly to extract the herniated fragment under direct endoscopic vision.

Clinical Outcomes

Yeung has reported his initial results using the Yeung Endoscopic Spine Surgery system in his first 307 patients with disc herniations who were candidates for open microdiscectomy.[31] The study included intracanal and extracanal herniations. Recurrent herniations and patients with previous surgery at the same level were not excluded. Results were reported with 1-year follow-up. Overall patient satisfaction was found to be 91%. The same percentage of patients said that they would undergo the procedure again if faced with the same diagnosis. The overall complication rate was 3.5%.[31] Tsou and Yeung separated out a subgroup of 219 patients with noncontained herniations and reported results at 1 year. Patient satisfaction was 91%.[32] These initial results demonstrated that endoscopic surgery could provide equivalent results to reported results of open microdiscectomy, even with noncontained herniations.

There are three prospective randomized studies comparing traditional microdiscectomy and percutaneous endoscopic discectomy. Hermantin et al.[1] performed a prospective randomized study with 30 patients in each group. The mean duration of follow-up was 31 months. Patient satisfaction was 93% in the open surgical group and 97% in the endoscopic group. The endoscopic group had shorter duration of narcotic use and shorter time out of work compared with the open discectomy group. Mayer and Brock[2] performed a randomized prospective study in 1993 with 20 patients in each group. They chose return to previous occupation as the measurement of success. This study showed a significant difference in this outcome measure. In the percutaneous group, 95% of patients returned to their previous profession, whereas only 72% of the microdiscectomy group returned to a previous profession. In 2008, Ruetten et al.[3] compared traditional microdiscectomy with full endoscopic discectomy via either the transforaminal or interlaminar route. There were 178 patients (87 microdiscectomy and 91 endoscopic) with 2-year follow-up. The microdiscectomy group had a 79% success rate and the full endoscopic group had an 85% success rate with no leg pain at all. It is noteworthy that all three of these prospective randomized studies showed a trend toward better outcomes with the endoscopic procedure, but statistically they were comparable.

Kambin et al.[40] reported an 82% success rate for the treatment of lateral recess stenosis and foraminal herniations using an oval cannula with two portals and the transforaminal approach. Even though they were working next to the exiting nerve root, they reported no neurovascular complications in their series. Successful posterolateral endoscopic treatment of foraminal and extraforaminal herniations has been described by many authors. Lew et al. reported an 85% success rate in 47 patients,[41] Choi et al. reported a 92% success rate in 41 patients,[42] Jang et al. reported an 85% success rate in 35 patients,[43] and Sasani et al. reported an 89% success rate in 66 patients.[44]

Yue et al.[45] described excellent results treating single-level, multifocal subarticular and paracentral and/or far-lateral lumbar disc herniations with a single-incision posterolateral endoscopic surgery in 15 patients with 15.3-month follow up. These herniations typically require both a posterior intracanal and extraforaminal surgical approach to alleviate compression of both exiting and traversing nerve roots. Total facetectomy and transforaminal lumbar interbody fusion is also often performed for this type of complex herniation.

Knight and Goswami[6] have reported on the use of the endoscope in foraminal decompressions for isthmic spondylolisthesis. In 79% of patients, a good or excellent outcome was obtained with an average follow-up of 34 months. Of the initial group, only two went on to have spinal fusion. Madhavan et al.[46] also described a case report using posterolateral endoscopic foraminal decompression to avoid fusion in a 31-year-old patient with isthmic spondylolisthesis. The patient was asymptomatic with 2-year follow-up.

Ahn and colleagues[47] reported an 81% success rate with PELD in 43 patients with recurrent disc herniations after a posterior microdiscectomy. Hoogland et al. also had good success (85%) using endoscopic transforaminal discectomy

for recurrent herniations in 262 consecutive cases from 1994 to 2002.[48] Of the 262 patients, 194 had a previous posterior microdiscectomy and 68 had a prior endoscopic discectomy. Both studies pointed out the advantage of avoiding the posterior scar tissue. Ruetten et al. also reported a prospective randomized study of 87 patients treated endoscopically after a recurrent herniation, with 79% reporting no leg pain and 16% with occasional leg pain.[49]

The ability to effectively remove pathology using endoscopic surgery has been validated by postprocedure imaging studies. Casey and colleagues[50] looked at a group of patients who had immediate postoperative computed tomography scans. The imaging studies demonstrated that 88.9% of patients undergoing biportal endoscopy had significant reduction in the amount of neural compromise. The results of uniportal, extraforaminal, and foraminal herniations showed only mild to moderate change in canal diameter. They concluded that arthroscopic discectomy had a high rate of canal clearance and removal of disc fragments.[50]

Lee and colleagues[4] reported on a matched cohort comparing radiographic changes 3 years postsurgery in PELD versus posterior microdiscectomy. They revealed less degenerative progression in the PELD group, with loss of disc height and foraminal height being statistically significant. Clinical success rates were 96% in the PELD group and 93% in the microdiscectomy group. The authors conclude that PELD is a less invasive procedure that causes less approach-related damage and less damage to the targeted disc.

Complications and Avoidance

The risks of serious complications or injury are low. The usual risks of infection, nerve injury, dural tears, bleeding, and scar tissue formation are present, as with any surgery. Because the transforaminal endoscopic approach passes adjacent to the exiting spinal nerve root and dorsal root ganglion, there is potential for nerve irritation (dysesthesia) or overt nerve damage. Dysesthesia occurrence is 5% to 15% and is almost always transient.[31,32] This rate of occurrence is similar to dysesthesia rates in posterior open discectomy. However, in the latter situation, because the dysesthesia affects the retracted traversing nerve root that was already the source of radiculopathy, the transient persistent or increased postoperative dysesthesia is generally not considered a complication after posterior discectomy. Both situations are transient the vast majority of the time. Routine injection of 80 mg of methylprednisolone acetate (Depo-Medrol) steroid medication in the foramen at the conclusion of the endoscopic discectomy has reduced the rates of dysesthesia significantly.

Avoidance of complications is enhanced by the ability to clearly visualize normal anatomy and pathoanatomy, the use of local anesthesia and conscious sedation rather than general or spinal anesthesia, and the use of a standardized needle placement protocol. The procedure is usually accomplished with the patient remaining comfortable during its entirety and should be done without the patient feeling severe pain except when expected, such as during evocative discography, annular fenestration, or when instruments are manipulated past the exiting nerve. Local anesthesia using 0.5% lidocaine allows generous use of this dilute anesthetic for pain control and still allows the patient to feel pain when the nerve root is manipulated. Thus, the awake and aware patient serves as the best indicator to avoid any nerve irritation/damage. Dural tears can be treated with a visualized blood patch or a hemostatic matrix such as Floseal (Baxter Healthcare) and observation because there is no dead space for cerebrospinal fluid collection or drainage.

Future Considerations

Perhaps the best future indication for the use of this technique and approach is in the realm of motion preservation (nucleus augmentation/replacement). A partial nuclectomy tract can be created and filled with one or more expandable hydrogel sticks to augment the degenerated nucleus. Alternatively, a complete endoscopic nuclectomy can be performed followed by insertion of a polymer to completely fill the nuclear cavity, redistribute the load across the disc space, and protect the anulus. Early companies focused on nucleus replacement completed pilot studies, but did not complete an IDE study. Interest in this technology has recently been rekindled.

Radical endoscopic discectomy with burring of the endplates and subsequent delivery of an interbody prosthesis with bone graft or bone morphogenetic protein can yield a truly minimally invasive interbody fusion, and early results of this technique are just starting to get reported. Transforaminal anatomy will limit the size of implant that can be delivered; this problem can be overcome by using expandable interbody or graft containment devices.

Future advances in the use of biomaterials and biologics may allow endoscopic annular reinforcement, tissue repair, tissue regeneration, anterior column stabilization by disc arthroplasty, and other alternatives to fusion for pain reduction. The future of spine surgery will most likely involve a mix of endoscopic and traditional open procedures. Studies comparing open and endoscopic procedures will have to be performed to determine which conditions will be best treated by minimally invasive procedures.

PEARLS

1. Initial proper placement of a needle or guide pin is critical to the entire procedure. Take the time to have best possible needle placement in both anteroposterior and lateral projections.
2. Use the inside-out technique when first adopting spinal endoscopy. Start the endoscopy by first entering the disc and then address the pathology accordingly. This is a safe starting point to avoid getting disoriented to your cannula position. Once you are within the disc, the herniation is between you and the affected nerve; this is advantageous because it protects the nerve from iatrogenic injury.
3. Fluoroscopy should be used to confirm location if there is any uncertainty about anatomy or location during endoscopy.
4. It is helpful to use the specially designed cannulas with a Penfield-like extension to retract and protect the exiting nerve when working in the foramen.

5. The patient is awake; thus, use this to your advantage! If significant leg pain is experienced, stop and reevaluate the patient; ask the patient about the distribution of the pain and reassess the position using fluoroscopy to prevent complications.
6. When bleeding is encountered, advance the scope back into the disc and slowly pull back the scope, cauterizing the bleeders when seen at the edge of the cannula.

PITFALLS

1. Make sure that the MRI and plain radiographs are numbered the same (i.e., look out for patients with transitional or six lumbar vertebrae).
2. Always visualize the action portion of your endoscopic tools to avoid dura or nerve injury. You want to clearly see the tissue you are grasping with the pituitary forceps, ablating with the bipolar radiofrequency probe, and firing the laser at.
3. It is recommended that the patient be *awake and alert* until the endoscope is within the disc space to avoid nerve injury. Avoiding excessive sedation before this point in the procedure is crucial, especially during needle insertion and dilator and cannula passage. We recommend against the use of a general anesthetic such as propofol.

KEY POINTS

1. PELD is a directly visualized surgical procedure and is not to be confused with the many nonvisualized percutaneous discectomy procedures for indirect disc decompression.
2. The surgeon can visually confirm that the traversing nerve root is adequately decompressed when removing an extruded paracentral herniation.
3. The literature shows that PELD is at least as safe and effective as traditional open posterior discectomy.

58 CHAPTER Interspinous Process Decompressive Devices

Clifford B. Tribus

Introduction

The interspinous process space has become a target for spinal implants to address degenerative conditions of the lumbar spine. The interspinous process decompression (IPD) devices employ a range of insertion techniques and materials but share the common goal of distraction to be maintained between the adjacent spinous processes to incur a clinical result. The variety of materials employed include titanium, polyetheretherketone, Silastic compounds, and allograft. Many of the implants are devised to be static in nature, while some employ dynamic techniques.[1,2] The clinical use of the Interspinous process space has continued to evolve. The indications have become less refined and the data mixed; leaving clinicians and payors less guidelines to follow.

The X-Stop (Medtronic International) is a titanium implant that was the first US Food and Drug Administration (FDA)-approved IPD device marketed in the United States, having been cleared by the FDA in November 2005 through an investigational device exemption (IDE) study. The indication for its use is spinal stenosis leading to neurogenic claudication. Medtronic recently chose to discontinue the marketing and sales of X-Stop. Coflex (Paradigm Spine LLC) received premarket approval in October of 2012 and Superion (VertiFlex Inc.) received premarket approval in May of 2015, both for similar indications.[3]

Many other IPD devices are marketed outside of the United States, including the following: Aperius (Medtronic), DIAM (Medtronic/Sofamor Danek), Wallis (Zimmer Spine), Viking (Sintea), Ellipse (Sintea), BacJac (Pioneer), ExtendSure (Nuvasiv), Promise, Rocker (Biomech), Helifix (Alphatec Spine), Biolig (Cousin Biotech), In-Space (Synthes), InSWing (Orthofix), I-MAXX (Maxx Spine), Flexus (GlobusMedical), and Spinos (Privelop).

Biomechanical studies of IPD devices have demonstrated the implants' ability to change forces in the disc and facet joints. These findings have led to diagnoses potentially helped by this technology, yet to be cleared by the FDA, as indications to include discogenic back pain, facet arthropathy, disc herniation, degenerative disc disease, and instability, including degenerative spondylolisthesis. Clinical studies differentiating these indications and guidance for utilization are lacking.

IPD devices all share characteristics that are relatively unique among spinal implants of the lumbar spine. They can be implanted with a modest degree of destruction to the local anatomy. Several do not require exposure of the neural elements, they are at least partially motion preserving, and they are relatively reversible. These features coalesce to an implant with a very favorable risk profile. It is up to randomized controlled studies to prove the efficacy, indications, and ultimately role in the armamentarium available to the spine surgeon in the care of the spinal patient.

The interspinous process space has also been exploited by a similar family of devices that were FDA approved as supplemental fusion devices: Affix (Nuvasiv), Aileron (LifeSpine), Aspen (Lanx), Axle (X-Spine), BacFuse (Pioneer Surgical), BridgePoint (Alphatec Spine), Inspan (SpineFrontier Inc.), PrimaLOK (OsteoMed), Octave (Life Spine), Spire (Medtronic/Sofamor Danek), SP-Fix (Globus), and Stabilink (Southern Spine). These devices have expanded the use of the interspinous spinal device but have a different surgical goal, which is fusion.

Design Rationale

Early criticisms of interspinous process decompression devices stem from the apparent kyphosing nature of the implant. It is indeed counterintuitive to apply posterior distraction to the lumbar spine. Yet, one need only look at the clinical presentation of a patient with lumbar spinal stenosis to appreciate the design rationale. A patient with lumbar stenosis typically walks with a forward stooped gate. Additionally, patients with spinal stenosis obtain symptom relief upon sitting down. The common feature in both of these postures is the relative flexion of the lumbar spine or avoidance of extension. Human beings are unable to segmentally kyphose their lumbar spine. Muscle insertions allow global motions of flexion and extension. However, spinal stenosis is often a focal phenomenon presenting with its worst clinical level at one or two lumbar segments. Therefore, the rationale of the device is to implant the interspinous process decompression device at the one or two levels where the stenosis is most severe. The implant then segmentally kyphoses the lumbar spine at the level of most severe stenosis and allows the rest of the lumbar spine to fall

into its natural posture of extension, having relieved the local stenosis.

An additional concept in the treatment of patients with lumbar spinal stenosis is how much nerve compression is clinically significant. While several studies have tried to elucidate this measurement, it appears to be an elusive number. Any clinician who has been involved in the care of the stenosis patient can appreciate the fact that for every octogenarian who presents with new-onset stenotic symptoms who has a spinal canal that is extraordinarily narrow, there is another patient who presents with similar symptoms in their 50s with magnetic resonance imaging (MRI) findings that are not nearly as impressive. With this variation in mind, it can be appreciated that spinal stenosis is a threshold disease. That is to say, the degree of tightness that elicits symptoms in any particular patient may in part be somewhat unique for that patient. Therefore, by extension, a device that can create additional room for the neural elements may only need to create enough room to get that patient to the other side of the threshold for symptoms. As surgeons, we may be a bit uncomfortable with this rationale, preferring to directly decompress the neural elements in their entirety and confirm this by direct visualization. This may represent overtreatment, however.

If we accept the concept of focal spinal stenosis causing symptoms at a particular threshold, then it must be shown that interspinous process decompressive devices can enact an effect on the canal diameter with acceptably minimal alterations to spine biomechanics. The majority of the current literature on this topic relates to the X-Stop interspinous process device. Whether this data can be extrapolated to other products in this category is up to the reader's discretion; however, these studies are presented as a design rationale for IPD devices.

The first reasonable question to pose in evaluating the design rationale of an IPD device is what is its net effect, on implantation, on the dimensions of the spinal canal. Richards et al.[4] attempted to address this question in studying eight cadaver specimens from L2–L5 that underwent MRI preimplantation and postimplantation of an X-Stop device at the L3–L4 level. Canal and foraminal dimensions were measured. The specimens were positioned and parameters measured in both 15 degrees of flexion and 15 degrees of extension. In extension, the canal area was increased by 18% when compared to the noninstrumented spine. Similarly, the subarticular diameter was increased by 50%, the canal diameter by 10%, the foraminal area by 25%, and the foraminal width by 41%.[4] In a subsequent in vivo study, Siddiqui et al.[5,6] presented results on 12 patients with 17 instrumented levels in which positional MRIs were obtained presurgery and postsurgery in the sitting flexed, sitting extended, and sitting neutral postures, as well as standing positions. The area for the dural sac increased from 77.8 to 93.4 mm at 6 months after surgery in the standing position. There was a similar increase in the foramina. It is important to note that no change in overall lumbar lordosis was observed.

These studies demonstrate the passive decompression obtained in placing an interspinous process decompression device. The question remains as to whether this degree of passive decompression is enough to be clinically relevant.

The other area of study as it relates to implantation of the interspinous process decompression device is the net effect on the kinematics and load sharing within the lumbar spine at both the instrumented level and the adjacent levels.[7] Swanson et al.[8] presented data on eight human cadaveric lumbar spines in which they tested intradiscal pressure preimplantation and postimplantation. The spines were positioned in flexion, neutral, and extension with intradiscal pressure transducers placed in the anterior and posterior aspect of the nucleus pulposus. The implants were placed at L3–L4 and the measurements of intradiscal pressure taken at L2–L3, L3–L4, and L4–L5. The device proved to be load sharing in both the extension and neutral positions. At L3–L4, which was the instrumented level, the authors measured a 63% decrease in pressure at the posterior anulus and a 41% decrease in pressure in the nucleus pulposus in extension. In the neutral position, the decrease in pressure was 38% in the posterior anulus and 20% in the nucleus pulposus. The adjacent levels did not show any significant change in intradiscal pressure.

Wiseman et al.[9] presented a similar study as it relates to facet loading. Pressure film was placed in the facets at the instrumented level, which was L3–L4, as well as the facets at L2–L3 and L4-L5. The film could then be measured for contact area, mean force, mean pressure, and peak pressure. At the implanted level, the contact area decreased by 47%, mean force decreased by 68%, mean pressure decreased by 39%, and peak pressure decreased by 55%. No changes of facet pressure were seen at adjacent levels. These mechanical studies provide the basis for the assumption that interspinous process decompression devices may be helpful in the clinical treatment of patients suffering from facet arthropathy or discogenic or degenerative disc–induced back pain. Yet, these are only biomechanical studies; the efficacy of IPD devices has not been shown clinically in these conditions.

The effect of the X-Stop IPD device on spinal kinematics was further measured by Lindsey et al.[10] Seven cadaveric specimens from L2–L5 were loaded in flexion, extension, axial rotation, and lateral bending to 7.5 Nm. There was a superimposed axial load of 700 N applied. Rigid markers were placed in each vertebral body as well as the supporting frame to measure the relative motion. Measurements were taken both preimplantation and postimplantation of an L3–L4 IPD device. There was no change in range of motion as measured in axial rotation or lateral bending. The intervertebral angle was changed by 1.9 degrees. An average of 7.6 degrees of extension at L3–L4 was reduced to 3.1 degrees after implantation of the device. Notably, the adjacent levels were not affected in flexion or extension with a device in place.

Two studies are presented to assess the question of kyphosis of the lumbar spine. Siddiqui et al., as referenced earlier, studied 12 patients with 17 implanted levels.[5-7] Comparing his postoperative to preoperative MRIs, the mean intervertebral angle changed less than 1 degree in extension. The overall mean lumbar lordosis changed 8 degrees in extension. Therefore, the change in overall lumbar lordosis was not statistically significant.[5–7] The mean intervertebral angle and mean lumbar lordosis were also measured in the pivotal study trial for FDA submission. This included 41 patients with data available

preoperatively and postoperatively. In the 23 patients receiving a single-level implant, the mean lumbar lordosis changed 0.1 degree in extension. In 18 patients who underwent double-level implants, the mean lumbar lordosis changed 1.2 degrees in extension.[11]

Surgical Technique

Surgical technique is variable depending on the implant used and surgeon preference. Placement of an IPD device may be performed in the outpatient setting. While the patient may be positioned prone, my preferred technique is to position the patient lateral, under general anesthesia, with the hips and knees flexed and taped in this position. The lumbar spine is forced into relative flexion to facilitate placement of the implant. The various devices are placed either as a primary decompression device or as a stabilization device after a direct surgical decompression. Fluoroscopy is used. Of note, the spinous processes may often be difficult to visualize, while the disc spaces are generally better delineated. The surgeon should watch for distraction of the appropriate disc space to confirm the surgical level. For the majority of the IPD devices, the implant should be positioned as far anterior as possible. Placement is planned and confirmed fluoroscopically.

Clinical Results

The X-Stop device was approved in 2005. Over the last decade, clinical studies have been reported comparing various interspinous devices to more traditional approaches. The data are evolving, as is the role for interspinous decompressive devices. The surgeon needs to be exacting in review of the literature. As alluded to earlier in this discussion, many of the IPD devices are placed with a simultaneous traditional open decompression (Wallis, Coflex) while others do not require direct neural decompression (X-Stop, Superion), relying on local distraction to provide a passive decompression. The implication is that the former are stabilization devices, with device efficacy difficult to distinguish from direct neural decompression versus lower surgical risk in the devices that obviate the need for direct decompression, though they do not permit the surgeon direct visualization of the neural elements. This latter technique may be viewed as an advantage because of decreased surgical risk or as a disadvantage because of the inability to visualize the neural elements. Clinical results of these latter devices, however, are easier to interpret.

Zucherman et al.[11] reported in 2005 on 191 age-matched patients enrolled in a prospective, randomized, multicenter study comparing X-Stop to controls. The 91 control patients consisted primarily of patients undergoing epidural steroid treatment. The 100 patients selected for the X-Stop had one (76 patients) or two (24 patients) implants placed. The levels instrumented were predominantly L3–L4 and L4–L5. Both study groups required symptoms to be refractory to 6 months of nonoperative care. The degree of stenosis could not exceed 50% of the normal canal diameter. All patients had to be older than 50 years, able to walk at least 50 feet, and obtain symptom relief with sitting. Outcomes were measured by the Zurich Claudication Questionnaire, Short-Form 36 questionnaire, and radiographic measurements. Results favored the instrumented group by showing statistically significant pain reduction and increase in physical function, which was obtained by 6 weeks' follow-up and maintained for the 2-year study period. Complications included incisional pain, hematoma, wound swelling, wound dehiscence, implant dislodgement, implant malposition, spinous process fracture, coronary ischemia, and respiratory distress.

Spinous process fracture warrants specific mention, as clinical outcomes are not always failures. The tip of the spinous process may fracture on insertion; yet, if the implant can still be positioned anterior to the fracture in a stable position, the outcome may still be good. If the fracture obviates stable intraoperative placement or the implant posteriorly displaces in the postoperative period, results may suffer but surprisingly not always or even routinely.

Anderson et al.[12] restudied a subgroup of 75 patients in the initial cohort who carried the additional diagnosis of grade 1 degenerative spondylolisthesis. This subgroup of patients similarly followed the index group by showing statistically significant pain reduction and increase in physical function obtained by 6 weeks' follow-up and maintained for the 2-year study period. Additionally, there was no increase in the degree of spondylolisthesis in the study group.

In a study with 13 years' follow-up, Senegas et al.[13] reported on 107 patients completing health questionnaires who were initially scheduled for decompression and fusion for canal stenosis, herniated nucleus pulposus, or both. They underwent decompression and stabilization with the Wallis device. Twenty patients had undergone revision fusion during the study period, while 80% of the patients reported good clinical results.

Verhoof et al.[14] reported on 12 patients treated with the X-Stop device for spinal stenosis in the setting of degenerative spondylolisthesis. The authors also showed no progression of the deformity. Four of their initial patients showed no improvement in symptoms, while eight patients showed complete resolution of their symptoms. Three of this latter group eventually developed recurrent symptoms for a failure rate of 58%.

Kondrashov et al.[15] presented further results of a subgroup of the initial cohort with 4 years' follow-up. A total of 77% of patients had experienced at least a 15-point improvement in their Oswestry Disability Index, which was maintained at the 4-year postoperative follow-up.

More recently, Stromqvist[16] presented 100 patients randomized in a prospective controlled study comparing 50 patients treated with the X-Stop and 50 patients undergoing traditional decompressive surgery. Both groups enjoyed significant clinical improvement as measured by the Zurich Claudication Questionnaire (ZCQ), the Visual Analog Scale and the Short-Form 36 questionnaire, which could not be distinguished at any time period to 2 years postoperatively. However, the X-Stop group had a 26% reoperation rate, while the decompressive group had a 6% reoperation rate.

The Superion IPD device recently obtained FDA approval. The FDA-IDE pivotal trial data were presented by Patel et al.[17] A total of 391 patients were randomized between the X-Stop and Superion. Noninferiority was demonstrated. With the ZCQ being the primary outcomes instrument, leg pain clinical success was 76% and 77% with Superion and X-Stop, respectively, at 2 years. Back pain clinical success was 67% and 68%, respectively. Patients' self-ratings of their treatment were "satisfied" or "somewhat satisfied" in 86% for the Superion group and 89% of the X-Stop group at 2 years. A total of 83% of the Superion group and 84% of the X-Stop reported that they would undergo the same treatment again. Reoperation rates were 23% for the Superion group and 19% the X-Stop group, primarily for inadequate pain relief or return of symptoms.[17]

In 2011, Wooter et al.[18] reported a meta-analysis on the effectiveness of IPD surgery in claudicant patients. Eleven studies were analyzed with combined databases on ZCQ questionnaires favoring IPD treatment over nonoperative care. The authors warned of "relatively soft" data and high costs.

Moojen[19] then reported in 2013 on a randomized controlled trial of IPD devices versus conventional decompressive surgery. At 1 year, there was no difference in ZCQ disability, yet the reoperation rate of 29% in the IPD group was substantially higher than the conventional decompression group (6%).

Then, 1 year later, the same research group reported on the cost-effectiveness of the IPD devices utilizing quality-adjusted life years and societal costs, concluding that IPD devices are highly unlikely to be cost-effective in the surgical treatment of lumbar spinal stenosis compared to conventional decompression.[20]

In a more favorable review, Gazzeri et al.[21] reported on a multicenter study of 1108 patients who underwent placement of one or two IPD devices in the lumbar spine for stenosis. A total of 8 different implants were represented with a variety of clinical indications. At 2 years' follow-up, 76.2% were very satisfied with their clinical result, 12.5% were somewhat satisfied, and 11.2% were not satisfied. The reoperation rate was 9.6%, with a mean follow-up of 44.8 months. Chief reasons for reoperation were implant dislocation (20 cases), no improvement (18 cases), spinous process fracture, overdistraction (27 cases), and/or recurrent symptoms after initial improvement (42 cases).

Summary

The interspinous process space is an appealing surgical target. The exposure is minimally destructive; therefore, the risk profile is relatively low. Broad clinical outcomes data from the various devices are evolving. Additionally, clinical outcomes data comparing interspinous process devices to more traditional surgical approaches are also lacking. The challenging subgroup of stenosis patients with concomitant degenerative spondylolisthesis or degenerative scoliosis needs to be vetted. These patients may benefit from IPD devices, as their insertion does not destabilize the spine and they perhaps offer a fusion alternative. Yet, while recent studies have shown clinical outcomes using IPD devices to be comparable to traditional decompressive surgery, surgeons sometimes are reluctant to use them because of higher cost and higher revision rates. Outcome studies for specific diagnoses and surgeon opinion, as well as reimbursement, will ultimately define their relative role in the armamentarium of surgical procedures utilized in the care of the stenosis patient.

PEARLS

1. Mark the planned incision with the patient upright.
2. Position the patient in maximum flexion.
3. Use disc space as a reference for confirming the surgical level.

PITFALLS

1. Avoid violating the supraspinous ligament (X-Stop).
2. Avoid overdistraction.
3. Assure anterior placement of the implant.

KEY POINTS

1. IPD devices are motion-preserving devices utilized in the treatment of spinal stenosis and neurogenic claudication.
2. Clinical results for IPD devices are less predictable than traditional surgical approaches but they have a favorable risk profile, especially when compared to decompression and fusion cases.

CHAPTER 59

Minimally Invasive Cervical Spine Techniques

SECTION VII

Scott I. Lee
Vinko Zlomislic

Introduction

Minimally invasive surgical techniques have gained increasing popularity, particularly for lumbar spine applications. While there is no strict definition of a minimally invasive technique, the proposed hallmarks include smaller incisions, muscle-splitting rather than muscle stripping, limiting soft tissue damage, and variable soft tissue retraction for visualization. Lumbar spine applications include tubular retractors for decompression and interbody fusions and percutaneous methods for posterior instrumentation.[1] Such techniques propose to reduce approach-related soft tissue injury associated with traditional open procedures. Subperiosteal muscle dissection and soft tissue retraction time and pressure have been shown to induce muscle edema and subsequent muscle necrosis.[2] This undoubtedly has an effect on a patient's pain, analgesic requirement, and functional recovery. Proponents of minimally invasive techniques point to early, albeit growing, evidence that these techniques result in less postoperative pain, decreased hospital length of stay, decreased blood loss, fewer surgical site infections, and a quicker return to function.[3]

Traditional open cervical spine techniques are well established with good clinical outcomes and relatively low complication rates. This brings into question whether there is even a role for minimally invasive techniques in the cervical spine. Approach-related morbidity in the cervical spine, while low, still leaves room for improvement. For example, the incidence of dysphagia following cervical surgery has been quoted to be as high as 71%.[4] While postoperative dysphagia is likely multifactorial in nature, retraction time and pressure have been proposed as contributing factors.[4,5] Furthermore, posterior cervical approaches are well known to cause significant postoperative pain and higher analgesic requirements due to muscle stripping and injury.[6] Furthermore, disruption of the posterior musculature and bony-ligamentous posterior tension band have been linked to instability and progressive kyphotic deformity.[7] In an analysis of Medicare trends, the adjusted rates of cervical spine fusions rose 206% from 1992 to 2005.[8] This increase in cervical spine surgery is partially related to a growing elderly population and resultant increase in cervical degenerative pathology amenable to surgical intervention. If minimally invasive techniques can reduce approach-related morbidity and subsequently improve patient recovery and outcomes, there certainly is a growing patient population that may benefit from these techniques.

This chapter describes approaches and applications of minimally invasive techniques for the cervical spine while highlighting existing evidence for their role in modern spine surgery.

Anterior Cervical Minimally Invasive Applications

Anterior cervical discectomy and fusion (ACDF) has long been the standard operation for cervical disc herniations that cause spinal cord and/or symptomatic root compression. While clinical outcomes are often excellent, ACDF still has its issues. Implant-related irritation, loss of segmental motion leading to adjacent-segment disease, pseudarthrosis, and the direct cost of surgical implants are just some of the issues with ACDF.[9,10] These issues have led to the development of minimally invasive anterior cervical techniques that may limit some of the downsides associated with ACDF while maximizing the benefits of anterior-based approaches (e.g., direct access to disc herniation for neural decompression, avoidance of paraspinal muscle dissection and associated patient discomfort). The following techniques will be highlighted: endoscopic anterior discectomy and cervical microendoscopic discectomy and fusion (CMEDF).

Endoscopic Anterior Discectomy

Indications and Contraindications

Endoscopic anterior discectomy (EAD) has been described for the treatment of unilateral cervical disc herniations and/or spondylotic osteophytes causing symptomatic unilateral radiculopathy. EAD does not require fusion and is a motion-sparing operation, as it avoids a complete discectomy, only

targets symptomatic areas of unilateral foraminal stenosis, and does not disrupt the posterior bony/ligamentous tension band. Contraindications to this technique include cervical myelopathy or severe cervical spinal stenosis, large disc herniations (particularly central, requiring near-complete discectomy), bilateral radiculopathy, preexisting cervical instability or fracture, calcified disc herniations, axial neck pain, and significant anterior cervical soft tissue scarring (e.g., prior surgery, radiation, tracheostomy).

Clinical Evaluation

History should focus on the location and quality of unilateral radicular complaints while simultaneously ruling out other potential etiologies for pain. Patients should complete a recommended course of conservative management (e.g., activity modification, physical therapy, medication, injections) prior to consideration for surgical intervention. A thorough neurologic examination should also ensure that there are no signs of myelopathy. Imaging evaluation should include radiographs (anteroposterior, lateral, flexion-extension) to ensure no cervical fracture or instability. Noncontrast magnetic resonance imaging (MRI) is essential to visualize the location and size of disc herniation, location and size of uncovertebral osteophytes, caliber of the spinal canal, presence or absence of myelomalacia, as well as any aberrant vertebral artery anatomy. A noncontrast computed tomography (CT) scan can also help further delineate bony anatomy.

Surgical Technique

The patient is positioned supine under general anesthesia. The arms are positioned at the side. A towel roll can be placed between the scapulae to aid cervical extension with or without use of Mayfield clamps. The cervical vertebrae and discs are palpated in the interval between the esophagus/trachea and sternocleidomastoid on the side of symptomatic nerve root compression. Skin markings and use of anteroposterior and lateral fluoroscopy can help aid localization toward the indicated disc level. A 5-mm skin incision is made to allow blunt dissection down to the platysma. A small transverse incision is made in the platysma to allow eventual passage of an initial blunt, thin dilator. With use of an index finger, bluntly sweep subplatysmal structures away through finger dissection. Care should be taken to palpate the trachea, larynx, carotid artery, and the desired cervical disc. Insert the initial blunt dilator to open the prevertebral fascia and sequentially dilate up. Fluoroscopy should confirm docking on the appropriate disc space in anteroposterior and lateral planes. The following represents the transuncal approach described by Jho in 1996[11] and Saringer and colleagues in 2003.[12] The longus colli is retracted to expose the disc space and lower vertebrae. The endoscope is then inserted (Figs. 59.1 and 59.2). While maintaining visualization and continuous irrigation with 0.9% saline, a 2-mm, high-speed burr is used to remove a thin cortical portion of the uncinate process. Maintain a thin lateral wall, as this will help to protect the vertebral artery, as well as a thin dorsal edge to protect the exiting nerve root. Alternating use of curettes and a Kerrison rongeur under endoscopic visualization will allow safe removal of disc material until visualization of the posterior longitudinal ligament. Care is taken to remove all herniated disc material using microsurgical instruments under endoscopic visualization. Complete the foraminotomy while ensuring protection of the exiting nerve root. Bipolar electrocautery and Gelfoam can help achieve hemostasis. The endoscope and outer sheaths are removed under direct visualization. The wound is closed in standard fashion without a drain. A soft collar can be used for the first 2 weeks to allow wound healing, after which the brace can be worn for comfort.

FIG. 59.1 Example of endoscopic anterior cervical discectomy instrumentation, consisting of an optic in an oval sheath with adjacent inserted rongeur.

Clinical Outcomes and Published Studies

Published clinical studies have shown encouraging results. Saringer et al. reported a series of 16 patients treated with EAD and reported overall good results with 87.6% satisfaction rate, reduction in neck disability index score, and 96% reduction in visual analog scale score for radicular pain.[12] Ruetten et al. designed a prospective randomized controlled trial comparing ACDF versus EAD.[13] The study reports no intraoperative complications, no significant difference in incidence of postoperative dysphagia, and significantly reduced operative time favoring EAD (32 minutes versus 62 minutes). Over the 2-year follow-up, clinical outcomes were noted to be "good" with similar low rates of revision surgery for persistent radicular arm pain (7.4% in the EAD group revised to ACDF, 6.1% in ACDF group revised with posterior laminoforaminotomy). Radiographic examination revealed no spontaneous fusion or adjacent-segment degeneration. However, 25% of the EAD patients developed degeneration

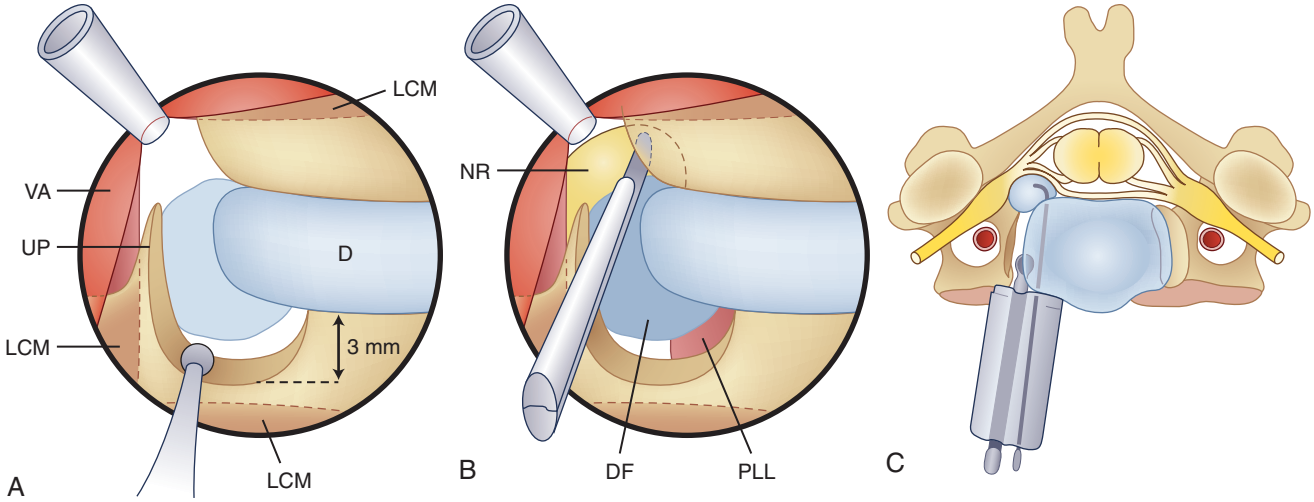

FIG. 59.2 Endoscopic anterior cervical discectomy technique for cervical disc herniation. (A) The medial edge of the longus colli muscle (LCM) is exposed in standard fashion, allowing visualization of the uncinate process (UP) and lateral edge of the intervertebral disc (D). The UP is drilled, leaving a thin edge as a landmark and to protect the adjacent vertebral artery (VA). (B) Fibrous annular disc material between the tip of the UP and caudal endplate is removed, allowing exposure of the underlying disc fragment (DF), nerve root (NR), and a portion of the posterior longitudinal ligament (PLL). (C) Maintaining constant visualization, a 1- or 2-mm Kerrison rongeur is used to remove disc fragments as well as the dorsolateral disc osteophyte complex from the nerve root.

of the operative disc level. In a retrospective study, Yang et al. examined 97 patients who had undergone a modified EAD.[14] The study reports 81% excellent results over an average of 4-year follow-up with no reported complications or cervical instability.

In these limited studies, the technique appears to be safe with good clinical outcomes and relief of radicular complaints on par with ACDF. However, one cannot ignore the strict indications for this technique as well as the potential for accelerated disc degeneration at the operative level, as observed by Ruetten et al.[13] The 25% incidence of disc degeneration in the 2-year study far exceeds the quoted rates of symptomatic disc degeneration (1.6–4.2% per year) following arthrodesis in the cervical spine.[10] EAD is a technique that appears to have clinical value but requires further clinical studies to ascertain its true benefit and complication rate.

Cervical Microendoscopic Discectomy and Fusion

Indications and Contraindications

CMEDF is indicated for symptomatic cervical spinal cord and/or nerve root compression from herniated disc material, osteophytes, spondylosis, congenital canal stenosis, and dynamic instability. CMEDF utilizes a similar approach as EAD. However, in contrast to EAD, the addition of a complete discectomy and placement of an interbody device for fusion opens up the indications to include patients with cervical myelopathy, large central disc herniations, bilateral radiculopathy, preexisting cervical instability or fracture, and axial neck pain. Contraindications include significant anterior cervical soft tissue scarring (e.g., prior surgery, radiation, tracheostomy), aberrant anatomy, retrovertebral stenosis, and multiple levels of symptomatic neurologic compression.

Clinical Evaluation

History should focus on the location and quality of unilateral radicular complaints while simultaneously ruling out other potential etiologies for pain. Patients should complete a recommended course of conservative management (e.g., activity modification, physical therapy, medication, injections) prior to consideration for surgical intervention unless the patient exhibits symptoms and signs of myelopathy. A thorough neurologic history and examination should be performed, with particular emphasis placed on motor strength, sensory function, balance, reflexes, and bowel/bladder function. Imaging evaluation should include radiographs (anteroposterior, lateral, flexion-extension) to ensure no cervical fracture or instability. Noncontrast MRI is essential to visualize the location and size of disc herniation, location, and size of uncovertebral osteophytes, caliber of the spinal canal, presence or absence of myelomalacia, and any aberrant vertebral artery anatomy. Noncontrast CT scan can also help further delineate bony anatomy.

Surgical Technique

Surgical setup and general concepts are very similar to that described for EAD (see earlier section). This section highlights key differences between EAD and CMEDF. A 2-cm transverse incision over the appropriate disc level affords sufficient exposure with eventual aid of the tubular retractor. Incise the

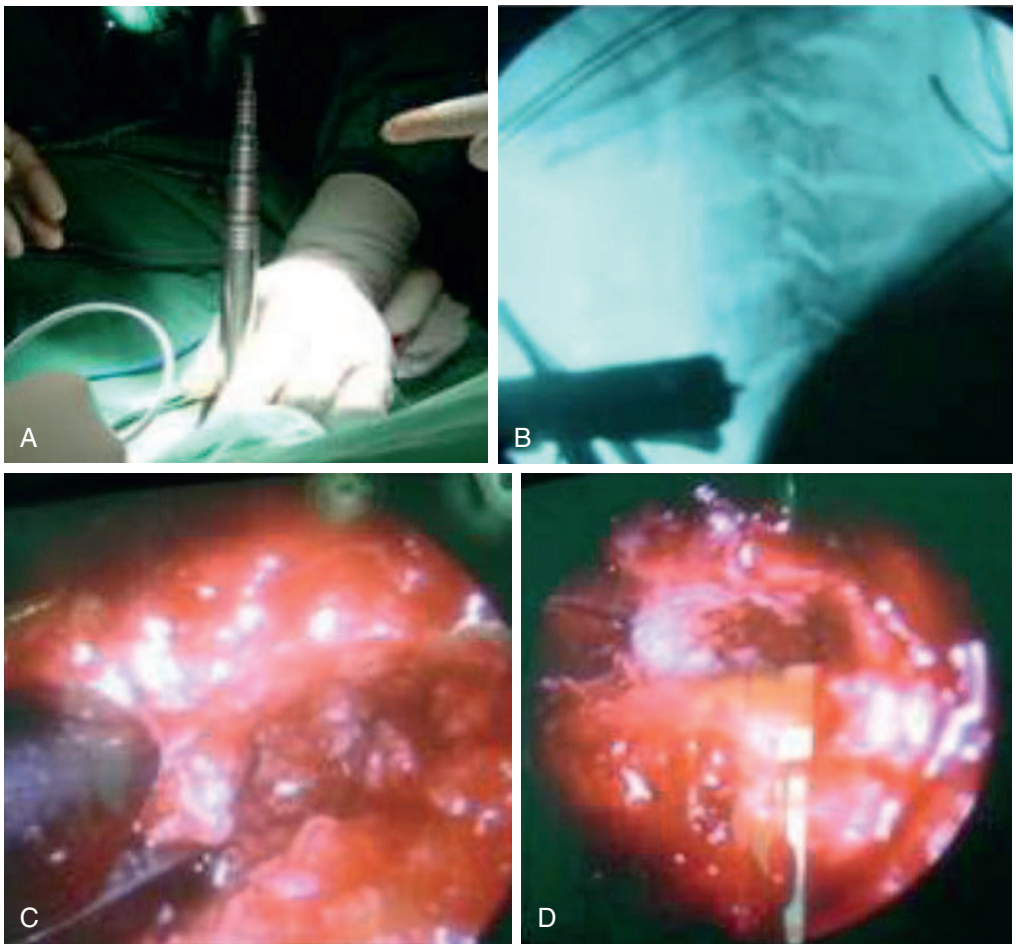

FIG. 59.3 Intraoperative endoscopic views. (A) Sequential placement of endoscopic dilators between strap muscles and esophagus medially and carotid sheath laterally. (B) Fluoroscopic imaging to confirm appropriate retractor positioning and level. (C) Begin discectomy with removal of anterior osteophytes immediately adjacent to the disc space. (D) Endoscopic view upon completion of discectomy with placement of graft.

platysma and bluntly dissect through subplatysmal structures to localize the trachea, esophagus, carotid sheath, and desired disc space. Endoscopic dilators are sequentially placed under fluoroscopic guidance. The final dilator is replaced with a tubular retractor that is secured to the operating table (Fig. 59.3). Subtle adjustments in angulation, tension, and placement of the retractor, as well as use of a mobile window, can help aid visualization of the appropriate disc space(s) while limiting soft tissue tension. After obtaining fluoroscopic images confirming that the retractor is docked at the correct disc level, remove the dilators and begin endoscopic discectomy (see Fig. 59.3). All steps for discectomy, endplate preparation, and interbody graft placement are similar to a standard open procedure. Manual cervical traction or sequential dilation of the disc space with osteotomes can help aid discectomy and interbody graft placement (Fig. 59.4). Published studies of this technique have not used an anterior cervical plate.[1,15,16] After obtaining appropriate hemostasis, the wound is closed in standard fashion without a drain. The patient is placed in a hard cervical collar for 4 to 8 weeks.

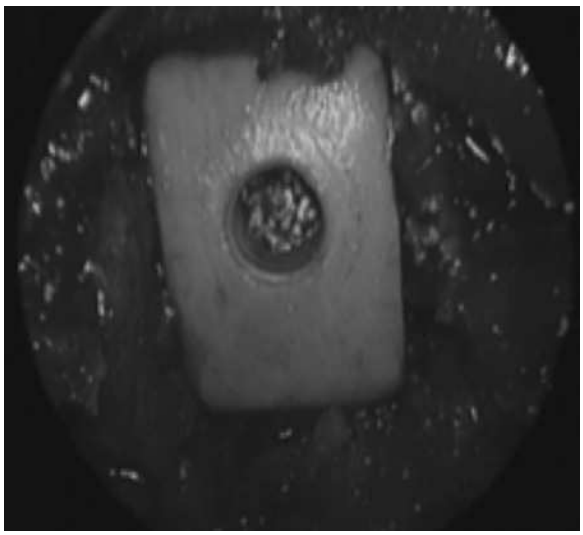

FIG. 59.4 Endoscopic image after graft placement.

Clinical Outcomes and Published Studies

In 2008, Tan et al. reported their short-term results of CMEDF in 36 patients: no intraoperative complications, no dysphagia, and significant improvement in Japanese Orthopaedic Association and visual analog scale scores over a mean 38-month follow-up.[15] While there was one postoperative hematoma, the study noted overall good clinical results and improved cosmesis. Yao et al. reported 5-year follow-up results of 67 patients who underwent CMEDF with carbon fiber interbody graft augmented with iliac crest bone graft.[1] In keeping with other studies, the technique was associated with good to excellent clinical results, with minimal blood loss, no intraoperative complications, and no persistent dysphagia. Furthermore, 91.1% of patients achieved radiographic fusion by 6 months. There was a 6% incidence of cage subsidence and the remaining patients either achieved radiographic fusion after 6 months or were noted to have asymptomatic pseudarthrosis. Only one patient required adjacent-segment ACDF for symptomatic disc herniation at 6 years postoperatively. Soliman reported results of a blinded randomized controlled trial comparing ACDF to CMEDF.[16] Both techniques were without anterior cervical plating and resulted in 91% good to excellent results in both groups. The study noted a significant reduction in average length of hospital stay (47 hours for ACDF, 26 hours for CMEDF), decreased self-reported rates of dysphagia, and decreased analgesic requirement favoring the CMEDF group. At 1 year, all patients had achieved fusion except for one asymptomatic pseudarthrosis in the CMEDF group.

CMEDF appears to be a viable option, with clinical and radiographic results in published studies that match those of ACDF. The purported benefits of cosmesis, reduced hospital stay, reduced pain, and reduced dysphagia are encouraging and require additional study to ascertain if these are true benefits over traditional ACDF.

Posterior Cervical Minimally Invasive Applications

Posterior-based techniques are attractive, as they can address neurologic compression while avoiding anterior structures (e.g., trachea, esophagus, vertebral artery, recurrent laryngeal nerve) and potentially preserving cervical motion. Posterior cervical laminoforaminotomy, first described by Spurling and Scoville[17] in 1944, has been shown to produce favorable results in treating cervical radiculopathy.[18] However, approach-related morbidity can make open posterior techniques less attractive due to considerable muscle injury, pain and spasms, and potential instability and progressive sagittal deformity due to disruption of the posterior tension band.[7,19] Preoperative sagittal alignment and the amount of operative muscular dissection and bony resection increase the risk of developing postoperative cervical kyphosis.[7,20] Concerns regarding postoperative kyphosis may prompt the addition of posterior instrumented fusion or a reconsideration of performing an anterior-based procedure. Supplementation with posterior instrumentation increases operative time, blood loss, potential risks to the patient, and pain and rehabilitation. Minimally invasive posterior cervical techniques may prove advantageous by limiting the extent of muscle dissection and minimizing the risk of postoperative instability. The following techniques will be highlighted: minimally invasive cervical laminoforaminotomy, minimally invasive posterior cervical discectomy, and minimally invasive lateral mass fixation.

Minimally Invasive Cervical Laminoforaminotomy

Indications and Contraindications

Minimally invasive cervical laminoforaminotomy is indicated for the treatment of cervical radiculopathy resulting from soft lateral disc herniation and/or foraminal stenosis. It can be performed for single- or multilevel disease and can be an effective treatment for patients with recurrent radicular symptoms following ACDF. Cases of bilateral same-level radiculopathy and/or foraminal stenosis from uncinate spurs may achieve better neurologic decompression from an anterior-based approach. Central disc herniations are not amenable to this technique due to the unsafe spinal cord retraction that would be required to access the disc space and herniated material. Other contraindications to minimally invasive cervical laminoforaminotomy include patients with cervical kyphosis, fracture or instability, axial neck pain, and severe central or retrovertebral stenosis with or without myelomalacia. Patients with these characteristics are likely better candidates for an anterior-based approach.

Clinical Evaluation

A thorough history and physical examination will localize the involved cervical nerve root(s) while also screening for cervical myelopathy. The patient should also be screened for axial neck pain and other sources of arm/shoulder pain. Radiographic examination should include anteroposterior, lateral, and flexion-extension views to evaluate for fracture and instability. A noncontrast MRI is essential to localize compressive pathology and evaluate the health of the cervical spine. The MRI should also be studied for any aberrant vertebral artery anatomy. A noncontrast CT scan can be helpful to further delineate bony anatomy but is not absolutely necessary for most cases. Prior to surgical intervention, the patient should undergo appropriate conservative treatment measures consisting of activity modification, medications, physical therapy, and injections.

Surgical Technique

After induction with general endotracheal anesthesia, the patient is placed in the prone position. The head can either be secured with use of Mayfield clamps or can be positioned on a well-padded headrest. Take care to ensure that there is no pressure on bony prominences or the eyes and that the

FIG. 59.5 A K-wire is advanced through posterior cervical musculature under fluoroscopic guidance and docked at the inferomedial edge of the cephalad lateral mass of the desired level.

FIG. 59.6 Intraoperative fluoroscopic image demonstrating positioning of working retractor with a Penfield elevator positioned on the dorsal anulus following safe removal of a herniated disc ventral to the nerve root.

endotracheal tube is secure. Slight flexion through the cervical spine and a military chin tuck can aid exposure.

With aid of posteroanterior fluoroscopic images, mark the skin in line with the location and orientation of the lateral masses and facet joints of the side of the proposed operation. Under lateral fluoroscopic views, mark the skin over the desired cervical segment(s), taking into account the trajectory of the lateral masses and laminae. The skin markings and subsequent incision will be 5 to 15 mm off of midline ipsilateral to and at the target level. If planning to decompress multiple levels, the incision can be made midway between the two desired levels. After making a stab incision, bluntly dissect through subcutaneous tissue. Using lateral fluoroscopic guidance, slowly advance a Kirschner wire (K-wire) through posterior musculature and dock at the inferomedial edge of the desired lateral mass (Fig. 59.5). Extend the stab incision approximately 1 cm cephalad and caudad to the K-wire. Dissect through the cervical fascia with monopolar electrocautery. Place the tubular dilators over the K-wire to serially dilate down to the desired cervical level. After confirming the correct level with a lateral fluoroscopic image, secure the tubular retractor to the table.

Alternatively, the procedure can be performed through a midline posterior incision centered over the spinous process(es) of the desired level(s). Incise through the underlying fascia 4 to 6 mm off of the midline. For bilateral procedures, make two separate fascial incisions to each side of the midline. Use finger dissection to bluntly dissect the paraspinal musculature until palpation of the facet joint. Introduce the smallest dilator and confirm the level with a lateral fluoroscopic image. After serially dilating, secure the tubular retractor to the table.

Decompression can be performed under loupe magnification, microscope magnification, or with use of an endoscope. Bipolar electrocautery can help remove any residual soft tissue overlying the desired lateral mass and facet. The ligamentum flavum is detached from the inferior edge of the lamina with use of a straight curette. Identify the medial edge of the facet as it joins into the lamina. This will help avoid over-resection of the facet articulation that could lead to iatrogenic instability and degeneration. Use Kerrison rongeurs and/or a high-speed burr to begin the laminotomy. Removal of the dorsolateral portion of the lamina as well as the medial border of the inferior articular facet will allow visualization of the exiting nerve root. Angled curettes can help dissect a safe tissue plane out laterally into the foramen. Bipolar electrocautery can help aid dissection, particularly of any overlying venous plexus. Straight or angled Kerrison rongeurs can complete the decompression of the foramen and exiting nerve root. When a Woodson elevator can be freely passed over the nerve root to the lateral pedicle border, the nerve root has been adequately decompressed in the foramen. Ensure that the nerve root has no additional ventral compression on imaging and with direct palpation ventral to the nerve with a Woodson elevator or small, angled curette (Fig. 59.6). If there is herniated disc material, the nerve root can be gently retracted medially to allow visualization of the disc space. If visualization is limited by bony anatomy, use a high-speed burr or Kerrison rongeurs to resect additional lamina and the superomedial pedicle to allow safe removal of herniated disc material with use of curettes and pituitary rongeurs. If there are additional levels for decompression, the tubular retractor can be angled and translated utilizing a mobile window for visualization. After manipulation of the retractor, be sure to confirm the level with a lateral fluoroscopic image. After irrigation and appropriate hemostasis, the incision is closed in standard fashion without a drain. A soft collar can be used for the first 1 to 2 weeks to allow wound healing, following which it can be discontinued.

Clinical Outcomes and Published Studies

Fessler et al. first reported their initial clinical experience in treating 25 patients with minimally invasive cervical laminoforaminotomy in 2002.[21] Clinical outcomes were equivalent to open posterior laminoforaminotomy with the added benefits of decreased blood loss, shorter postoperative stays (20 vs. 68 hours) and reduced narcotic requirements. These initial short-term benefits have been confirmed by multiple other studies including a randomized controlled trial comparing open posterior laminoforaminotomy versus tubular retractor assisted cervical laminoforaminotomy and discectomy.[6] In a recent systematic review, Clark et al.[22] reported 19 studies comparing minimally invasive cervical laminoforaminotomy to open posterior decompression for cervical radiculopathy. Across these studies, the minimally invasive procedure was found to have decreased blood loss (52.8 vs. 173.5 mL), a shorter surgical time (58 vs. 108 minutes), less inpatient analgesic use (2.5 vs. 27.6 Eq), and a shorter hospital stay (1.0 vs. 3.2 days). Symptom relief following minimally invasive cervical laminoforaminotomy across the literature is between 87% and 97%.[18] The advantages of the minimally invasive approach appear to be long-lasting. Lawton et al. reported on the long-term outcomes of minimally invasive cervical laminoforaminotomy with up to 6-year follow-up data showing persistence of patient satisfaction, low neck disability index scores, and low visual analog scale for both neck and arm.[23]

Currently, ACDF remains the most-common operation for cervical radiculopathy. However, minimally invasive cervical laminoforaminotomy compares favorably to ACDF. Ruetten et al.[13] reported a prospective randomized trial comparing 175 patients randomly assigned to ACDF versus full-endoscopic posterior cervical laminoforaminotomy. In 2-year follow-up, clinical results were similar in both groups with 87.4% of patients reporting complete relief of arm pain and 9.2% with occasional arm pain. The minimally invasive group had a 3.4% recurrence rate which was similar to the ACDF group and comparable to other published data.

Minimally invasive posterior cervical laminoforamintomy appears to be clinically efficacious when used for the correct indications. However, it is still a posterior-based approach. As such, concerns remain for the development of neck pain, instability, and adjacent-segment degeneration due to potential iatrogenic violation of the bony and ligamentous posterior tension band without an adjunct instrumented fusion for support. In a retrospective review of 303 patients following posterior cervical laminoforaminotomy, Clarke et al. found the annual rate of developing same-segment or adjacent-segment pathology to be 0.7%.[24] This is similar to published data in regard to ACDF; the risk of developing clinically significant adjacent-segment pathology following ACDF is 1.6% to 4.2% per year.[10] In regard to neck pain, Steinberg et al. found no difference in the postoperative neck pain visual analog scale or neck disability index scores of patients undergoing minimally invasive cervical laminoforaminotomy and ACDF.[25] Such data suggest that the minimally invasive approach helps preserve the posterior tension band, preventing the need for secondary fusion. However, if there is clinically significant neck pain, instability, and/or recurrent radicular symptoms following minimally invasive cervical laminoforaminotomy, ACDF is a potential treatment option. Skovrlj et al.[18] examined a prospective cohort of 70 patients following minimally invasive cervical laminoforaminotomy; 7.1% of patients required ACDF at a mean of 55 months from the index procedure either at the index level or adjacent level for symptomatic disc pathology. This incidence of revision following minimally invasive cervical laminoforaminotomy is lower than quoted rates for revision following ACDF. A meta-analysis of class I US Food and Drug Administration trials for ACDF reported a 9.8% reoperation rate due to pseudarthrosis, adjacent-level disease, and recurrent radicular symptoms following ACDF.[26]

Multiple studies describe an initial learning period with this technique. Complication rates are low, with studies citing rates from 1.1% to 9% and include durotomy and radicular injury secondary to root manipulation.[21,23,27,28] Minimally invasive cervical laminoforaminotomy is an evolving surgical technique with good clinical outcomes. Given that much of the concerns with open, posterior-based approaches is centered on soft tissue disruption, this is an ideal clinical scenario to apply this minimally invasive technique.

Minimally Invasive Lateral Mass Fixation

Indications and Contraindications

Lateral mass screws can be placed using minimally invasive techniques in most clinical scenarios that require posterior cervical instrumented fusion. It can be combined with minimally invasive cervical laminoforaminotomy and discectomy if neurologic decompression is required. It is also an excellent option when decompression is not necessary and the patient requires only supplemental fixation and stability (e.g., prior multilevel anterior corpectomy). This technique is contraindicated in patients with lateral mass fracture, small or absent lateral mass, or abnormal vertebral artery anatomy.

Surgical Technique

After induction with general endotracheal anesthesia, the patient is placed in the prone position. The head can either be secured with use of Mayfield clamps or can be positioned on a well-padded headrest. Take care to ensure that there is no pressure on bony prominences or the eyes and that the endotracheal tube is secure. Slight flexion through the cervical spine and a military chin tuck can aid exposure.

The procedure is performed through a midline posterior incision centered over the spinous process(es) of the desired level(s). Fluoroscopy can help localize the incision. Incise through the underlying fascia 4 to 6 mm off of the midline bilaterally. Use finger dissection to bluntly dissect the paraspinal musculature until palpation of the facet joint. Take care not to dissect past the lateral border of the lateral mass, as this is unnecessary muscle dissection that can lead to significant bleeding. Introduce the smallest dilator and confirm the level with a lateral fluoroscopic image. The dilators should be placed

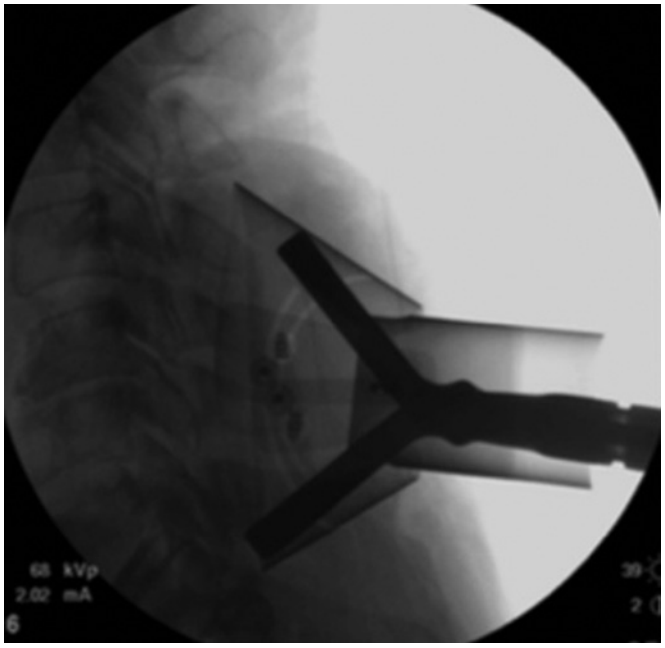

FIG. 59.7 Intraoperative fluoroscopic image demonstrating expansion of a deployed rivet retractor to allow deep exposure over multiple levels. It is necessary to use fluoroscopy during expansion to ensure that retraction remains seated over the intended surgical levels.

with a 15-degree cephalad angulation to help facilitate proper trajectory for screw placement. After serially dilating, secure the tubular retractor to the table, ensuring proper trajectory. Obtain a lateral fluoroscopic image to confirm docking at the desired level. A sliding rivet retractor can also help with visualization of multiple levels (Fig. 59.7). Use bipolar electrocautery and pituitary rongeurs to clear off the lateral mass to enable complete visualization of the medial, lateral, cephalad, and caudad borders (Fig. 59.8). Take care not to violate the facet articulations of segments not included in the fusion construct.

Placement of lateral mass instrumentation is in standard fashion as open techniques. Preoperative templating on MRI and CT scan is invaluable in determining drill/screw length and trajectory. Use a drill with a preset drill depth (8–14 mm) to avoid blowing out the lateral mass and subsequently risking injury to neurovascular structures. The starting point is in the center of the lateral mass relative to the cephalad-caudad borders and 1 mm medial to the center of the lateral mass relative to the medial-lateral borders. The drill should be angled approximately 15 to 20 degrees cephalad to match the trajectory of the lateral mass. It should also be angled 25 to 30 degrees lateral to avoid injury to the superior facet articulation, exiting nerve root, and the vertebral artery. The drill hole is then checked with a ball-tip feeler to ensure no cortical wall breech. Trajectory and length can also be checked on lateral fluoroscopic imaging. The hole is then tapped prior to placement of a 3.5-mm polyaxial screw. For each additional level, the retractor should be translated to ensure appropriate visualization of bony anatomy. Confirm on lateral fluoroscopic image that the retractor is well seated on the posterior aspect of the desired lateral mass and the trajectory has not changed. Once lateral mass screws are secured, the exposed posterior cortical surfaces and facet articulations are decorticated with a high-speed burr. Local bone autograft, iliac crest bone autograft, and allograft can be packed onto the decorticated surfaces prior to placement of an appropriately lordosed rod. After the rod is secured into place, the tubular retractor is slowly removed while maintaining visualization to ensure appropriate hemostasis. The wound is closed in standard fashion without a drain. The patient is then placed in a hard cervical collar.

Clinical Outcomes and Published Studies

Lateral mass screw fixation has been shown to be safe and effective in promoting stability and fusion in large patient studies.[29,30] While there are very few clinical studies examining the minimally invasive technique, the available data indicate that the technique enables safe placement of instrumentation while minimizing violation of the posterior musculature and ligaments.[31] In a retrospective analysis, Wang et al. noted no intraoperative complications, bony fusion in all cases, and no aberrant screw placement, as confirmed by CT scan.[31] The study did note that two patients had to be converted to an open procedure, as fluoroscopic imaging was inadequate at the lower cervical levels due to patient anatomy. Wang et al. also limited the minimally invasive technique to two-level fusions. Mikhael et al. demonstrated minimally invasive lateral mass fixation in C3–C7 constructs.[32]

Conclusions

Minimally invasive techniques are continually evolving in spine surgery. The application of these techniques to the cervical spine has lagged behind the techniques in use for the lumbar spine. However, there is certainly a role for these techniques in both anterior and posterior cervical applications. Studies have shown that these techniques are safe and demonstrate similar or superior clinical efficacy compared to traditional open techniques, with the added benefit of significantly reducing approach-related soft tissue morbidity. This has a profound impact on postoperative pain and recovery; as such, these minimally invasive techniques represent an attractive surgical option. Certainly, these techniques are still relatively new and require additional study before widespread application. It is important to use these techniques for the proper indications and not lose sight of the traditional open procedures. Like any new technique, there is an associated learning curve. Having a strong foundation with the open procedures can help avoid complications, solve intraoperative issues, and reinforce anatomy. Minimally invasive techniques require appropriate visualization (via direct visualization, endoscope, microscope, and fluoroscopy) in order to safely operate through a smaller window. As these techniques are refined, the surgical indications may expand. Regardless, further clinical study will be essential to improve these techniques.

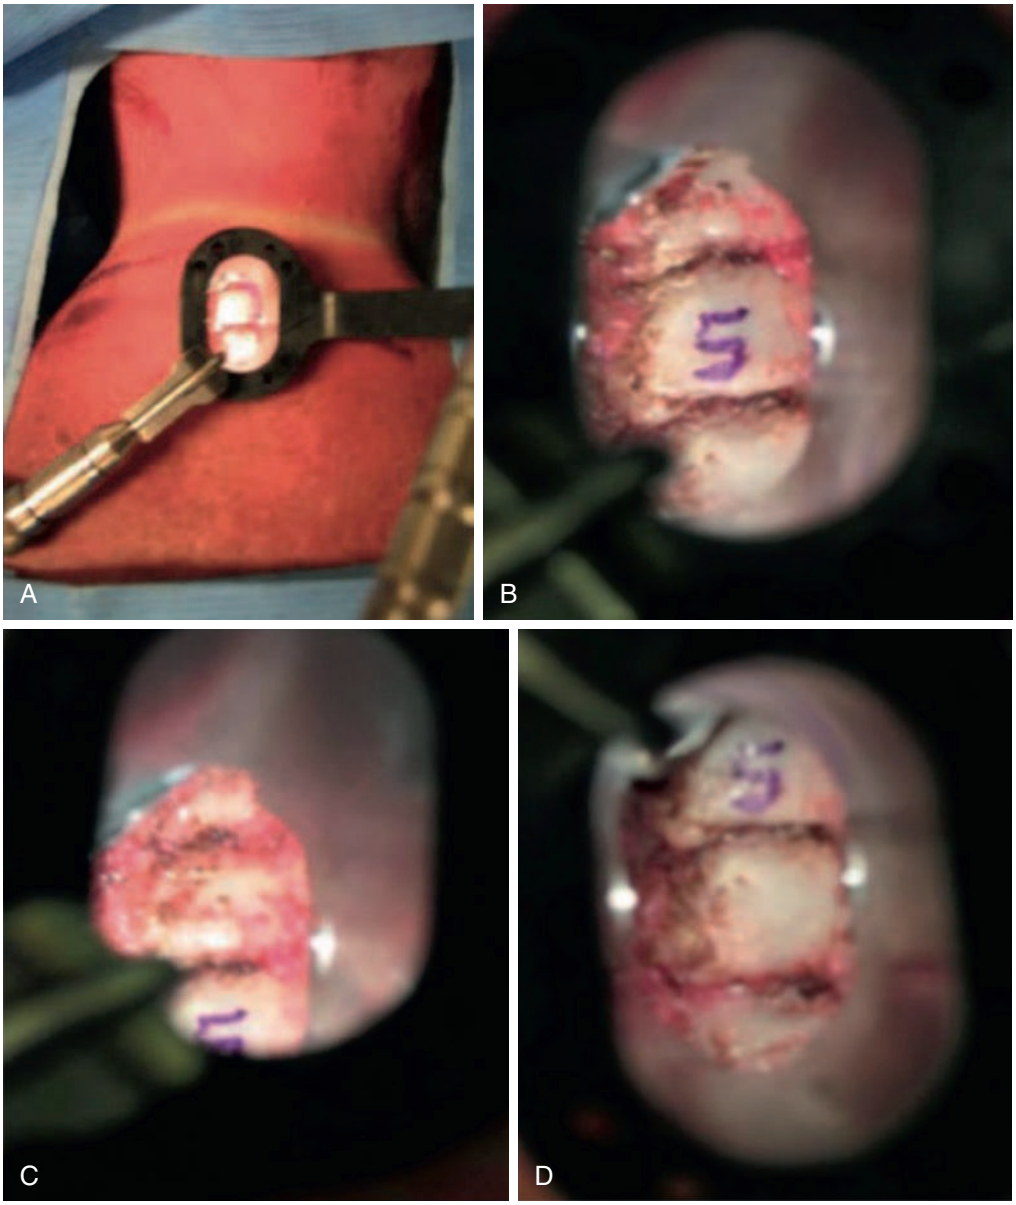

FIG. 59.8 (A) Intraoperative image showing final retractor setup with attachment to flexible mounting system. (B) This allows for complete exposure of the lateral mass, with visualization of the medial and lateral facet joint. Repositioning and angulation of the retractor allows for easy access to the (C) cephalad and (D) caudad levels if necessary.

CHAPTER 60

Future Directions in Minimally Invasive Spinal Surgery

SECTION VII

Xiaobang Hu
Isador H. Lieberman

The use of minimally invasive spinal surgery (MIS) is a philosophy focused on targeting the offending pathology while minimizing the collateral tissue damage. MIS is not any single specific device, technique, or use of an implant. The principal goal of MIS is to reduce approach-related soft tissue injury and complications while reducing postoperative pain, blood loss, and recovery time, still achieving the same or even better clinical outcomes as compared with traditional open surgery.[1,2] Over the past 2 decades, advances in tissue retractors, intraoperative navigation, specialized minimally invasive instruments, and visualization through microscopy and endoscopy have revolutionized the field of MIS. Over the same time span, continuing advances in diagnostic capabilities and biologic therapeutics have evolved that will no doubt merge with MIS techniques to further advance treatment options and minimize the need for traditional invasive surgical procedures. This chapter explores several exciting areas in MIS and discusses possible future directions.

Minimally Invasive Approaches to the Spine: Understanding the Anatomy and Designing Retractors

The first report of using a tubular retractor system (METRx, Medtronic) to treat symptomatic herniated discs was described by Foley and Smith in 1997.[3] The pioneering MIS approach that they described demonstrated that microdiscectomy, a routine spine procedure, can be performed using a novel retractor system and an attachable endoscope, allowing for visualization of the pathology with minimal tissue trauma and virtually no obstruction for the passage of instruments through a defined working channel.[4] Several prospective, randomized studies confirmed that minimally invasive tubular microdiscectomy is as safe and effective as traditional open microdiscectomy.[5–7] The patients who underwent a tubular microdiscectomy had lesser operative time and intraoperative blood loss, lower complication rates, a shorter duration of postoperative disability, and less narcotic usage.[6,7] Today, treatment of herniated discs via minimally invasive tubular microdiscectomy is one of the most commonly performed MIS techniques in the United States.[8] In recent years, working through a defined corridor or channel has evolved to be used for various spinal disorders, including decompression for lumbar stenosis and epidural compression due to metastatic or primary tumors of the spine.[9–12]

Over the last 10 years, by virtue of the experience gained with tubular microdiscectomy, surgeons implemented various design modifications to the tubular retractor, which have now allowed spine surgeons to perform spinal fusions through far less invasive approaches, including direct lateral transpsoas and posterolateral transforaminal approaches. The current technique of minimally invasive transforaminal lumbar interbody fusion (MI-TLIF) for the treatment of low-grade spondylolisthesis, recurrent disc herniation, degenerative disc disease, postlaminectomy instability, and spinal trauma has become a popular approach for interbody fusion. Recent studies have shown that MI-TLIF is associated with reduced blood loss, decreased complication rates, and shorter hospital length of stay. Meanwhile, the rates of fusion and operative time are similar between MI-TLIF and open TLIF.[13,14] Some authors suggest that this technique will be the gold standard to evaluate emerging techniques for the treatment of spondylolisthesis and degenerative disc disease in the future.[4] Newly designed implants, such as deployable cages, along with biologic materials to provide osteoinductive, osteoconductive, and osteogenic potential, will facilitate the evolution of spinal fusion from an inpatient procedure to a day surgery procedure.

The future of tubular spine surgery techniques lies in the surgeon's ability to understand the anatomy, to place the tube, and provide a corridor to the offending pathology in the least invasive and shortest distance from skin to target. This will be accomplished with either guidance technology, such as robotics or navigation, or with mechanically manipulated technology, such as flexible endoscopy.

Percutaneous Pedicle Screw Placement, Image Guidance and Robotics

Traditional open spinal fusion procedures require extensive tissue dissection to expose the entry points and provide adequate lateral to medial orientation for optimal pedicle screw trajectory. This extensive dissection leads to muscular denervation, facet capsule disruption, proximal facet joint

damage, and weakening of ligamentous structures, which could lead to prolonged postoperative pain and morbidity.[15] These disadvantages have led to the increasingly popular minimally invasive percutaneous pedicle screw fixation technique, especially in the lumbar spine. The traditional midline incision and extensive paraspinal muscle dissection is largely eliminated with minimally invasive percutaneous pedicle screw fixation. Traditionally, percutaneous pedicle screw placement is performed with the use of C-arm fluoroscopy.[16,17] However, accurate percutaneous pedicle screw placement is often challenging because subtle anatomic variations and altered screw trajectories that are identifiable with open approaches may not be easily identified with fluoroscopic MIS approaches due to poor image quality or image parallax, which distorts the anatomy. In addition, the surgeon cannot rely on bony palpable and visual landmarks,which they typically use to guide placement.[18]

In the past decade, various intraoperative image-assisted line-of-sight navigation systems and robotic guidance systems have been developed with the aim of increasing the accuracy of percutaneous pedicle screw placement. The most commonly used image-assisted navigation systems use two-dimensional (2D) fluoroscopy, or cone-beam computed tomography (CT), or three-dimensional (3D) CT image acquisition to register and reference the spine in 3D space.[19,20] At present, the only US Food and Drug Administration (FDA)–approved robotic guidance system is a bone-mounted hexapod miniature robot consisting of a cylindrical device composed of two endplates and six pistons that maneuver the endplates over six degrees of freedom.[21] This system relies on 2D fluoroscopy image acquisition, which is matched to a preoperative CT scan for registration and referencing. Multiple recent studies have shown that percutaneous pedicle screw placement using image-assisted navigation or robotic guidance are both safe and effective, and provided improved overall accuracy compared with conventional fluoroscopic techniques.[21–24] However, image-assisted navigation and robotic-guided surgery should be considered as an adjunct to a surgeon's thorough knowledge of spinal anatomy and should not be used as a substitute for it.[25] These technologies could be technically demanding and the learning curve can be treacherous. The future success of these technologies will depend on the ease of use and increased efficiency that they can provide. Meanwhile, further studies are needed to better assess the cost effectiveness of these technologies and their contribution to patient outcomes. Remember that both image-assisted navigation and robotic guidance will not make a bad surgeon good. Both, however, do make a good surgeon more efficient and precise.

Motion Preservation Techniques

Discectomy and fusion has been considered the gold standard for the treatment of symptomatic degenerative discs. However, a commonly recognized adverse outcome of spinal fusion is the development of adjacent-level deterioration above or below the fused segments. The nonfused segments adjacent to the fusion are subject to concentrated stresses and strains depending on the level within the spine and the sagittal balance after the fusion.[26–28] In the past decade, significant progress has been made in the field of motion preservation techniques. The primary goal of these techniques is to closely replicate normal or near-normal biomechanics of the motion segment in an effort to restore patient mobility and minimize the development of clinically significant adjacent-segment disc disease.[29]

Currently, the most commonly performed motion-preserving surgery is total disc replacement (TDR). Most TDR devices today require an anterior approach, which, over time and with experience, has become far less invasive. The use of a focused retroperitoneal approach has minimized much of the morbidity associated with the traditional thoracoabdominal or transperitoneal approaches.

The clinical effectiveness of lumbar TDR has long been a source of debate. There is still currently much skepticism and limited acceptance of lumbar TDR in the United States, although several recent reports suggest that, at long-term follow-up, lumbar TDR is superior for the treatment of symptomatic lumbar degenerative discs compared with fusion.[30,31]

Contrasting cervical TDR with lumbar TDR, the safety and efficacy of cervical TDR have been more easily established with a series of prospective, randomized clinical trials with intermediate and long-term follow-up.[32–35] Currently, cervical TDR is considered to be a viable alternative to anterior cervical discectomy and fusion in select patients with symptomatic one- and two-level cervical radiculopathy or myelopathy.[32]

Despite the previously described advances, the question as to whether TDR can reduce the incidence of adjacent-segment disc degeneration remains unclear. Solid long-term data will be needed before the role of TDR can be fully appraised.

The enthusiasm for motion preservation has also led to the development of several devices, particularly in the lumbar spine, such as interspinous spacers, dynamic stabilization screws and rods, and total facet replacement products. Currently, there is a lack of studies regarding the long-term effectiveness of these devices, and many of the specific devices originally conceived and used are no longer clinically available or failed to prove their effectiveness in clinical trials.[29]

The field of spine motion preservation surgery is constantly evolving, and we are likely to see many new devices in the near future. There is no doubt that second to sagittal alignment, the restoration of native disc function, including axial load-bearing properties, will be important in the advancement of minimally invasive disc replacement technologies.

Spinal Radiosurgery for the Treatment of Metastatic Spine Diseases

Metastatic spine tumors may occur in up to 30% of all cancer patients at some point in their disease course.[36] Spinal cord compression and myelopathy could occur in 25% to 50% of these patients.[37] The treatment goals for metastatic spine tumors include an improvement in the patient's quality of life, relief of tumor-mediated or biomechanically mediated pain, and preservation or restoration of neurologic function. The

most common treatments for metastatic spine tumors are palliative in nature and consist of radiation therapy, systemic chemotherapy, surgery, or some combination of these depending on the histology and behavior of the malignancy.

Recent advances in radiation oncology have ushered in the era of spinal stereotactic radiosurgery (SRS), which has had a profound impact on patient outcomes and function. The use of SRS has demonstrated improved local tumor control compared to conventional external beam radiation.[38] In the spine, SRS allows for the delivery of a high dose of radiation to the tumor site while minimizing the amount delivered to the healthy neighboring tissues. Total radiation doses ranging from 8 to 30 Gy can be safely given as a single fraction or even in multiple fractions with SRS.[39] Tumors that have typically been considered radioresistant, such as renal cell carcinoma, are now becoming target sites of treatment with SRS.[40]

SRS can be applied as isolated treatment or after spine surgery for the treatment of metastatic spine diseases. The development of newer technologies has allowed spine surgeons to perform minimally invasive surgical decompression, which removes only the compressive component of a tumor. This will allow an appropriate separation between the tumor and the spinal cord so that a high dose of radiation can be delivered with minimal risk of radiation-induced spinal cord myelopathy. SRS can be applied as soon as 2 weeks after the surgery to achieve durable local tumor control without the concern of skin damage and delayed healing.[40] Various studies have shown that the majority of patients treated with SRS reported effective palliation of pain and improvement of progressive neurologic symptoms.[38,41–43] SRS will likely become an essential tool in the multimodality treatment for spine tumors in the near future.

The addition of percutaneous vertebral augmentation, vertebroplasty and kyphoplasty, along with SRS, have also changed the surgical paradigm for treating spinal tumors. Vertebral augmentation provides structural stability, while SRS provides tumor burden control.[44] Current efforts are now exploring the addition of radiotherapeutics and chemotherapeutics in the cement substrate to provide even more local tumor control.[45,46]

Spinal Biologics

Ongoing research and development of biologic materials for the treatment of spinal disorders is one of the most exciting areas in this field. Various bone graft extenders, such as demineralized bone matrices and calcium phosphate salts, as well as substitutes, such as bone morphogenetic proteins (BMPs), have been used by spine surgeons to enhance fusion rates and avoid the morbidity of harvesting iliac crest bone graft.[47] However, as with all new technologies, the long-term problems may not be readily recognized. This, in turn, has led to controversies regarding the use of BMPs in spine surgeries. Recently, a systematic data analysis was not able to find convincing data to warrant recombinant human BMP-2 (rhBMP-2) use over iliac crest bone graft.[48,49] It has been suggested that rhBMP-2 should be reserved for patients whose risk of failed spine surgery outweighs the risks of rhBMP-2 (theoretical risks of retrograde ejaculation, heterotrophic bone formation, or induction of malignancy), as rhBMP-2 still remains one of the most powerful commercially available osteogenic agents.[50] Polymethylmethacrylate has been an effective filler material for the treatment of vertebral compression fractures, but development of alternate materials with improved biomechanical and biologic properties, good radiopacity and handling for vertebroplasty and kyphoplasty is also underway.[51–53]

Significant progress in the fields of tissue engineering, regenerative medicine, and harvesting and propagation of stem cells has fueled many in the spine field to start using these technologies with the aim of treating and reversing disc degeneration. Biologic therapies can be protein based or cell based.[54] Protein-based therapy involves administration of biologic factors into the disc to delay degeneration, stop inflammation, or enhance matrix synthesis using various proteins, such as osteogenic protein-1, growth factors, interleukin-1 receptor antagonists, and platelet-rich plasma.[55–59] The goal of cell-based therapy is to either replace necrotic or apoptotic cells or minimize cell death. Various cell sources, such as autologous chondrocytes, disc cells, and mesenchymal stem cells, have been considered for cell replacement for treating symptomatic degenerative discs. However, the science is still not fully supportive of these treatment options.[60–62] Many technical challenges associated with biologic treatments and their application still exist, and their use is still far from clinical practice.[54] Further knowledge about the molecular mechanisms of disc degeneration and a more thorough understanding of various biomolecules, as well as a better understanding of the degenerative environment of the host disc space, will allow the future development of multidisciplinary approaches for the treatment of symptomatic disc degeneration.

Summary

The field of MIS will continue to evolve. The continued development and incorporation of MIS techniques into the field of spine surgery has the potential of greatly benefiting all those afflicted with spinal pathology. In the meantime, more vigorous, prospective, long-term clinical studies, coupled with surgeons' and scientists' insatiable imaginations, will be needed to critically evaluate these new techniques and technologies.

SPINAL STENOSIS

This page intentionally left blank

61 CHAPTER Spinal Stenosis: Pathophysiology, Clinical Diagnosis, and Differential Diagnosis

Chetan K. Patel
Eeric Truumees

Spinal stenosis is one of the most common conditions in the elderly. It is defined as a narrowing of the spinal canal. The term *stenosis* is derived from the Greek word for narrow, which is *stenos*. The first description of this condition is attributed to Antoine Portal in 1803. Verbiest[1–10] is credited with coining the term *spinal stenosis* and the associated narrowing of the spinal canal as its potential cause. Kirkaldy-Willis[11–15] subsequently described the degenerative cascade in the lumbar spine as the cause for the altered anatomy and pathophysiology in spinal stenosis.

The term *spinal stenosis* refers to an anatomic diagnosis that increases with age and can occur in asymptomatic individuals.[16,17] The exact reason for why some with this condition have debilitating symptoms while others have no symptoms is not well understood. These differences in presentation may be related to the different abilities of individuals to compensate for the anatomic changes that have occurred. When symptoms do present, they usually occur on the basis of the location of neural compression. Patients with central canal stenosis typically present with neurogenic claudication, whereas those with lateral recess and foraminal stenosis present with radicular pain. Patients with significant symptoms that do not respond to conservative treatment often elect surgical treatment. In fact, in adults older than age 65, spinal stenosis is the most common reason to undergo lumbar spine surgery.[18,19]

Anatomy

In order to understand how spinal stenosis causes symptoms, we must first have a good understanding of the normal anatomy of the lumbar spine. The spinal canal's anterior border is formed by the vertebral body, the disc, and the posterior longitudinal ligament. The lateral border is formed by the pedicles, the lateral ligamentum flavum, and the neural foramen. The posterior border is formed by the facet joints, lamina, and ligamentum flavum. The shape of the spinal canal may be circular, oval, or trefoil (Fig. 61.1). The circular and oval canal shapes provide the most space for the neural elements centrally and in the lateral recess. The trefoil canal has the smallest cross-sectional area.[20] It is present in 15% of individuals and predisposes these individuals to lateral recess stenosis.

Disc

Disc degeneration is believed to be the first step in degeneration of the spine. At birth, the nucleus pulposus and the anulus occupy roughly 50% of the disc area. The nucleus is gelatinous and there is a discrete boundary between the nucleus and the anulus. Over time, the collagen content increases and the demarcation between the nucleus and the anulus becomes less distinct. Other structures within the disc also change with aging. The chondroitin sulfate concentration decreases, and the ratio of keratin sulfate to chondroitin sulfate increases. Because keratin sulfate has less hydrophilic potential, the disc dehydrates over time.

Hydration of the disc also changes due to an alteration in the type of collagen within the disc over time. The anulus contains 60% type II and 40% type I collagen, whereas the disc contains mainly type II collagen. Type I collagen is associated with decreased water content compared with type II collagen. Thus, as the type I collagen content increases with age, hydration of the disc decreases. The normal nucleus pulposus typically consists of 85% water, whereas the anulus consists of 78% water. With degeneration of the disc, the water content drops to roughly 70%. A desiccated disc has a decreased ability to handle mechanical load.

The Kirkaldy-Willis[21] theory explains how these changes progress over time. This theory is based on viewing the spine as a tripod, with the disc and the two facet joints making up the three legs. This analogy makes it easier to understand how alteration in one joint can alter the others. The initial stage in the degenerative cascade is circumferential tearing of the anulus, which progresses to radial tears. This, along with the biochemical changes in the disc described previously, lead to further degeneration of the disc and disc height loss. Altered disc structure and disc height loss lead to bulging of the disc and the posterior longitudinal ligament. This causes narrowing of the spinal canal and potential neural impingement. The lost disc height also leads to buckling of the ligamentum flavum and settling of the facet joints. The facet joints

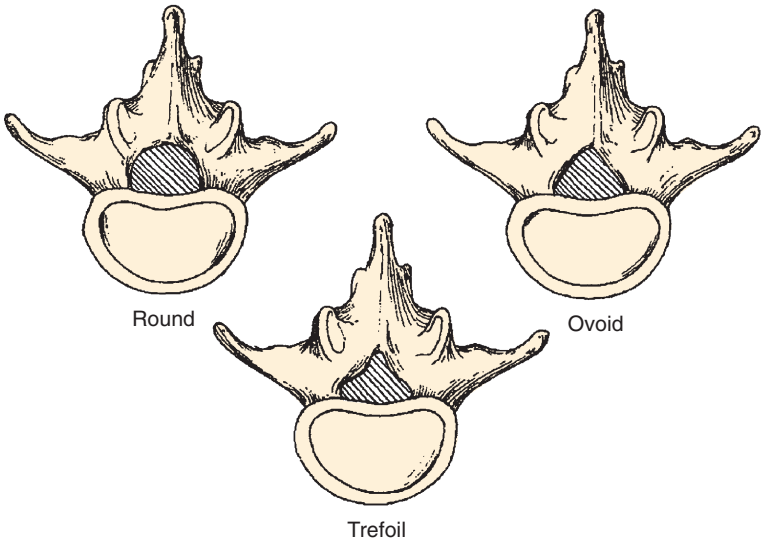

FIG. 61.1 The three typical shapes of the spinal canal. Trefoil canals have the smallest cross-sectional area. (From Hilibrand AS, Rand N. Degenerative lumbar stenosis: diagnosis and management. *J Am Assoc Orthop Surg*. 1999;7:239–248.)

subsequently deteriorate and form osteophytes, which further narrows the spinal canal. The ligamentum flavum also hypertrophies over time. The altered structure, motion, and biomechanics then lead to additional disc deterioration, which propagates the cycle of degeneration.

Facet Joints

The lumbar facet joints are encapsulated structures that have a uniform cartilaginous surface to produce a smooth gliding motion. The superior articular process is concave and its articular surface faces medially and dorsally. The inferior articular process is convex and its articular surface faces laterally and ventrally. Lumbar facet joints are oriented 90 degrees in the sagittal plane and 45 degrees anterior in the coronal plane. Studies show that more sagittally oriented facet joints are associated with a degenerative spondylolisthesis. The two facet joints are usually symmetrical with respect to their joint angles at each level. Facet tropism refers to an asymmetry between the facet joints and has been theorized to lead to degeneration.

As the disc degenerates and narrows, the facet joints settle and increased stress is placed across the facet joint. This leads to facet joint degeneration, hypertrophy, and osteophyte formation. These osteophytes can cause impingement of the thecal sac within the spinal canal or the nerve root in the neural foramen.

Intervertebral Foramen

The anterior boundary of the intervertebral foramen is made up of the posterior wall of the vertebral body and the disc. The posterior boundary is made up of the lateral aspect of the facet joint and the ligamentum flavum. Superior and inferior boundaries are formed by the pedicles of the vertebral bodies

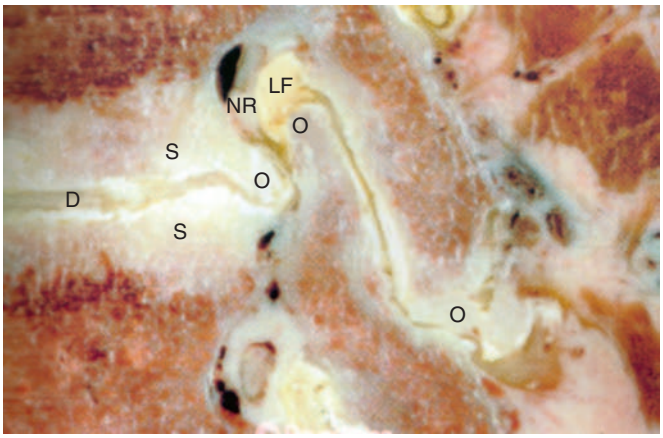

FIG. 61.2 Sagittal cross-section demonstrating disc desiccation (D), endplate sclerosis (S), osteophyte formation (O), hypertrophy and buckling of the ligamentum flavum (LF), and nerve root (NR) compromise within the foramen. corresponding to that segment. The foramen is typically larger than the ganglion and the nerve that it contains. The additional space is occupied by fat and loose areolar tissue that can accommodate for changes in size of the foramen with motion. With degeneration, hypertrophy of the facets can cause posterior compression of the neural elements (Fig. 61.2). Anterior compression of the neural elements usually arises from endplate osteophytes or foraminal disc herniations. Decrease in disc height with degeneration can cause a decrease in the foraminal height and neural compression. This type of vertical or up-down foraminal stenosis is important to recognize because a posterior decompression alone may not significantly improve the vertical compression and may result in persistent symptoms after surgery.

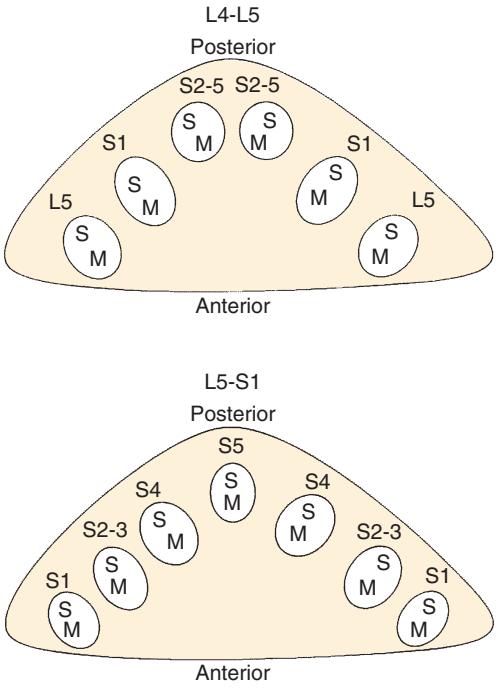

FIG. 61.3 Neural organization within the thecal sac at the L4–L5 and L5–S1 disc levels. M, motor components; S, sensory components. (From Garfin SR, Herkowitz HN, Mirkovic S. Spinal stenosis: instructional course lecture. *J Bone Joint Surg Am*. 1999;81:572–586.)

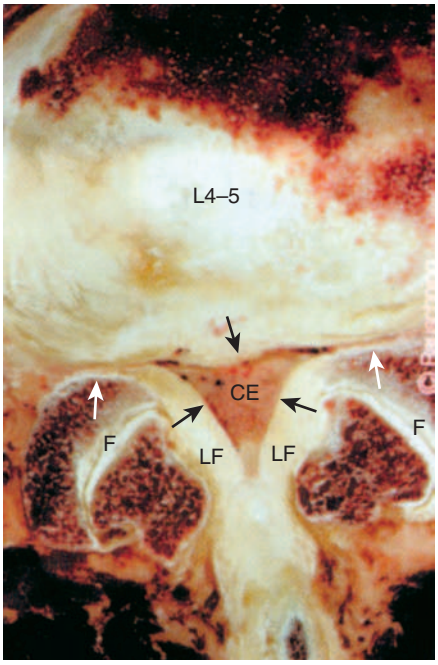

FIG. 61.4 Axial cross-section view at the L4–L5 disc level showing advanced degenerative changes. Cauda equina (CE) compression is caused by hypertrophic facets (F) and ligamentum flavum (LF) disc protrusion. (From Gallego J, Schnuerer AP, Manuel C. *Basic Anatomy and Pathology of the Spine*. Memphis, TN: Medtronic Sofamor Danek; 2001. Photograph by Wolfgang Rauschning, MD, PhD.)

Cauda Equina

The thecal sac lies in the spinal canal and gives rise to nerve roots at each segment. The nerve root initially courses along the medial aspect of the pedicle and then progresses laterally, inferior to the pedicle in the neural foramen. The nerve roots within the cauda equina are arranged in a predictable pattern within the thecal sac (Fig. 61.3). Cross-section of the thecal sac demonstrates the most caudal roots to be present in a central and posterior position. The more cephalad roots are located sequentially, and are more lateral and anterior. At each level, the motor fibers of a root are anterior and medial to the larger sensory component. Dorsal root ganglia exist at every level and can be intraspinal or intraforaminal. A variety of clinical presentations arise on the basis of the anatomic location of neural compression.

Classification

Stenosis can be anatomically classified as central, lateral recess, and foraminal on the basis of the location of neural compression. With aging, central canal stenosis occurs as degenerative changes progress. As the axial height of the disc and facet joints decreases, the disc bulges into the spinal canal. The central canal is further narrowed by posterior impingement from enlarged facets and the hypertrophied ligamentum flavum (Fig. 61.4). Hypertrophy of the soft tissues is responsible for 40% of spinal stenosis.[22] With extension, the hypertrophied ligamentum buckles centrally into the canal and worsens the central stenosis. This explains why patients with stenosis typically report worsening of their symptoms in extension.

Lateral recess stenosis typically results from posterior disc protrusion in combination with some superior articular facet hypertrophy. Lateral recess stenosis can present with lumbar radiculopathy; incidence of lateral recess stenosis ranges from 8% to 11%.[23–25] These patients present with pain or neurologic symptoms in a dermatomal distribution on the basis of the nerve that is compressed in the lateral recess.

Foraminal stenosis causes compression of the exiting nerve root and ganglion and leads to lumbar radiculopathy. Foraminal stenosis occurs most commonly in the lower lumbar spine, with the fifth lumbar nerve root being the most commonly involved. Foraminal stenosis can occur from loss of disc height, vertebral endplate osteophytes, facet osteophytes, spondylolisthesis, and disc herniations. Like central canal stenosis, foraminal stenosis is worse in extension; thus, exacerbating and alleviating factors for symptoms from foraminal compression are similar to those from central canal stenosis.[26]

Spinal stenosis can also be classified on the basis of the etiology, which can be congenital, acquired, or both. Congenital stenosis is present as a normal variant in the population and is a feature of certain conditions, such as dwarfism. In these conditions, patients have short pedicles that are closer together than in the normal lumbar spine.[6] In congenital stenosis, few degenerative changes are required to cause neural compression

BOX 61.1 Classification of Spinal Stenosis

I. Congenital/Developmental
- A. Idiopathic
- B. Achondroplastic
- C. Osteopetrosis

II. Acquired
- A. Degenerative
  1. Central
  2. Lateral recess
  3. Foraminal
- B. Iatrogenic
  1. Postlaminectomy
  2. Adjacent to fusion
  3. Malposition of hardware in the canal
  4. Postprocedure epidural hematoma
- C. Miscellaneous disorders
  1. Acromegaly
  2. Paget disease
  3. Fluorosis
  4. Ankylosing spondylitis
- D. Traumatic

III. Combined

Any combination of congenital/developmental or acquired stenosis

and symptoms. As one would expect, congenital stenosis becomes symptomatic much earlier in life and patients usually become symptomatic in the fourth decade. Acquired stenosis can be caused by trauma, neoplasms, and infection, along with other causes listed in Box 61.1.

Deformity and Instability

The static changes discussed thus far can be worsened by dynamic factors such as segmental instability. Instability typically arises from degenerative changes and can be in the form of translational or rotational abnormality. Translational abnormality is found most commonly in women as a degenerative anterolisthesis of L4 on L5.[27] The attachment of the iliolumbar ligaments to the L5 level may act as a restraining force and cause more relative motion at L4–L5. The more sagittally oriented facet joints between the fourth and fifth lumbar vertebrae can be an additional predisposing factor for instability at this level.[28] Because the lamina and the spinous process typically project inferior to the vertebral body, the amount of room available between the inferior aspect of the L4 lamina and the posterior superior aspect of L5 is substantially decreased. This anterior translation of the L4 posterior elements, along with hypertrophy of the facets and ligamentum flavum, leads to central and lateral recess stenosis. Foraminal stenosis can also occur in this setting, with collapse of the disc space, disc herniation, endplate osteophytes, or facet hypertrophy. With scoliosis, lateral subluxation and rotational instability can cause altered biomechanics that accelerate further degeneration. The altered anatomy can also directly cause narrowing of the central canal, lateral recess, and foraminal regions. Degenerative changes superimposed on abnormal anatomy lead to stenosis in these patients.

Pathophysiology

The term *spinal stenosis* describes the anatomic narrowing of the spinal canal. How does spinal stenosis result in pain and altered neurologic function? A number of cadaver and animal studies have attempted to elucidate the mechanism of these symptoms. Schonstorm evaluated the changes in nerve pressure that occur as the spinal canal narrows.[29] In his human cadaver study, thecal sac constriction of 45% or more led to an increased pressure in the nerve roots. As the degree of compression increased, the pressure in the nerve roots increased. Delamarter and colleagues[30] also demonstrated the importance of the magnitude of thecal sac compression in alteration of neural function. They noted no alteration in neurologic function when the animal's cauda equina was constricted by 25%, whereas more than 50% compression led to motor or sensory deficits. Pedowitz and colleagues[31] demonstrated that the duration of compression was also an important factor in neural dysfunction.

Rydevik and colleagues[32–37] demonstrated another effect of compression of the thecal sac. They noted that once pressure of more than 50 mm Hg was achieved, capillary restriction and electrophysiologic alteration occurred in the nerve roots. Even at pressures as low as 5 to 10 mm Hg, venous congestion of the intraneural microcirculation occurred. Solute transport decreased 45% across nerve root segments with the low pressure of 10 mm Hg. This suggests that low-grade sustained compression of the nerve roots could lead to vascular impairment and potential detrimental changes in the function of the nerve roots. In addition to neural compression and altered nutrition, inflammatory chemical mediators have also been shown to be a cause of pain.[38–43]

The presence of stenosis increases with aging; however, it often does not produce any symptoms. What causes pain in some individuals with mild spinal stenosis and no symptoms in others with severe stenosis? The experimental evidence reviewed earlier suggests that each individual may have an innate ability to compensate for the accumulating pathologic changes. Because the magnitude an individual can compensate for is different for different people, two individuals with the same amount of stenosis may not exhibit the same symptoms. The rate at which these changes are occurring also appears to be important. Individuals may become symptomatic with a lower magnitude of compression if it occurs rapidly. This explains how a patient with stenosis can become symptomatic with an acute mild disc herniation.

Natural History

Patients with congenital stenosis typically become symptomatic earlier in life. Due to congenital narrowing of the canal in these patients, significant stenosis is present at multiple levels even with little degenerative change.[44] Patients

with degenerative stenosis present later in life (during their 60s) and have far more advanced degeneration in their spine. Females are more commonly affected with stenosis, with the L4–L5 level being the most common segment involved.[45]

Recent studies have also shed light on the prevalence and likelihood of developing symptoms from spinal stenosis. A portion of the Framingham Heart Study participants were prospectively enrolled in a study evaluating lumbar symptoms and computed tomography (CT) findings of the lumbar spinal canal.[46] In the group of 191 study participants with the mean age of 52.6 years, the prevalence of lumbar stenosis was 23.6%. The prevalence of lumbar stenosis increased with age, as expected, and led to a threefold higher risk of having symptoms. Will the patients without any symptoms continue to remain asymptomatic? A separate retrospective study of asymptomatic lumbar stenosis attempted to answer this question. A group of 41 patients with cervical myelopathy who had asymptomatic lumbar stenosis and a mean age of 69 years were followed.[47] At a mean of 5 years after the diagnosis, 23% developed symptoms, suggesting that patients with known asymptomatic stenosis should be informed of symptoms that could develop.

Multiple studies have looked at the short-term and long-term results of nonoperative treatment of patients with symptomatic lumbar stenosis.[48–55] These studies show that a significant number of patients respond favorably to nonoperative treatment. Some patients, however, do not improve and some even worsen. Johnsson and colleagues reviewed the results of 32 patients who declined to have surgery at a 4-year follow-up period.[56] They noted that 70% of patients were unchanged, while 15% were the same and 15% worsened.

Recently, prospective studies have reported short-term and long-term results of nonoperative and operative treatment. The prospective observational Maine Lumbar Spine Study reported 8- to 10-year follow-up results on 97 patients.[57] They noted that a large number of patients (39%) that had initially elected nonsurgical treatment subsequently elected to undergo surgery. Of the patients who continued nonoperative treatment, most had stable symptoms. Miyamoto and colleagues reported prospective results of nonsurgical treatment in 120 patients.[58] Of these patients, 16% required surgical treatment during the follow-up period of 5 years. Of the nonsurgically treated patients, 53% reported no hindrance during the activities of daily living. No sudden neurologic deterioration was reported. Roughly 23% of patients had worsened but did not elect to undergo surgical intervention.

The Finnish Lumbar Spinal Research Group reported the results of a randomized controlled trial in 2007.[59] They randomized 94 patients with mild to moderate stenosis into either the surgical group or nonoperative group. At the 2-year follow-up, patients in both groups noted improvement of symptoms; however, the outcome of patients undergoing surgical treatment was significantly better. The most recent prospective study to evaluate patients with lumbar stenosis is the Spine Patient Outcomes Research Trial (SPORT).[60–62] This study reported prospective outcomes of 634 patients at 2-, 4- and 8-year follow-up. Patients undergoing surgical treatment had better outcomes than those who underwent nonsurgical treatment in the as-treated analysis at each of the time points. Pain, function, satisfaction, and self-rated progress were all better in those that underwent surgery. Patients in the nonsurgical treatment group showed small improvements in most outcome measures. It should be noted that no disastrous neurologic deterioration was noted with nonoperative treatment.

The original and recent updated North American Spine Society evidence-based guidelines for diagnosis and treatment of lumbar stenosis provide some tangible conclusions from these studies.[63,64] They state that in one-third to one-half of patients with mild to moderate stenosis, the natural history is favorable. Unfortunately, predicting which patients with stenosis will worsen over time is impossible. In some studies, symptomatic patients with severe stenosis did poorly over time, but overall there is not sufficient evidence to draw any conclusions. What is known is that rapid or catastrophic deterioration is rare in patients with spinal stenosis. Knowing this can be helpful in guiding treatment and evaluating these patients. When a patient with spinal stenosis has rapidly worsening neurologic status, other causes of neurologic dysfunction should be investigated.

Clinical Presentation

Patients with lumbar spinal stenosis most commonly present with leg pain.[22] This leg pain presents as either neurogenic claudication or radicular leg pain. Patients with neurogenic claudication report a feeling of pain, heaviness, numbness, cramping, burning, or weakness. The symptoms typically start from the back or the buttocks and bilaterally radiate down below the knees. One lower extremity may be worse than the other; however, both legs are typically involved. Symptoms usually do not follow a dermatomal pattern and are usually related to activities. These abnormal sensations are typically worse with extension of the lumbar spine during walking or standing for a prolonged time. Some report worsening weakness if they keep walking. They may note ankle dorsiflexion weakness that is typically described as feet slapping or even falling as they attempt to keep walking. Walking downhill is more challenging for these patients as the lumbar spine is extended while going downhill. Most describe a set distance they can walk before the symptoms become disabling. As the stenosis worsens, this distance typically decreases, further disrupting the daily life and function of these patients. Relief of symptoms typically comes from flexing the lumbar spine by leaning forward, sitting, or lying down. As discussed earlier, the degree of stenosis decreases as the lumbar spine is flexed and patients naturally learn to position themselves in a posture that minimizes discomfort and maximizes function. Keeping this in mind, it is easy to understand why these patients typically lean forward on a grocery cart and have an easier time riding a bike, walking uphill, or driving while sitting in a car.

In contrast to neurogenic claudication arising from compression of the thecal sac, radicular pain arises from compression

of a particular nerve root in the lateral recess or the neural foramen. Unlike claudication, radicular leg pain is described by the patients in a specific dermatomal pattern corresponding to the compressed nerve root. The most common presentation of this is L5 radiculopathy from lateral recess stenosis causing compression of the L5 nerve root. In addition to numbness in the L5 distribution, weakness can be seen in the extensor hallucis longus and tibialis anterior muscle groups.

Low back pain is also a common complaint in patients with stenosis. Although most patients note the radiation of this pain into their legs, some present without leg pain or note radiation of the pain only into their buttocks. Exacerbating and alleviating factors for claudicatory low back pain are similar to those for the leg pain. Spondylotic change with or without spondylolisthesis is a common finding in this patient population and often the cause for low back pain. Patients with symptoms in both the low back and leg have a greater disability than those who have symptoms only in one location.[65]

Severe neurologic symptoms, such as bowel and bladder incontinence or profound weakness, are uncommon in patients with stenosis. Urinary dysfunction is a common complaint in this elderly population and can be present in 50% to 80% of patients.[66,67] Because various causes of urinary dysfunction (such as preexisting stress incontinence, urinary tract infections, and prostatic hypertrophy) are common in this population, a careful history can help exclude these nonspinal causes. The factors more commonly noted in patients with neurogenic bladder dysfunction are perianal sensory disturbance, longer duration of symptoms, and higher mean residual volumes on urodynamic studies.[68]

In addition to obtaining a history specific to the patient's pain and neurologic symptoms, it is important to obtain a comprehensive medical history. A patient's report of preexisting peripheral arterial occlusive disease, hip arthritis, multiple sclerosis, or neuropathy would substantially alter what symptoms are attributed to the stenosis. Similarly, obtaining an overall picture of the medical comorbidities and physiologic condition will also shed light on the ability of the patient to safely undergo any invasive procedures. Knowing the patient's other medical conditions can also help identify patients who may be at risk for inferior outcomes. Cardiovascular comorbidities, depression, and disorders influencing walking ability have all been noted to be preoperative predictors of poor postoperative outcomes.[69]

Physical Examination

A good physical examination of patients with lumbar spinal stenosis should start with observation. Often, these patients will be sitting flexed forward on a chair in the examination room. While standing and ambulating, stenosis patients still often flex their trunk forward to decrease their symptoms. This may also be noticed when checking their range of motion as a decrease in the active lumbar extension. Reproduction of the patient's usual symptoms by prolonged lumbar extension can also be helpful in confirming the diagnosis. Neurologic examination is often normal in spite of long-standing debilitating symptoms. Lateral recess stenosis is more commonly responsible for neurologic changes.[70] When motor weakness or sensory deficit is present, it is most often in the L5 distribution. A frequent neurologic finding is an asymmetrical deep tendon reflex at the patellar or Achilles tendon. A symmetrical decrease in the reflexes is more indicative of age-related changes. Nerve root tension signs are usually not present.[71] Changes in neurologic examination may become more obvious after stressing the patient's neurologic system. This can be accomplished by asking the patient to walk until he or she experiences significant symptoms. Reexamination at this point may reveal changes in motor, sensory, or reflex examination that were not detected before the stress.

It is useful to review physical examination findings found in some studies to get a better idea of their frequency. Amundsen and colleagues[72] prospectively evaluated the clinical and radiographic features of 100 patients with symptomatic spinal stenosis. They reported a motor weakness in 23% and sensory deficit in 51%. In the 2007 randomized controlled trial of 94 stenosis patients from the Finnish Lumbar Spinal Research Group,[59] 22% of patients had an L5 motor weakness and 19% had a sensory deficit. The straight-leg raise test was positive in 3% of the patients. In the recent SPORT study, asymmetrical reflexes were noted in 26%, motor weakness was noted in 28%, and sensory deficit was noted in 29%.[60-62]

An important part of the physical examination is identifying other common causes of similar symptoms. The neurologic examination should focus on eliciting signs that would suggest other neurologic causes of the patient's symptoms. Hyperreflexia, clonus, and upgoing toes, along with other upper motor neuron findings, can suggest the presence of myelopathy from cord compression. Sensory disturbance in a stocking distribution suggests the presence of neuropathy. A general musculoskeletal examination must include assessing the irritability and limitation of motion in the hips to rule out hip pathology. Palpation of the greater trochanter and iliotibial band can help detect pathology in these easily treated structures. Diminished peripheral pulses along with diminished skin hair are important clues that the symptoms may be coming from vascular claudication.

Diagnostic Studies

Radiography

The diagnostic testing of patients with spinal stenosis often starts with plain radiographs. In addition to the anteroposterior and lateral radiographs, flexion and extension lateral views should be obtained. Most patients suspected of having stenosis are elderly and thus likely demonstrate a variety of spondylotic changes on radiographs. Particular attention should be paid to diagnosing scoliosis and spondylolisthesis in addition to any dynamic instability that can be detected on the flexion–extension views. If scoliosis is noted, long-cassette scoliosis films would be helpful in evaluating the full extent of the deformity in both the coronal and sagittal planes. Narrowing of the neural foramen and inferred narrowing of the spinal canal from the location and extent of degenerated structures

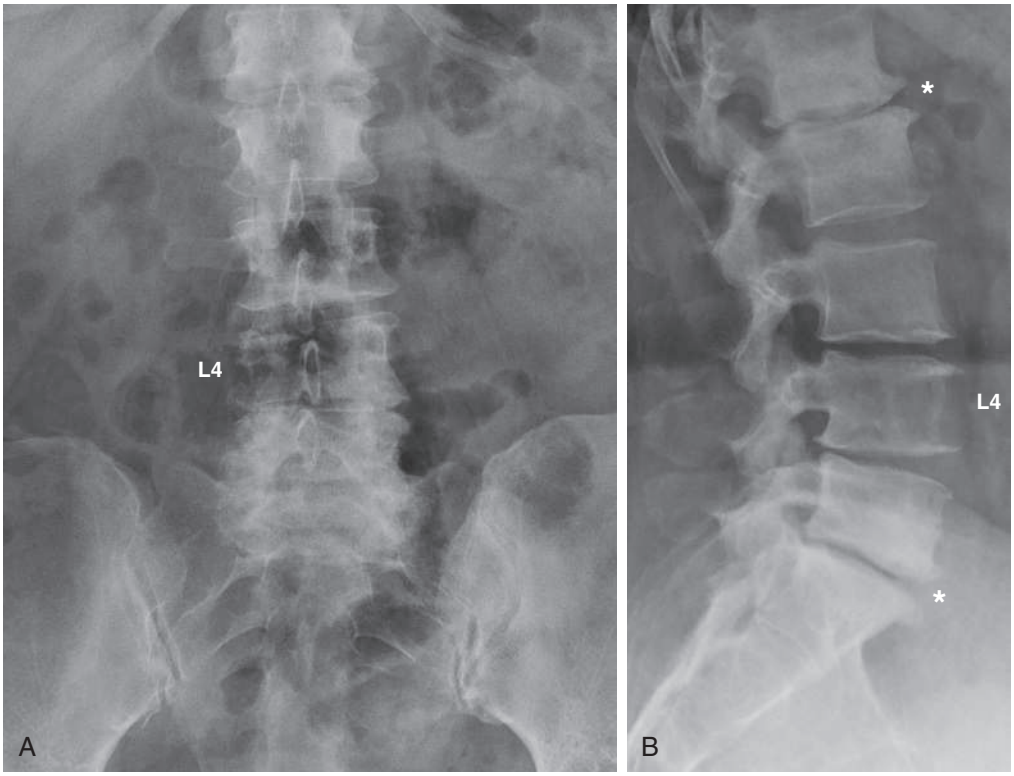

FIG. 61.5 (A) Anteroposterior (AP) and (B) lateral radiographs of a patient with progressively worsening right lumbar radiculopathy. *Asterisk* denotes the degenerative changes in the form of disc height collapse, endplate sclerosis, and osteophytes. On the AP radiograph, the right side of the superior and lateral walls of the vertebral body are indistinct, with collapse of the height of L4 on the right compared with the left. On the lateral radiograph, radiolucency is present in the L4 body along with an indistinct anterior wall. After additional workup, this patient was diagnosed with multiple myeloma in the L4 vertebral body.

should be evaluated. Ossification of ligamentous structures, ankylosis of the spine, erosion of the disc space, or any abnormal appearance of the bony structures should be assessed (Fig. 61.5). It should be kept in mind that even severe degenerative changes can be seen in asymptomatic patients.[73]

Computed Tomography With and Without Myelography

Prior to the common availability of magnetic resonance imaging (MRI), a CT scan was the study of choice for visualizing pathologic anatomy in the axial plane. Because a significant portion of the stenosis comes from soft tissue pathology, visualization of the soft tissues is the top priority in axial imaging. A CT scan is a poor modality for detailed analysis of the soft tissue pathology (Fig. 61.6). A metaanalysis demonstrated that the sensitivity of a CT scan in detecting spinal stenosis ranges from 70% to 100%.[74]

Diagnostic utility of the CT scan can be improved by combining it with myelography.[75,76] The dye injected in the cerebrospinal fluid during a myelogram provides good contrast between the thecal sac and the surrounding soft tissue and bony pathology. Preoperative complete contrast block on a CT-myelogram has been correlated with an improved surgical outcome.[77] The invasiveness of the myelogram and the radiation associated with the CT are the two biggest drawbacks of this diagnostic modality. Given these limitations, patients who

FIG. 61.6 Soft tissue window of a computed tomography scan through the L4–L5 level demonstrating stenosis. Note the facet and ligamentum hypertrophy are better seen on the magnetic resonance imaging of this patient in Figs. 61.9 and 61.10.

are unable to have an MRI, who have scoliosis, or who have previous spinal instrumentation are the most likely to undergo this study (Figs. 61.7 and 61.8). In cases in which MRI findings are unclear, a CT or a CT-myelogram should be considered to gain further information about the pathology.

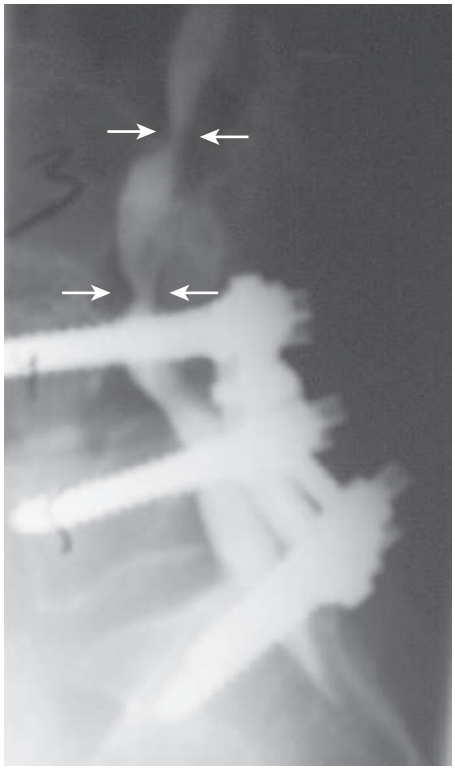

FIG. 61.7 Myelogram of a patient with neurogenic claudication who had a history of a previous lumbar instrumented fusion. The *arrows* identify the two levels of adjacent-level stenosis.

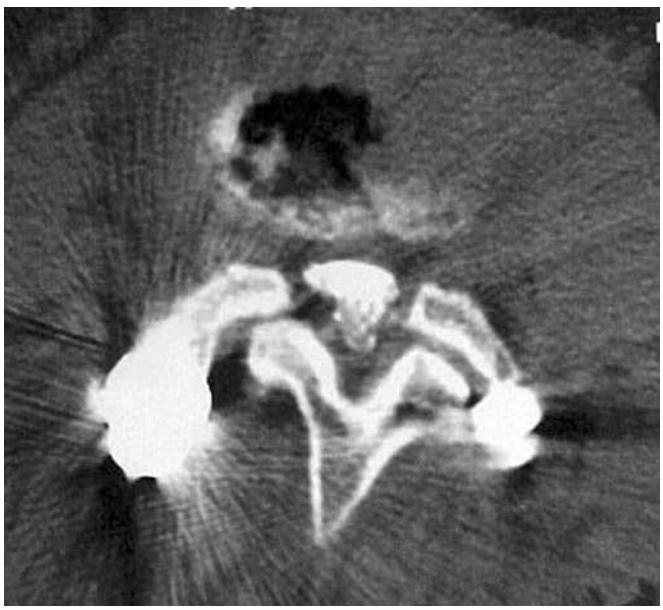

FIG. 61.8 Postmyelogram computed tomography through the adjacent-level stenosis of the patient in Fig. 61.7.

Magnetic Resonance Imaging

MRI is the diagnostic modality of choice in patients with suspected lumbar spinal stenosis. It is noninvasive and provides images in axial, coronal, and sagittal planes. MRI offers details of both the bony and soft tissue anatomy. It provides improved visualization of the soft tissue elements of the spine (Figs. 61.9 and 61.10). The degree of compression of the neural elements and the offending pathology are both easily visualized. The central canal, lateral recess, and neural foramen can all be visualized along with the degree of stenosis that is present in each of these regions. Facet arthropathy, ligamentum hypertrophy, disc bulges or herniations, and other compressive pathology, such as synovial cysts, are easily identified on MRI (Fig. 61.11). Foraminal stenosis is best visualized on T1-weighted sagittal images in which the nerve root and dorsal root ganglion are contrasted with the surrounding fat.

Overall, the diagnostic accuracy of MRI is similar to that of the CT-myelogram and does not have the drawbacks of ionizing radiation and contrast injection in the cerebrospinal fluid.[78–81] The reliability of MRI interpretation has also been investigated, and there appears to be significant inter-reader variability in assessing some anatomic locations.[82–85] The measurement of thecal sac area, as well as the ratings of the degree of central and foraminal stenosis, show good reliability.[86] The reading of the degree of lateral recess stenosis, on the other hand, shows significant variability. Although some have noted correlation between the degree of stenosis and outcomes of treatment, others have not been able to identify any such relationship.[87–90] The nerve root sedimentation sign describes the typical sedimentation of lumbar nerve roots in the dorsal part of the thecal sac due to gravity. The absence of this sedimentation is considered a positive sign of lumbar stenosis.[91]

It has been theorized that supine MRIs may understate the degree of stenosis because the patients may not be in the position of the worst compression during the study. Attempts have been made to demonstrate pathology in MRI scans that is obvious only under dynamic conditions.[92-96] A typical supine static MRI that demonstrates fluid-filled facets on T2-weighted axial images may indicate instability and would require careful scrutiny of flexion–extension radiographs.[97] Alternatively, MRIs in flexion, extension, axial loading, and upright positions can be performed. Investigation of this approach, however, has not provided any conclusive evidence regarding its utility. It is unclear what the results of invasive treatment will be for those patients whose stenosis can only be detected under dynamic conditions. What the existing studies do point out is that the static images on the current MRIs should be supplemented with the dynamic information available from clinical presentation as well as flexion and extension radiographs. One study noted that supine MRIs performed with the lumbar spine extended (by having the hips and knees extended) demonstrated more thecal sac compression than the images obtained in the flexed position.[98] This suggests that position of the lower extremities during the MRI should be ascertained as a routine part of the patient's history.

Electromyography, Nerve Conduction Studies, and Somatosensory Evoked Potentials

Electromyography (EMG), nerve conduction studies (NCSs), and somatosensory evoked potentials (SSEPs) are not part of the routine workup of patients with spinal stenosis. EMG

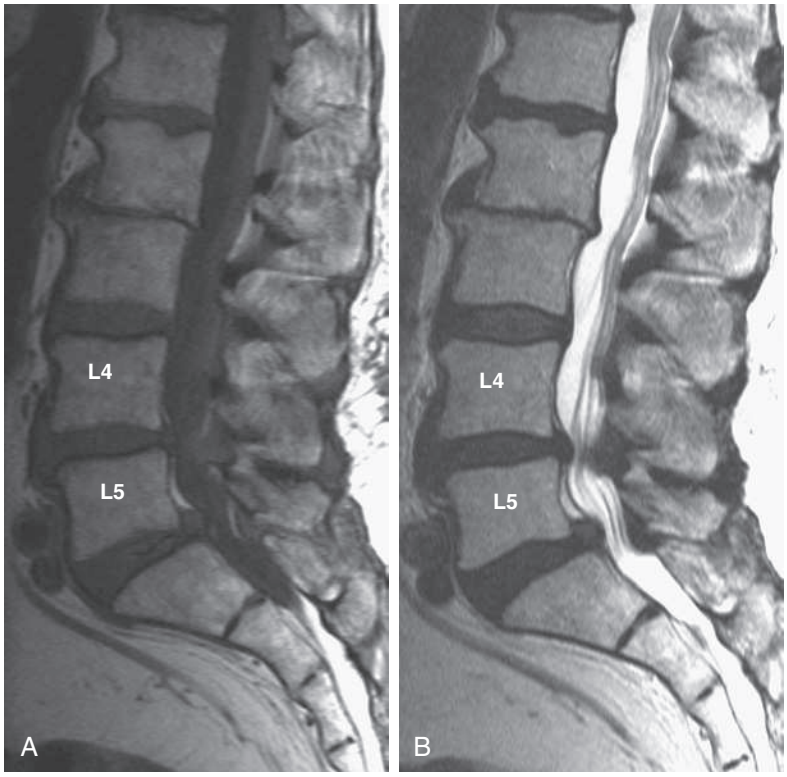

FIG. 61.9 (A) T1-weighted and (B) T2-weighted sagittal MRI of the patient in Fig. 61.6 with L4–L5 and L5–S1 stenosis. Note the disc bulges and ligamentum hypertrophy at the L4–L5 and L5–S1 levels.

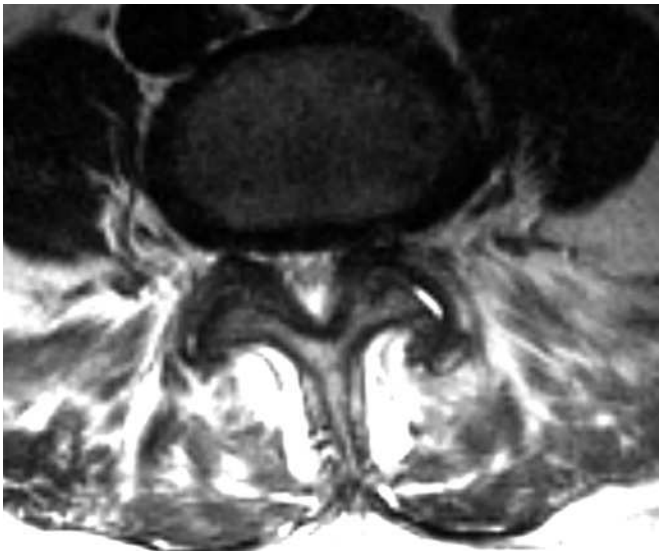

FIG. 61.10 Axial T2-weighted magnetic resonance imaging of the patient in Fig. 61.6 through the L4–L5 level demonstrating facet and ligamentum hypertrophy along with a disc bulge causing stenosis. Note increased T2 signal in the facet joint corresponding to the instability that this patient had on flexion-extension radiographs at the L4–L5 level.

identifies the effect of nerve function through recording the electrical activity of muscle at rest and with stimulation. EMG identifies lower motor neuron dysfunction and does not evaluate any sensory dysfunction. Electromyographic changes have been documented in up to 80% of patients with spinal stenosis.[90,99–102] EMG can be useful in differentiating chronic changes from active ongoing denervation. However, it should be kept in mind that there is a significant incidence of false-negative electromyograms in patients with spinal stenosis. This can be attributed to the fact that EMG does not measure sensory dysfunction and thus does not catch the more common abnormality in patients with neurogenic claudication. EMG also does not help differentiate symptomatic from asymptomatic patients.

NCSs measure the speed with which impulses travel down an axon. NCSs are useful in differentiating changes that are occurring from neuropathy versus radiculopathy. SSEPs measure the electrical transmission of sensory stimulation starting from the peripheral nerves and going through the spinal cord and brain. A lesion in the peripheral nerve will prolong the latency response, whereas lesions of the root and cord will cause changes in the waveform. An SSEP is more sensitive and specific compared with an EMG, although there continue to be false-negatives and false-positives.[103–105]

Differential Diagnosis

Neurogenic claudication is the hallmark of spinal stenosis. Patients describe a variety of abnormal sensations that radiate down their legs with ambulation. Symptoms are typically relieved by forward flexion of the lumbar spine and are worse with extension. Sudden onset or severe motor weakness and bowel and bladder dysfunction in these patients should prompt evaluation of other etiologies of these symptoms, such as cord compression. In spite of various attempts to create

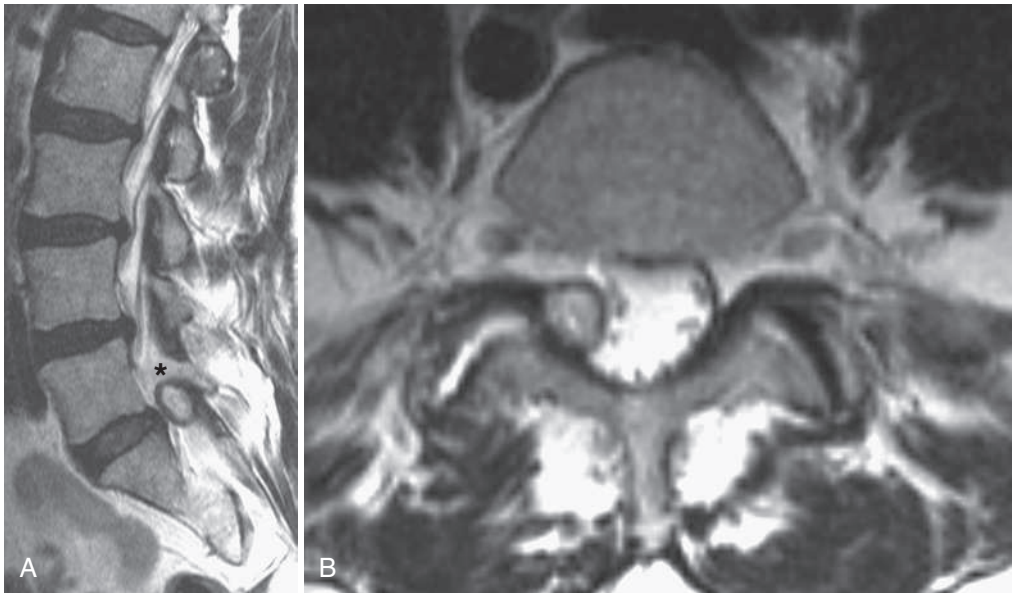

FIG. 61.11 T2-weighted (A) sagittal and (B) axial magnetic resonance imaging of a patient with a right L5–S1 synovial cyst causing a right lumbar radiculopathy. *Asterisk* denotes the synovial cyst on the sagittal view. In the axial view, the cyst is noted to arise from the right facet joint and causes neural compression.

a single validated method of consistently diagnosing spinal stenosis, no single test or algorithm is available to accurately diagnose all patients with symptomatic spinal stenosis.[63,106–108]

The differential diagnosis of spinal stenosis includes vascular claudication, lumbar spondylosis, lower extremity arthritis, cord compression, neurologic disorders, peripheral neuropathy, infection, tumors, and lumbosacral plexus lesions. Symptoms from neurogenic claudication start proximally and progress distally, whereas symptoms from vascular claudication start distally and progress proximally. Vascular claudication causes symptoms with a constant level of exertion regardless of the position of the lumbar spine. Thus, leaning forward on a grocery cart or going uphill does not allow these patients to walk longer. Similarly, patients with vascular claudication continue to be limited on a bike, while the patients with neurogenic claudication have better endurance on a bike. On physical examination, painless full extension of the lumbar spine; shiny, hairless legs; and weak peripheral pulses are all hallmarks of vascular claudication. If clinical suspicion of vascular claudication exists, then a peripheral pulse examination is not sufficient to diagnose peripheral arterial occlusive disease. Ankle brachial index and toe brachial index tests should be obtained. In a recent prospective study of 201 patients with lumbar stenosis, peripheral arterial disease was also present in 26% of patients, with a significant number of these cases only diagnosed using a combination of ankle brachial index and toe brachial index tests.[109]

Lumbar spondylosis typically causes pain in the low back without significant pain or abnormal sensation in the legs. Peripheral neuropathy typically causes burning pain and paresthesias that are unrelated to activity. A history of diabetes, vitamin deficiencies, alcoholism, chemotherapy, drug abuse, and exposure to toxins should be elicited in these patients. Physical examination in neuropathy patients will typically demonstrate hypoesthesia or dysesthesia in a glove-and-stocking distribution. Ankle reflexes will often be absent bilaterally. NCSs are helpful in establishing a diagnosis in these patients.

A history of isolated joint pain with ambulation will help identify patients with lower extremity arthritis. Hip arthritis typically presents with groin pain radiating into the anterior thigh but can also be a cause of buttock pain. Physical examination demonstrating hip irritability and limitation in internal rotation suggests that hip pathology is symptomatic. A thorough history and physical examination can thus help eliminate the majority of common conditions that mimic lumbar spinal stenosis. Presence of constitutional symptoms and intense nighttime pain suggest a possible infection or malignancy. These symptoms should trigger an MRI and laboratory studies, which would help eliminate these more rare conditions.

Finally, the coexistence of more than one condition must be considered. Tandem stenosis of cervical and lumbar spine is known to occur in 5% to 25% of individuals with neural compression in one region.[110–113] The clinical picture in these patients can be quite confusing since they will present with a mix of symptoms from cervical and lumbar stenosis. A small percentage of these patients will have sufficient symptoms to require surgical treatment of both conditions.[47] Thus, every patient diagnosed with lumbar stenosis should be carefully evaluated for cervical stenosis and any signs or symptoms of myelopathy.[112]

Summary

Lumbar spinal stenosis is a common finding in the elderly. With the aging population in the United States, the number of patients with spinal stenosis seeking treatment will dramatically increase over the next decade. Because pathologic changes can be present in asymptomatic patients, abnormalities found

on imaging modalities are not a good method of diagnosing symptomatic spinal stenosis. Findings from a thorough history and physical examination should be correlated with corresponding pathologic abnormalities on MRI or a CT-myelogram. This is especially important if any invasive treatment will be recommended. Plain radiographs complement the other imaging modalities to create a full clinical picture that includes the detection of any dynamic instability. EMG, NCSs, and SSEPs are typically not helpful in confirming the diagnosis of stenosis. Despite our long history of treating patients with spinal stenosis, there is no single diagnostic test that can help identify patients with symptomatic spinal stenosis.

PEARLS

1. In patients with mild to moderate lumbar spinal stenosis, rapid or catastrophic neurologic deterioration is rare.
2. MRI is the noninvasive study of choice in patients suspected of having spinal stenosis.
3. Imaging studies should be correlated with specific findings on history and physical examination that would be expected on the basis of the specific neural elements that are compressed.
4. No single diagnostic test can confirm the presence of symptomatic spinal stenosis.

PITFALLS

1. Abnormal imaging is not a reliable method of diagnosing symptomatic lumbar spinal stenosis. The incidence of clinically silent lumbar degenerative disease is high.
2. A small but significant number of patients with lumbar stenosis will also have cervical myelopathy.
3. Lumbar stenosis and peripheral arterial occlusive disease often coexist. A peripheral pulse examination alone is not sufficient to exclude peripheral arterial occlusive disease in patients suspected of having vascular claudication.
4. Electrodiagnostic studies are not typically helpful in the diagnosis of spinal stenosis.
5. Most patients with spinal stenosis have a normal neurologic examination.
6. In evaluating patients with stenosis, do not forget to examine the hip joints and lower extremity vascularity.

KEY POINTS

1. Lumbar disc degeneration is a nearly universal finding in the aging population.
2. Degeneration alone does not imply a pathologic entity. A disease may be said to exist relative to the symptoms with which the patient presents.
3. In the absence of pathognomonic findings, the diagnosis of spinal stenosis rests on a Venn diagram approach in which historical elements overlap with physical examination and imaging findings.
4. Once symptomatic, most patients will continue to have symptoms on at least an intermittent basis.
5. Lumbar stenosis does not progress rapidly and catastrophic neurologic deterioration is rare. Therefore, a trial of nonoperative management is indicated in most cases.
6. Patients with symptomatic stenosis may present with one or more of a combination of axial pain, radiculopathy, and neurogenic claudication. Each of these is associated with different historical and examination findings.
7. Patients with lumbar stenosis often have other coexisting pathologies—such as hip or knee arthritis, vascular claudication, and cervical myelopathy—that may confuse the clinical picture.
8. Every patient with lumbar stenosis should be screened for cervical myelopathy.

62 CHAPTER Nonoperative Management of Lumbar Spinal Stenosis

Daniel Mazanec

Lumbar spinal stenosis (LSS) is best defined as a clinical syndrome of buttock or lower extremity pain, with or without low back pain, resulting from diminished space for neurovascular elements in the spinal canal.[1] A clinical definition is preferred because imaging findings do not correlate with symptoms. Approximately 20% of asymptomatic individuals older than 60 years have stenosis on magnetic resonance imaging (MRI).[2] Anteroposterior spinal canal diameter is not predictive of symptoms or prognosis.[3] Since its description as a distinct clinical entity in the early 1950s, LSS has been increasingly identified as a common clinical problem in older adults and now represents the most common diagnosis requiring spinal surgery in patients older than 65 years.[4]

Clinical Aspects

The classic symptom of LSS is pseudoclaudication—leg pain, paresthesias, and/or weakness provoked by walking or standing and relieved with forward flexion (i.e., sitting or squatting), noted in more than 90% of patients.[5] Though axial lumbar pain may be present, most patients with LSS report greater lower extremity discomfort than spinal pain. Physical examination in patients with LSS may be unremarkable, with a minority of patients demonstrating provocation of leg symptoms with spinal extension or an abnormal Romberg test. Findings such as diminished patellar or Achilles reflexes, focal muscle weakness, or positive nerve tension signs are noted in only a minority of patients.

The physical examination is crucial, however, in identifying common alternative causes of back and leg pain in this population, including osteoarthritis of the hip, peripheral arterial disease, and greater trochanteric pain syndrome. These conditions may produce symptoms that superficially mimic the pseudoclaudication of LSS. In addition, older patients with LSS may have coexisting hip or vascular disease (i.e., the "hip-spine syndrome").

Natural History of Lumbar Spinal Stenosis

Understanding the natural history of untreated spinal stenosis is crucial to making any recommendation for treatment, medical or surgical. Unfortunately, surprisingly little information about the course of untreated LSS is available. Johnson[6] reported the course of 32 patients with myelographically confirmed stenosis and radicular or claudication pain followed for a mean of almost 4 years without any medical/interventional or surgical treatment. Pain, as assessed by visual analog scores, was unchanged in 70% at final follow-up, improved in 15%, and worse in 15%, suggesting a benign course in most patients. Functionally, walking capacity at 4 years was unchanged from baseline. In these untreated patients, no severe or catastrophic neurologic deterioration occurred.

Several studies have compared surgical and nonsurgical treatment in patients with LSS, but none has included an untreated control group. As a result, they do not provide further insight into the natural history of untreated LSS. However, the results do suggest that approximately 50% of patients with mild to moderate LSS who were managed without surgery have a favorable course. Malmivaara[7] reported a prospective randomized controlled trial comparing surgical treatment (undercutting laminectomy) with medical management (physical therapy) in 94 patients with symptomatic LSS severe enough to warrant treatment. Both groups demonstrated improvement at their 2-year follow-up. Clinically significant improvement in the Oswestry Disability Index (ODI) was noted in 55% of surgical patients and 42% of nonoperative patients. No difference in walking ability was detected. Weinstein reported a prospective randomized trial with an observational cohort comparing surgical and nonsurgical treatment in patients with LSS who were believed to be surgical candidates.[8] Though surgical patients demonstrated superior improvement at 2 years, nonoperatively treated patients demonstrated improvements as well, in the ODI and bodily pain and physical function indices of the Short-Form 36 questionnaire. The Maine Lumbar Spine Study reported the results of a prospective cohort trial comparing medical and surgical treatment of 148 patients with LSS, some followed for up to 10 years.[9,10] Patients were treated in community-based orthopedic and neurosurgery practices in Maine. Medical treatment was not specified by the study, but most frequently included physical therapy (modalities and exercises), manipulation, analgesics, and epidural injections. After 4 years, 70% of the surgically treated patients and 52% of the medically treated patients reported improvement in their dominant symptom. After 8 to 10 years, a similar percentage of surgical and medically treated patients available for evaluation

reported improvement in their predominant symptom (54% vs. 42%). Both groups reported comparable satisfaction with their current status (55% and 49%). In a cohort of 68 patients with LSS with moderate symptoms who were treated medically, Amundsen reported about 70% of persons had good outcomes at 10 years.[11] Medical treatment included a 1-month stay in a rehabilitation unit with bracing. Outcomes in conservatively managed patients who ultimately required surgery did not differ from patients who were selected for initial surgical treatment (i.e., delay in surgery did not adversely affect results). Finally, Delitto et al. reported the results of a randomized study in 169 patients with stenosis who had been consented for surgery and then randomized to surgical decompression or a 6-week structured physical therapy program with 2-year follow up.[12] Intention-to-treat analysis demonstrated no difference in physical function; however, 57% of patients randomized to physical therapy crossed over to surgery. Successful outcomes of treatment were found in 61% of surgical patients, 55% of crossover patients, and 52% of physical therapy patients.

These studies suggest that, although surgical results are generally superior in the short term (1–4 years), a significant proportion of patients do well with nonoperative care for as long as 10 years without catastrophic neurologic deterioration. In most trials, the decision for early surgery was based on severity of symptoms rather than anatomic factors such as spinal canal dimensions, which are not predictive of symptoms, much less need for urgent surgical intervention. The study by Delitto et al.[12] suggests that crossover patients who tried physical therapy (mean, 7.8 visits) had comparable success to patients who had earlier surgery. This would suggest that delaying surgery for several weeks does not adversely impact outcome. In patients with moderate or less severe symptoms, on the basis of these data, a trial of conservative management is certainly reasonable. None of these trials included an untreated control group, however, making attribution of success to a specific treatment impossible.

Nonoperative Management

Whether medical and interventional treatments improve the outcome of patients with spinal stenosis compared with the generally favorable natural history of the disease remains uncertain. A recent Cochrane review of nonoperative treatment for LSS with neurogenic claudication including 21 trials (1851 participants) concluded that "moderate and high-quality evidence for nonoperative treatment is lacking and thus prohibits recommendations for guiding clinical practice."[13] Another systematic review of the literature found no direct comparisons of active treatment to an untreated control group.[1] Medical treatment is therefore based primarily on clinical experience and training guided by limited clinical outcome data. In most patients, a combination of physical therapy, medications, and spinal injections are considered with the objectives of relieving pain and functionally improving walking and standing time.

Drug Therapy

Though widely used, the efficacy of analgesics and nonsteroidal antiinflammatory drugs (NSAIDs) has not been investigated in patients with lumbar stenosis. In the absence of studies demonstrating that NSAIDs are superior to simple analgesics, the risk of NSAID toxicity becomes the determining factor in therapeutic decision making. For osteoarthritis, on the basis of cost and toxicity associated with NSAIDs, the American College of Rheumatology and the European League Against Rheumatism have both recommended acetaminophen as initial therapy.[14] However, a recent study comparing acetaminophen to placebo in acute back pain found no difference in outcome.[15] In addition, a systematic review and metaanalysis of acetaminophen for spinal pain also concluded that the drug is ineffective.[16] Typically, patients with LSS are older and more likely to have common comorbidities, including hypertension, cardiovascular disease, and diabetes, that increase the risk of NSAID-induced cardiovascular, renal, and gastrointestinal toxicity.[17–19] Extrapolating from these guidelines, pure analgesics—including opioids—would be the agents of first choice in patients with LSS. The fact that inflammation is not believed to play a central role in the pathogenesis of LSS lends further rationale for the choice of a pure analgesic in this high-risk population. However, even therapy with opioid analgesics often fails to produce significant functional improvement, as assessed by increased walking or standing tolerance. The adverse effects of long-term opioid therapy, including cognitive impairment and sedation, are of particular concern in older stenosis patients at increased risk of falls.[20]

Gabapentin is an anticonvulsant and analgesic agent that has been found in multiple trials to be effective in the treatment of various neuropathic pain syndromes, including diabetic neuropathy and postherpetic neuralgia.[21] Two small trials of gabapentin suggest possible efficacy in patients with LSS. Yaksi et al. reported a randomized trial of 57 patients comparing standard treatment (physical therapy, NSAIDs) with standard treatment plus gabapentin. Gabapentin resulted in significantly increased walking distance, as well as improved pain scores and recovery of sensory deficits.[22] A more recent 4-week prospective cohort study using an extended-release form of gabapentin reported significant improvement in sleep and pain.[23] Careful attention to common adverse effects of gabapentin, particularly sedation and dizziness, is crucial in treating patients with LSS. Other drugs used to treat neuropathic pain syndromes—including pregabalin, tricyclic antidepressants, and duloxetine—have not been studied in LSS. Because of potential cardiovascular toxicity, tricyclics should be used with caution in this population.

Physical Therapy

Though nonoperative treatment of spinal stenosis typically includes physical therapy, a recent systematic review of physical therapy interventions for degenerative LSS found that evidence was scarce and insufficient to identify which physical therapy treatment is best.[24] The authors found no evidence that addition of physical therapy modalities (ultrasound,

transcutaneous electrical nerve stimulation, heat packs) to exercise had any impact on outcome. Exercise was superior to no exercise but specific exercise programs have not been well studied. Traditional empirically based exercise programs in patients with stenosis have focused on the goals of decreasing lumbar lordosis and extension forces on the spine while improving abdominal "core" strength. Commonly, flexion-based lumbar stabilization exercises are recommended. This approach should include identification and treatment of hip flexion contractures, which may result in increased lumbar lordosis. Many patients with LSS are deconditioned as a result of symptom-limited walking and age-related comorbidities. Options for low-impact, aerobic training include stationary cycling, elliptical trainers, or aquatic exercise programs. Recent trials comparing structured physical therapy approaches in younger (mean age, 58 years) LSS patients demonstrated comparable improvement in walking tolerance, pain, and ODI scores with body weight–supported treadmill walking and cycling as the cardiovascular/aerobic component of a therapy program.[25,26] Other potential benefits of active aerobic exercise include improvement in depression, assistance with weight control, and opportunities for increased socialization (group exercise programs). Physical therapy programs must be tailored to individual circumstances to optimize compliance, particularly in older, frailer patients.

A lightweight lumbar corset that maintains a slight degree of lumbar flexion may offer some patients modest benefit. Prateepavanich and colleagues[27] noted improved treadmill walking distance and decreased pain in 21 patients with neurogenic claudication who were provided a lumbosacral corset.

Epidural Corticosteroid Injection

Epidural steroid injection (ESI) for spinal stenosis is directed at treatment of the presumed inflammatory reaction and edema present at the stenotic segment. Fluoroscopic guidance is strongly recommended for caudal, interlaminar, or transforaminal injection to ensure accurate needle placement. Renfrew et al.[28] demonstrated that nonfluoroscopically assisted injections were actually in the epidural space in only 62% of procedures performed by experienced physicians.

Whether ESI results in significant long-term improvement in patients with LSS is uncertain. A recent subgroup analysis of the Spine Patient Outcomes Research Trial (SPORT) found that ESIs were associated with less improvement at 4 years among all patients, whether treated nonoperatively or surgically.[29] Ng and colleagues[30] found no difference in pain or walking distance at 12-week follow-up between patients with LSS who received a single transforaminal, fluoroscopically guided ESI. A randomized trial comparing epidural steroid injections with epidural injections of lidocaine only in 400 patients with spinal stenosis found no difference in functional outcomes at 6 weeks.[31]

However, several case series using a multiple injection regimen in patients with LSS suggest that from one-third to two-thirds of patients may experience long-term improvement extending to almost 2 years. In a multiple-injection protocol, after an initial injection, an additional injection is performed only when severe symptoms recur. Botwin and colleagues[32] reported a prospective series of 34 patients with LSS treated with a multiple-injection protocol of transforaminal lumbar epidural steroid injections and followed for 12 months. Of the patients, 75% had at least a 50% improvement in pain scores, and 64% noted improvement in walking tolerance. The average number of injections per patient was 1.9. Hoogmartens and colleagues[33] reported that 32% of patients with severe pseudoclaudication defined by a walking distance of less than 100 m treated with multiple caudal injections reported good to excellent improvement in symptoms at an average follow-up of 23 months. In a more recent retrospective study of 140 patients with LSS treated with either fluoroscopically guided transforaminal or caudal ESI, Delport and colleagues reported that 32% of patients experienced pain relief at their 2-month follow-up after an average of 2.23 injections.[34] Of the patients, 53% reported improvement in their functional abilities.

Before an epidural injection, anticoagulants and antiplatelet agents, including NSAIDs and clopidogrel, are usually discontinued for approximately 1 week. In anticoagulated patients with severe comorbid cardiovascular disease with LSS who are not surgical candidates, this may be contraindicated, eliminating this nonoperative option. A relatively common adverse effect, transient headache, is seen in up to one-quarter of patients treated with epidural steroids.[35] More serious complications—including epidural abscess, meningitis, and spinal hematomas—are rare.[36]

Lumbar Spinal Stenosis: Evidence-Informed Approach to Management

Evidence-informed treatment of symptomatic lumbar stenosis rests on at least three principles derived from the recent clinical studies reviewed earlier:

1. Severity of symptoms rather than spinal canal dimensions should dictate aggressiveness of treatment because the correlation between spinal anatomy and symptoms is poor.
2. Surgical treatment offers patients with severe pain and functional impairment more rapid short-term improvement.
3. Because up to 70% of patients with LSS have a favorable untreated or medically treated long-term outcome and catastrophic neurologic deterioration is rare, most patients should be offered a trial of medical treatment.

For most individuals, an informed choice of initial medical or surgical treatment is influenced by severity of pain, functional status, comorbid medical conditions, and personal preference.

Choice of medical treatments is also influenced by severity of symptoms. A reasonable, evidence-informed approach in most patients begins with the least invasive options—physical therapy and gabapentin. Because of frailty or severe comorbid medical conditions, however, some persons may be unable to engage in even limited exercise programs. In such patients, a trial of bracing may be appropriate. For some severely limited nonsurgical patients, a rolling walker significantly improves

walking distance and balance. Patients with a significant component of back pain in addition to pseudoclaudication may benefit from an analgesic. A trial of an epidural injection is reasonable in patients without contraindications whose leg pain has not responded to simpler meabat di sures. If the response to a single injection is significant and somewhat durable, a multiple-injection approach over time may be effective in some patients.

PEARLS

1. LSS is a clinical diagnosis. Most patients with radiographic stenosis do not exhibit symptoms of pseudoclaudication.
2. Most patients (70%) with LSS do well with nonoperative care without catastrophic neurologic decline.
3. Gabapentin may be superior to pure analgesics in treating the neuropathic pain of LSS.
4. Episodic epidural steroid injections may provide longer-term relief of pain with improved function in some patients with LSS.

PITFALLS

1. Imaging findings of LSS are found in up to 20% of persons without the clinical syndrome.
2. NSAIDs have not been shown superior to pure analgesics in LSS and pose a greater risk of adverse effects in this older population.
3. Frail, elderly LSS patients with severe comorbid medical conditions may be unable to engage in even limited trials of exercise-oriented physical therapy.

KEY POINTS

1. LSS is a clinical diagnosis. Radiographic stenosis is common in asymptomatic persons.
2. Though the diagnosis of LSS is based primarily on the history of neurogenic claudication, the physical examination is crucial in identifying alternative diagnoses that may mimic LSS, including hip disease and peripheral arterial disease.
3. The long-term (10-year) outcome of patients with LSS treated medically compares favorably with surgically treated patients.
4. For most patients with LSS, appropriate initial medical treatment includes physical therapy and gabapentin or a pure analgesic.
5. For most patients, an informed choice of initial medical or surgical treatment is influenced by severity of pain, functional status, comorbid medical conditions, and personal preference.

CHAPTER 63

Surgical Management of Lumbar Spinal Stenosis

SECTION VIII

Peter B. Derman
Jeffrey Rihn
Todd J. Albert

Indications for Surgery

Spinal stenosis is the most common reason for lumbar spine surgery in adults older than 65 years of age.[1] Lumbar stenosis occurs secondary to spondylotic changes at the facet joints and uncinate processes, spondylolisthesis, ligamentum flavum buckling or hypertrophy, disc herniations or bulging, and/or a congenitally narrow canal. Pathologic changes affect the central vertebral canal, lateral recess, and neural foramina (Fig. 63.1). Spondylotic lateral recess stenosis typically emanates from the superior articular process of the caudal vertebra. This compresses the traversing nerve root, leading to neurogenic claudication (e.g., overgrowth of the superior articular process of L5 produces stenosis at the L4–L5 level, which compresses the L5 nerve root; Fig. 63.2). Spinal stenosis does not necessarily worsen over time, and a substantial proportion of patients remain unchanged or even improved with nonoperative treatment.[2]

Proper patient selection is critical to achieving a good outcome with spinal stenosis surgery. Ultimately, patient desire combined with failure of conservative treatment (physical therapy, activity modification, medication, and steroid injections) drive the decision for operative treatment. The ideal patient has symptoms of neurogenic claudication, which include pain, numbness, and paresthesias in the posterolateral legs and thighs associated with prolonged walking or with activities that cause back extension (e.g., standing). Neurogenic claudication may also manifest as cramping or fatigue in the lower extremities. Activities such as sitting, leaning forward on a walker or shopping cart, and riding a bicycle typically alleviate the symptoms. It is important to rule out vascular claudication as a source of lower extremity symptoms.

Deen and colleagues[3] performed a review of patients with early failure after lumbar laminectomy and found that the most common presentation prior to the index procedure was an absence of classic symptoms of neurogenic claudication coupled with a lack of severe stenosis on imaging studies. Other authors have reported that surgical outcomes are significantly better in patients who preoperatively exhibited greater disability, predominant leg pain over low back pain, neuroforaminal stenosis, or a neurologic deficit; not lifting at work and not smoking have also been associated with better outcomes.[4–6] Selective nerve root blocks are good prognostic indicators of surgical outcome. Patients who obtain more than 50% relief of leg pain for at least 1 week after an injection tend to have greater relief of leg pain after surgery.[7] Additionally, those with long-standing symptoms (>12 months) are less likely to have a positive surgical outcome and are more likely to undergo reoperation.[7,8]

Surgical decompression can be performed on an elective basis unless the patient has a rapidly progressing neurologic deficit or bowel/bladder dysfunction, both of which are rare presentations of spinal stenosis. Before surgical intervention, we routinely obtain standing anteroposterior, lateral, and flexion-extension radiographs, as well as magnetic resonance imaging (MRI) or computed tomography (CT) myelogram. It is important to recognize that instability is a dynamic process that is most evident on flexion-extension radiographs and may not necessarily be apparent on static supine imaging. Although numerous surgical techniques have been described to treat lumbar stenosis, there currently is insufficient evidence to determine which is most effective.[9,10] Surgical options include decompressive laminectomy with or without fusion, laminotomy, minimally invasive decompression, and placement of an interspinous process device.

Laminectomy

Laminectomy has been the gold standard for the surgical treatment of central, lateral recess, and foraminal stenosis in the absence of instability.[10] After induction of anesthesia, the patient is positioned face down on an operating table. Surgeons can choose from several different positions (e.g., prone and kneeling) and support devices, each with its own set of advantages and disadvantages.[11,12] The Andrews frame, for instance, places the patient in a kneeling position, which has been shown to decrease vena caval and central venous pressures, leading to a reduction in blood loss when compared with a Cloward surgical saddle.[13,14] In addition, flexion of the hips reduces normal lumbar lordosis and widens the interlaminar space, making it easier to access the spinal canal. Use of a Wilson frame also allows for reduction of lumbar lordosis

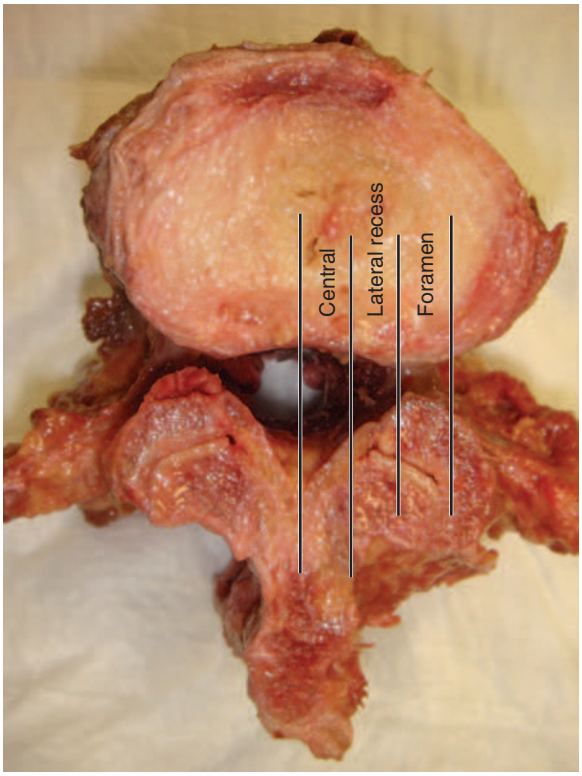

FIG. 63.1 Lumbar stenosis is anatomically categorized into compression within the central canal, lateral recess (subarticular), and neural foramina.

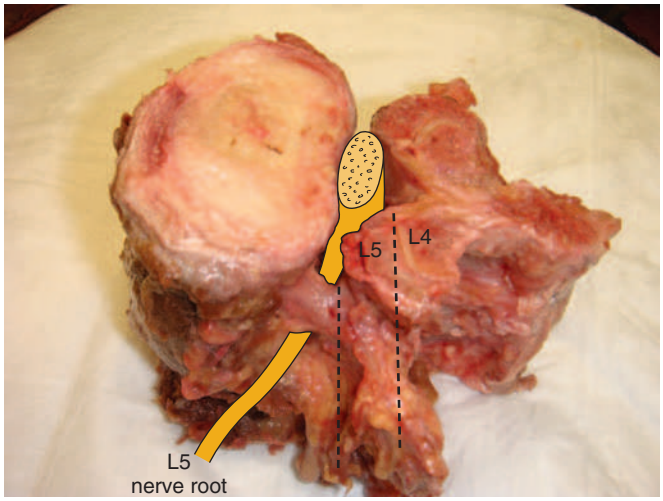

FIG. 63.2 Stenosis at the lateral recess leads to compression of the traversing nerve root by the superior articular process of the caudal vertebra (e.g., spondylosis at the L4–L5 level leads to compression of the L5 nerve root as it traverses the lateral recess before exiting the foramen).

during decompression, although not to the same degree as the Andrews frame. It is important to note that placing a patient in a kneeling position can lead the surgeon to underestimate the true degree of stenosis when compared to the lordotic position obtained on a flat Jackson table. Also, when performing a fusion in addition to a decompression on a lordosis-reducing frame, care must be taken to avoid the tendency to fuse the lumbar spine in a hypolordotic position. The Wilson frame can be used in the fully cranked position for the laminectomy and then uncranked for the final fusion to prevent arthrodesis in a nonlordotic position. Given the ease of use and more accurate portrayal of native lordosis, we prefer to use a flat Jackson table with bolsters as long as the patient can be supported with the abdomen hanging free. We believe that flexion of the knees with the use of pillows under the shins is also important because it has the potential to reduce tension on the sciatic nerve.

We routinely use ×2.5 or ×3.5 loupe magnification and an operating headlight. The relationship of the iliac crests to the lower lumbar levels on preoperative radiographs should be carefully examined to help guide placement of the incision. Using a scalpel, a standard midline skin incision is made over the desired levels. The incision should be long enough to allow for exposure of the pedicles of the cephalad and caudal levels to be decompressed. For example, an L3 to L5 pedicle-to-pedicle decompression requires enough exposure such that the inferior aspect of the L3 pedicle and the superior aspect of the L5 pedicle can be easily palpated at the end of the decompression. Dissection is carried down to the thoracolumbar fascia using electrocautery. The fascia should be clearly exposed approximately 1 cm off of midline with a Cobb elevator to ensure a distinct layer for fascial closure at the conclusion of the case. The spinous processes are easily palpated and can be used to fine-tune the fascial incision for exposure of the appropriate levels. Electrocautery is then used to dissect just lateral to the spinous processes, taking care to preserve the supraspinous and interspinous ligaments.

At this point, a Kocher clamp is placed on the cephalad aspect of one of the spinous processes so that the clamp is in line with the pedicle of interest. Alternatively, a Woodson elevator can be placed in the interlaminar space to mark the appropriate surgical level. An intraoperative radiograph that includes the Kocher clamp or Woodson elevator and the sacrum is then taken in order to confirm. This step is critical because, despite the potentially disastrous repercussions of wrong-level surgery, 50% of spine surgeons report performing at least one such case over the course of their careers, and 71% of the wrong-level cases occur in the lumbar spine.[15]

Once the correct levels are identified, subperiosteal dissection of the paraspinal muscles is carried laterally with a combination of a Cobb elevator and electrocautery, allowing for exposure of the spinous processes and lamina. During the dissection, the midlateral pars (MLP) must be clearly identified so that it can be used later as a landmark for bony resection (Fig. 63.3). As the dissection is carried out laterally, care should be taken to preserve the facet joint capsules, which lie superficial to the level of the lamina and MLP. It has been demonstrated in cadaveric models that excision of the capsule and cartilage of the facets results in increased motion in both the sagittal and axial planes, potentially leading to clinical instability.[16] For an isolated laminectomy, dissection should be carried out as far laterally as the lateral aspect of the facet capsule. Hemostasis with bipolar electrocautery is critical for visualization, particularly around the facet joint, where bleeding may occur from medial and lateral parafacetal arteries.[17] If a posterolateral fusion is planned, the dissection needs to extend laterally to the transverse processes, taking

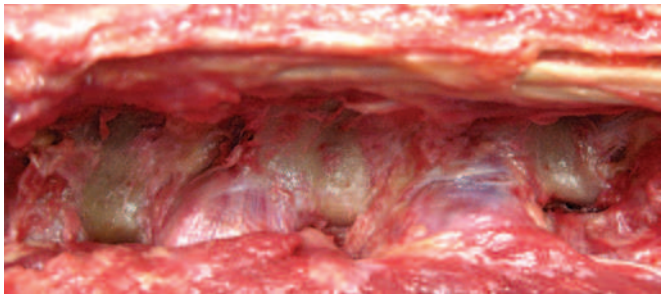

FIG. 63.3 Exposure for a laminectomy must include clear delineation of the midlateral pars at each level, as this landmark provides a guideline for the degree of final bony resection. Dissection should be taken out to the lateral aspect of the facet, taking care to preserve the facet capsule.

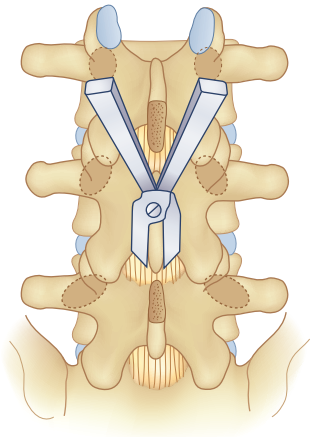

FIG. 63.4 Decompression begins by delineating the extent of bony resection with a rongeur. For an L3–L5 decompression, this includes the inferior half of the L3 spinous process and the superior half of the L5 spinous process (*shaded area*). A Horsley bone cutter is used to remove the intervening spinous processes down to the level of the spinous process/lamina junction.

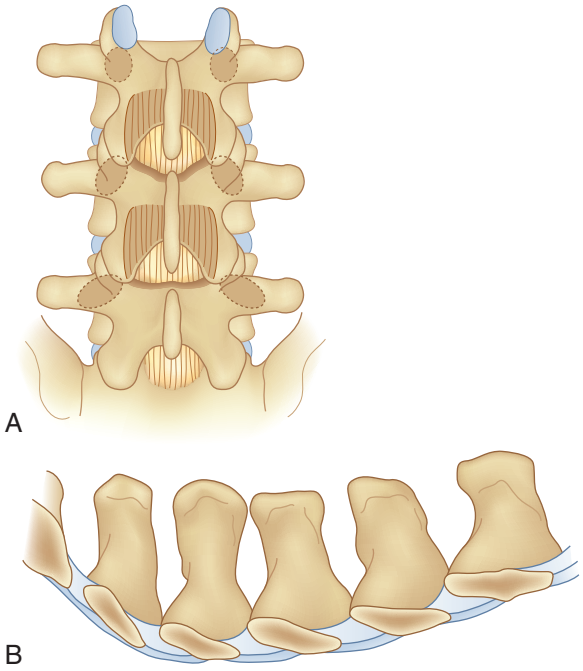
care to maintain the integrity of the intertransverse membrane between each level.

The cephalad and caudal limits of the laminectomy are delineated with a Leksell rongeur. The inferior half of the spinous process at the cranial aspect of the decompression and the superior half of the spinous process of the most caudal aspect of the decompression are removed. Performing a laminectomy between these bounds is typically sufficient to permit palpation of the pedicles of the cephalad and caudal levels to be decompressed. A Horsley bone cutter is used to remove the intervening spinous processes (Fig. 63.4). These are resected down to the spinous process/laminar junction. The rongeur is then used to thin the lamina. Any bleeding from cancellous bone should be controlled with bone wax.

The decompression should begin centrally because the central zone is typically the least stenotic. The laminae of the lower spine have a much greater proportion of their anterior surface covered by the deep layer of the ligamentum flavum (Fig. 63.5).[18,19] A curette is used to dissect the underlying ligamentum flavum from the inferior aspect of the lamina (Fig. 63.6). A Kerrison punch is then used to remove bone from the inferior aspect of the lamina, using the ligamentum flavum as a protective layer. The decompression is carried cephalad until



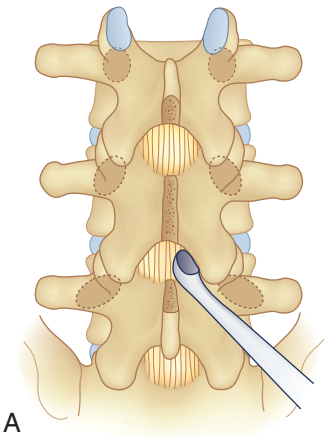


FIG. 63.5 (A) In general, the ligamentum flavum originates from halfway up the lamina of the cephalad level and inserts onto the superior aspect of the caudal lamina. (B) From the sagittal view, the laminae of the lower spine have a much greater proportion of their anterior surface covered by the deep layer of the ligamentum flavum. (From Olszewski AD, Yaszemski MJ, White AA III. The anatomy of the human lumbar ligamentum flavum. New observations and their surgical importance. *Spine.* 1996;21:2307–2312.)

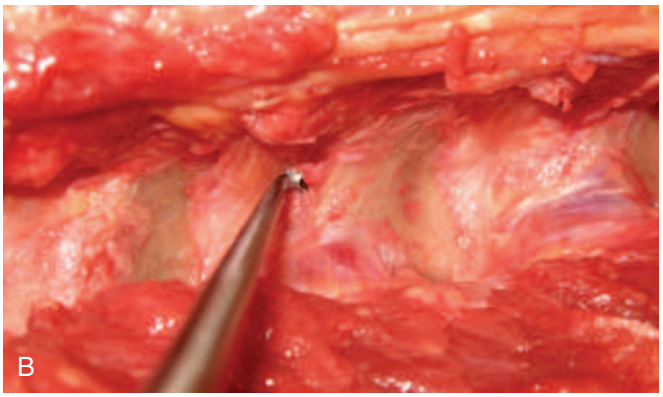

FIG. 63.6 A curette is used to dissect the underlying ligamentum flavum from the inferior aspect of the lamina.

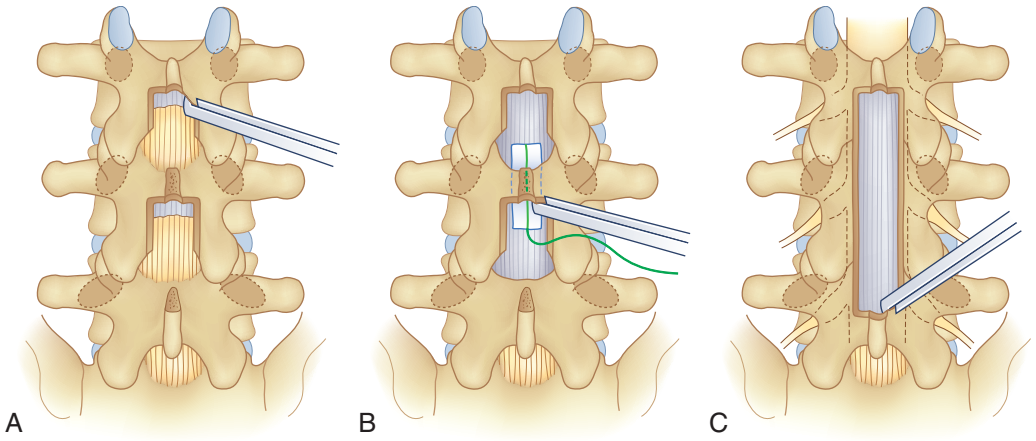

FIG. 63.7 (A) In an L3 to L5 decompression, we recommend beginning at the inferior aspect of the L4 lamina and, once the dura is identified, moving on to removing the inferior aspect of the L3 lamina. (B) A cottonoid is then placed between the dura and remaining L4 laminar bridge, which is removed with a Kerrison punch. (C) The central trough is finalized by removing the superior aspect of the L5 lamina and any residual ligamentum flavum.

the ligamentum flavum ends and epidural fat or dura is encountered. In our experience, this typically occurs at the level of the inferior aspect of the pedicle of the lamina being removed. In an L3 to L5 decompression, we recommend beginning at the inferior aspect of the L4 lamina and, once the dura is identified, moving on to removing the inferior aspect of the L3 lamina (Fig. 63.7A). A cottonoid is then placed between the dura and remaining L4 laminar bridge, which is removed with a Kerrison punch (Fig. 63.7B). Fibrous connections between the dura and the ligamentum flavum[20] or laminae[21] should be identified and carefully released with the use of a Woodson elevator or a Penfield No. 3 dissector to avoid inadvertent durotomy. The central trough is finalized with complete removal of the superior aspect of the L5 lamina and any remaining ligamentum flavum (Fig. 63.7C). Laterally, resection of more than 25% of the lamina immediately cephalad to the inferior articular process at the level of the laminectomy (measured in a medial to lateral direction) is associated with increased risk of postoperative facet fracture.[22] Care must also be taken to preserve approximately 1 cm of the pars interarticularis during this process in order to prevent iatrogenic pars fracture. The location of the medial aspect of the pedicle with respect to the MLP varies with each lumbar level. Su and colleagues[23] described the percentage of pedicle medial and lateral to the MLP and found that less pars remains when the decompression is carried out to the medial aspect of the pedicle in the more cephalad levels (Fig. 63.8). Particular caution should be taken at levels cephalad to L4 to not take too much of the lamina, leaving a narrow pars susceptible to fracture. As such, with a decompression from L2 to S1, the laminectomy should appear to be trapezoidal with a narrower laminectomy trough in the more cephalad levels and a wider trough in the more caudal levels.

The next step involves decompression of the lateral recesses. The most common technical error resulting in early failure after lumbar laminectomy is inadequate neural decompression[3]; thus, careful attention to the lateral recesses is critical.

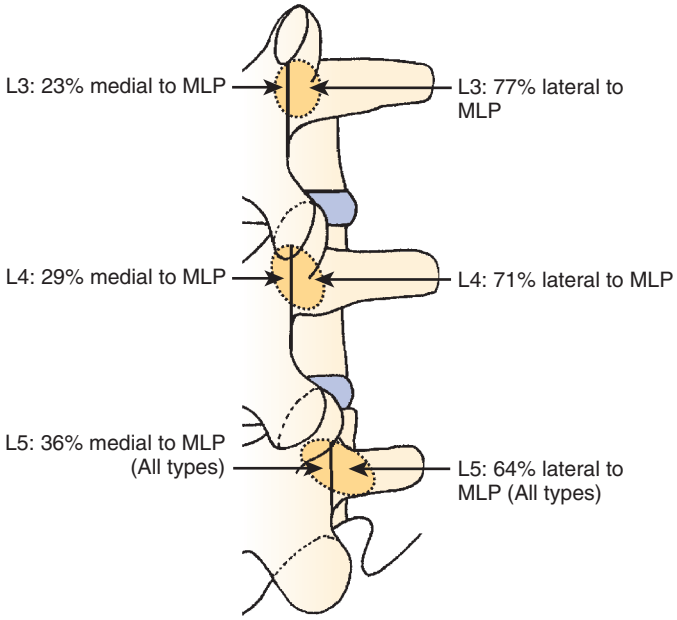

FIG. 63.8 At more cephalad levels, there is less distance between the medial pedicle to the midlateral pars (MLP). Particular caution should be taken at levels cephalad to L4 to not take too much of the lamina, leaving a narrow pars susceptible to fracture. As such, with a decompression from L2 to S1, the laminectomy should appear to be trapezoidal with a narrower laminectomy trough in the more cephalad levels and a wider trough in the more caudal levels. (From Su BW, Kim PD, Cha TD, et al. An anatomical study of the mid-lateral pars relative to the pedicle footprint in the lower lumbar spine. *Spine [Phila Pa 1976].* 2009;34:1355–1362.)

A high-speed burr may be used cautiously to thin the lamina and delineate the area of bony resection. The surgeon must be particularly careful at the cephalad aspect of the lamina, where the cortical bone is thin and not protected by the ligamentum flavum. Lateral recess decompression is performed with a Kerrison punch (Fig. 63.9). Depending on the surgeon's experience, the medial aspect of the inferior facet can be removed

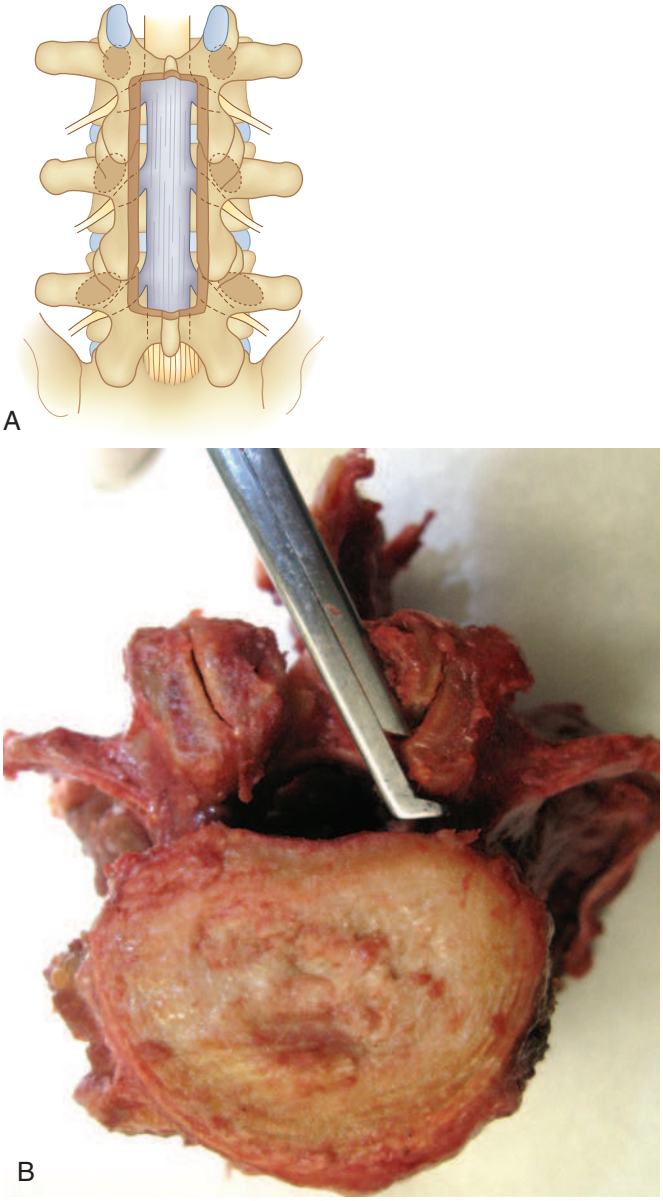

FIG. 63.9 (A) Lateral recess decompression is performed with a Kerrison punch and should preserve at least 50% of the facet joint (*axial view*). (B) Final decompression after undercutting the lateral recess.

using an osteotome, exposing the underlying superior facet. Undercutting the superior facet using a Kerrison punch assists in bone removal while preserving the facet joint and the pars interarticularis. Because of the angle of approach, this maneuver should be performed from the opposite side of the operating table to ensure complete visualization of the dura during the decompression. Decompression should progress laterally until the medial wall of the pedicle is easily palpated with a Woodson or angled dural elevator. Cadaveric studies have shown that decompression with even partial medial facetectomy results in measurable increases in segmental range of motion and decreases in stiffness.[24] In addition, postlaminectomy CT scans reveal that, on average, patients suffering from postoperative facet fracture had significantly more of the articular surface resected than those without fractures.[22] As such, we ensure that at least 50% of each facet joint is preserved to minimize postoperative instability. In the cranial-caudal dimension, the pedicles of the superior and inferior segments should be palpable. Decompression of the lateral recess often leads to bleeding from the epidural venous plexus. Hemostasis is obtained with the use of bipolar electrocautery and hemostatic agents, such as an absorbable gelatin sponge and cross-linked gelatin granules with topical human thrombin.

The last stage of the decompression involves foraminotomies at each level. Each nerve root should be traced as it passes underneath the pedicle and into the foramen. Any compressing bone or soft tissue is removed with a Kerrison punch placed dorsal and parallel to the root as it exits the foramen. In the presence of exit-zone stenosis, bony spurs from the dorsal and lateral aspect of the superior facet should be resected. As in lateral recess decompression, this should be performed from the contralateral side to prevent iatrogenic durotomy of the nerve root sleeve. A Woodson elevator or Murphy probe is used to assess the decompression by passing it into the foramen dorsal to the nerve root; a 4-mm ball tip probe should pass without difficulty.[25] The nerve root can also be assessed for mobility by gently retracting the dural sac and nerve root medially into the canal with a Penfield No. 4 dissector. The nerve should demonstrate 1 cm of medial displacement if adequately decompressed.[25] At the end of the decompression, any sharp spikes of bone should be smoothed with a curette or a Kerrison punch to prevent them from lacerating the dura. Finally, each level should be examined for an extruded herniated disc fragment, which should then be removed in a routine manner. We do not recommend a discectomy for well-contained discs. Before closure, hemostasis is once again obtained, and the wound is irrigated. We routinely place a 15-Fr fully fluted Blake drain in the deep wound. The fascia is closed with interrupted figure-of-eight No. 1 absorbable sutures. The subcutaneous tissue is closed with buried 2-0 absorbable sutures, and the skin is closed with a nonlocked running 3-0 nylon suture or 3-0 absorbable subcuticular suture.

Outcomes of Laminectomy

The evidence to support surgical decompression for the treatment of patients with symptomatic lumbar stenosis has been mounting, with evidence-based guidelines now finding sufficient data to recommend operative intervention for moderate to severe lumbar stenosis when nonoperative modalities have failed.[26] The largest and most well-known study addressing this subject, the Spine Patient Outcomes Research Trial (SPORT), was a multicenter randomized controlled trial with a concurrent observational cohort that evaluated the surgical treatment of conditions associated with low back and leg pain, including lumbar stenosis.[27] In 2008, the 2-year outcomes of the SPORT study evaluating laminectomy versus conservative treatment for lumbar stenosis were reported.[28] All patients who had a history of at least 12 weeks of symptomatic lumbar stenosis without spondylolisthesis were considered surgical candidates. A total of 289 patients were enrolled in the randomized cohort, and 365 patients were enrolled in the

observational cohort. By 2-year follow-up, however, 43% of those who were randomly assigned to receive nonsurgical care underwent surgery (compared to 67% of the patients randomly assigned to the operative group). Despite the high incidence of crossover, intention-to-treat analysis revealed a significant treatment effect favoring surgery on the Short-Form 36 General Health Survey (SF-36) scale for bodily pain. However, there were no significant differences in scores on the SF-36 scale for physical function or on the modified Oswestry Disability Index (ODI). The as-treated analysis, which included the randomized and observational cohorts, showed a significant advantage for surgery compared with nonoperative treatment by 3 months for the ODI and both SF-36 components. These changes remained significant for all subsequent time points in the 2-year duration of the study. At 2-year follow-up, on the basis of the as-treated analysis, 63% of patients treated surgically rated themselves as having major improvement with their condition versus 29% of the group treated nonoperatively.[28]

The long-term outcomes of the SPORT study were published in 2015.[29] At 8-year follow-up, no significant differences remained between randomized cohorts in intent-to-treat analysis. By this point, however, 52% of those randomized to nonoperative care had undergone surgery, which began to approach the 70% of patients in the operative group who actually underwent surgery. As-treated analysis of the randomized group showed that the benefit of surgery diminished over time and was not significant after 5 years. However, the significantly better early outcomes (SF-36 bodily pain and physical function, ODI) associated with surgery in the observational group were maintained out to 8 years. These results suggest that laminectomy for symptomatic degenerative spinal stenosis provides significant improvements in function, pain, and disability, but that these effects likely diminish to some degree over the long term. From a financial standpoint, comparative effectiveness analysis of the SPORT data shows that, even over a 4-year horizon, laminectomy for spinal stenosis produces good value compared to nonoperative care with a cost per quality-adjusted life year (QALY) gained of $59,400 in 2004 dollars[30] (approximately $74,400 in 2015 dollars).

Arthrodesis After Laminectomy

Some authors have recommended that arthrodesis be performed when stenosis is associated with spondylosis and substantial low back pain or with instability.[31,32] Grob and colleagues[33] randomized 45 patients with lumbar spinal stenosis (LSS) without instability to receive decompression with and without arthrodesis. Instability was defined as greater than 5 mm of motion between segments in the sagittal plane or greater than 5 mm of lateral offset in the coronal plane. All patients had significant clinical improvement compared with preoperative values at an average of 28-month follow-up with no significant differences between fusion and nonfusion groups. These results suggest that, in the absence of instability, decompression with care taken to not destabilize the spine does not necessitate an arthrodesis. However, authors of a more recent retrospective review of 50 elderly patients with LSS without instability found that decompression with fusion resulted in greater improvement in back pain than decompression alone.[34] The most likely explanation is that spondylotic changes in patients with degenerative stenosis but no instability contribute to a component of low back pain. We currently do not fuse patients who have stenosis secondary to spondylosis unless they exhibit a significant component of low back pain.

As mentioned earlier, instability is another important factor to consider when creating a surgical plan. Herkowitz and colleagues[35] performed a prospective comparative study of 50 patients with spinal stenosis and associated degenerative spondylolisthesis to determine whether noninstrumented arthrodesis produced better outcomes than decompressive laminectomy alone. At a mean of 3-year follow-up, patients in the arthrodesis group had significantly greater back and lower extremity pain relief. Furthermore, only 28% of patients in the fusion group experienced slip progression after surgery, while the slip distance increased in 96% of those in the nonfusion group. Fischgrund and colleagues[36] investigated the effects of instrumentation in a randomized study of patients with spondylolisthesis and stenosis. Although the addition of instrumentation increased the fusion rate compared to noninstrumented arthrodesis (82% vs. 45%) in the 67 patients available for 2-year follow-up, clinical outcomes were similar between the groups.[36] However, longer-term follow-up (average, 7 years, 8 months) of the cohort of patients who underwent noninstrumented fusion from these two studies revealed that clinical outcomes were significantly more likely to be good or excellent in patients who achieved solid arthrodesis than in those with a pseudarthosis (86% vs. 56%, $P = .01$).[37] Evidence-based guidelines have not found sufficient evidence to recommend the addition of instrumentation to improve clinical outcomes in patients with spinal stenosis and degenerative spondylolisthesis[32] despite the findings that utilization of instrumentation increases rates of fusion[36] and successful fusion leads to better clinical outcomes.[37] However, it is our current practice to perform arthrodesis with pedicular fixation along with decompressive laminectomy if there is associated instability at the involved motion segments (>5 mm), degenerative scoliosis (curve progression or >30 degrees), revision decompression at the same level, or resection of greater than 50% of the facet joints.[17]

The cost per QALY gained with surgical treatment of spinal stenosis with degenerative spondylolisthesis has been calculated for patients in the SPORT study at $64,300 in 2004 dollars over a 4-year postoperative time frame[30] (or approximately $80,500 in 2015 dollars). This figure is about 8% higher than that reported for isolated spinal stenosis.[30] The fact that patients without spondylolisthesis tended to undergo decompression alone while those with stenosis and spondylolisthesis typically underwent fusion as well (which carries a higher upfront surgical cost) likely contributed to this difference. The value of surgical treatment of spinal stenosis with degenerative spondylolisthesis may improve with longer-term follow-up, assuming that the observed improvements in quality of measures are lasting and that the need for additional treatment and revision surgery is minimal.

Laminotomy

In patients with primarily lateral recess stenosis, laminotomy (or laminoforaminotomy) is an alternative to laminectomy. Laminotomy involves performing a decompression through a microdiscectomy-like approach to target the stenotic levels either unilaterally or bilaterally. Only the caudal aspect of the superior lamina and the cephalad portion of the inferior lamina at the stenotic level are resected, leaving the spinous process and interspinous and supraspinous ligaments intact.[10] This is performed via a unilateral approach for unilateral pathology, while bilateral stenosis can be addressed either via bilateral approaches or through a unilateral approach for bilateral decompression (Fig. 63.10).[10] Advocates argue that leaving the midline structures intact decreases the chance of iatrogenic instability and back pain.[38,39] Others believe that little additional stability is gained by performing multiple laminotomies compared to a facet-sparing laminectomy because the majority of stability is provided by the intervertebral disc and the facet–joint capsule complex.[38]

Gurelik and colleagues[40] performed a randomized trial comparing unilateral laminotomy for bilateral decompression to laminectomy for the treatment of lumbar stenosis in 52 patients split evenly between groups. Average follow-up was 9.1 months. While maximal walking distance and ODI scores improved in both groups, the authors observed no statistically significant difference between the groups in the magnitude of these effects. They did find that laminectomy resulted in a significantly larger increase in dural sac area than laminotomy. Postoperative instability occurred in five of the laminectomy patients and none of the laminotomy patients; however, unilateral total facetectomy was performed in 27% of patients in the laminectomy group and none of those in the laminotomy cohort.

Thomé and colleagues[41] compared bilateral laminotomy, unilateral laminotomy for bilateral decompression, and conventional laminectomy for lumbar stenosis. Forty patients were randomized to each group, and the mean follow up was 15.5 months. Bilateral laminotomy resulted in a significantly lower complication rate than laminectomy (5.0% vs. 22.5%, $P < .05$) but did not differ significantly from unilateral laminotomy (17.5%). Dural tear was the most common complication in all groups. While all three techniques produced highly significant symptomatic and functional improvement (e.g., visual analog [VAS], SF-36, walking distance, patient satisfaction scores), bilateral laminotomy demonstrated the best overall outcomes, with unilateral laminotomy and laminectomy providing similar results.

Celik and colleagues[42] conducted a randomized trial comparing bilateral laminotomy to conventional laminectomy. Each group had 40 patients, and average follow-up was 5 years. Postoperative CT and MRI demonstrated adequate decompressions in both groups. The laminectomy groups suffered from significantly more perioperative complications and postoperative instability, and there was a nonsignificant trend toward superior walking distance, pain control, and disability scores in the laminotomy group.

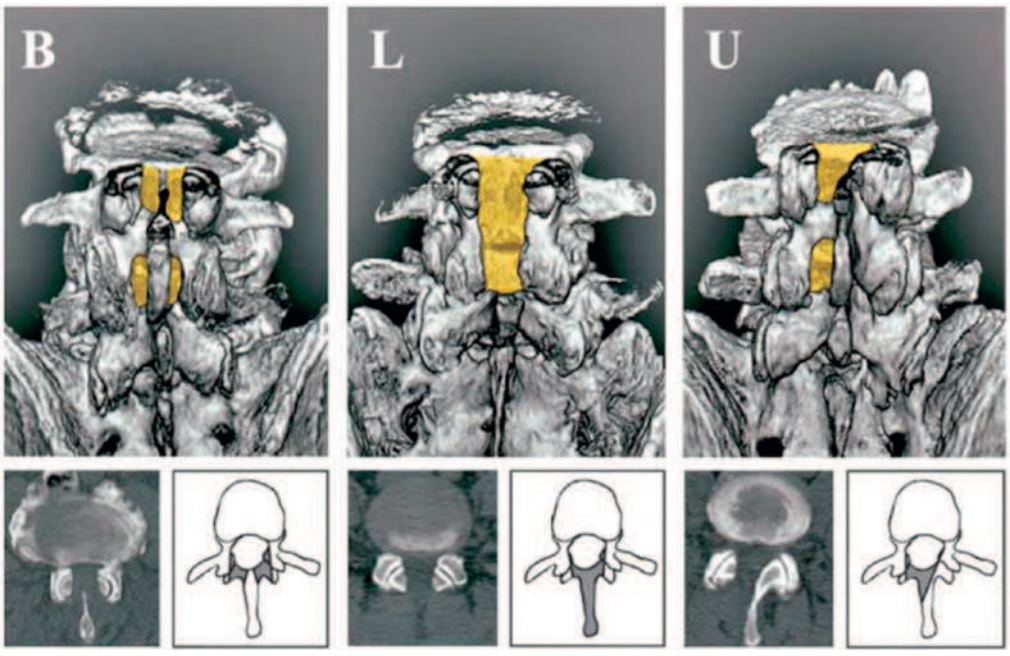

FIG. 63.10 *Top,* Postoperative three-dimensional reconstructions of lumbar computed tomographic (CT) scans following bilateral laminotomy (*B*), laminectomy (*L*), and unilateral laminotomy for bilateral decompression (*U*). In each technique, different osseous windows are created to access the spinal canal (*yellow*). *Bottom,* Axial postoperative CT scans and corresponding illustrations demonstrating the surgical corridors (*gray*). (From Thomé C, Zevgaridis D, Leheta O, et al. Outcome after less-invasive decompression of lumbar spinal stenosis: a randomized comparison of unilateral laminotomy, bilateral laminotomy, and laminectomy. *J Neurosurg Spine.* 2005;3[2]:129–141.)

In similar study performed by Fu and colleagues,[43] 152 patients were evenly randomized between bilateral laminotomy and conventional laminectomy. Functional outcomes were evaluated at approximately 40 months postoperatively. A total of 89% of the patients in the laminotomy group and 63% of the patients in the laminectomy group had good to excellent results, suggesting that a laminotomy can lead to good long-term results with few complications.

These studies and several others were synthesized in a 2015 Cochrane review, which was able to draw a limited number of conclusions based on the existing data.[10] The authors concluded that bilateral laminotomy resulted in better perceived recovery at final follow-up than laminectomy. Unilateral laminotomy for bilateral decompression and bilateral laminectomy led to lower rates of iatrogenic instability than conventional laminectomy (although the rates were low in all groups). There was a clinically small but statistically significant difference in the severity of postoperative low back pain favoring bilateral laminotomy over laminectomy. However, there was insufficient evidence to show a difference in complications, procedure length, length of hospital stay, or postoperative walking distance between techniques. It is our recommendation that a less invasive unilateral or bilateral laminoforaminotomy is a reasonable option in one- or two-level lateral recess stenosis without significant central stenosis.

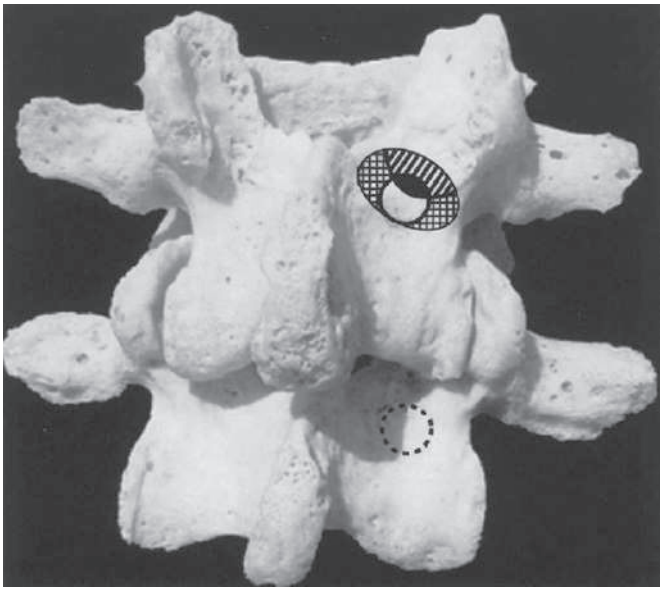

FIG. 63.11 Fenestration technique. A view of the lower lumbar spine showing the position of the laminal fenestration in relation to the superior articular facet. The *dotted circle* is the laminal fenestration. *Solid shading* is the portion of the pedicle drilled away through the hole. *Diagonal lines* represent the part of the pedicle undercut through the hole. *Hatched lines* represent the amount of laminal undercutting through the hole. (From Shenouda EF, Gill SS. Laminal fenestration for the treatment of lumbar nerve root foraminal stenosis. *Br J Neurosurg.* 2002;16:494–496.)

Fenestration

The use of fenestration to treat stenosis has been described in multiple reports but with notable variability in surgical techniques, many of which closely resemble traditional laminotomy.[44–49] While the nomenclature is nonspecific, these procedures aim to preserve the midline structures and minimize soft tissue and bony resection while addressing sites of neurologic compression.

Shenouda and Gill[46] described a unique fenestration technique that involves decompression through a 5-mm drill hole in the pars interarticularis immediately below the superior facet. The hole exposes the inferior aspect of the pedicle and the nerve root in the foramen. Using a 2-mm diamond drill bit through an operating microscope, the inferior aspect of the superior pedicle is drilled away, and the dorsal aspect of the nerve root is decompressed by undercutting the lamina and hypertrophied facet (Fig. 63.11). The authors note that, unlike other previously described techniques of fenestration, their method addresses foraminal in addition to lateral recess stenosis. Although there were no clinical or radiographic outcomes reported, the authors suggest that their technique preserves spinal stability and allows for early mobility, thereby shortening hospital length of stay.[46]

Laminoplasty

Distraction laminoplasty and expansive lumbar laminoplasty are two alternatives to standard laminectomy. Distraction laminoplasty is a technique for decompression of central and lateral recess stenosis with minimal bony resection. This method, formally described by O'Leary and colleagues,[50] involves mechanical distraction of the stenotic interspace to facilitate spinal canal access. Similar to a standard laminectomy, the procedure begins with removal of the inferior half of the cephalad vertebra's spinous process and lamina as well as the superior edge of the caudal vertebra. Distraction is then applied across the spinous processes of the segments, opening the interlaminar working space by mobilizing the cephalad lamina proximally and the caudad lamina distally (Fig. 63.12). The motion occurs through the facet joints and disc, and the increase in interlaminar space (typically 1 cm) allows for improved visualization. After removal of the ligamentum flavum, the lateral recesses are decompressed by removing 10% to 20% of the facet joint in a tapered fashion. The undersurface of the cephalad lamina is then thinned from inside out to 30% to 50% of its thickness. Caution is required in patients with significant osteoporosis in whom vigorous distraction may result in fracture of the spinous process or laminar edge. Although the technique has been well described, there is a lack of clinical outcomes data comparing distraction laminoplasty with other decompression techniques. In the setting of an open decompression, we have found that use of a laminar spreader between the spinous processes tenses the dura, making neural decompression easier and decreasing the chance of dural violation.

Expansive lumbar laminoplasty is a technique developed by Tsuji and colleagues[51] that aims to provide osteoplastic enlargement of the spinal canal while retaining spinal stability

in the treatment of spinal stenosis. The technique is analogous to cervical laminoplasty, and involves opening one side of the lamina by using the contralateral side as a hinge (Fig. 63.13). Bone grafts from excised spinous processes are placed in the opened laminae and fixed with braided wire or nylon suture. The original developers of the technique reported the outcomes of 54 patients undergoing expansive lumbar laminoplasty with an average follow-up of 5.5 years.[52] Average intraoperative blood loss was higher and operative time longer than that typical of standard laminectomy. At final follow-up, the average Japanese Orthopaedic Association (JOA) score had improved significantly compared to preoperative baselines. Patients aged 56 years or older had significantly less improvement than those aged 55 years or younger. Nine patients had worsening of their JOA scores, seven of whom developed lesions at adjacent levels. Five patients developed new spondylolisthesis at an adjacent level. Interlaminar fusion was observed in 43% of patients, and range of motion was reduced to 58% of the preoperative range in those who avoided interlaminar fusion. The authors concluded that these results were "satisfactory" and suggested that the best indications for the procedure were young and active patients with isolated central spinal stenosis.

Sangwan and colleagues[53] performed a review of 25 patients who underwent expansive lumbar laminoplasty with follow-up ranging from 3 to 5 years. Patients experienced an average enlargement in anteroposterior spinal canal diameter of 124% (as measured on CT scan), and 22 had good or excellent results. However, because of the inability of this operation to fully address lateral recess stenosis, mediocre clinical outcomes, and the high interlaminar fusion rate, we do not currently employ this procedure for the treatment of lumbar stenosis.

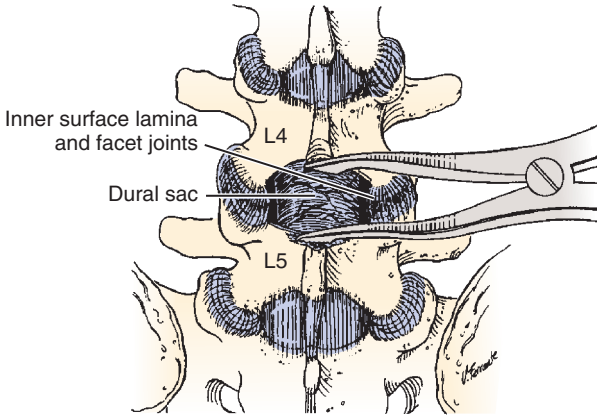

FIG. 63.12 Distraction laminoplasty. Distraction is applied across the spinous processes of the segments. This expands the interlaminar working space by mobilizing the cephalad lamina proximally and the caudal lamina distally. The lamina is then undercut to address the stenosis. (From O'Leary PF, McCance SE. Distraction laminoplasty for decompression of lumbar spinal stenosis. *Clin Orthop Relat Res.* 2001;384:26-34.)

Microendoscopic Decompressive Laminotomy

Many authors have advocated the concept of minimally invasive decompression, which involves decompression of the neural elements through a smaller skin incision with preservation of soft tissue and bony anatomy. Although procedures such as laminotomy and fenestration are considered less

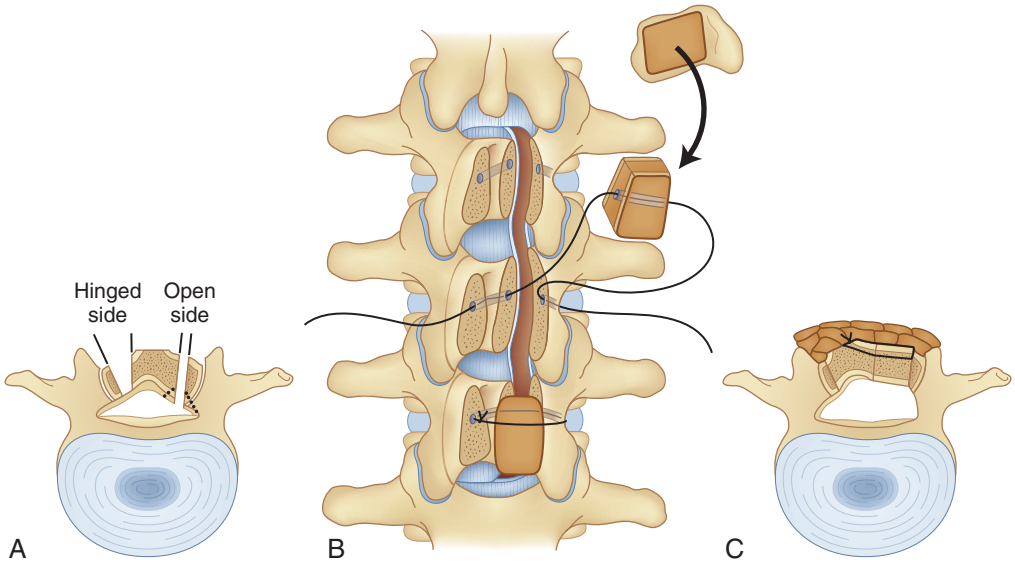

FIG. 63.13 Expansive lumbar laminoplasty technique. (A) After the spinous process is removed, a high-speed burr is used to make a groove in either side of the lamina. One groove extends completely through the lamina, while the other is incomplete. (B) The lamina is hinged open through the site of the incomplete groove and held open with autograft from the excised spinous processes. These are secured with a wire or suture. (C) This increases the cross-sectional area of the spinal canal. Additional bone graft is packed dorsally over the osteotomy sites. (From Kawaguchi Y, Kanamori M, Ishihara H, et al. Clinical and radiographic results of expansive lumbar laminoplasty in patients with spinal stenosis. *J Bone Joint Surg Am.* 2005;87[Suppl 1, Pt 2]:292–299.)

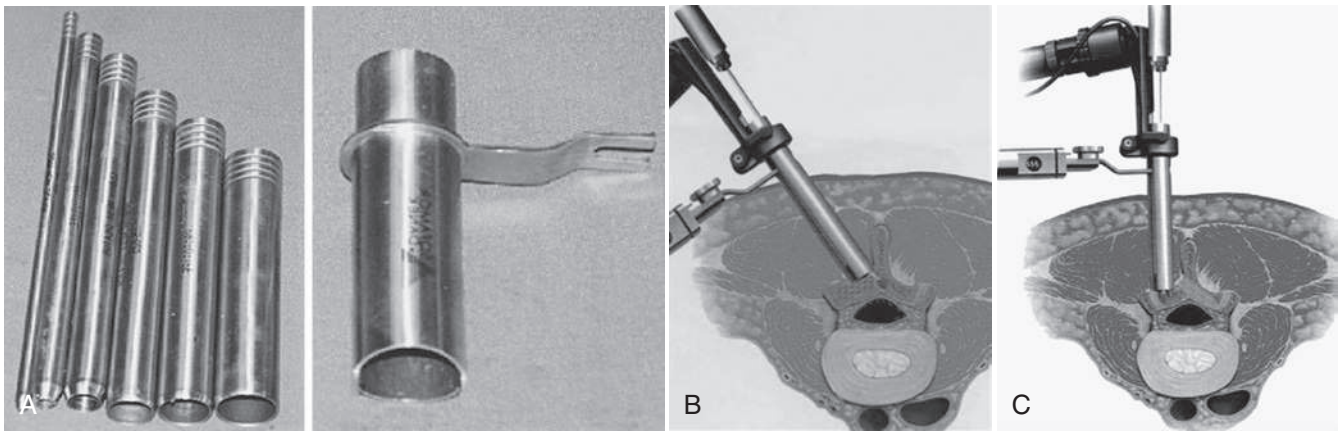

FIG. 63.14 Bilateral decompression through a unilateral microscopic decompressive laminotomy approach. (A) METRx sequential soft tissue dilators and 18-mm working channel with retractor. (B) Medial angulation of the retractor tube ensures optimal visualization of the spinolaminar junction and facilitates a proper trajectory for drilling of the anterior aspect of the lamina. Drilling continues until the contralateral lateral recess and foramen are reached. (C) The tubular retractor is then angled laterally toward the ipsilateral lamina–medial facet junction, and decompression is performed on this side as well. (From Asgarzadie F, Khoo LT. Minimally invasive operative management for lumbar spinal stenosis: overview of early and long-term outcomes. *Orthop Clin North Am* 2007;38:387–399.)

invasive than conventional laminectomy, the term "minimally invasive" has been tied to microendoscopic decompression by surgeons, patients, and industry. Microendoscopic decompressive laminotomy (MEDL) was first investigated in a 2002 cadaveric study that used postdecompression CT scans to demonstrate that endoscopic techniques could be used to achieve equivalent bony resection compared to open decompression.[54] Asgarzadie and Khoo[55] described a surgical technique for bilateral decompression through a unilateral MEDL approach using the METRx system (Medtronic). Under fluoroscopic guidance, a Steinmann pin is inserted from a starting point approximately 3 cm off midline on the side of the approach to lie on the spinolaminar junction. A 2.5-cm longitudinal incision is made about the guide pin, over which a series of dilators are passed until the final 18-mm tubular retractor can be inserted (Fig. 63.14). The contralateral lamina is decompressed first. In order to accomplish this, the tubular retractor is angled medially and a high-speed burr used to drill the anterior aspect of the lamina at the superior aspect of the interlaminar space. Drilling continues until the contralateral lateral recess and foramen are reached. Specialized endoscopic Kerrison rongeurs are used to complete the laminotomy and partial medial facetectomy. The ipsilateral side is then addressed by angling the tubular retractor laterally toward the junction of the ipsilateral lamina and medial facet. Drilling is again performed, followed by completion of the decompression with endoscopic curettes.

Four-year outcomes of MEDL were presented for 48 patients with lumbar central and/or lateral recess stenosis but no instability or deformity.[55] Of the patients, 80% had an increase in walking endurance, and 88% of patients reported an improvement in symptoms. There were no cases of neurologic injury or subsequent instability requiring fusion. The rate of dural violations (4%) was notably less than that reported by the same authors 5 years earlier (16%).[55,56] They attributed this decrease to the fact that they had initially been decompressing the ipsilateral side first, which they believe increased the risk of dural tears because unprotected dura was exposed while subsequently drilling the contralateral side.[55] For procedures in which a cerebrospinal fluid leak was encountered, direct repair was difficult secondary to the small surgical working field. The authors used fibrin glue or fat and muscle grafts to tamponade small leaks rather than attempt direct repair. They suggest that large leaks could be repaired if special endoscopic instruments are available[55]; however, enlarging the incision or converting to a nonendoscopic technique may be necessary to facilitate direct repair of the dura.

A randomized trial by Yagi and colleagues[57] and another by Mobbs and colleagues[58] compared the results of MEDL to conventional open laminectomy. Mean follow-up was approximately 1.5 years in the former study and 3 years in the latter. MEDL was associated with significantly less operative blood loss, shorter time to mobilization and length of hospital stay, lower chance of requiring opioids for postoperative pain, less muscle destruction (as measured by creatine phosphokinase muscular-type isoenzyme levels drawn 24 hours after surgery), and less low back and leg pain at final follow-up. However, there were no significant differences between groups with respect to the magnitude of improvement in function (ODI and JOA scores), quality of life (Short-Form 12 Mental and Physical Component Summary scores), or patient satisfaction.

While these data suggest that MEDL produces comparable outcomes to open laminectomy, potentially with less perioperative morbidity, there is a learning curve for all new techniques, and it is essential to become closely familiar with the endoscopic system and anatomy by performing the procedure in cadaveric specimens before attempting it in a clinical setting.

Interspinous Process Devices

Interspinous process (ISP) devices distract the spinous processes. This causes relative kyphosis of the instrumented segment, which stretches the infolded ligamentum flavum to achieve indirect canal decompression. Additionally, longitudinal distraction between two vertebrae increases the neuroforaminal dimensions, resulting in indirect decompression of the exiting nerve roots. Richards and colleagues[59] used MRI to quantify the spinal canal and neural foramina dimensions of cadaveric lumbar spines before and after placement of an ISP device. During extension, the implant increased the canal area by 18% and the foraminal area by 25%.[59] Clinically, positional MRIs performed on patients before and 6 months after implantation of an ISP device demonstrated that, in extension, the left and right foramina increased by 34.2% and 25.4%, respectively; the dural sac area increased by 20% in standing and 16.3% in neutral.[60]

There are two categories of ISP spacers: static and dynamic. Static devices are available in a variety of different noncompressible materials that maintain a constant amount of distraction between spinous processes.[61] For instance, the X-STOP device (Medtronic) is composed of an oblong central core that is stabilized by two lateral wings (Fig. 63.15). It is inserted as two components that are fixed to each other to straddle the interspinous region (Fig. 63.16). The device is composed of titanium so that it is compatible with postoperative MRI. Because static implants have a tendency to fit tighter when the lumbar spine is positioned in extension than flexion, some static devices include features intended to supplement fixation.[61] The Wallis ISP device (Zimmer Biomet), for example, has polyester bands that encircle the spinous processes on either end of the device to more broadly distribute the distraction forces during flexion. Alternatively, dynamic ISP devices, which compress during extension and expand during flexion, have been developed.[61] These include the Coflex device (Paradigm Spine), an axially compressible U-shaped titanium component, and the DIAM (Device for Intervertebral Assisted Motion; Medtronic), which is composed of silicone and polyester and acts as a rubbery spacer between the spinous processes.

FIG. 63.15 The X-STOP device is a titanium spacer composed of an oblong central core stabilized by two lateral wings that straddle the interspinous region. (From Bono CM, Vaccaro AR. Interspinous process devices in the lumbar spine. *J Spinal Disord Tech.* 2007;20:255–261.)

ISP spacers are not recommended for use in patients with low bone mineral density. These individuals may not have sufficiently strong bone stock to support these devices and may suffer intraoperative or postoperative fractures.[61–64] Talwar and colleagues[65] performed a cadaveric biomechanical study utilizing the X-STOP spacer and found that the lateral force necessary to place the device averaged 66 N (range, 11–150 N), and the lateral force necessary to fracture the spinous process averaged 317 N (range, 95–786 N). While these means were statistically significantly different, there was some overlap in the ranges such that the greatest insertion force was sufficient to break the weakest spinous process. Furthermore, there was a significant positive correlation between bone mineral density and failure force. Idler and colleagues[66] attempted to address this issue by developing a technique for augmenting the spinous processes of osteoporotic patients with polymethylmethacrylate (PMMA) in order to decrease the risk of ISP device-related fracture. After injecting osteoporotic cadaveric spinous processes with PMMA and placing an ISP spacer, the mean failure load of the PMMA-treated specimens was significantly higher than that of the nonaugmented group.[66]

Wu and colleagues[67] performed a meta-analysis to determine the effectiveness of ISP spacers versus traditional decompression for LSS. They included two randomized controlled trials and three nonrandomized prospective studies with a total of 204 ISP device and 217 traditional decompression patients in their analysis. The authors found that there were no significant differences in 12- to 24-month results between the groups with respect to low back or leg pain, ODI scores, Roland Disability Questionnaire scores, or complication rates. However, traditional decompressive surgery was associated with a significantly lower reoperation rate than ISP device implantation (relative risk, 3.34; 95% confidence interval, 1.77–6.31; $P < .001$). Because ISP devices can be inserted through minimally invasive, percutaneous approaches or via open surgery, the authors performed subgroup analyses to independently compare each of these approaches to traditional decompression. They again found similar clinical outcomes but significant reoperation rates with ISP spacers.

Hong and colleagues[68] performed their own meta-analysis, and identified 21 publications with a total of 3155 ISP device and 50,983 open decompression patients for analysis. Follow-up ranged from 6 to 54 months, but was 1 year or longer in 90% of the trials. Investigators determined that there was no significant difference in ODI scores, improvement rates, or VAS scores for back or leg pain between ISP device and open decompressive surgery groups. ISP spacer use led to a significantly faster operative time, less perioperative blood loss, lower postoperative complication rate (1.7% vs. 2.1%; $P = .02$), and shorter hospital length of stay. However, the ISP spacer group also had a significantly higher reoperation rate (16.2% vs. 8.7%; $P < .001$). As a result, the authors concluded that ISP spacers may be a viable alternative in the treatment of lumbar

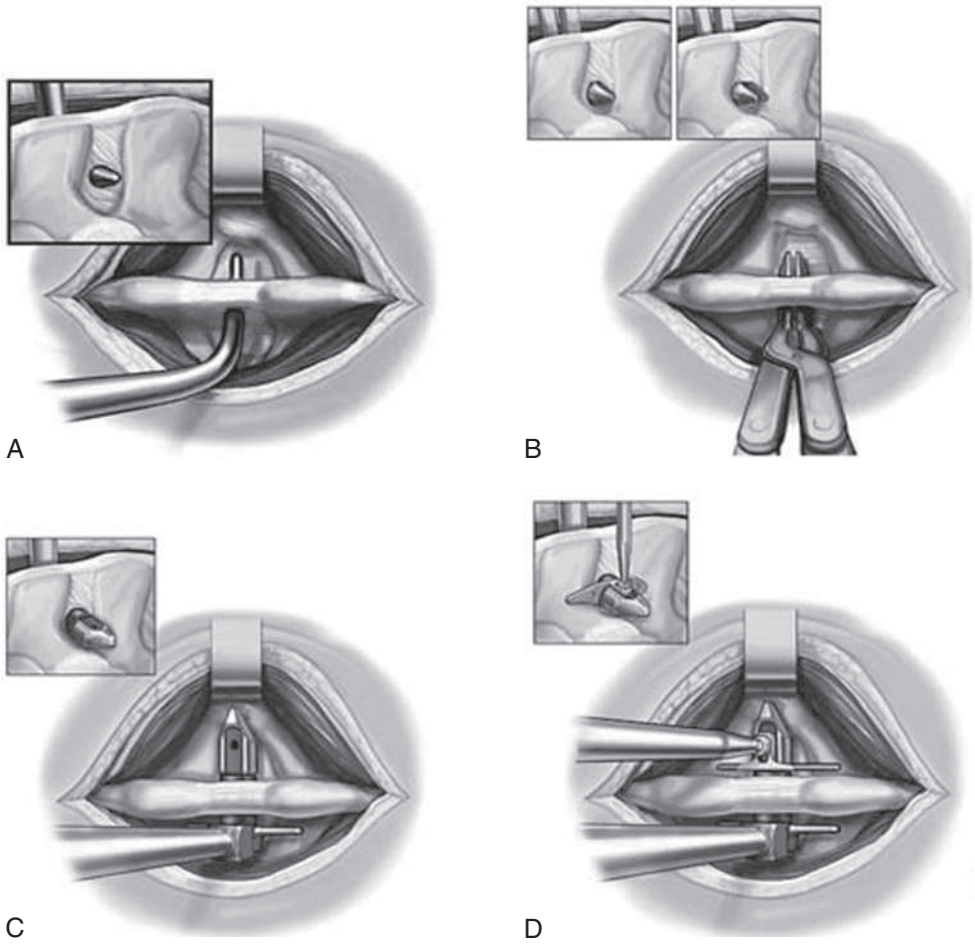

FIG. 63.16 X-STOP interspinous process device insertion. (A) The curved dilator is inserted into the anterior margin of the interspinous space. (B) The sizing distractor is inserted to determine the implant size. (C) The X-STOP is inserted into the interspinous space. (D) The adjustable wing is fastened to the implant. (From Zucherman JF, Hsu KY, Hartjen CA, et al. A prospective randomized multi-center study for the treatment of lumbar spinal stenosis with the X-STOP interspinous implant: 1-year results. *Eur Spine J.* 2004;13:22–31.)

stenosis but that open decompressive surgery remains the gold standard.

Because of the lack of sufficient long-term follow-up in a large cohort of patients, we still perform a laminotomy or laminectomy when there is stenosis in the absence of instability. Our primary indication for use of an ISP device is for patients with mild to moderate intermittent neurologic claudication with grade 1 degenerative spondylolisthesis who cannot tolerate a decompression and fusion procedure. We do not recommend use of an interspinous device for greater than a grade 1 spondylolisthesis. When considering utilizing the procedure, it is essential that the patient's symptoms of neurogenic claudication are alleviated within 5 minutes of sitting because spinal unit distraction is the mechanism by which the device functions.

Postoperative Care

All patients are encouraged to get out of bed with physical therapy and ambulate as soon as possible. Even in the setting of a short-segment fusion, patients are given a long-acting local anesthetic and mobilized the day of surgery. In the event of a dural tear, however, the patient is placed on bed rest for 1 to 2 days before standing and ambulating. We rarely prescribe a lumbar binder or orthotic for patients who have undergone decompression alone. For patients who receive a fusion procedure, we occasionally use a lumbosacral orthotic for the first 6 weeks. An orthotic with a leg extension is used for those patients fused to the sacrum with questionable bone quality. All patients are advised to avoid bending, lifting, or twisting for 6 to 12 weeks postoperatively. The first postoperative visit is typically at 2 to 3 weeks, at which time the wound is assessed, radiographs are taken, and outpatient physical therapy is initiated. If a fusion procedure was not performed, patients are then seen at 3 months and 1 year after surgery. Flexion-extension radiographs are taken at each follow-up visit to ensure that the patient does not develop instability at the decompressed level. If a fusion procedure was performed, patients are seen more frequently: at 6 weeks, 3 months, 6 months, 1 year, and annually up to year 5 postoperatively. This long-term follow-up is required to ensure that fusion is

obtained and that there are no hardware-related complications. Radiographic evidence of a posterolateral fusion is typically evident at 6 months to 1 year with complete arthrodesis expected at 2 years. Absence of bridging bone at 2 years and symptoms suggestive of a pseudarthrosis should prompt a CT to better assess the fusion mass.

Complications

Complications of lumbar decompressive surgery include dural tear, nerve root injury, infection, vascular complications, epidural hematoma, nonunion or hardware failure following fusion, instability, bony regrowth, and adjacent-segment degeneration.

Dural tears are a well-known complication of lumbar stenosis surgery, with rates in the literature ranging from 1.8%[69] to 17.4%.[70] Khan and colleagues[71] performed a large retrospective series of 3183 consecutive degenerative lumbar spine operations (decompression and/or fusion) and identified a dural tear rate of 7.6% during primary cases and 15.9% for revision procedures. Incidental durotomies are most commonly created while the surgeon is using the Kerrison punch.[72] It is our protocol to perform a closure of all dural tears at the time of durotomy. Primary repair is performed with 6-0 Gortex suture followed by placement of a spinal sealant system such as DuraSeal (Covidien) and/or Duragen (Integra LifeSciences). All repairs are tested with a Valsalva maneuver. Closed-suction wound drainage does not appear to aggravate the leak and can be used safely in the presence of a dural repair.[73] Patients are given ceftriaxone for meningitis prophylaxis, placed on bed rest for 24 to 48 hours, and then slowly permitted to ambulate. Primary watertight closure of the dura has been shown to produce good results without long-term deleterious effects or increased rates of postoperative infection, neural damage, or arachnoiditis.[73] However, others have reported inferior 10-year outcomes with significantly greater chance of headaches and lower Tegner scores for general activities of daily living in patients whose surgeries were complicated by dural tear.[74] After primary closure, a small fraction of patients may require a secondary procedure for a persistent spinal fluid leak; this represented 1.8% of the patients in the Khan et al. series described earlier.[71] In this scenario, a promptly performed direct repair or a fascia lata graft typically leads to good results.[71,75]

The vascular complications of posterior lumbar surgery include deep vein thrombosis (DVT), pulmonary embolism (PE), postoperative hematoma, and catastrophic vascular events. Although major vascular injury during lumbar decompression is rare, it is important to recognize this complication in the operating room or in the early postoperative period because the best prognosis for recovery occurs with immediate treatment within 24 to 48 hours.[76] Unexplained hypotension is highly suggestive of a vascular catastrophe, and is an indication for arteriography in the stable patient and laparotomy in the unstable patient. Patients with preexisting vascular disease are predisposed to such injuries.[76]

DVT is a more common vascular complication, with rates of 5% after lumbar laminectomy and 3.1% after lumbar fusion procedures reported in a systematic review by Glotzbecker and colleagues.[77] No instances of PE were reported in these patients. The authors recommended the use of compression stockings and pneumatic sequential compression devices as a primary method of prophylaxis, as this was associated with a lower overall rate of DVT. There was insufficient evidence to support the use of pharmacologic prophylaxis or DVT screening in patients undergoing routine elective spinal surgery.[77] However, others suggest that mechanical prophylaxis for thromboembolism may not be sufficiently protective for patients undergoing combined anterior/posterior spine surgery.[78] This ambiguity manifests as wide variability in spinal surgeons' estimation of DVT rates as well as in their choice and timing of thromboembolic prophylaxis.[79] We currently feel that the relatively low risk of postoperative DVT and PE, when weighed against the potentially disastrous effect of epidural hematoma, does not justify the use of pharmacologic DVT prophylaxis with lumbar decompression surgery. We routinely use sequential compression stockings and early ambulation in patients undergoing elective posterior spinal surgery.

Infection rates after surgery for lumbar stenosis were investigated by Deyo and colleagues[80] using the Veterans Affairs National Surgical Quality Improvement Program database. In the 12,154 decompression and/or fusion procedures identified, the 30-day rate of superficial wound infection, deep wound infection, and wound disruption were 1.9%, 1.2%, and 0.3%, respectively. Higher American Society of Anesthesiologists class and fusion procedures (as opposed to decompression alone) were associated with significantly elevated rates of these wound complications. Infection rates in other large series for lumbar spine surgery have ranged from 2%[48] to 4.4%.[81] Fang and colleagues[81] observed that the majority of infections occurred during the early postoperative period (<3 months). Age older than 60 years, smoking, diabetes, previous surgical infection, increased body mass index, and alcohol abuse were statistically significant preoperative risk factors.[81] Instrumented fusion has also been reported as a risk factor for infection.[82]

It is critical to diagnose infections early in the postoperative period. Measuring C-reactive protein (CRP) levels has been shown to be a useful adjunct to physical examination findings. Mok and colleagues[83] examined perioperative trends in CRP and erythrocyte sedimentation rate in 149 patients who underwent spine surgery. Postoperative infection complicated 20 (13%) of these cases. In patients with an uncomplicated postoperative course, CRP peaked 2.7 days after surgery, then showed an exponential decrease with a half-life of 2.6 days.[83] A second rise or a failure to decrease as expected had a sensitivity, specificity, positive predictive value, and negative predictive value of 82%, 48%, 41%, and 86%, respectively, for infectious complications. Erythrocyte sedimentation rate was a less predictable and responsive measure.[83] Once diagnosed, postoperative wound infections should be aggressively managed with operative irrigation and debridement and a minimum of 6 weeks of culture-guided intravenous antibiotics.[84] Loose bone graft should be removed, but intact hardware

should be maintained unless the infection cannot be controlled otherwise.[84] Repeat irrigation and debridement may be indicated 48 to 72 hours postoperatively in the presence of extensive muscular necrosis, an immunocompromised host, or multiorganism infection.[84] In instrumented cases, antibiotics will ideally postpone the need for hardware removal until a fusion mass has formed.[84] This approach has led to good clinical results[82] with similar functional outcome scores at a mean follow-up of 62 months when compared with a cohort of noninfected patients.[85]

Prophylactic antibiotics significantly reduce the risk of postoperative spinal wound infections[86]; they should be administered prior to incision, then postoperatively for up to 24 hours.[84] However, prolonged antibiotic treatment has been shown to prolong the duration of hospitalization, inhibit normalization of body temperature, and elevate CRP levels.[87] We routinely administer perioperative antibiotics immediately before surgery and for 24 hours thereafter.

Meningitis is a rare complication of spinal surgery, with a documented incidence of 0.18% in a series of 2180 spinal operations.[88] Patients typically present with fever, headache, photophobia, and neck stiffness within 6 to 14 days after surgery.[88] Good outcomes can be expected with prompt diagnosis and treatment.[88]

Although spondylotic spinal stenosis is typically a condition of older patients with greater comorbidities, several studies have demonstrated that decompression and/or fusion in elderly patients is relatively safe with an acceptable rate of morbidity when compared with younger patients.[89–93] Benz and colleagues[89] found that preoperative medical comorbidities did not predict early postoperative complications in patients older than 70 years who underwent spinal decompression. The total complication rate was 40%, and serious complications potentially affecting quality of life occurred in 12% of patients. The early mortality rate was 1.4%.[89] Ragab and colleagues[90] found an overall morbidity rate of 20% in a group of patients aged 70 to 101 years with spinal stenosis who underwent decompressive surgery. Because their results were comparable to those reported in younger populations, they concluded that advanced age does not increase the morbidity associated with lumbar decompression.[90] Reindl and colleagues[91] compared complications of elective spinal decompression with those of total hip arthroplasty in patients aged 65 to 80 years and found that these surgeries resulted in a similar number of life-threatening complications (approximately 20%).[91] However, it should be noted that there were twice as many minor complications in the spinal decompression group.[91] An analysis of patients at least 80 years of age with lumbar stenosis and degenerative spondylolisthesis from the SPORT trial found that operative treatment produced significant benefit over nonoperative treatment.[93] Furthermore, this older population experienced no significant increases in complication or mortality rates after surgery compared with younger patients. Finally, Glassman and colleagues[92] studied the 2-year outcomes of single-level decompression and posterolateral arthrodesis with iliac crest bone graft for single-level degenerative disc disease in patients older and younger than 65 years. Older patients actually experienced significantly greater relief of leg pain with similar improvements in ODI scores, back pain, and SF-36 scores at final follow-up. However, there were significantly more serious postoperative adverse events in the older patient group (38% vs. 17%; $P = .003$), including significantly more cardiac events, respiratory events, and infections.[92]

Despite adequate decompression, substantial back and leg symptoms develop in up to 10% to 15% of patients who have undergone an adequate lumbar decompression.[94] Early studies suggested that osseous regrowth after decompression may be the cause of symptomatic recurrence and decreased patient satisfaction.[95,96] Chen and colleagues[96] followed 48 patients treated for lumbar stenosis for an average of 4.5 years after posterior decompression. Plain radiographs were used to quantify the amount of bone regrowth at the original laminectomy site. Of the patients, 44% were observed to have more than 40% regrowth of the lamina, and spinal instability was found to accelerate this process. Patients with moderate and marked osseous regrowth exhibited statistically significantly poorer clinical outcomes than those with no significant and mild regrowth. However, more recent studies have contradicted these findings. Guigui and colleagues[97] evaluated 23 patients for an average of 8 years following laminectomy using both plain radiographs and CT. They found that radiographs significantly overestimated bone regrowth compared with CT scans. Using axial imaging, they determined that mean regrowth at final follow-up was only 7.7%, with no patients exhibiting greater than 20% regrowth. Furthermore, no association between osseous regrowth and clinical outcome was identified. Similarly, Dohzono and colleagues[98] found relatively low degrees of bone regrowth on CT scan with no correlation between regrowth and clinical outcomes after microscopic bilateral decompression via a unilateral approach in a group of 85 patients. The authors postulated that the minimally invasive technique allowed for greater preservation of the facet joints, which led to less iatrogenic instability and therefore a relatively small amount of osseous regrowth. In light of this conflicting evidence, it seems reasonable to take precautions to avoid destabilization of the spine, as bone regrowth may result in neural compression and recurrent symptoms.

Adjacent-segment pathology is one of the main clinical issues encountered after lumbar fusion.[99] In a systematic review containing 27 studies, the incidence of radiographic evidence of adjacent-level degeneration ranged from 8% to 100%, but only 0% to 27.5% of patients were symptomatic.[100] The wide range of estimates may be due to varying definitions, measurement methodologies, and follow-up periods in each study. Nonetheless, the results suggest that degeneration is commonly observed on radiographs but is only clinically symptomatic in a subset of these patients. Ghiselli and colleagues[101] reported on 215 patients who underwent posterior lumbar arthrodesis with mean follow-up of 6.7 years. Over the course of the study, 27% of the patients had evidence of degeneration at adjacent levels and elected to undergo additional surgery. The rate of surgery to address adjacent segments was predicted to be 16.5% at 5 years and 36.1% at 10 years following the index procedure. However, Radcliff and colleagues,[8] in a subgroup analysis of the SPORT study, demonstrated

that the addition of fusion (with or without instrumentation) in the surgical treatment of spinal stenosis without instability did not result in increased reoperation rates at the index or adjacent levels when compared to decompression alone over a 4-year period. This refutes the classical hypothesis that lumbar fusion results in elevated rates of adjacent-segment disease.

PEARLS AND PITFALLS

1. The surgical exposure should clearly identify the midlateral pars and facet capsule to prevent overresection of bone, which can lead to iatrogenic pars interarticularis fractures.
2. Laminectomy should begin centrally, starting from the caudal portion of the lamina where the ligamentum flavum protects the dura, followed by decompression of the lateral recesses.
3. Distraction laminoplasty using a laminar spreader between spinous processes at the level of interest allows for improved visualization of the spinal canal during decompression, with minimal resection of the posterior osseous elements.
4. Decompression of the lateral recess and foramen should be performed from the contralateral side to avoid iatrogenic durotomy.

KEY POINTS

1. Ideal surgical candidates have symptoms of neurogenic claudication in a distribution that correlates with radiographic findings of spinal stenosis.
2. Open decompressive laminectomy is the gold standard for treatment of stable lumbar stenosis.
3. Fusion should be performed in conjunction with decompressive laminectomy in the presence of instability at the involved motion segment (>5 mm), degenerative scoliosis (curve progression or >30 degrees), prior decompression at the same level, or the need to resect greater than 50% of the facet joints.
4. The SPORT study, the largest level 1 prospective randomized study to evaluate the surgical treatment of conditions associated with low back and leg pain, demonstrated the efficacy of operative treatment over nonoperative treatment for spinal stenosis.
5. Candidates for interspinous process devices should have neurogenic claudication completely relieved with sitting and no greater than a grade 1 spondylolisthesis.

   This cadaveric study showed that decompression with even partial medial facetectomy results in measurable increases in segmental range of motion and decreases in stiffness.
2. Weinstein JN, Tosteson TD, Lurie JD, et al. Surgical versus nonsurgical therapy for lumbar spinal stenosis. *N Engl J Med*. 2008;358:794-810.
   The 2-year outcomes of the SPORT study, a large multicenter randomized controlled trial with a concurrent observational cohort evaluating laminectomy versus conservative treatment for lumbar stenosis, were reported in 2008. All patients who had a history of at least 12 weeks of symptomatic lumbar stenosis without spondylolisthesis were considered surgical candidates. A total of 289 patients were enrolled in the randomized cohort, and 365 patients were enrolled in the observational cohort. By 2-year follow-up, however, 43% of those who were randomly assigned to receive nonsurgical care underwent surgery (compared to 67% of the patients randomly assigned to the operative group). Despite the high incidence of crossover, the intention-to-treat analysis revealed a significant treatment effect favoring surgery on the SF-36 scale for bodily pain. However, there were no significant differences in scores on the SF-36 scale for physical function or on the modified ODI. The as-treated analysis, which included the randomized and observational cohorts, showed a significant advantage for surgery compared with nonoperative treatment by 3 months for the ODI and both SF-36 components. These changes remained significant for all subsequent time points in the 2-year duration of the study. At 2-year follow-up, on the basis of the as-treated analysis, 63% of patients treated surgically rated themselves as having major improvement with their condition versus 29% of the group treated nonoperatively.
3. Lurie JD, Tosteson TD, Tosteson A, et al. Long-term outcomes of lumbar spinal stenosis: eight-year results of the Spine Patient Outcomes Research Trial (SPORT). *Spine*. 2015;40(2):63-76.
   The long-term outcomes of the SPORT study were published in 2015. At 8-year follow-up, no significant differences remained between randomized cohorts in intent-to-treat analysis. By this point, however, 52% of those randomized to nonoperative care had undergone surgery, which began to approach the 70% of patients in the operative group who actually underwent surgery. As-treated analysis of the randomized group showed that the benefit of surgery diminished over time and was not significant after 5 years. However, the significantly better early outcomes (SF-36 bodily pain and physical function, ODI) associated with surgery in the observational group were stably maintained out to 8 years. These results suggest that laminectomy for symptomatic degenerative spinal stenosis provides significant improvements in function, pain, and disability but that these effects likely diminish to some degree over the long term.
4. Grob DT, Humke T, Dvorak J. Degenerative lumbar spinal stenosis. Decompression with and without arthrodesis. *J Bone Joint Surg Am*. 1995;77:1036-1041.
   The authors randomized 45 patients with lumbar spinal stenosis without instability to receive decompression with and without arthrodesis. Instability was defined as greater than 5 mm of motion between segments in the sagittal plane or greater than 5 mm of lateral offset in the coronal plane. All patients had significant clinical improvement compared with preoperative values at an average of 28-month follow-up with no significant differences regardless of whether or not a fusion was performed. These results suggest that, in the absence of instability, decompression with care taken to not destabilize the spine does not necessitate an arthrodesis.
5. Herkowitz HN, Kurz LT. Degenerative lumbar spondylolisthesis with spinal stenosis. A prospective study comparing decompression with decompression and intertransverse process arthrodesis. *J Bone Joint Surg Am*. 1991;73:802-808.
   This study randomized 50 patients with spinal stenosis and associated degenerative spondylolisthesis to determine whether noninstrumented arthrodesis produced better outcomes than decompressive laminectomy alone. At a mean of 3-year follow-up, patients in the arthrodesis group had significantly greater back and lower extremity pain relief. Furthermore, only 28% of patients in the fusion group experienced slip progression after surgery, while the slip distance increased in 96% of those in the nonfusion group.

and arthrodesis with and without spinal instrumentation. *Spine*. 1997;22:2807-2812.
This study investigated the effects of instrumentation in a randomized trial of patients with spondylolisthesis and stenosis. Although the addition of instrumentation increased the fusion rate compared to noninstrumented arthrodesis (82% vs. 45%) in the 67 patients available for 2-year follow-up, clinical outcomes were similar between the groups (P < .435).

7. Kornblum MB, Fischgrund JS, Herkowitz HN, et al. Degenerative lumbar spondylolisthesis with spinal stenosis: a prospective long-term study comparing fusion and pseudarthrosis. *Spine*. 2004;29:726-733.
A longer-term follow-up (average 7 years, 8 months) of the cohort of patients who underwent uninstrumented fusion from the above two studies revealed that clinical outcomes were significantly more likely to be good or excellent in patients who achieved solid arthrodesis than in those with a pseudarthosis (86% vs. 56%, P = .01).

8. Overdevest GM, Jacobs W, Vleggeert-Lankamp C, et al. Effectiveness of posterior decompression techniques compared with conventional laminectomy for lumbar stenosis. *Cochrane Database Syst Rev*. 2015;(3):CD010036.
A 2015 Cochrane review compared posterior decompression techniques for lumbar stenosis. The authors concluded that bilateral laminotomy resulted in better perceived recovery at final follow-up than laminectomy. Unilateral laminotomy for bilateral decompression and bilateral laminotomy led to lower rates of iatrogenic instability than conventional laminectomy (although the rates were low in all groups). There was a clinically small but statistically significant difference in the severity of postoperative low back pain favoring bilateral laminotomy over laminectomy. However, there was insufficient evidence to show a difference in complications, procedure length, length of hospital stay, or postoperative walking distance between techniques.

9. Hong P, Liu Y, Li H. Comparison of the efficacy and safety between interspinous process distraction device and open decompression surgery in treating lumbar spinal stenosis: a meta-analysis. *J Invest Surg*. 2015;28(1):40-49.
A meta-analysis comparing the outcomes of ISP spacers versus open decompression for lumbar stenosis. The authors identified 21 publications with a total of 3155 ISP device and 50,983 open decompression patients for analysis. Follow up ranged from 6 to 54 months, but was 1 year or longer in 90% of the trials. Investigators determined that there was no significant difference in ODI score, improvement rate, or VAS scores for back or leg pain between ISP device and open decompressive surgery groups. ISP spacer use led to a significantly faster operative time, less perioperative blood loss, lower postoperative complication rate (1.7% vs 2.1%, P = .02), and shorter hospital length of stay. However, the ISP spacer group also had a significantly higher reoperation rate (16.2% vs 8.7%, P < .001). As a result, the authors concluded that ISP spacers may be a viable alternative in the treatment of lumbar stenosis but that open decompressive surgery remains the gold standard.

A total of 641 patients who underwent lumbar decompression (14% of whom had a dural tear) were reviewed. The article describes primary repair of the tear followed by bed rest. Closed-suction wound drainage did not appear to aggravate the leak and can be used safely in the presence of a dural repair. Primary watertight closure of the dura produced good results without long-term deleterious effects or increased rates of postoperative infection, neural damage, or arachnoiditis.

11. Pearson A1, Lurie J, Tosteson T, et al. Who should have surgery for spinal stenosis? Treatment effect predictors in SPORT. *Spine*. 2012;37(21):1791-1802.
An analysis of SPORT study data demonstrated that surgical outcomes for spinal stenosis are significantly better in patients who preoperatively exhibited greater disability, predominant leg pain over low back pain, neuroforaminal stenosis, or a neurologic deficit; not lifting at work and not smoking were associated with better outcomes.

CHAPTER 64

Degenerative Spondylolisthesis

SECTION VIII

Andrew Z. Mo
Gordon R. Bell
Darren R. Lebl

Degenerative spondylolisthesis (DS) was first described in 1930 by Junghanns, who coined the term *pseudospondylolisthesis* to describe the presence of forward slippage of a vertebral body in the presence of an intact neural arch.[1] The clinical and pathologic features of this entity were further defined by Macnab, who described the condition as "spondylolisthesis with an intact neural arch."[2] The term *degenerative spondylolisthesis* was originally used by Newman and Stone[3] and is the terminology most commonly used to describe the anterior slippage of one vertebral body on another in the presence of an intact neural arch. More recently, an etiology-based classification has been proposed that distinguishes between the pathologic processes that may cause spondylolisthesis.[4] Under this classification, two broad types of spondylolisthesis have been defined: *developmental* and *acquired*. DS, as described initially by Macnab and subsequently by Newman and Stone, is a subtype of the *acquired* form subsequently described by Marchetti and Bartolozzi.[4,5] In that classification, DS may be either primary or secondary. *Primary degenerative spondylolisthesis* is typically seen in middle-aged women and usually presents with clinical spinal stenosis. *Secondary degenerative spondylolisthesis* occurs as a result of a predisposing factor, such as adjacent-segment degeneration and slip above a preexisting fusion.

Epidemiology and Biomechanics

DS is a condition of older people and rarely affects those younger than 40 years of age. It most commonly involves the L4–L5 level, although other levels may be affected. It much less commonly involves the L5–S1 level, in contrast to isthmic spondylolisthesis, which most commonly occurs at L5–S1. Factors that have been reported to predispose to anterolisthesis at the lumbosacral junction include an L5 vertebral body that is less deeply seated within the pelvis, a more slender L5 transverse process, and increased sacral inclination, all of which are more common in women than men.[6]

DS is approximately four to five times more common in females than in males and is more common in black females than in white females.[7] The female preponderance is thought to be due to greater ligamentous laxity and hormonal effects.[8–10] A significantly increased expression of estrogen receptors has been found in facet joints of postmenopausal women having severe facet arthritis associated with DS compared with those with spinal stenosis only. It was not clear whether the higher expression of estrogen receptors aggravated the degenerative facet changes or was a causative factor for DS.[9]

In an epidemiologic survey of 4151 patients, the Copenhagen Osteoarthritis Study found that the incidence of DS was 2.7% in males and 8.4% in females.[11] The only factors associated with an increased risk of DS in women were elevated body mass index, increased age, and increased angle of lordosis. In men, only increased age was associated with a higher risk of DS. There was no association between DS and age at menopause, smoking, or occupational lifting exposure.

It is likely that the development of DS is multifactorial and dependent on anatomic factors, such as intervertebral disc pathology, ligament laxity, posterior facet joint arthrosis, the amount of lumbar lordosis, hormonal factors, and prior pregnancy. Genetic factors are also a likely contributor to the development of spinal stenosis with DS in some patients. One study demonstrated that a type IX collagen gene polymorphism that introduced a tryptophan residue into the protein's triple helix predisposed its carriers to development of spinal stenosis with DS.[12] Results from another study linked estrogen receptor alpha gene polymorphisms to the prevalence of DS.[13]

A cadaveric model investigating the relative contributions of disc integrity and the anterior and posterior longitudinal ligaments in the development of low-grade anterolisthesis found that integrity of the disc was more important than ligamentous factors, although disruption of both was necessary to produce significant destabilization.[14] The effect of facet joint orientation has also been reported to be a potential factor in the development of DS. Specifically, more sagittally oriented L4–L5 facet joints have been implicated as a cause of DS.[15–17] In one study, individuals in whom both L4–L5 facet joint angles were sagittally oriented more than 45 degrees were 25 times more likely to have DS than those with less than 45 degrees of facet angulation.[14] Whether the sagittal orientation is developmental or acquired is unclear and is a matter of debate. One study reported that sagittal orientation is a result

of facet joint remodeling associated with arthrosis rather than the cause of anterior subluxation.[17] In another study, it was found that destabilization of both the facet complex and disc was required to achieve anterior listhesis consistent with DS.[18]

A retrospective, age- and sex-matched, case-control radiographic study of middle-aged women found that decreased anterior disc height and increased lumbar index (lumbar index = posterior vertebral body height/anterior vertebral body height) were two independent predictors of DS.[19]

Natural History

The natural history of DS, like many other spinal conditions, is not well characterized.[20] A meta-analysis of the literature on DS between 1970 and 1993 found that only 25 of the 152 studies reviewed, representing 889 patients, satisfied their inclusion criteria.[21] Only three of these studies, encompassing 278 patients, described the natural history of DS.[22,23] Overall, 90 of these 278 patients (32%) achieved satisfactory results without treatment. A study by Matsunaga and colleagues[24] represented the best of the three studies and was the only true natural history study. In that study, 40 patients who received no treatment were followed from 5 to 14 years (mean, 8.25 years). Only 4 of 40 patients (10%) showed clinical deterioration over the course of the study and all were in the group of 28 patients who exhibited no slip progression over the follow-up period. Progressive slip was noted in 12 patients (30%), although none of the 12 patients exhibited clinical deterioration. The majority of the patients in this study showed slight improvement in their clinical symptoms over time. In general, no correlation was noted between slip progression and clinical deterioration. No slip progression was noted in patients with intervertebral disc narrowing, spur formation, subcartilaginous sclerosis, or ligamentous ossification, suggesting that these anatomic factors were protective against further slip and represented a mechanism of spinal restabilization. The lack of correlation between slip progression and progression of symptoms has also been reported by other authors.[20,25,26] The generally favorable prognosis of DS was confirmed by a North American Spine Society work group consensus statement that summarized evidence-based clinical guidelines on the diagnosis and treatment of DS.[20] Although it did not distinguish between natural history and conservative care, that committee reported that most patients without neurologic signs or symptoms did well without surgery.

Clinical Features

The clinical features of DS are the same as those of spinal stenosis. DS, like spinal stenosis, may be either asymptomatic or may produce low back and/or leg pain. Back pain with DS is typically mechanical and may be aggravated by back extension or by arising from a bent posture. It is to be distinguished from discogenic back pain, which is typically provoked by flexion or sitting. Only a small percentage of patients with DS may experience low back pain. A report that investigated a small cohort of patients from the Framingham Heart Study concluded that there did not appear to be an association between low back pain and DS as diagnosed by computed tomography.[27]

TABLE 64.1 Characteristics of Vascular vs. Neurogenic Claudication

Evaluation	Vascular	Neurogenic
Walking distance	Fixed	Variable
Palliative factors	Standing	Sitting/bending
Provocative factors	Walking	Walking/standing
Walking uphill	Painful	Painless
Bicycle test	Positive (painful)	Negative (painless)
Pulses	Absent	Present
Skin	Loss of hair/shiny	Normal
Weakness	Rarely	Occasionally
Back pain	Occasionally	Commonly
Back motion	Normal	Limited
Pain character	Cramping/distal to proximal	Numbness/aching/ proximal to distal
Atrophy	Uncommon	Occasionally

Leg pain may be either radicular or referred in a characteristic pattern of neurogenic claudication. *Neurogenic claudication,* also known as *pseudoclaudication,* is a clinical condition consisting of leg pain associated with walking.[28] Neurogenic claudication must be distinguished from vascular claudication, which has slightly different clinical features, a different etiology, and completely different treatment (Table 64.1). Neurogenic claudication is defined as lower extremity pain, paresthesias, or weakness associated with walking or standing.[29,30] Pain is the predominant symptom, being present in up to 94% of patients with spinal stenosis, with numbness (63%) and weakness (43%) being less common.[29,30] Bilateral involvement is common. Patients with neurogenic claudication may present with either unilateral radicular pain or with diffuse, nondermatomal symptoms beginning in the buttocks and extending a variable distance into the legs. Radicular pain is typically dermatomal in distribution and is often unilateral. It is the presenting type of symptom in 6% to 13% of symptomatic patients with stenosis.[30] It is often seen with lateral recess stenosis, foraminal stenosis, or concomitant disc herniation. The clinical effects of spinal canal narrowing are magnified by the presence of a degenerative slip that further narrows the spinal canal.

Typical neurogenic claudication is less dermatomal in character than is radicular pain. It is frequently bilateral and may have a radicular component to it. Symptoms are typically produced by standing or walking and are relieved by sitting or bending forward (see Table 64.1). Patients may preferentially assume a stooped-over posture when walking or standing to ameliorate symptoms ("shopping cart sign"). Other leg symptoms, such as weakness or numbness, may also occur in association with standing or walking. Night pain is an uncommon feature of spinal stenosis, although it has been described in patients with lateral stenosis (lateral recess stenosis or

foraminal stenosis). Unusual symptoms of spinal stenosis, such as priapism associated with intermittent claudication during walking, have also been reported.

The relationship of symptoms to posture can be explained on the basis of variation in canal size with posture.[31,32] Cadaveric studies have demonstrated that spinal canal cross-sectional area, midsagittal diameter, subarticular sagittal diameter, and foraminal size are significantly reduced in extension and are increased with flexion.[31] Similarly, neural compression is greater in extension than in flexion. An association between posture and epidural pressure measurements has also been demonstrated. In vivo studies relating posture to epidural pressure measurements have shown that epidural pressures at the level of stenosis were higher in standing compared with lying and sitting, and were increased with extension and decreased with flexion.[31]

Neurogenic claudication should be distinguished from vascular claudication because their causes and treatments are different (see Table 64.1). Although both conditions may present as leg pain associated with walking, only patients with neurogenic claudication typically have leg pain with standing. Leg pain associated with neurogenic claudication is highly position dependent, whereas vascular claudication is unaffected by back flexion or extension. Leg pain with cycling in a sitting position is common with vascular claudication but not with neurogenic claudication.[33] Patients with vascular claudication will typically have more leg pain produced by walking uphill than downhill, whereas patients with a neurogenic claudication will typically have less pain walking uphill owing to the slightly flexed posture of the lumbar spine that results in neuroforaminal widening and reduced neural compression. Patients with neurogenic claudication may actually have increased leg pain when walking down an incline owing to associated lumbar lordosis and consequent neuroforaminal narrowing.

The radicular pattern of spinal stenosis with DS most commonly involves the L5 nerve root, which is usually compressed within the lateral recess. This radicular pain is typically located in the posterolateral thigh, extending into the lateral calf and occasionally into the dorsum of the foot. The presence of a degenerative slip also narrows the L4–L5 neural foramen and can therefore result in L4 radicular pain from foraminal compression of the L4 nerve root. Pain in an L4 distribution is characteristically located in the anterior thigh to the knee and along the anterior shin. It can occasionally be confused with pain from a hip etiology; thus, careful attention must be given to the possibility of hip pathology as a cause for anterior thigh pain.

Radiographic Diagnosis

The diagnosis of DS is a radiographic diagnosis that is made on the lateral lumbar radiograph (Fig. 64.1). Although the slippage (anterolisthesis) may also be evident on a supine lateral radiograph, it is important that the lateral radiograph be performed in the standing position because there can be a dynamic component to the slip, causing it to reduce in the supine position and appear normal.[34] One recent study investigated asymmetric facet hypertrophy at C3–C4 and C4–C5, finding an association with lumbar degenerative spondylolisthesis on upright lateral films even in the absence of anterolisthesis on supine magnetic resonance imaging (MRI).[35] It is not unusual for a patient to present with a normally aligned supine MRI study as the only radiographic study. Unless standing lumbar radiographs are obtained, however, the presence of a degenerative slip could be missed. In a recent study, 22% of L4–L5 degenerative slips, as documented by standing lateral flexion–extension radiographs, were not detectable on supine MRI.[36] Other dynamic radiographic views, such as sitting or standing flexion–extension views and distraction–compression radiography, may also be considered.

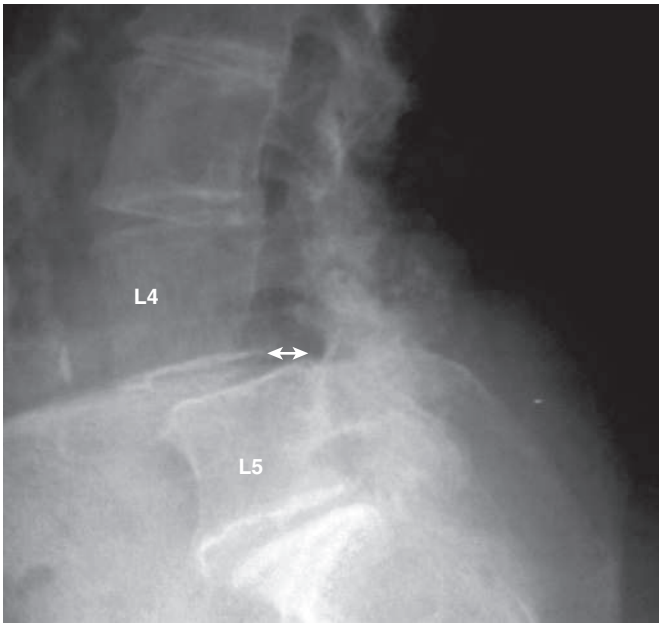

FIG. 64.1 Standing lateral lumbar radiograph showing the anterior slippage (*arrow*) of L4 on L5.

MRI may show an increased signal within a facet joint at the level of the slip.[36–38] Large facet effusions greater than 1.5 mm were found to be highly predictive of L4–L5 DS, even in the absence of a measurable slip on the supine MRI.[36] Therefore, a patient who presents with only an MRI should be suspected of having a DS if a large facet effusion is detected, in which case standing lumbar radiographs should be obtained. Alternatively, the slip can be documented by upright or axial loaded MRI.[37,39]

Although the actual measurement of translation is generally straightforward, the distinction between what is normal dynamic translation and abnormal segmental motion (instability) is not.[40,41] There is no consensus as to what constitutes clinically significant radiographic instability of the lumbar spine, nor even what is considered to be the normal range of translation between motion segments.[40,41] As with routine radiographs, there exists a spectrum of normal translation that can exist in the absence of symptoms.[40,41] One study showed that more than 90% of asymptomatic volunteers exhibited between 1 mm and 3 mm of translation on flexion-extension

lateral lumbar radiographs and that a dynamic change of greater than 4 mm was therefore considered abnormal.[40]

It is important not to base the decision for type of surgery on the MRI or myelography/CT findings without obtaining a preoperative standing lateral lumbar radiograph. Failure to identify a listhesis preoperatively could result in performing the incorrect procedure, namely, isolated decompression rather than decompression and fusion. Furthermore, without preoperative standing lateral radiographs, it cannot be determined if the presence of postoperative spondylolisthesis in a patient with poor pain relief after surgery was the result of destabilization from the surgery or if it was a preexisting condition.

Treatment

As mentioned previously, both the natural history of DS and, until recently, its optimal treatment are incompletely understood. The well-publicized Spine Patient Outcomes Research Trial (SPORT) was a prospective evaluation of the 2-year[42] and 4-year[20,43] outcomes of 607 patients with DS. Half of the patients were enrolled in a randomized cohort and half in an observational cohort. Preenrollment nonoperative care was not specified, and the type of surgery or nonoperative treatment during the study period was left to the discretion of the treating physicians. This study was hampered by a significant crossover and nonadherence to treatment between the two groups, leading to both an *as-treated* and an *intent-to-treat* analysis of the data. When both the randomized and observational cohorts were combined, the as-treated analysis revealed that the surgically treated patients had significantly better outcomes for both pain and function at 2-year and 4-year follow-ups. This study did not allow comparison of types of treatments; thus, it did not answer the question of which surgical treatments provided better outcomes.

That same SPORT trial examined radiographic predictors of outcome in both surgically and nonoperatively treated patients.[44] Radiographic features examined included degree of slip (grade I vs. grade II), disc height (<5 mm vs. >5 mm), and mobility (stable vs. hypermobile). As noted previously, surgically treated patients had better outcomes than nonsurgically treated patients across all three radiographic parameters examined. For nonoperative patients, those with a grade I slip did better than those with a grade II slip, and those with a hypermobile slip did better than those with a stable slip.

In a long-term follow-up of patients with DS, progressive slip was noted in 34% of the 145 nonsurgically managed patients who were observed for a minimum of 10 years.[45] This study was not a true natural history study because it included patients who had various nonsurgical interventions. Seventy-five percent of the patients were neurologically normal at the beginning of the study and the majority (76%) remained so at final follow-up. Of the 34% who had neurologic symptoms, 83% experienced neurologic deterioration and had a poor outcome. There was no correlation between slip progression and clinical symptoms. This study suggested that conservative (nonsurgical) treatment in neurologically normal patients can result in a satisfactory clinical outcome at an average of 10 years' follow-up in the majority of patients.

Decompression Without Fusion

A review of Medicare patients undergoing surgery for stenosis, with or without spondylolisthesis, from 2002 to 2007 found that only 21% of patients undergoing surgery for stenosis with spondylolisthesis in 2007 had simple decompression surgery compared with 79% having some form of decompression with fusion.[46] Although the trend in type of surgical procedure performed over this 6-year period was not examined for patients with stenosis associated with DS, the study noted that for patients with stenosis the trend was one of increasing complexity of surgical procedure. The rate of *complex* fusion, defined as fusion involving more than two levels or a 360-degree fusion, increased 15-fold from 2002 to 2007. It is likely that a similar increase in the rate of complex surgery occurred for patients with stenosis associated with DS.

One reason for considering decompression without fusion in select patient populations is that it is less invasive than fusion and reduces the morbidity and mortality associated with spinal fusion in elderly patients.[46–50] In the retrospective review of Medicare claims for patients undergoing surgery for spinal stenosis between 2002 and 2007, patients having a complex fusion had greater morbidity, more life-threatening complications, greater likelihood of rehospitalization within 30 days of surgery, and higher costs compared with patients having decompression alone or decompression with *simple* fusion (defined as one- or two-level fusion through a single surgical approach).[46] In a recent retrospective review of Medicare claims from 2005 to 2009, 1-year readmission rates after spinal stenosis decompression surgery with and without fusion were found to be 9.7% and 7.2%, respectively.[51]

A meta-analysis of the literature on DS between 1970 and 1993 found only 11 papers, encompassing 216 patients, reporting outcome measures after decompression without fusion that met their inclusion criteria (Table 64.2).[21] One of these studies was retrospective and nonrandomized[22]; two were prospective and randomized[52,53]; and the remaining eight were retrospective, nonrandomized, and uncontrolled. Overall, 69% of patients in this meta-analysis reported a satisfactory outcome with decompression alone, with 31% having an unsatisfactory result.

One report that supported decompression without fusion for DS reviewed an elderly (average age, 67 years) population

of 290 patients, 250 of whom had a one-level slip and 40 of whom had a two-level slip.[54] The data from that study were self-reported by the surgeons and were retrospective. The decompressive procedures included laminectomy in 249 patients and fenestration procedures in 41 patients. Fenestration procedures typically involved bilateral laminotomy with partial medial facetectomy and foraminotomy. Only patients with a "stable" slip having less than 4-mm translation and less than 10 to 12 degrees of angulation on dynamic lateral radiographs were included. At an average follow-up of 10 years (range, 1 to 27 years), 69% of patients reported an excellent outcome, 13% good outcome, 12% fair outcome, and 6% poor outcome. These authors concluded that 82% excellent/good outcomes was acceptable in this elderly population, in whom fusion is associated with higher morbidity and mortality.

Similar results were reported in a retrospective review of 49 elderly patients (mean age, 68.7 years) with symptomatic degenerative lumbar spondylolisthesis, without evidence of hypermobility on flexion–extension radiographs and who underwent decompression without fusion.[55] At a mean follow-up of 3.73 years, 73.5% of the patients reported excellent or good results, although 10% underwent revision surgery with an instrumented fusion. The study concluded that limited decompression alone can be helpful in a select group of elderly patients without hypermobility.

Bilateral decompression through a unilateral approach has also been described in patients with spinal stenosis, both with and without DS. A retrospective study using that technique compared patients with and without spondylolisthesis and showed similar functional outcomes between the two groups at 2 years.[56] Although there was a statistically significant increase in the percentage slip postoperatively in the patients with spondylolisthesis, it did not appear to produce an adverse functional outcome. Nevertheless, the presence of an increased slip at 2 years is a cause for concern and caution.

One prospective study assigned a group of 67 patients with spinal stenosis to either laminectomy or multilevel laminotomy and included a small subgroup of patients with DS.[57] Nine of the patients assigned to the laminotomy group crossed over to the laminectomy group, which caused some difficulty in interpreting the results. However, no patient who underwent multilevel laminotomy developed instability as a result of the surgery, compared with three patients who developed instability following laminectomy. These authors recommended multilevel laminotomies for patients with developmental stenosis, mild to moderate degenerative stenosis, or DS. Bilateral laminectomy was recommended for patients with severe degenerative stenosis or marked DS.

Another study prospectively evaluated 54 consecutive patients who underwent decompression without fusion for spinal stenosis.[58] In the small subgroup of 15 patients who had concomitant DS, 87% (13 of 15 patients) showed no change in the amount of preoperative slip. Overall, 88% of the 54 patients reported a good/excellent clinical outcome; the results were comparable between patients with and without DS. The study concluded that degenerative spinal stenosis, including patients with DS, can be decompressed effectively without the need for fusion.

Noninstrumented Posterolateral Fusion

Although the beneficial role of fusion in the surgical treatment of spinal stenosis associated with DS is less controversial than the role of fusion in the treatment of other degenerative back conditions, incontrovertible evidence supporting fusion is sparse. An attempted meta-analysis of literature reported between 1970 and 1993 found only six studies meeting the inclusion criteria that reported results of decompression with noninstrumented fusion for DS.[21] In that review, 90% of patients having decompression with noninstrumented fusion reported a satisfactory clinical outcome and 86% achieved a solid arthrodesis, although the fusion rate varied from 90% to 100% (Table 64.3).[59] Patients undergoing decompression with noninstrumented fusion achieved a statistically significantly better clinical outcome than those treated with decompression alone (90% vs. 69%, respectively).

Many studies on the surgical treatment of DS report unfavorable outcomes after decompression without fusion. One early small study by two groups of surgeons from two different institutions included two populations of patients with spinal stenosis and DS: one group underwent decompression alone and the other had decompression and fusion.[22] In the patients undergoing decompression alone, 5 of 11 (45%) were rated as having a good (satisfactory) outcome and 6 of 11 (55%) as having a fair/poor (unsatisfactory) outcome. In contrast, 5 of 8 patients (63%) undergoing decompression with in situ posterolateral fusion achieved a satisfactory outcome. This study suggested that patients did better when their decompression was accompanied by noninstrumented fusion.

Several studies have supported the position that patients undergoing fusion with decompression for DS do clinically better than those undergoing decompression alone.[22,53,60] It is difficult to gain a clear understanding of this issue from a review of existing literature, however, because well-done studies reporting surgical outcome after surgery for DS are uncommon.

Although most studies report no correlation between clinical outcome and the amount of slip progression, one study suggested that poor outcome was associated with slip progression.[52] That study was a prospective randomized study that included a subgroup of 11 patients undergoing decompression and noninstrumented fusion for DS. Of the 10 patients available for follow-up, only 3 (30%) reported improved functional outcome and 7 had an increase in their preoperative

spondylolisthesis, suggesting that slip progression was associated with poor clinical outcome.

A landmark prospective randomized study comparing decompression alone with decompression and noninstrumented posterolateral spinal fusion in the treatment of L3–L4 and L4–L5 DS with spinal stenosis reported superior results when concomitant fusion was performed with the decompression.[53] A satisfactory outcome was more than twice as common in the fused group compared with the unfused group (96% vs. 44%, respectively). Furthermore, the percentage of excellent results was significantly and dramatically greater in the fused group (44% excellent) than in the unfused group (8% excellent; $P < .0001$) (Table 64.4). This study concluded that the results of surgical decompression with in situ arthrodesis were superior to those of decompression alone in the treatment of spinal stenosis associated with L3–L4 or L4–L5 DS. Outcome was influenced by neither the age nor sex of the patient nor the preoperative height of the disc space. These authors concluded that the decision for concomitant arthrodesis should be based purely on the presence or absence of a preoperative slip rather than on other preoperative factors, such as the age or sex of the patient, disc height, or intraoperative factors (e.g., amount of bone resected during the decompression). This study showed that the results of decompression with an *attempted* arthrodesis produced superior results to decompression alone, even if the fusion was unsuccessful (pseudarthrosis). Although, postoperatively, there was a significant (P =.002) increase in the slip in patients not receiving an arthrodesis compared with those undergoing fusion, 36% of the arthrodesis group were also noted to have a pseudarthrosis, although all had an excellent or good result.

A long-term review of 96 patients undergoing decompressive surgery for spinal stenosis followed for at least 5 years included a subset of patients with associated DS.[61] Although this subgroup was not fully analyzed separately and the study itself was retrospective, nonrandomized, and uncontrolled, some important trends were noted. Twenty-six patients (27%) of the entire group were considered failures: 16 because of recurrent neural symptoms and 10 because of low back pain. The incidence of DS was significantly greater in the surgical failure group (12 of 26 patients [46%]) than in the surgical successes (16 of 64 [25%]). These authors concluded that, because of the higher incidence of recurrent symptoms in patients with preexisting DS, all patients with an associated slip should be fused.

One well-recognized cause of long-term failure of decompression for spinal stenosis is subsequent bone regrowth causing recurrent neural compression. One study reported the relationship between bone regrowth, occurring an average of 8.6 years after surgical decompression for spinal stenosis, and long-term outcome.[59] Of the 40 patients in the study, 16 had preoperative DS, 10 of whom had concomitant arthrodesis. Although all 16 patients with preexisting DS showed some bone regrowth, the degree of regrowth was less severe in the 10 patients undergoing arthrodesis than in the 6 patients who were not fused (Table 64.5). Furthermore, the proportion of satisfactory results was significantly higher in patients who had spinal fusion. Although this study was retrospective and not randomized, it suggested that arthrodesis stabilized the spine, resulting in less bone regrowth causing recurrent stenosis, and produced superior long-term results.

One problem associated with noninstrumented in situ fusion is the difficulty, if not inability, to restore normal lumbar lordosis. This is particularly true with a multilevel noninstrumented fusion, which can produce a flatback deformity, although it can occur even with a single-level noninstrumented fusion. It has been demonstrated that an L4–L5 in situ fusion that produces kyphosis or hypolordosis results in increased motion at the adjacent L3–L4 level.[62] Such hypermobility may be one factor in adjacent-level degeneration after fusion.

An important issue with the use of spinal instrumentation in the elderly patient is its potential biomechanical effect on adjacent unfused levels. There is concern and evidence that the rigidity produced by a solid fusion, particularly with instrumentation, may cause significant stresses at adjacent levels above or below the fusion, with the potential for adjacent-level failure (Fig. 64.2). Such failure may be manifested by symptomatic or asymptomatic degeneration or by adjacent-level vertebral compression fracture or stress fracture because of the osteoporotic nature of the bone. The use of instrumentation may also produce direct injury to the superior facet by either capsular disruption or articular facet damage. These are arguments against pedicle screw fixation in the elderly patient with osteoporosis. Therefore, the use of less rigid instrumentation or no instrumentation may be preferable to rigid instrumentation because of theoretically reduced stresses on adjacent levels by the presence of a less

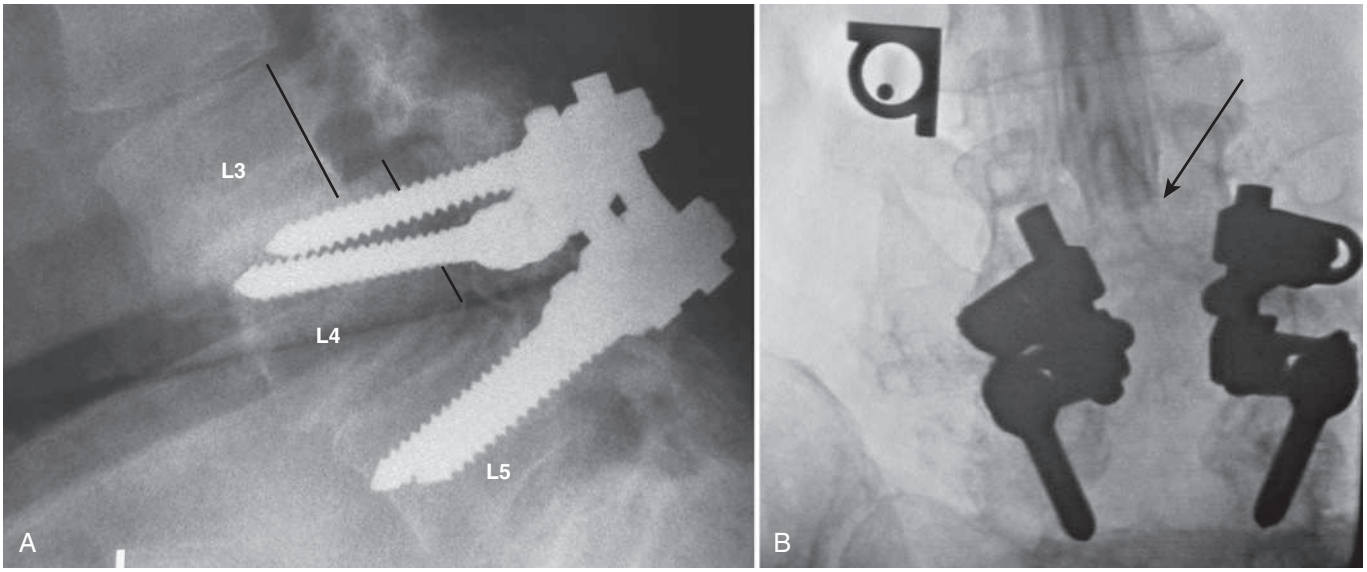

FIG. 64.2 (A) Standing lateral lumbar radiograph showing 7-year follow-up of L4–L5 instrumented fusion for L4–L5 degenerative spondylolisthesis. Note the adjacent-level degeneration at L3–L4, characterized by disc space collapse and L3–L4 slip (posterior aspect of L3 and L4 vertebral bodies marked by line). rigid fusion or even a stable pseudarthrosis, or by less risk to the superior facet joint by a pedicle screw.

A common clinical and radiographic scenario in older patients is the presence of symptomatic multiple-level spinal stenosis and a single-level (usually L4–L5) DS. Some of the possible permutations of treatment options include multilevel decompression of all stenotic levels without fusion, multilevel decompression with instrumented fusion of all decompressed levels, multilevel decompression with instrumented fusion at the listhetic level only, multilevel decompression with noninstrumented L4–L5 fusion only, and multilevel decompression and noninstrumented fusion of all decompressed levels. A multilevel decompression without any fusion is certainly a reasonable option in some elderly patients, particularly those with multiple comorbidities, even though the literature generally supports concomitant fusion. A multilevel instrumented fusion is a significant operative procedure in many older patients and may not be warranted because of the magnitude of the surgery. A one-level instrumented fusion with a multilevel decompression runs the risk of creating a stiff instrumented segment, which can result in transmission of significant forces to the adjacent decompressed segments, thereby rendering them potentially unstable and increasing the risk of developing a slip at another level. Multilevel noninstrumented fusion carries a high probability of pseudarthrosis at one or more levels and runs the risk of producing iatrogenic flatback deformity. Thus, it is reasonable to decompress all symptomatic stenotic levels and to perform a noninstrumented fusion at only the spondylolisthetic level. Even if this results in a stable pseudarthrosis rather than a solid arthrodesis, this may be sufficient to minimize the risk of slip progression and is less likely to transmit significant forces to adjacent decompressed levels, therefore creating less risk of adjacent-level failure.

Posterior Instrumented Fusion

The long-term clinical outcome of surgical decompression with instrumented spinal fusion for DS, particularly when compared with the outcome of decompression with noninstrumented fusion, is not completely known. A comprehensive search of the English literature on lumbar or lumbosacral fusion from 1979 to 2000[63] identified only two prospective and randomized studies that were limited to DS.[53,64] Although that study identified a nonsignificant trend toward greater use of instrumentation technology for lumbar fusion, generally, the clinical benefit of that pattern was unclear.

A Cochrane review of lumbar surgery found that there was limited evidence that fusion produced a better outcome or resulted in less slip progression than decompression alone. Although there was strong evidence that the use of adjunct instrumentation produced a higher fusion rate than noninstrumented fusion with decompression, a superior outcome was not demonstrated.[65]

A randomized controlled trial comparing surgery with nonsurgical treatment for spinal stenosis found that patients undergoing fusion with decompression had less pain and better functional outcomes at 2-year follow-up than patients undergoing decompression alone.[66] This was also true for a smaller subset of patients with DS who underwent instrumented fusion. Although the number of patients undergoing instrumented fusion was too small to permit extensive analysis, these authors felt that instrumented fusion should be considered for stenosis associated with DS.

A prospective nonrandomized study of patients with grade I DS compared decompression alone with decompression with instrumented fusion with 1-year follow-up.[67] The study demonstrated statistically significant functional improvement in the fusion group compared with the decompression group

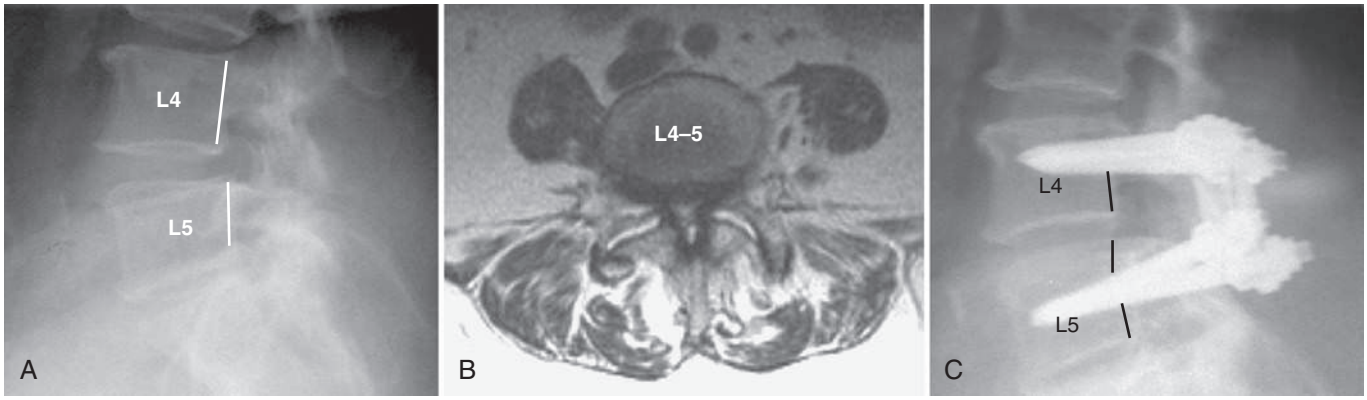

FIG. 64.3 (A) Preoperative standing lateral lumbar radiograph showing a small L4–L5 degenerative spondylolisthesis. by Oswestry Disability Index and Short Form-36 (SF-36). The type of surgery was at the discretion of the treating surgeon and was done at two institutions by two surgeons. The nonrandom nature of the study and its restriction to patients with grade I slips only limited the generalization of the conclusions.

Most studies looking at fusion with instrumentation in the treatment of DS involve concomitant decompression (Fig. 64.3). One study, however, investigated the role of instrumented fusion with slip reduction and minimal decompression for DS.[68] The decompression involved only bilateral foraminotomies to safely visualize and mobilize the exiting nerve root. At a mean month follow-up of 33 months, 82% of patients with leg pain and 75% of those with back pain showed relief. The degree of anterolisthesis was reduced by 90% at follow-up. These authors concluded that the clinical, functional, and radiographic outcomes produced results comparable with the published outcomes of in situ fusion after formal laminectomy and that formal laminectomy may not always be necessary in the treatment of degenerative lumbar spinal stenosis with spondylolisthesis.

Although there is little argument that segmental instrumentation produces a more solid arthrodesis than noninstrumented fusion, there are conflicting data relating a solid arthrodesis to better clinical outcome. The multicenter historical cohort study of spinal fusion using pedicle screw fixation involved a retrospective review of 2684 patients with DS.[69] Solid radiographic fusion was noted in 89% of patients undergoing pedicle screw fixation compared with 70% of those without instrumentation. The clinical outcome was also better in the group of patients undergoing instrumented fusion. This report, however, was a retrospective historical review rather than a prospective randomized study; the validity of its conclusions is therefore limited.

A prospective randomized study followed 124 patients for 1 year after either instrumented or noninstrumented fusion for various diagnoses, including DS.[60] Two types of spinal instrumentation were employed: a rigid system and a semirigid system. Outcome was based primarily on radiographic fusion rate. The overall fusion rate was 65% for the noninstrumented group, 77% for the semirigid fixation group, and 95% for the rigid fixation group. For the subgroup of patients with DS, fusion was achieved in 65% of the noninstrumented patients, 50% of the semirigid fixation group, and 86% of the rigid fixation group. A trend of better clinical outcomes with increasing rigidity of fixation was also observed: 71% of the noninstrumented group, 89% of the semirigid group, and 95% of the rigid group reported excellent or good results.

A retrospective review of 30 patients undergoing decompression and instrumented fusion for DS reported both radiographic outcomes by fusion rate and functional outcomes by patient questionnaire and the SF-36 survey.[70] Both fusion rate and patient satisfaction were 93%. However, 13 patients (43%) had complications, including dural tears (3 patients), excessive blood loss (2 patients), pseudarthrosis (2 patients), pulmonary embolus (1 patient), deep infection (1 patient), urinary tract infections (3 patients), and unstable angina (1 patient). Patients with complications were found to have poorer outcomes. The study concluded that patients treated with decompression and fusion for DS had improved patient-reported functional outcomes but a significant risk of complications.

Some studies have concluded that the addition of spinal instrumentation to a fusion did not necessarily improve outcome. A randomized prospective study of patients undergoing posterolateral lumbar fusion, with and without pedicle screw instrumentation, for a variety of conditions concluded that the addition of instrumentation did not produce a significant incremental clinical benefit to that obtained from noninstrumented fusion, although there was a slight but nonsignificant trend toward higher fusion rate in the instrumented fusion group.[71] Overall, there was no statistical difference in patient-reported outcomes between the two groups. Although there was a slight nonsignificant trend toward an increased radiographic fusion rate in the group with instrumentation, this did not correlate with increased patient-reported improvement. For the entire group, the results did not show a

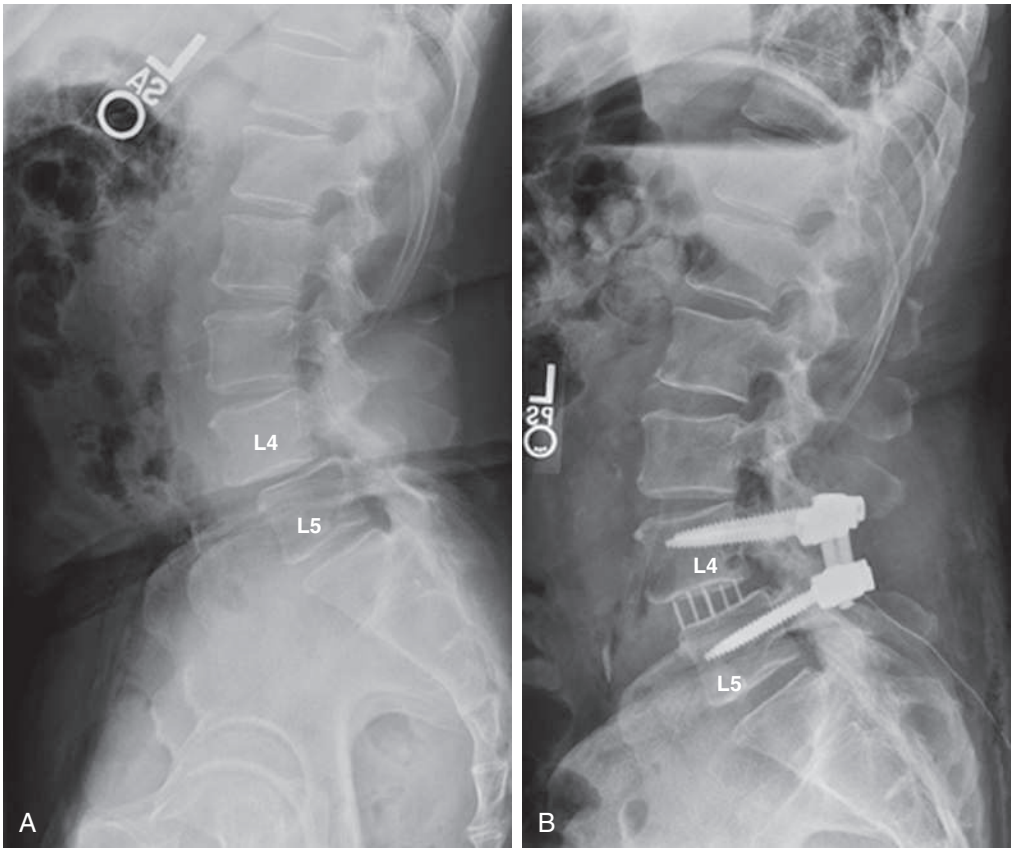

FIG. 64.4 (A) Preoperative standing lateral lumbar radiograph showing L4–L5 degenerative spondylolisthesis. clinical benefit from the addition of instrumentation in elective lumbar fusions. For a small subgroup of 10 patients who had DS, 5 underwent instrumented fusion and 5 underwent noninstrumented in situ fusion. Four of the five patients with DS undergoing instrumented fusion achieved an excellent/good outcome, compared with two of five of those undergoing noninstrumented fusion. For this small subgroup of patients with DS, the clinical outcome appeared to be better than that of the overall population studied, although this subgroup was too small to achieve statistical significance.

A prospective randomized study of 68 patients with spinal stenosis and DS compared decompression and arthrodesis without instrumentation to decompression with segmental transpedicular instrumentation.[64] At an average of 2 years' follow-up, successful fusion was significantly more common in the instrumented group than in the noninstrumented group (83% vs. 45%, respectively), although there was no significant improvement in clinical outcome between the two groups (76% vs. 85% excellent/good outcomes, respectively). These authors concluded that the presence of successful fusion did not predict or influence short-term clinical outcome at 2 years.

In a long-term follow-up of 58 patients previously reported and prospectively randomized to decompression with noninstrumented fusion,[53,64] 47 were available for review at an average of 7 years, 8 months postoperatively (range, 5 to 14 years).[72] Excellent and good clinical outcomes were reported in 86% of patients achieving a solid arthrodesis but in only 56% of those patients having a pseudarthrosis. Patients with a solid fusion had significantly less back pain and better function than those with a pseudarthrosis. This study demonstrated a clear benefit of a solid arthrodesis on clinical outcome for patients undergoing decompression for spinal stenosis with DS. The short-term improvement in outcome noted at 2 years' follow-up in Herkowitz and Kurz's[53] and Fischgrund and colleagues'[64] initial studies deteriorated at final follow-up in patients who did not achieve a solid arthrodesis. The finding of better clinical outcome associated with solid fusion was also confirmed in another retrospective comparison of patients having a solid noninstrumented arthrodesis compared with patients with a pseudarthrosis.[73]

A 7-year follow-up of 47 patients treated with decompression and noninstrumented fusion found that long-term outcome was better in patients having a solid arthrodesis compared with those with a pseudarthrosis.[72] These authors inferred that the use of adjunct instrumentation might produce better long-term clinical outcomes than fusion without instrumentation. However, they did not compare the long-term clinical outcomes of the noninstrumented but solidly fused patients from their initial study with instrumented patients from their subsequent study; thus, a definitive conclusion on

the value of instrumentation on clinical outcome could not be made.[64,74] Therefore, the issue of whether the addition of spinal instrumentation confers long-term clinical outcome that is superior to, worse than, or the same as that of a solid noninstrumented arthrodesis has not been answered by this or any other study.[75–77]

Most recently, Ghogawala et al. published 4-year results of a prospective randomized controlled trial that compared laminectomy alone to laminectomy and instrumented posterolateral fusion in 66 patients with degenerative spondylolisthesis and stenosis.[78] They found greater improvements in SF-36 scores with fusion than laminectomy alone. In contrast, Oswestry Disability Index scores were not significantly different between treatment groups. The most striking difference between treatments was the reoperation rate, which was 14% in the fusion group and 34% in the laminectomy-alone group. Most reoperations following fusion were for adjacent-level disease; most in the decompression-alone group were for recurrent stenosis. Published in the same issue, Försth et al. reported no difference in a subgroup of patients with degenerative spondylolisthesis and stenosis who were treated with decompression alone versus decompression and fusion.[79] Methodologically, these two studies differed in that the former controlled all aspects of the surgical technique and the indications for surgery were determined by a physician panel. In the latter, there were a variety of surgical techniques, both for decompression and fusion. These differences might help explain the disparate findings between the two studies.

Posterior Fusion With Anterior Column Support

Some authors have recommended the use of concomitant posterior fusion with anterior column support in the surgical management of some types of spondylolisthesis. Most commonly, anterior column support is provided by either a posterior lumbar interbody fusion (PLIF) or a transforaminal lumbar interbody fusion (TLIF), although anterior lumbar interbody fusion has also been used. Recent advances have allowed for lateral lumbar interbody fusion, in particular, minimally invasive lumbar interbody fusion (so-called extreme lateral interbody fusion [XLIF] and direct lateral interbody fusion) and minimally invasive TLIF (MIS TLIF) (Fig. 64.4). Minimally invasive surgical techniques such as XLIF and MIS TLIF allow for a smaller surgical site with similar, if not decreased, surgical complications and decreased surgical recovery times compared to traditional open approaches. A retrospective review comparing PLIF and MIS TLIF found that patients undergoing PLIF experienced higher operative blood loss, higher volume of blood transfusion, and increased complications compared to those who underwent TLIF, although hospital length of stay was comparable.[80] In a recent prospective multicenter study, Sembrano et al. found similar clinical outcomes at 2-year follow-up when comparing XLIF to MIS TLIF, in particular, back and leg pain relief when compared to baseline (73% and 64%, respectively).[81] Anterior column support has been more commonly recommended for isthmic spondylolisthesis, although its use for DS has also been advocated.[82–85] As with posterior instrumented fusion, generally, convincing data comparing posterior fusion with anterior column augmentation with other types of fusion do not exist. Furthermore, there is no evidence to suggest that the biomechanics and potential mechanism of failure for isthmic spondylolisthesis are the same as those for DS.

Purported advantages of interbody fusion with PLIF, TLIF, or XLIF compared with posterior instrumented fusion without an interbody fusion include greater likelihood of fusion, better indirect foraminal decompression, better reduction of the spondylolisthesis, and better lordosis.[81,82,85] In a one-level spondylolisthesis, however, it is not clear whether a slight improvement in slip reduction or lordosis produces a better clinical outcome. Nor is it known whether the potential for a slight incremental improvement in sagittal alignment or an increase in lordosis is worth the risk of potential nerve root injury as a result of interbody fusion.

Options for interbody fusion devices include metallic cages, carbon fiber cages, polyetheretherketone cages, or bone. A study comparing combined anterior and posterior lumbar reconstruction using anterior cages to posterior pedicle screw fixation alone investigated the biomechanical effects of interbody cages on construct stiffness, pedicle screw strain, and adjacent-level changes.[86] This study found that for spinal instability with preserved anterior load sharing, pedicle screw fixation alone was biomechanically adequate and recommended that interbody cages not be used because they further increased segmental motion at the adjacent level. Where anterior column support was deficient, however, posterior stabilization with pedicle screws alone provided inadequate stability and resulted in a high level of implant strain. Under such circumstances, the addition of an interbody cage significantly increased the construct stiffness and decreased hardware strain, although it resulted in increased motion at the adjacent segment. Similar adverse effects on the adjacent level were demonstrated in another biomechanical study that showed that rigid fusion using posterior pedicle screw fixation and an interbody cage produced higher loads at the superior adjacent level than posterior instrumented fusion without an interbody cage because of the increased stiffness of the fixed segments using the cage.[87]

In the absence of a head-to-head, prospective, randomized controlled study comparing the clinical outcome of instrumented to noninstrumented fusion for DS, it is difficult to know which treatment is better. In the absence of such data, the decision for treatment will inevitably be based largely on complications and cost.

From a societal perspective, fusion, particularly instrumented fusion, adds significantly to the incremental costs of treating spinal stenosis with DS. Kuntz and colleagues looked at the 10-year costs, quality-adjusted life-years (QALY), and incremental cost-effectiveness ratios (reported as dollars per quality-adjusted year of life gained) for patients undergoing decompressive surgery, with or without spinal fusion, for spinal stenosis with DS.[88] Laminectomy with noninstrumented fusion was found to cost $56,500 per QALY versus laminectomy without fusion. The cost-effectiveness ratio of instrumented fusion, compared with noninstrumented fusion, was $3,112,800 per QALY. A cost-effectiveness ratio of $82,400 per

QALY was calculated if the proportion of patients experiencing symptom relief after instrumented fusion was 90% as compared with 80% for patients with noninstrumented fusion. The study concluded that the cost-effectiveness of laminectomy with noninstrumented fusion compared favorably with other surgical interventions, such as lumbar discectomy for treatment of herniated lumbar disc or coronary artery bypass grafting for triple-vessel coronary artery disease. The cost-effectiveness, however, depended greatly on the true effectiveness of the surgery to alleviate symptoms and also on how patients valued the quality-of-life effect of relieving severe stenosis symptoms. Instrumented fusion was expensive compared with the incremental gain in health outcome. The study further concluded that better data on the effectiveness of this and other alternative procedures were necessary to justify their incremental cost.

The SPORT looked at the cost-effectiveness of spine surgery at 2-year follow-up.[89] This study evaluated the 61% of patients with DS who had surgery. Of these surgical patients, 93% had fusion, most (78%) with instrumentation. The study found that surgery significantly improved quality of life compared with nonoperative treatment, with an average cost of $115,000 per QALY gained. These authors concluded that surgery was not highly cost-effective compared with other elective orthopaedic surgeries over the 2-year follow-up period but did compare favorably with many other health interventions. Whether or not surgery for DS is cost-effective in the long run depends on long-term benefits and the ongoing costs associated with fusion surgery (e.g., the potential for future revision surgery).

The cost-effectiveness of fusion was also examined in a Swedish study that compared a group of patients who were randomized to one of four treatment groups for chronic low back pain: noninstrumented posterolateral fusion, instrumented posterolateral fusion, instrumented posterolateral fusion with interbody fusion, and a nonsurgical control group.[90] This study did not specifically examine patients with spinal stenosis and DS but concluded that the cost of treatment of chronic low back pain at 2-year follow-up was significantly higher if fusion was performed. Although the treatment effect of all surgical groups was found to be better than the control (nonoperative) group, the added (incremental) cost per QALY for fusion compared with nonoperative care ranged from $52,000 to $157,000 in the United States, depending on the magnitude of the assumed average annual QALY.

A recent study that reviewed major medical complications and charges associated with surgery for spinal stenosis in Medicare patients from 2002 to 2007 found that adjusted mean hospital charges for *complex* fusion procedures, defined as fusion involving more than two levels or a 360-degree (interbody) fusion, cost $80,888 compared with $23,724 for decompression alone.[46]

Besides the added cost of instrumented fusion, other adverse effects of fusion have been noted. It has been demonstrated that lumbar fusion is associated with greater morbidity than decompression alone.[47,48,50] In addition, a greater potential for complications exists with instrumentation than without it. A retrospective 6.5-year follow-up (range, 5–10.75 years) of 36 patients undergoing instrumented fusion for DS reported a patient satisfaction rate of 83%.[91] Although there were no neurologic deficits, pseudarthroses, recurrent stenosis at the fused segment, or progression of deformity at the fused level, five patients had symptomatic adjacent-level degeneration (transition syndrome) and an additional seven patients had asymptomatic radiographic transition syndromes. These authors concluded that although the rate of major complications (2%), implant failures (2%), and symptomatic pseudarthroses (0%) was low, radiographic degeneration at levels adjacent to the fused levels (transition syndrome) was common.

Alternative Surgical Strategies

Indirect spinal canal and foraminal decompression via interspinous process distraction has been proposed as an alternative to decompression for spinal stenosis with DS.[92] A randomized controlled study of 42 patients with spinal stenosis associated with DS was compared with 33 control patients treated nonoperatively.[92] The study found that the use of an interspinous process distraction device produced a better functional outcome than nonoperative management in patients with neurogenic claudication associated with degenerative spondylolisthesis. The question of whether or not that device was as good as, worse, or better than traditional decompression or decompression and fusion was not addressed by this study.

A contrary view of interspinous process distraction was reported in a study of 12 consecutive patients with DS and DS treated by interspinous process distraction and followed for a mean of 30 months.[93] That study reported a high failure rate: although two-thirds of patients had complete relief of their preoperative symptoms, one-third had no relief and 58% underwent surgical decompression and fusion within 24 months of their index procedure.

Significant reduction in total sagittal range of motion has been reported with one interspinous process distraction device that used both a mechanical blocking component and a tension band.[93] The tension band resulted in a significant additional restriction in total motion, including flexion, compared with the device without the tension band (43% reduction in motion compared with 16% reduction).

The use of motion-sparing technology has been advocated by some authors as an effective alternative to fusion that can reduce the potential for adjacent-level degeneration.[56,94–96] One prospective, minimum 4-year follow-up study of 26 consecutive patients with DS reported significantly improved pain and walking distance without progression of the spondylolisthesis.[56,95] Three patients demonstrated radiographic screw loosening and one patient had screw breakage. Nearly half of the patients showed some degeneration at adjacent levels. Comparable clinical outcome using the same device was reported in a prospective randomized, multicenter U.S. Food and Drug Administration investigational device exemption trial with a 1-year follow-up.[96] Early results from that study showed significant improvement in both back and leg pain, as well as function, but the study cautioned that further follow-up was necessary.

Summary of Treatment Options

Currently, there does not appear to be a clear consensus as to the optimal way to treat patients with symptomatic DS. Some studies suggest that patients undergoing surgery do better when decompression is accompanied by fusion. It is less clear, however, whether fusion should be augmented with instrumentation. Although a fusion is more robust and solid with instrumentation than without it, the incremental benefits of instrumentation on clinical outcome are less clear. It seems reasonable that in the presence of clear evidence of instability on flexion–extension radiographs, the immediate stability provided by instrumentation warrants the additional time, expense, and potential morbidity associated with its use. This is especially appropriate for young active patients with good bone stock. On the other hand, the indication for the use of hardware in a patient with a collapsed disc space, no motion at the spondylolisthetic level, or the presence of osteoporotic bone is less clear. A 2005 focus issue in *Spine* on lumbosacral fusion contained a combined position statement by *Spine* and the Scoliosis Research Society. It noted a positive long-term correlation between fusion and improved clinical outcome. It also noted a clear association between the use of instrumentation and higher fusion rates. Accordingly, the use of spinal instrumentation was recommended for spinal stenosis associated with DS. The position statement concluded by stating that the effectiveness of other posterior or anterior techniques (e.g., interbody fusion techniques) has yet to be established.[97]

Summary

The optimal surgical treatment of spinal stenosis, particularly when associated with DS, is still somewhat controversial. Such controversy involves the method and extent of decompression, the role of fusion, and the use of spinal instrumentation. Although spinal stenosis is a diffuse degenerative condition with many segmental levels often showing evidence of radiographic stenosis, decompression of *every* level showing *any* degree of radiographic stenosis is clearly not always warranted. Obviously, all symptomatic levels should be decompressed. There is no clear consensus, however, on whether to decompress asymptomatic levels; this decision depends on many factors. Because restenosis at a previously decompressed level or the development of symptomatic stenosis at a previously asymptomatic and unoperated stenotic level is a common reason for failure of surgery for spinal stenosis, it is generally more prudent to decompress any stenotic level suspected of being potentially symptomatic than not to. When diffuse degenerative changes produce unilateral symptoms with multilevel stenosis, particularly in an elderly patient, decompression by multilevel unilateral hemilaminectomies is a good therapeutic option. If symptoms are bilateral and the stenosis is diffuse and multilevel, multiple bilateral laminotomies, rather than multiple complete laminectomies, can be considered. Multilevel decompression with bilateral laminectomies carries the risk of developing instability and therefore mandates consideration of fusion to ameliorate this risk.

Because fusion is associated with higher morbidity in the elderly population, it is prudent to consider a less extensive surgical decompression that could obviate the need for fusion in these patients. Such an approach reduces the need for concomitant fusion by preserving the uninvolved laminae and ligamentous structures, thereby minimizing the risk of developing late instability. The arguments against such limited decompression are the risk of performing an inadequate decompression, the potential for recurrence of stenosis, and technical challenges associated with a unilateral approach. Unilateral (foraminal) neural decompression without sacrificing the facet joint is difficult in the presence of an intact spinous process because the spinous process inhibits the ability to angle instruments enough to adequately decompress the neural foramen. This can be obviated to some degree by the use of angled rongeurs, although foraminal decompression is still difficult with intact midline structures.

As noted previously, many studies suggest that patients with spinal stenosis and DS have better clinical outcomes when decompression is accompanied by arthrodesis. The issue of whether to augment the fusion with segmental (pedicle) instrumentation is not yet completely resolved. In a *younger, healthy, and active patient* with focal spinal stenosis associated with DS, particularly if associated with well-maintained disc height, fusion of the listhetic level is recommended, usually with segmental fixation, because of the risk of developing subsequent instability. For an *older patient* with combined stenosis and DS, fusion is also generally warranted, particularly if the patient is active and generally healthy. The issue of whether to instrument the fusion, however, is not completely resolved. Although most studies show the beneficial effect of instrumentation on fusion rate, its relationship to improved short-term clinical outcome is not completely known. Because long-term clinical outcome is improved by the presence of a solid fusion and because the use of instrumentation has been shown to increase the likelihood of achieving a solid fusion, instrumentation is generally recommended. In *elderly low-demand patients with multiple comorbidities,* the decision to fuse must be balanced against the increased morbidity associated with arthrodesis. Arthrodesis may not be a therapeutic imperative in the elderly low-demand patient with a listhetic level associated with decreased disc height, spur formation, subchondral sclerosis, or ligament ossification because these degenerative changes may provide enough stability to the listhetic level to minimize the risk of slip progression. Under such conditions, consideration of hemilaminectomies or unilateral or bilateral laminotomies to preserve uninvolved stabilizing structures is warranted.

Decompression and fusion with pedicle fixation are indicated and recommended as a means to promote stability at the level of the slip for active, healthy, physiologically young patients with spinal stenosis associated with DS. Decompression and instrumented fusion is also generally recommended for older, healthy, active patients with a relatively well-maintained disc height at the listhetic level. Elderly and inactive patients can be managed by decompression with either instrumented or noninstrumented fusion. Elderly low-demand patients with multiple comorbidities and significant degenerative changes

that reduce the likelihood of slip progression are usually best managed by limited decompression without fusion or decompression with noninstrumented fusion.

PEARLS AND PITFALLS

1. Degenerative spondylolisthesis (DS), also known as spondylolisthesis with an intact neural arch, is an acquired condition that rarely presents before the age of 50 years.
2. DS most commonly affects the L4–L5 level, although other levels may be affected; it rarely affects the L5–S1 level, in contrast to isthmic spondylolisthesis, which most commonly affects L5–S1.
3. It is important to always get a standing anteroposterior and lateral lumbar radiograph of any patient suspected of having a DS because supine radiographs may fail to detect the slip.
4. DS may be asymptomatic or may present with low back pain and neurogenic claudication.
5. In general, the surgical treatment of DS is decompressive laminectomy and fusion.
6. Long-term surgical outcome appears better with a solid arthrodesis than with a pseudarthrosis. It has been shown that posterior instrumented fusion produces a more solid arthrodesis than noninstrumented fusion. Therefore, the durability of surgery may be more reliable with instrumented fusion than with noninstrumented fusion.
7. The role of fusion in the elderly patient with DS must be balanced against the potential morbidity of fusion surgery. Decompression without fusion may be the better option in selected elderly patients with significant medical comorbidities and limited activity.

SECTION IX

SPINAL FUSION AND INSTRUMENTATION

This page intentionally left blank

65 CHAPTER Techniques and Complications of Bone Graft Harvesting

Kenny Kwan
Kenneth M.C. Cheung

Solid spinal fusion requires bone healing, similar to the process of fracture healing, through a combination of intramembranous and enchondral ossification. Spinal fusion in a rabbit model is comprised of three distinct phases: early inflammatory phase (weeks 1–3), the middle reparative phase (weeks 4–5), and the late remodeling phase (weeks 6+).[1]

Local bone graft from spinous processes and laminae can be effective in lumbar fusion, either as standalone graft or as graft extender in combination with nonlocal autogenous graft. One study has shown that the mean volume of local bone graft harvested can be approximately 25 mL.[2] A retrospective comparative study showed that for single-level fusion in degenerative lumbar cases, the fusion rate was similar between local bone and iliac crest graft. However, in multilevel fusion, defined as two or more levels, the fusion rate was significantly lower in the local bone group.[3] However, in children undergoing surgery for adolescent idiopathic scoliosis, fusion rate is not greatly influenced by the type of bone graft used.[4,5]

Iliac crest bone graft (ICBG) is still considered the gold standard for spinal fusion by many surgeons today. It is readily available, has inherent fusion-developing properties (i.e., osteogenic potential, osteoinductivity, and osteoconductivity), is biocompatible, and can provide structural support. Harvested bone contains osteoblasts, bony matrix, and factors such as bone morphogenetic proteins, and transforming growth factor-β. The cancellous bone from ICBG contains readily available channels for vascularization[6,7] and important growth factors that facilitate each of the three phases of fusion.

Apart from local bone and ICBG, other sources of autologous bone graft in spine surgery include the rib and both vascularized and nonvascularised fibula.

Surgical Anatomy and Techniques

Anterior Iliac Crest

The ilium was introduced by Abbott in 1942 as a bone graft reserve,[8] and since then the iliac crest and outer table of the ilium have been used as a source of cancellous or corticocancellous bone grafting. Corticocancellous graft can be harvested from the anterior iliac crest. It can be bicortical or tricortical bone graft for use in anterior cervical arthrodesis after discectomy or corpectomy. This is the preferred site for anterior spinal surgery due to easier access without the need to turn the patient prone.

The patient is placed in the supine position. A roll or sandbag is placed underneath the gluteal area of the side from which bone graft will be harvested. This elevates and internally rotates the iliac crest, making it more readily accessible. This area is prepped and draped separately from the main wound. It is our practice to prep this area in all cases of anterior cervical spine surgery in the event that autogenous bone graft is needed.

The surgical incision is made parallel to the iliac crest, beginning at least 2 cm posterior and lateral to the anterior superior iliac spine (ASIS), at the iliac tubercle (Fig. 65.1A). This incision can reduce the amount of fibrous scar healing by preserving the skin around the ASIS.[9] The skin is pulled superiorly so the incision is not directly on the crest itself. This maneuver can reduce discomfort from having a scar directly over a bony prominence. The iliac tubercle marks the anterior portion of the ilium and is the area containing the largest amount of corticocancellous bone. An incision here will avoid a variant course of the lateral femoral cutaneous nerve (LFCN). The LFCN most commonly exits the pelvis about 2 cm medial to the ASIS and passes beneath the inguinal ligament and sartorius muscle, both of which attach to the ASIS. The most superficial and dangerous variant course (in about 4% of cases) occurs when the LFCN exits through the abdominal wall, approximately 2 cm posterior to the ASIS, and crosses the iliac crest.[10] An incision at least 2 cm lateral to the ASIS should avoid the LFCN.

After incising the skin, the incision is continued through the subcutaneous fat and deep fascia onto the periosteum (Fig. 65.1B). The deep fascia can be incised in the manner of a flap, such that after closure it can act as "tent" to cover up the defect. The next step depends on whether cancellous bone or corticocancellous bone graft is required. If only cancellous bone is required, a trapdoor method is used to elevate the cortex of the iliac crest, which can subsequently be "closed" after the cancellous bone is harvested to maintain the contour of the iliac crest. An osteotome is used to make horizontal cut over the crest and at the outer periosteal table, while the inner table is kept intact by the periosteum and fascial attachments of

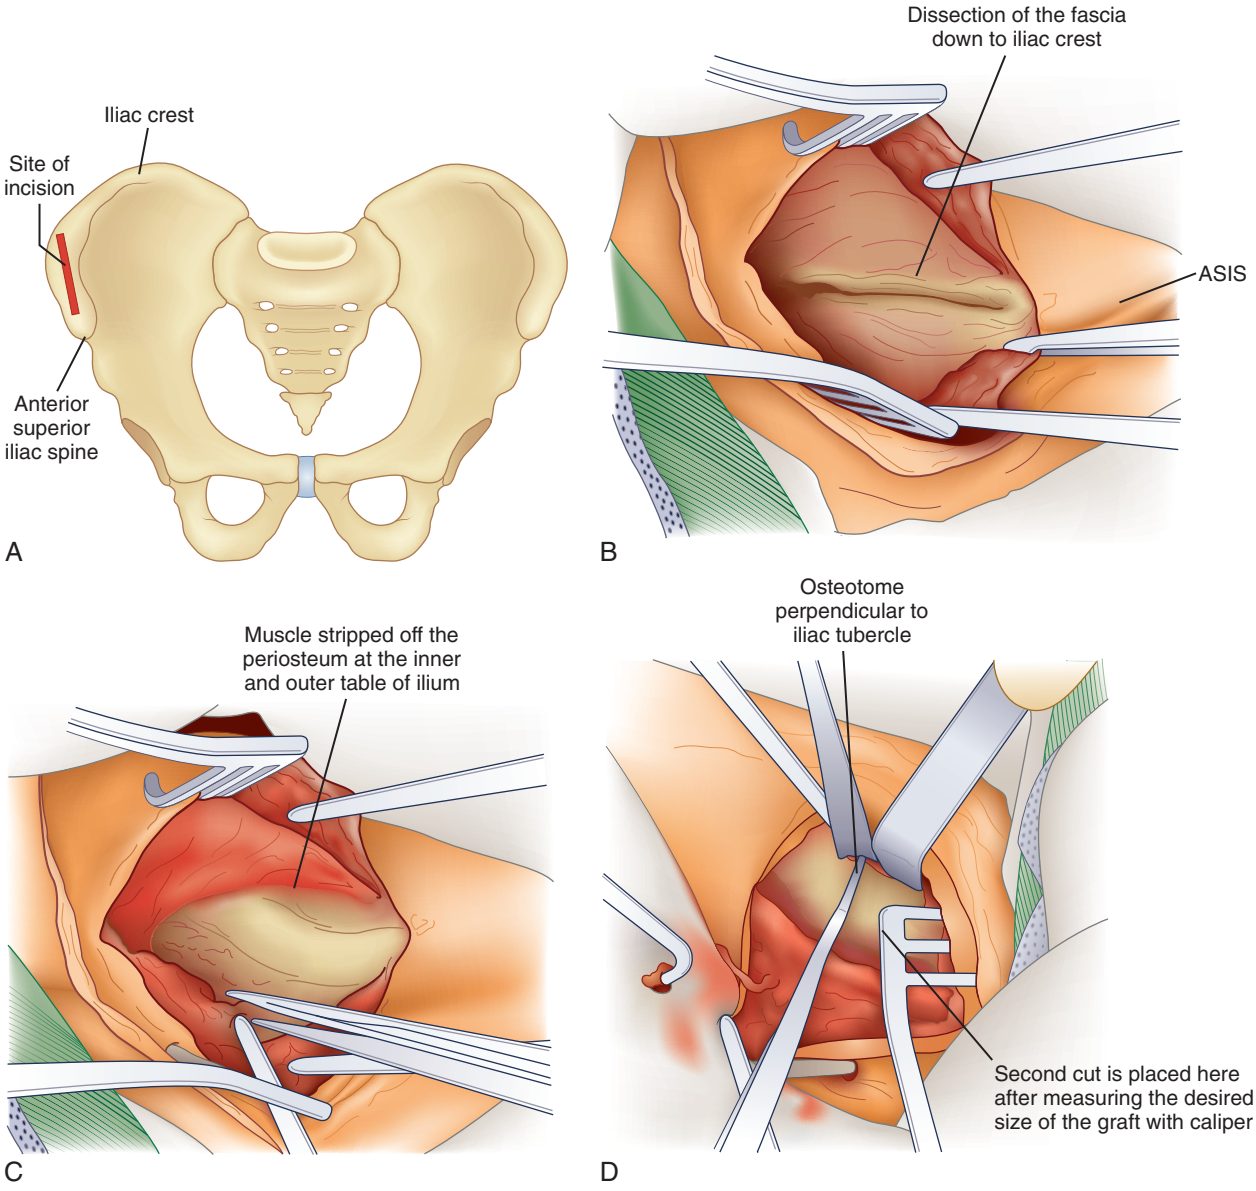

FIG. 65.1 (A) Incision is made 2 cm posterolateral to the anterior superior iliac spine over the iliac crest. This decreases the risk of fracture, and the incision is not made directly over the bone defect. (B) Incision is continued over the skin, subcutaneous tissues, and a deep fascia flap. (C) The deep fascia and muscles are stripped from the periosteum so the surfaces of the iliac crest are exposed. (D) An osteotome or oscillating saw can be used to make a cut perpendicular to the iliac tubercle. A spare saw blade can be left in place to guide a second parallel cut of the predetermined-size bone graft. The graft cut is completed with an osteotome at the base of the bone. (E) A tricortical bone graft of the desirable size is harvested.

iliacus and the abdominal wall muscles. This serves as a hinge for the cortex to "open" like a trapdoor, and cancellous bone can be harvested with a curette. The periosteum and fascia can be approximated subsequently and the cortex of the crest will heal in its original position.

For harvesting tricortical cancellous graft, subperiosteal stripping of the muscles off the inner and outer table either using cauterization or a periosteal elevator and sponge packing provides adequate exposure (Fig. 65.1C). The length and depth of the required graft are measured with a caliper. The harvest site must be at least 2 fingerbreadths posterior to the ASIS to reduce the likelihood of a stress fracture from the downward pull of the sartorius and rectus femoris. A complete block of the ilium can be removed with an oscillating saw or osteotome to make two cuts perpendicular to the surface of the iliac tubercle (Fig. 65.1D) and is completed with an osteotome at the base of the crest (Fig. 65.1E). To obtain cuts parallel to each other, a spare saw blade can be placed in the first cut to act as a guide for the second cut. Hemostasis with bone wax and gel foam can be applied to the defect, and the fascia is repaired. We do not routinely use a drain at the harvest site.

Posterior Iliac Crest

The superior and posterior margin of this bone graft donor site is the posterior iliac crest, with the inferior margin being the greater sciatic notch. The anterior margin is the anterior limit of the superior limb of the sacroiliac joint, although this remains unseen during the bone graft harvest.

This site of harvest is typically used in posterior spinal surgery since the patient is already placed in the prone position. The posterior superior iliac spine (PSIS) and the subcutaneous part of the iliac crest are readily palpable. Either an oblique incision centered over the PSIS in line with the crest (Fig. 65.2A) or a longitudinal incision can be used. An anatomic study using cadavers and dry ilium specimens showed that the average distance from the superior cluneal nerve laterally to the PSIS medially was 68.8 mm.[11] The incision therefore should be placed well within this distance to avoid injury to this nerve and formation of painful neuromas. Alternatively, if the patient is undergoing lumbosacral spinal surgery, the incision can be extended distally and the posterior iliac crest can be accessed via the midline fascial splitting technique.

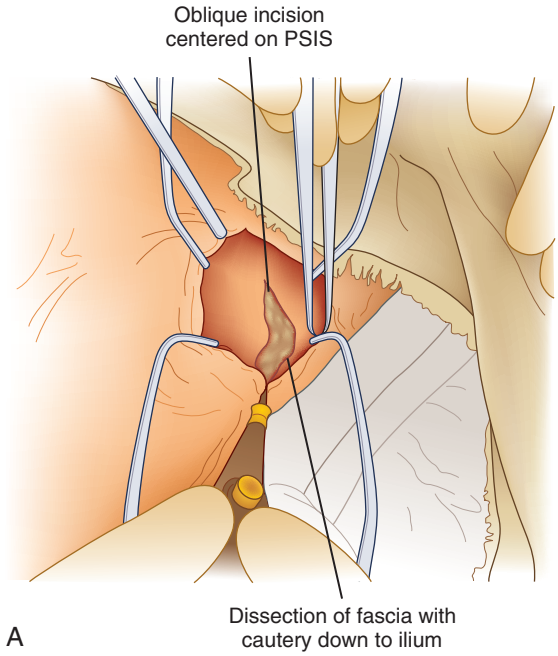
The midline fascial splitting approach was described by Hutchinson and Dall.[12] After incising the dorsal lumbar fascia and releasing the fascial insertion from the spinous process, the two posterior planes of the fascia (i.e., the fascial extension of the latissimus dorsi and the fascia of the erector spinae muscles) are separated. Both fascial layers attach to the iliac crest, so the surgeon is led directly to the border of the iliac crest. Electrocautery is used to cut directly down onto the crest to release the insertion of the fascia of the gluteus maximus. The gluteus can be elevated from the crest subperiosteally with a Cobb elevator (Fig. 65.2B–C).

Xu et al.[11] proposed that the largest and thickest area of the posterior iliac crest was bound by the superior extension of the posterior border of the superior limb of the articular surface anteriorly, and a line extending from the PSIS to the apex of the sacroiliac joint and oriented perpendicular to the posterior margin of the superior limb inferiorly. The average anterior limit was 34 mm lateral to the PSIS, with an average maximum thickness of 17.1 mm.

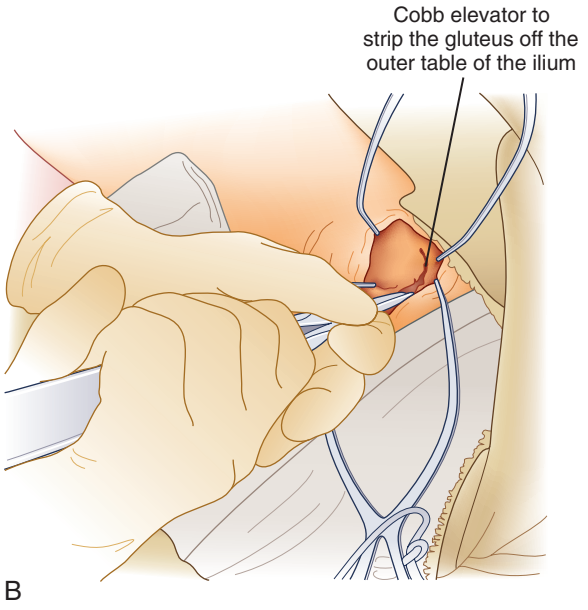
An osteotome is used to make an initial cut parallel to the superior aspect of the iliac crest. Then longitudinal cuts are made to the outer cortical table and completed with a gouge at the inferior limit to obtain cortical strips of bone graft (Fig. 65.2D). Afterward, the exposed underlying cancellous bone can be removed by careful stripping using the gouge without breaching the inner table (Fig. 65.2E). Both cortical and cancellous bone grafts can be obtained and used as needed (Fig. 65.2F). When both the outer cortical table and the cancellous bone beneath it are harvested, significantly more bone can be obtained than when just the cancellous bone is taken from between the inner and outer cortices (average 36 g vs. 25.7 g).[13] Before closure, hemostasis should be achieved with bone wax and gel foam. The wound is thoroughly irrigated before closing the incision in layers. We do not routinely use a suction drain at the harvest site because there is evidence suggesting that suction drainage does not improve patient outcomes.[14-16]

Rib

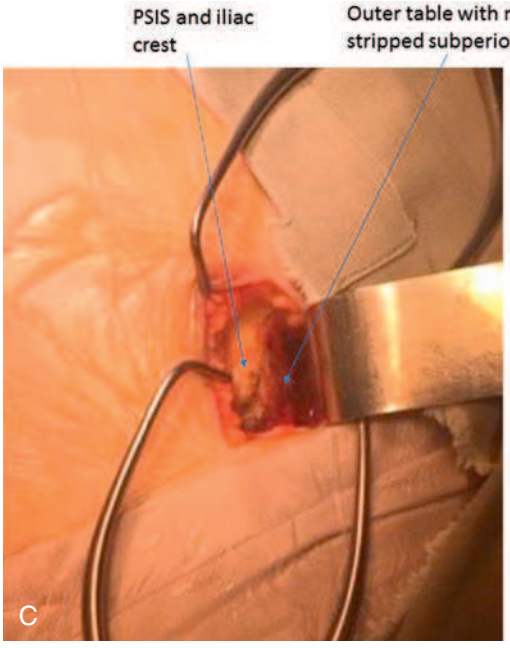
During anterior thoracic or thoracoabdominal approaches to the spine, a piece of rib may be excised to facilitate access to the thoracic cavity. The rib can be saved and trimmed to the appropriate size for the graft.



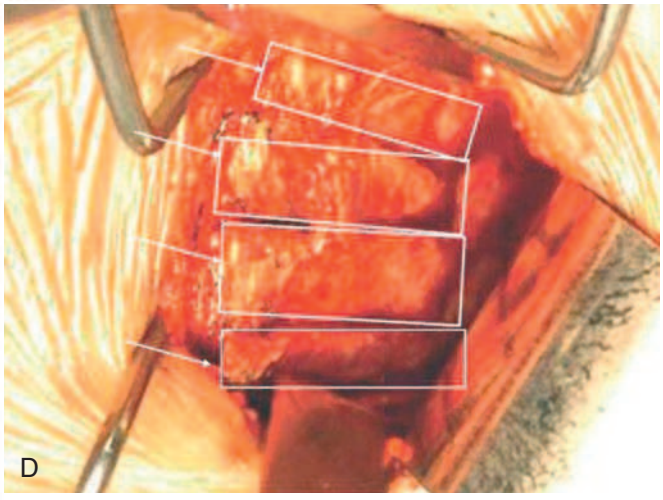
The incision should be centered over the appropriate rib, and skin, subcutaneous tissue, and the intercostal muscles are incised down to the rib. The periosteum is stripped with a periosteal elevator, taking care not to inadvertently incise the parietal pleura during this stage (Fig. 65.3). The costochondral junction can be cut medially with a rib cutter, as close to the angle of the rib as possible. The rib can then be wrapped with a piece of wet gauze until the graft is needed. The rib should be cleared of soft tissue to ensure good bony fusion and cut to the appropriate size.



Fibula



Autogenous fibula graft is rarely used these days because other sites for harvesting or allograft bone are usually available. The relatively high morbidity of autogenous fibular harvest precludes its routine use because it may affect ambulation. Nevertheless, the fibula can be used as a strut graft for anterior reconstruction after multilevel corpectomies in the cervical and thoracic spine.



A direct lateral incision is made parallel to the posterior border of fibula, at the middle third of the fibula, and carried directly down to the bone. The superficial peroneal nerve and surrounding soft tissues should be protected. Subperiosteal elevation of the peronei, extensor digitorum longus, tibialis posterior, flexor hallucis longus, and soleus from the bone is performed (Fig. 65.4). Once stripped of the muscles, a suitable length of bone can be harvested with an oscillating saw.

The syndesmosis of the ankle joint is 10 cm proximal to the joint, so harvesting should extend no more distally than 10 cm

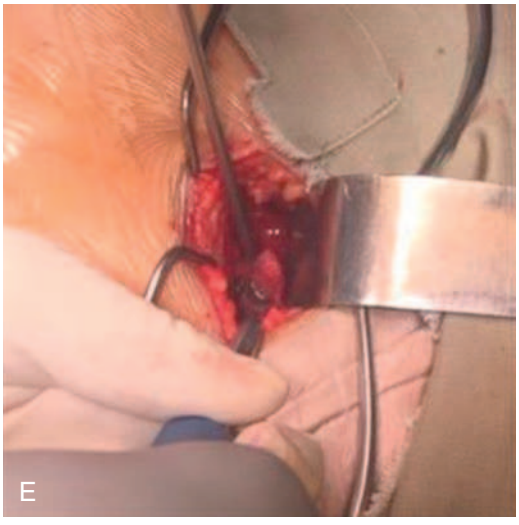


FIG. 65.2 (A) After an oblique skin incision is made over the posterior superior iliac crest, subcutaneous tissue is incised down to the iliac crest, and deep fascia is stripped. (B) A Cobb dissector is used to strip the gluteus muscle off the outer table of the ilium. (C) The top of the iliac crest and the outer table of the ilium are now completely exposed. (D) The outer cortex of the posterior iliac crest is harvested as cortical strips (*arrows*) with an osteotome and gouge. (D) The underlying cancellous graft is taken separately with a gouge. (E) The cortical strips (left) and cancellous graft (right) harvested from the posterior iliac crest.

above the ankle joint, or else there is a risk of ankle joint instability. Proximally, the common peroneal nerve courses over the neck of the fibula within the substance of the peroneus longus muscle, then divides into the deep and superficial branches. Hence the ideal harvest site lies at the junction of the distal third and middle third of the fibula.

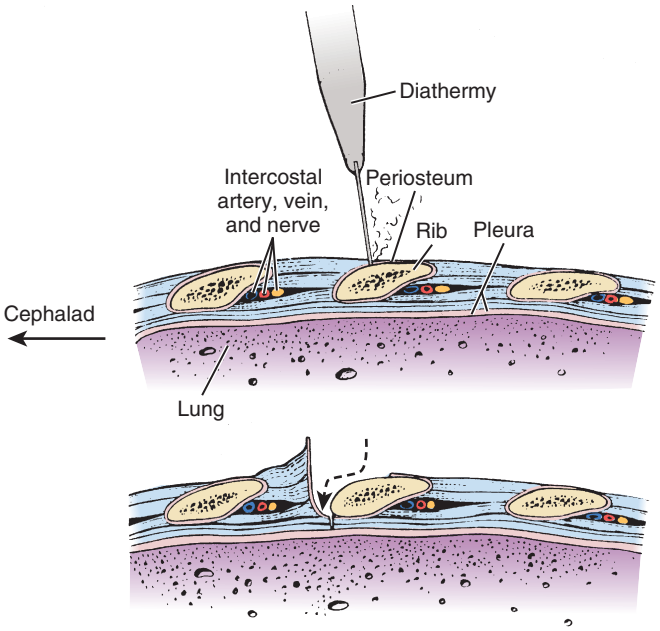

FIG. 65.3 The pleura is entered superior to the rib to avoid damage to the intercostal neurovascular bundle, which courses along the rib's posteroinferior border.

Complications of Bone Graft Harvesting

General

Hematoma

Arterial injury is uncommon during bone graft harvesting. Harvesting bone grafts from the inner table of the anterior ilium can damage the arterial anastomoses formed by the lumbar artery, iliolumbar artery, and deep circumflex iliac artery that supplies iliacus. In posterior bone grafting, the superior gluteal artery can be injured (see below).

After the bone graft is harvested, adequate hemostasis must be obtained with bone wax applied over the cancellous bone surfaces and other sites of bleeding and filled with gel foam. If adequate hemostasis is achieved intraoperatively, a suction drain is optional.

Infection

Donor site infection is uncommon and no more likely than in other orthopedic procedures. The principles of treatment are identical to any other surgical site infections.

Anterior Iliac Crest

Complications include pain, infection, cosmetic deformity, peritoneal perforation, and herniation of abdominal contents through the defect in the ilium. Stress fracture of the anterior ilium has also been reported.

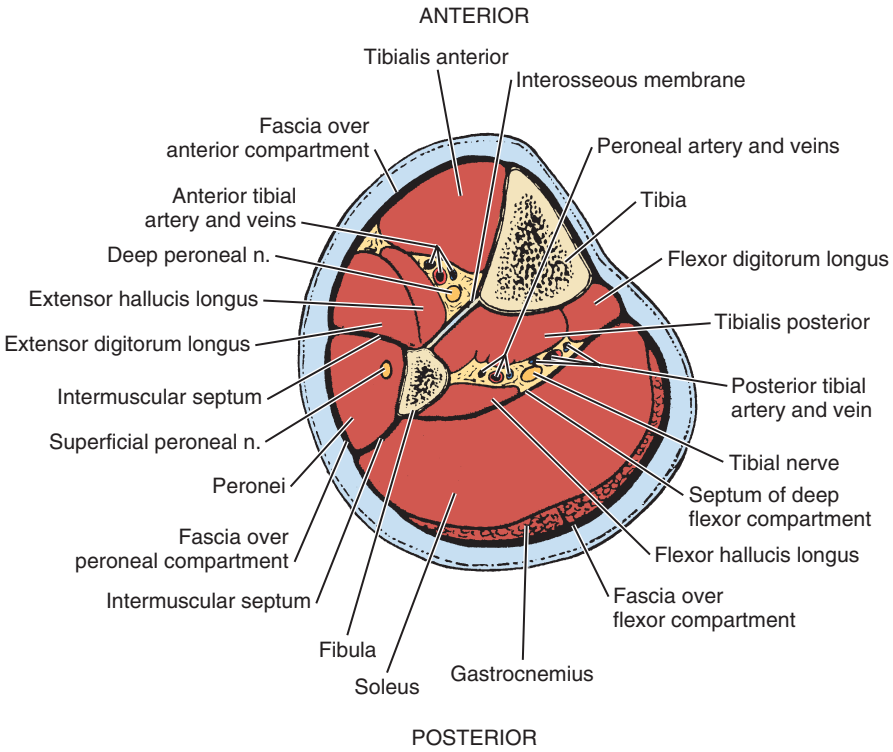

FIG. 65.4 Axial view of the lower leg depicting the fibro-osseus compartments as well as the neurovascular structures.

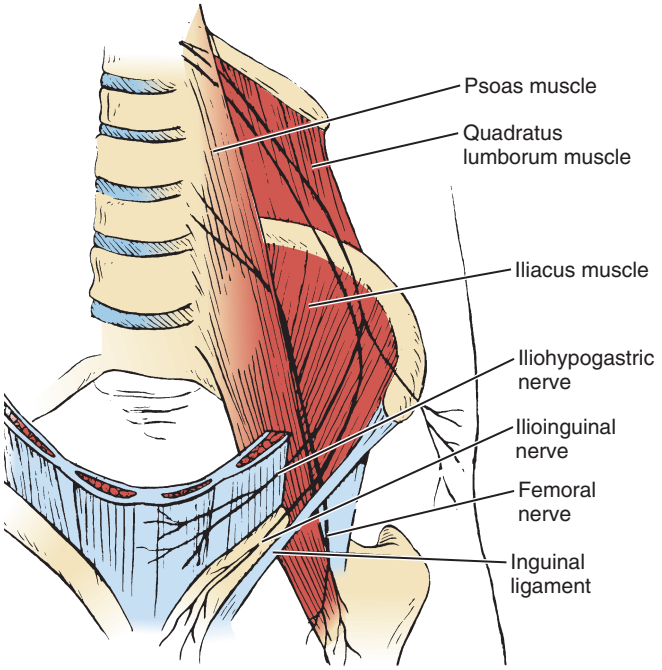

FIG. 65.5 Anteroposterior view of the abdomen and pelvis showing the normal course of the ilioinguinal, iliohypogastric, and femoral nerves.

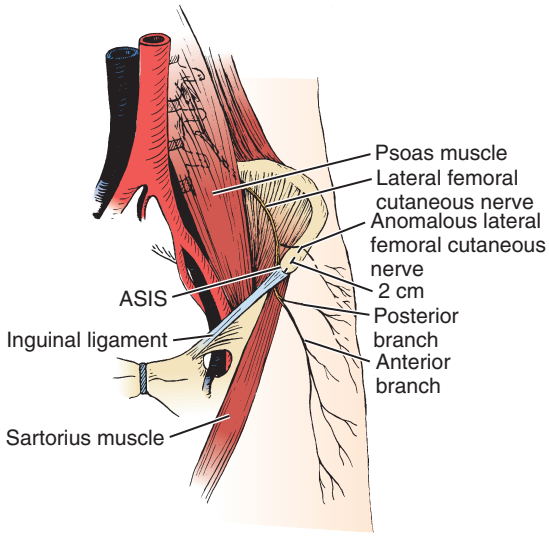

FIG. 65.6 Anteroposterior view of the pelvis depicting the normal and anomalous course of the lateral femoral cutaneous nerve. ASIS, anterior superior iliac spine.

Nerve Injuries

Nerve injuries are uncommon, but the ilioinguinal, iliohypogastric, and lateral femoral cutaneous nerves can be injured during anterior bone graft harvesting (Fig. 65.5).

The ilioinguinal nerve is a branch of L1. It traverses the internal oblique and transversus abdominis, passes under the external oblique, and enters the inguinal canal. It supplies sensation to parts of the penis, proximal and medial thigh, scrotum, and adjacent abdomen. Gentle retraction should be applied to iliacus and abdominal wall muscles to minimize injury to this nerve.

The iliohypogastric nerve has a similar course to the ilioinguinal nerve and supplies the sensation to the anterior two-thirds of the iliac crest and motor function of the lower portion of the abdominal wall.

The LFCN is a pure sensory nerve and supplies sensation to the anterolateral aspect of the thigh. The nerve passes into the thigh near the ASIS. Its normal course is beneath the inguinal ligament and sartorius, both of which attach to the ASIS, and is not encountered during the dissection. However, in 10% of cases the nerve crosses over the anterior iliac crest approximately 2 cm lateral to the ASIS, making it liable to damage during bone graft harvesting (Fig. 65.6). LFCN neurapraxia due to retraction will present itself as meralgia paresthetica, manifesting as paresthesia, pain, and numbness. It is usually self-limiting and resolves within 3 months.

Pain

The incidence of persistent donor site pain from anterior iliac crest harvesting ranges between 2% and 40%. Nonetheless, no differences have been found in health-related outcomes between patients who had autograft and those who did not; at 6 weeks postoperatively, the majority of the pain is resolved.[17]

Posterior Iliac Crest

Pain, cluneal nerve injury, infection, stress fracture, sacroiliac joint injury, alterations in gait (i.e., gluteal gait), vascular injury, and ureteral injury have been reported.

Cluneal Nerve Injury

The cluneal nerves arise from the dorsal rami of L1, L2, and L3 nerves and supply sensation to the buttocks. A posterior iliac bone graft approach should be within 8 cm of the PSIS to avoid injury to the superior cluneal nerves. Damage to these nerves can result in numbness and painful neuromas but can be asymptomatic due to cross-innervation in this area.

Sciatic Nerve Injury

The sciatic nerve arises from branches of the sacral plexus L4–S3, exits the pelvis to enter the gluteal region through the sciatic notch and courses down the posterior thigh (Fig. 65.7). After dissection of the gluteal muscles off the posterior iliac crest, we palpate the outer cortical table of the ilium toward the sciatic notch with a MacDonald dissector. Subsequent harvesting should be taken no more than 1 cm in proximity to this plane to avoid injuries to the contents of the sciatic notch.

Superior Gluteal Artery Injury

Injury of the superior gluteal vessels can cause a false aneurysm, arteriovenous fistula, and hemorrhage. The superior

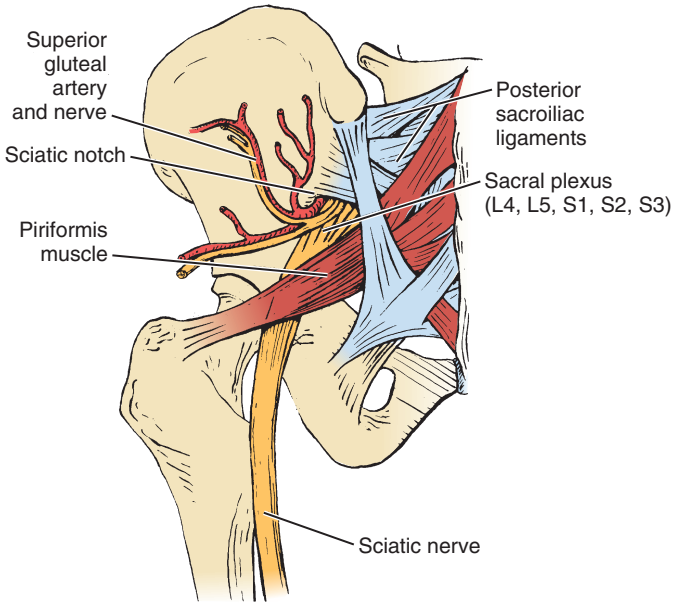

FIG. 65.7 Posteroanterior view of the pelvis showing the neurovascular structures in the sciatic notch.

gluteal vessels leave the pelvis through the superior portion of the greater sciatic notch, staying against the bone. The average distance between the PSIS and the superior gluteal vessels was 62.4 mm from anatomic studies of dry specimens.

Management of superior gluteal artery injury includes direct pressure, enlargement of the upper margin of the sciatic notch to allow better access to bleeding vessels, immediate supine positioning to allow approach to the vessels anteriorly, angiographic-controlled embolization,[18] and subperiosteal elevation of the gluteus maximus to identify the vessel at the superior border of piriformis.[19]

Pain

A retrospective study found that most patients who had ICBG were unable to identify which side the iliac crest had been harvested.[20] Another study found that in patients who did not have any ICBG harvesting, 51% had tenderness over the iliac crest, and patients who had ICBG harvesting had an equal likelihood of having pain over the unharvested ilium as the harvested one.[21] Other studies have also found that patients may not be able to differentiate between donor site pain and residual low back pain.[22] These studies put in perspective the general gluteal pain experienced by patients after posterior lumbar fusion and dispute the common belief of the severity and frequency of donor site pain.

Nonetheless, some studies have shown significant rates of persistent pain and morbidity from iliac bone graft harvest.[23] One prospective observational cohort study found that at 12 months postoperatively, 15.5% of patients reported more severe pain from the harvest site than from the primary operative site, and 29.1% reported numbness. Reported effects have included functional limitation due to harvest site pain, including difficulty in walking (15.1%) and problems with employment (5.2%), recreation (12.9%), household chores (14.1%), sexual activity (7.6%), and irritation from clothing (5.9%).[24]

Fracture

Iliac crest fractures have been reported after ICBG harvesting.[25,26] Risk factors include age, osteoporosis, and comorbidities.

The best way to reduce the risk of structurally weakening the posterior crest is to maintain its continuity and enter the bone below the crest on the outer table. Graft sites that cross the anterior plane of the sacroiliac joint are subjected to tensile and shear forces that may exceed the strength of the remaining bone. Hence, pelvic integrity is least compromised if the area of harvest is limited to the iliac bone posterior to the posterior coronal plane of the sacroiliac joint to avoid pelvic ring fracture.

Kurz and colleagues[14] recommend that long splitting of the iliac tables should be avoided to prevent undue stress concentrating on the remaining ilium.

Fibula

The incidence of complications after fibula bone graft harvesting ranges from 40% to 57.7%. The most common short-term complication is pain at the donor site for up to 3 months postoperatively. Infection either in the form of cellulitis or deep wound infection has also been reported. Long-term complications include incisional pain lasting more than 3 months postoperatively, injury to the superficial peroneal nerve causing paresthesia and neuroma, infection, tibial stress fractures, and ankle instability. Other complications that have been reported include delayed wound healing, contracture of the flexor hallucis longus, and weakness of toe flexor and extensor muscles due to disruption of the interosseous membrane.

Rib

Each intercostal neurovascular bundle is located in the groove on the posteroinferior edge of the rib. Subperiosteal dissection of the rib should avoid damage to these structures. Intercostal analgesia near the costovertebral junction before wound closure can decrease postoperative pain.

CHAPTER 66

Principles of Bone Fusion

SECTION IX

George F. Muschler

Spinal fusion may be defined as a bony union between two or more vertebral bodies. Spinal fusion was first reported in 1911 for treatment of Pott disease. The mechanical stability provided by fusion was intended to inhibit progressive deformity and the spread of the tuberculous infection.[1] Surgery to accomplish spinal fusion has now been extended to treat a variety of spinal conditions, including scoliosis, kyphosis, fracture, dislocation, spondylolisthesis, and intervertebral disc disease.

Much has changed since the pioneering efforts of Albee[1] and Hibbs[2] in the early part of the twentieth century. Specialized techniques and surgical approaches have been developed for internal fixation and fusion of every part of the spine. Additionally, there have been significant advances in diagnostic techniques, intraoperative image guidance, intraoperative monitoring, minimally invasive surgical approaches, and bone graft materials. These advances have allowed for the aggressive correction of many severe spinal deformities with relative safety and predictability. Furthermore, the biologic principles on which these procedures are based have become better understood and used.

All fusion surgery involves preparation of bony surfaces at the site of the intended fusion. This usually involves the removal of soft tissues and decortication of bony surfaces. The stimulus for the bone healing response, commonly referred to as the "bone graft," may be autologous or homologous bone (i.e., allograft bone) or one of an increasing number of synthetic materials or bioactive substances. As the graft is incorporated, bone tissue is formed by osteogenic cells. Union is accomplished when the newly synthesized bone matrix becomes mineralized and remodels with mature bone, having sufficient strength to bear physiologic loads without injury, thus becoming mechanically contiguous with the local host bone. Failure of bone formation, union, or effective remodeling results in pseudarthrosis. The incidence of pseudarthrosis ranges from 5% to 34% in large adult series.[3–11] A recent review of revision spine fusion procedures found that 23.6% were performed for pseudarthrosis.[10,11]

The fundamental requirements for a successful spinal fusion are (1) availability of an adequate population of osteogenic cells; (2) the presence of an osteoconductive matrix within the region where new bone tissue is desired, osteoinductive signals within the graft site; (3) an adequate local blood supply to support a bone healing response; and (4) a local mechanical environment suitable for bone formation. The following is a discussion of these fundamental concepts and principles, with a review of the orthopaedic and neurosurgical literature regarding the bone grafting materials that are currently used or under evaluation in clinical spine fusion.

Biology of Fusion Sites

Bone growth between vertebrae in a spinal fusion, as in all bone healing, is a cellular process, and unless cells are added to the fusion site, the tissues at the site are the only source of viable cells. Conventional *autogenous* bone grafts add osteogenic cells; however, it has long been recognized that only a small fraction of these cells survive.[12–17] Consequently, preparation of the fusion site and handling of the tissue bed are of paramount importance for a successful arthrodesis. The components of the tissue bed that contribute most to the healing process are the local population of osteogenic stem cells and progenitor cells, local vascular tissues, the cells contributing to the inflammatory response, and the formation of a stable clot within the void spaces of the graft site. Bone, fat, and muscle have all been shown to contain osteogenic stem cells and progenitors that can contribute to new bone formation.[18–26] These basic elements of the graft bed may be affected by local or systemic disease. However, the quality of these elements within the graft site is largely determined by surgical technique.

To preserve the local blood supply, the surgeon must attempt to minimize trauma to the host tissue bed imposed by the trauma of retraction, cautery, and/or desiccation. Any avascular, nonviable, or heavily traumatized tissues should be

removed. The importance of the local blood supply cannot be overstated. The blood supply serves as (1) a source of oxygen and other nutrients to the healing tissue as well as control of local pH; (2) a vehicle for endocrine stimulation; (3) a conduit for recruitment of inflammatory cells, which both produce paracrine factors, which may mediate the early proliferation of osteoblastic progenitor cells, and serve to reduce the potential for infection; (4) a source of endothelial cells that produce paracrine factors, which may enhance osteoblastic differentiation[27,28]; and (5) a potential source of osteoblastic progenitors in the form of the vascular pericyte[29,30] or circulating osteogenic cells.[31,32]

The effect of the postoperative hematoma on the success of fusion has been debated. It has been suggested that spinal fusion wounds should not be drained because the fibrin-rich local hematoma may provide an osteoconductive scaffold or matrix, which may assist some of the initial phases of bone healing. Additionally, the trapped platelets in the hematoma release platelet-derived growth factor (PDGF), epidermal growth factor (EGF), basic fibroblast growth factor (bFGF or FGF-2), vascular endothelial growth factors (VEGFs), transforming growth factor beta (TGF-β), and other growth factors that play a critical role during the repair process (discussed later).[33–35] On the other hand, the presence of a large hematoma may displace some of the vascular tissue surrounding the graft site away from the graft, slowing the vascularization of the graft site. It may also increase the chance for displacement of the graft and the potential for nonunion or bone formation outside the intended site.

The inflammatory response in the wound site and the grafted bed represents a critical event in the healing process. This response will involve the removal of necrotic tissue debris, lysis of the local fibrin clot, the establishment and reestablishment of a vascular supply to the graft and host tissue, and synthesis of an early matrix rich in hyaluronic acid.[14,36–42] After the surgical procedure, polymorphonuclear cells, lymphocytes, monocytes, and macrophages migrate to the fusion site and perform their various functions. Among these, and possibly the most important in terms of affecting vascular endothelial cells and osteoblastic progenitors in the graft site, is the local production of paracrine signals: cytokines, kinins, and prostaglandins. These messages act as chemotactic signals and growth factors, affecting the proliferation, migration, differentiation, and activity of a variety of cells, as well as modulation of local blood flow, vascular permeability, and angiogenic response of local endothelial cells. In this way, the inflammatory response establishes the local environment in which the early events of the bone healing response occur. It is not surprising, therefore, that agents that inhibit the inflammatory response have been shown to alter or inhibit bone healing.[43–48] While the use of nonsteroidal antiinflammatory drugs (NSAIDs) has been associated with impaired healing in patients undergoing spinal fusion,[48] a more recent meta-analysis of clinical trials did not support the hypothesis that use of NSAIDs increases the risk of nonunion.[49] NSAIDs reduce inflammation by inhibiting cyclooxygenases (COX). The *COX-2* isoform specifically induces osteogenesis via the anabolic effect of prostaglandin E_2 and the subsequent upregulation of *Runx2*, a transcription factor that is necessary for osteoblastogenesis.[50] These findings have led to the recommendation that clinicians weigh the theoretical risks of impaired bone healing against the potential for pain benefit of NSAID therapy.[42,51]

In addition to the influence of the local blood supply and the inflammatory response, the host bone surface itself is known to have a profound effect on the healing process in spinal fusions. When properly prepared by the surgeon, local bone will serve as a reservoir of osteogenic cells and osteoinductive signals. It also provides an osteoconductive surface for graft incorporation and serves as part of the local blood supply to the graft site. As such, the goal of surgical preparation of local bone is to minimize cellular and mechanical damage to the host bone, while maximizing the availability of osteoprogenitor cells and the osteoconductive and osteoinductive properties of this surface. This is generally achieved by subperiosteal dissection with or without decortication or roughening of the underlying bone to expose vascular osteonal or endosteal bone spaces. Decortication can be achieved with manual tools such as a rongeur or osteotome. Alternatively, a power burr may be used, provided that caution is exercised to prevent thermal necrosis of the bone owing to the heat of friction at the site by using continuous irrigation and limiting periods of contact between the burr and bone at any one site.[52] The surface area of cancellous bone exposed during decortication is another factor thought to affect the success of a spinal fusion. Increasing the available surface area also increases the number of osteogenic cells at the fusion site, which should have a positive effect on the amount of bone formed and the rate of graft incorporation. Additionally, increasing the area of contact between the osteogenic host bone and the graft material should lead to an increase in the osteoconductive surface area available and potentially lead to greater mechanical strength of the subsequent bony union. This may account for the greater success of allografts in anterior fusions[53] as compared with posterior fusions, which generally rely on a smaller area of decorticated bone per fusion segment. Similarly, this may also contribute to the lower fusion rates seen in myelomeningocele,[54,55] in which the laminae are not available as a surface for fusion. In theory, any exposure of the local bone surface, osteonal spaces, or marrow spaces that does not excessively weaken the mechanical strength of local bone should increase the number of osteoblastic progenitors with access to the graft site.[56,57]

Bone Graft Biology and Materials

Bone grafting is performed to accelerate, augment, or substitute for the normal regenerative capacity of bone. There is no single ideal or optimal graft. The functional demands and the biologic assets and deficiencies of each graft site vary with the clinical setting. As a result, the surgeon must rely on both past experience and clinical judgment and must be familiar with the new and expanding knowledge base of bone healing biology and clinical grafting materials.

All bone-grafting strategies involve either the transplantation or targeting of osteoblastic stem cells or progenitor cells. Bone grafts have been described as having osteogenic, osteoinductive, and osteoconductive properties. Grafts may also

contribute to mechanical stability and vascularity at the graft site.[58–60] Detailed reviews of the principles underlying these practical clinical concepts have been published.[15,59–63]

The osteogenic property of a graft is derived from viable stem and progenitor cells that may be transplanted as part of the graft under conditions in which they can survive and contribute directly to new bone formation. Osteoinductive activity refers to the capacity of some stimuli, usually peptide growth factors, to stimulate cellular events that transform an uncommitted cell into a cell that becomes activated and committed to new bone formation. The prototype for osteoinductive factors is the family of bone morphogenetic proteins (BMPs), particularly BMPs 2, 4, 6, 7, and 9, which appear to be the most osteoinductive. However, other matrix-bound and soluble growth factors also contribute to this process, such as TGF-β, insulin-like growth factors I and II (IGF-I and IGF-II), and bFGF. These factors may also be delivered as autocrine and paracrine factors that are released from or secreted by local or transplanted stem cells and progenitor cells, platelets, or other cells associated with the local inflammatory response.

In contrast to osteoinduction, osteoconduction is the result of the structural and surface features of a graft matrix. Osteoconductivity refers to the capacity of a graft matrix to enhance the attachment, migration, proliferation, and differentiation of osteoblastic stem cells and progenitors as well as other cells that contribute to the bone healing response. As a result, osteoconduction promotes the distribution of a bone healing response of the graft. The osteoconductivity of a matrix is a function of its macrostructure or architecture, the size and connection between pores on the material, and its surface chemistry and surface texture. In the case of degradable materials, the degradation properties of the material are also critical, specifically the degradation rate, the chemical species that are released by degradation, and their rate of clearance from the site.[15,64,65]

Cell attachment and migration is mediated by the presence of cell adhesion molecules and other proteins in or bound to the surface of a matrix. These matrix ligands can also have a profound effect on the survival and retention of cells within the graft site and on their differentiation. Examples of biomolecules that may serve as adhesion molecules are collagens, fibronectin, osteonectin, laminin, vitronectin, hyaluronan, bone sialoprotein, heparin, and various proteoglycans. Binding domains similar to those provided by these molecules can also be provided by smaller peptides of 7 to 30 amino acids, a strategy that is being exploited in many current development efforts. The extracellular matrix of an allograft is a prototype for an osteoconductive scaffold, which assists the distribution of a bone healing process throughout a graft site.

The following section reviews the specific functional elements and clinical outcomes of each of the major spinal fusion grafting options.

Autogenous Cancellous Bone

Autologous cancellous bone has traditionally been considered to be the gold standard of graft materials. Autograft has maintained a track record as the most reliable and effective graft material, particularly in the challenging clinical setting of spinal fusion.[66–69] This finding is reinforced by the recognition that an autogenous cancellous graft provides all three areas of functionality: osteogenic bone and marrow cells; an osteoconductive matrix of collagen, mineral, and matrix proteins; and a spectrum of osteoinductive proteins provided within the transplanted matrix of cells. However, the limitations and disadvantages of autogenous cancellous bone have become increasingly evident in recent years as more effective and less morbid grafting options have become available.

The principal disadvantage of autogenous cancellous bone graft relates to the process of graft harvest. Autograft harvest adds operative time, pain, and blood loss. It also carries an increased risk of infection, cutaneous nerve damage, and even local fracture. Autograft harvest leaves the patient with permanent scars and a risk of long-term pain at the graft site.[70–73] Increased blood loss attributable to the graft harvest results in an increased potential exposure to blood products along with all the associated costs and risks of transfusion. The incidence of major complications associated with the harvest of iliac crest bone graft (ICBG) was, in earlier studies, reported to be 5% to 10%.[74–76] A subsequent prospective study of 170 patients undergoing spinal fusion with autologous ICBG found that 24% reported numbness at the graft harvest site 3.5 years postoperatively, and 19% reported that the pain at their graft harvest sites impaired their ability to perform routine chores.[77] However, there is marked variability in techniques to retrieve bone (e.g., cortical window for cancellous, tricortical for structural) in the reported incidence and severity of pain as well as other major and minor complications associated with harvest of ICBG.[70,76–91] Less invasive bone graft harvest methods may decrease the incidence of complications and pain.[78,92] While randomized controlled trials (RCTs) have shown no differences in clinical outcome measures between patients undergoing lumbar fusion with ICBG and those receiving bone graft substitutes without ICBG,[78,85,93,94] these studies specifically investigated and reported the incidence of bone graft pain in the ICBG groups and not in the groups receiving bone graft substitutes. ICBG donor site pain may be overestimated, however, since patients undergoing lumbar spine fusion have difficulty distinguishing between residual back pain and donor site pain.[78,92,95]

A second disadvantage of autograft is that, in addition to its cost and morbidity, the amount of autogenous bone is limited and may be insufficient in many settings, particularly in children undergoing arthrodesis over multiple segments. Autogenous bone also has a biologic limitation as a cellular graft. Although cancellous bone from the pelvis is the most abundant source of osteoblastic stem cells and progenitors, these cells represent only about 1 in 20,000 cells in normal bone marrow. ICBG is packed with many other cells that do not necessarily contribute to bone healing. When autogenous cancellous bone is harvested, its diverse mixture of highly metabolic cells is dissociated from its blood supply and is then implanted under conditions in which each cell must compete with all of the other cells in bone and marrow for the limited amount of oxygen and other nutrients that are available to diffuse into the graft site. The metabolic demand within the graft site far exceeds the capacity

for nutrient diffusion. This results in profound hypoxia as one moves more than 1 to 2 mm into the graft, and few deeply placed cells survive. This fact was recognized by Burwell from histologic assessment in the 1960s and can now be defined in more quantitative terms on the basis of chemical engineering principles,[16,96] Necrosis within the graft places an additional burden on the site. Necrotic debris must be removed before new bone formation can occur. In addition, cell debris and the cytokines that are released by dying cells escalate the local inflammatory response, bringing in additional cells that further increase local metabolic demand.

Autologous Cortical Bone

Cortical bone grafts are less biologically active than cancellous grafts as a result of several factors. Cortical bone contains fewer osteoblastic stem cells and progenitors than trabecular bone. Furthermore, the cells that are present are less likely to survive because a larger fraction of cells are located within osteons, which are buried in the matrix, where diffusion is insufficient to provide adequate nutrients to support viability. The absence of nonosteogenic marrow cells and endothelial cells further limits the biologic potential of a cortical graft. In addition, in contrast to trabecular bone, cortical grafts have a much lower available surface area per unit volume. This reduces the potential surface for new bone formation (and therefore osteoconductive potential) and may also reduce the bioavailability of osteoinductive factors buried in the matrix. The marked reduction in porosity of cortical bone also represents a barrier to vascular ingrowth and bony remodeling, both of which are critical to bone healing and the development of optimal mechanical strength.

The only advantage of cortical bone versus cancellous bone and other graft materials is its superior mechanical strength and the availability of cortical segments of sufficient size to fill virtually any skeletal defect. The ability to provide immediate mechanical strength at the time of implantation is a critical advantage in many situations, particularly in anterior interbody fusions. However, the mechanical strength of a cortical graft is not constant over time. Allograft bone is remodeled by the process of creeping substitution, resulting in increased porosity and progressive loss of strength during the first 12 to 24 months after implantation before remodeling and new bone formation reconstitutes the mechanical properties of the grafted segment.[58,97–101] This is associated with increased risk of graft failure and collapse during the first 24 months after implantation.

Combined grafts consisting of intact cortical and cancellous bone from the iliac crest are common and readily available graft materials with good mechanical properties and biologic properties of incorporation. The mechanical strength of these grafts is variable, however. Grafts from the anterior crest exhibit greater mechanical compressive strength than grafts from the posterior crest.[60,102]

Vascularized Autologous Grafts

Vascularized grafts are used extensively in many centers for musculoskeletal reconstructive procedures. High rates of vascular patency can be achieved by experienced microsurgeons. Many studies have shown clear advantages to using vascularized grafts in a number of settings.[103–109] In anterior spinal fusions, donor vessels are available to support the vascularized graft. Suitable grafts with good mechanical strength are available from the anterior iliac crest, posterior iliac crest,[110] fibula,[107,111] or rib.[112] An iliac graft pedicle flap on quadratus lumborum has also been described.[113] In intrathoracic procedures, a vascularized rib graft may be mobilized on its intercostal pedicle, with limited additional morbidity and in much less time than a free vascularized graft.[114,115] However, a rib graft provides less mechanical strength when compared with the iliac crest or fibula[116] and therefore must be mechanically supplemented by additional cortical bone or internal fixation.

Although routine use of vascular grafts is limited by concerns regarding their increased operative time, technical difficulty, and added morbidity, the improved incorporation of these grafts may make them highly desirable in some settings in which incorporation of avascular grafts may be compromised, such as in areas of radiation-induced fibrosis, dense scar, or previous infection.[107] The ability of vascular grafts to withstand higher levels of irradiation than nonvascularized grafts has markedly increased the use of vascularized grafts in the treatment of bone tumors.[104,107,117–119]

Autologous Bone Marrow

Bone marrow is a valuable and easily accessible source of osteogenic cells that is probably underused in contemporary clinical practice. The osteogenic potential of transplanted bone marrow was first documented in 1869 by Goujon[120] and later in 1889 by Senn.[121] Studies by Burwell in the 1960s concluded that the formation of new bone following autografting resulted from the differentiation of osteogenic precursor cells contained within the marrow in addition to osteoblasts on the surface of the graft material itself.[16] Burwell postulated that, following transplantation, these reticular cells free themselves from the sinusoidal walls to become primitive migratory cells. They then differentiate into osteogenic cells when they are exposed to osteoinductive substances released from the necrotic portion of the graft[122] or perhaps from osteoinductive materials contained within or secreted by the marrow itself.

Many studies have demonstrated the ability of marrow cells to form bone intramuscularly,[123,124] subcutaneously,[125] interperitoneally,[126–128] in the anterior chamber of eye,[129] and orthotopically. Using a suspension of marrow cells in diffusion chambers, Friedenstein showed that hematopoietic cells die following transplantation, whereas fibroblasts and other stromal elements are more resistant to hypoxia and may proliferate close to the surface of the graft to produce immature bone, suggesting the presence of an undifferentiated precursor cell in postnatal marrow.[125,128,130,131] It has been well established that the osteogenic cells that contribute to this response are not derived from one homogeneous population of cells but rather appear to come from two or more compartments of stem cells or progenitor cells that are upstream from the osteoblastic population in bone.[63,125,132,133] A more mature preosteoblastic

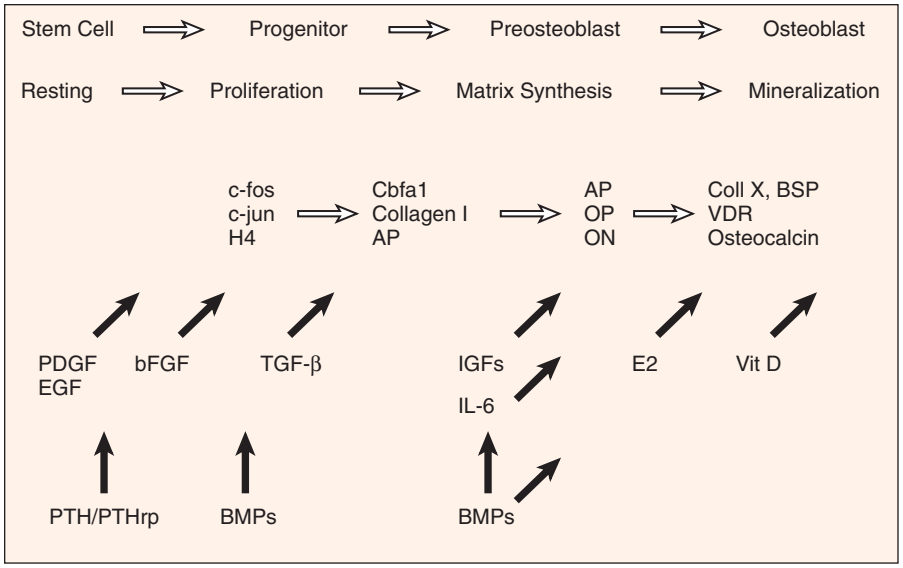

FIG. 66.1 The osteoblastic pathway. This figure illustrates the stages of osteoblastic differentiation, the predominant activity of the differentiation cell at each stage, some of the characteristic genes expressed at each stage, and the approximate site of principal action for some of the principal osteotropic growth factors and hormones. AP, alkaline phosphatase; bFGF, basic fibroblast growth factor; BMPs, bone morphogenetic protein family members; BSP, bone sialoprotein; E2, estradiol; EGF, epithelial growth factor; H4, H4 histone; IGFs, insulin-like growth factors I and II; IL-6, interleukin-6; ON, osteonectin; OP, osteopontin; PDGF, platelet-derived growth factor; TGF-β, transforming growth factor-beta; VDR, vitamin D receptor; Vit D, vitamin D_3.

cell appears to be localizable to the marrow space adjacent to trabecular surfaces or osteonal bone. One or more populations of less mature and potentially multipotent cells appear to be present in the more liquid phase of bone marrow space, possibly including cells associated with perivascular tissue of vascular sinusoids or other marrow vessels. Overall, one can estimate that, on average, 60% to 70% of osteogenic stem and progenitor cells are from the trabecular surface population.[134]

Osteoblastic differentiation proceeds in a series of steps, which can be conceptually divided into phases.[135,136] An initial proliferative phase is characterized by expression of H4 histone, c-*fos,* and c-*jun.* A matrix synthesis phase is characterized by a reduction in proliferation and upregulation of gene products for type I collagen, osteopontin, osteonectin, and alkaline phosphatase. Finally, a matrix mineralization phase culminates in an osteoblastic phenotype characterized by expression of osteocalcin, bone sialoprotein, and responsiveness to 1,25-dihydroxyvitamin D and parathyroid hormone. A conceptual summary of the large body of literature related to osteoblastic differentiation is presented in Fig. 66.1.[63,137]

The value of bone marrow as a bone graft, used alone or as a component in a composite bone graft material, has been supported by numerous studies in rats and rabbits.[122,125,128–130,138–145] Lane et al.[146] demonstrated the efficacy of autogenous bone marrow grafting in a 5-mm rat femoral defect and showed that the efficacy of bone marrow grafts were dependent on transplantation of viable cells. Yasko et al.[147] also showed that bone marrow enhanced the performance of an effective synthetic BMP-2 material in rats, a finding consistent with prior materials.[143] However, in contrast to clinical practice, almost all of these studies in rodents have used bone marrow obtained by open harvesting of bone and/or irrigation of bone explants rather than by aspiration.

Increasing evaluation of bone marrow grafting has been carried out in larger nonrodent models. Johnson et al.[148] found canine bone marrow much less osteogenic than rabbit marrow when transplanted in diffusion chambers. Using a canine tibial model, Tiedeman et al.[144] found that the percutaneous injection of marrow mixed with demineralized bone matrix powder produced overall results comparable with open cancellous grafting.

There have been series of reports showing that aspirated bone marrow can improve bone healing.[122,140,149–154] Connolly reported successful treatment of 18 of 20 nonunions treated with casting or intramedullary nails plus percutaneous marrow injection.[139]

Recognizing the potential biologic value in various clinical settings, many surgeons currently use bone marrow as an adjuvant to allograft bone. This practice is indicated primarily because the risk and morbidity of bone marrow aspiration from the iliac crest are low. The prospective trials needed to document the value or limitations of bone marrow grafting are only now being organized. These investigations are justified by a significant volume of clinical information regarding methods and cellular yield of bone marrow aspiration[155–157] and by a robust set of preclinical studies.[158–162]

The method of bone marrow aspiration has a significant effect on the concentration and prevalence of bone marrow–derived osteogenic cells. Muschler et al.,[156] in a cohort of normal subjects undergoing elective orthopaedic procedures, showed that a mean of approximately 2100 osteoblastic progenitors (colony-forming units or CFU-Os) could be harvested in a 2-mL aspirate of human bone marrow from the iliac crest and that the mean prevalence of CFU-Os among nucleated marrow cells was approximately 1 in 37,000 cells.

They further documented that the yield of CFU-Os harvested dropped rapidly as the volume of bone marrow aspirated was increased owing to dilution with peripheral blood. On the basis of these findings, they recommended that aspiration of marrow be limited to 2 mL from each aspiration site in order to maximize the concentration of CFU-Os in the marrow graft. Further studies have demonstrated that the yield of osteoblastic stem cells and progenitors tends to decrease with age and that the prevalence of these cells may decrease more rapidly in women than in men.[155,157,163–165] However, these data also show that there is marked variation from individual to

individual in the cellularity of marrow and the prevalence of osteogenic cells that is not associated with age or gender.

The vertebral pedicle can be a source of bone marrow aspiration during spinal arthrodesis; however, the available volume is limited. McLain et al.[166] obtained iliac crest and transpedicular aspirates from the vertebral bodies of 21 adults undergoing posterior lumbar arthrodesis and pedicle screw instrumentation. The concentration of osteogenic progenitor cells was, on average, 71% higher in the vertebral aspirates than in the paired iliac crest samples ($P = .05$).

In a subsequent clinical study, the same authors evaluated sequential aspirations from the different depths of the vertebral body, along the same transpedicular axis in 13 patients.[167] Four aspirations of 2.0 mL each were taken from lumbar pedicles prior to placement of pedicle screw fixation. The authors found that the most superficial aspiration sites in the vertebral bodies had significantly greater concentrations of connective tissue progenitors (CTPs) and that concentrations decreased progressively and significantly with sequentially deeper aspirates.

Several authors have addressed the potential value of harvesting bone marrow by aspiration and then processing the cells that are collected to concentrate those that are most likely to be of value while eliminating cells that may not contribute to fusion or inhibit fusion. Connolly et al.[138] described concentration of marrow-derived cells using centrifugation techniques and showed that a three-fold to four-fold increase in the concentration of nucleated cells increased the amount of bone formation in a diffusion chamber in the rabbit. Several recent reports have described the results of clinical spine fusion procedures using bone marrow as a cell source and concentrating marrow-derived cells using a centrifuge (density separation).[168–171] Other methods have been described that allow rapid intraoperative concentration and selection of osteoblastic stem cells and progenitors from bone marrow using an appropriately designed implantable allograft matrix as an affinity column to select osteoblastic cells on the basis of attachment behavior (i.e., selective retention).[159,160,172,173] Both density separation and selective retention can be used to rapidly concentrate marrow-derived nucleated cells. However, selective retention has the theoretical advantage of concentrating osteogenic CTP-Os; while removing 50% to 80% of the other nucleated cells (non-CTPs) may improve the survival of transplanted cells and reduce local inflammation associated with necrotic cell debris.[172] A clinical cohort study using bone marrow concentration strategies to lumbar interbody fusion has also reported a fusion rate of 85%, comparable with historical autograft controls.[174] Use of bone marrow aspirate from the vertebral body, as accessed during spinal fusion procedures utilizing instrumentation, has been shown to augment fusion rates in the absence of donor site morbidity.[175–178]

Muschler et al.[15,62,63,179,180] have published four more detailed reviews of the biologic principles and practical strategies for harvest and use of stem cells and progenitor cells for bone healing applications. Use of genetically modified cells as a delivery system for gene products promoting bone fusion has been explored in several studies. This strategy is addressed in other chapters in this text.[181–191]

More recent investigations have demonstrated that although the concentration and prevalence of CTPs decrease in frequency and function with age,[179,192] this may be overcome, at least partially, by rapid intraoperative processing methods designed to enrich the population of CTPs. Several studies have explored the possible use of culture-expanded, bone marrow–derived cells that have been referred to as mesenchymal stem/stromal cells (MSCs) based on the premise that they are immunoprivileged, or hypoimmunogenic.[179,193,194] While a meta-analysis of 36 clinical trials investigating systemic administration of culture-expanded MSCs has confirmed that treatment can be safe,[179,195] the ability of culture-expanded MSCs to contribute to formation of new tissue has not been substantiated.

In a systematic review of the literature specifically comparing clinical outcomes of cell-based grafts combined with bone graft extenders to outcomes using autologous bone grafts for spinal fusion, Khashan et al.[196] concluded that the actual overall evidence for the use of culture-expanded MSCs or BMA combined with synthetic or allograft materials is insufficient to support their use as a substitute for iliac crest grafts. A paucity of high-quality, prospective, comparative controlled trials currently limit the use of these cell-based therapies in place of autograft or allograft bone for spinal fusion.[196] In another recent systematic review, Hsu et al.[197] concluded that there were no studies available providing data of sufficient quality to assess the cost-effectiveness of cell-based products and other synthetic carriers.

RIA (Reamer-Irrigator-Aspirator)

Recent studies have evaluated the potential for use of a reamer-irrigator-aspirator (RIA), a novel system for harvest of intramedullary reamings and fatty marrow contents from the intramedullary canal of the femur and tibia. There are clinical reports that RIA grafts have osteoconductive and angiogenic properties comparable to ICBGs.[198,199] If the intramedullary canal of the femur or tibia is readily available in the operative field, RIA provides a large volume of graft compared with ICBG harvest procedures.[200–202] However, the clinical utility for spine fusion is debated, as is the extra cost of the RIA device as compared to the ICBG. In addition, Henrich et al. found that culture-expanded MSCs from the femur harvested with the RIA had reduced expression of *BMP2* and *WNT* family genes, compared with MSCs obtained from the iliac crest by aspiration.[203] They also found trends toward increased methylation of the *RUNX2* gene, as well as decreased methylation of the *SMAD5* and *WNT3A* genes. Biologic potential of cells harvested by RIA may be altered by different mechanical stresses on the cells or by harvest of a mixture of fat and bone-derived CTPs. RIA harvests are prone to variation in the amount of cells harvested from patient to patient and due to differences in reamer diameter and the bone endosteal diameter.

Structural Bone Allografts and Cages

Use of allograft bone has been well characterized over the past 30 years.[204] There are four principal advantages of allografts.

First, they eliminate the morbidity associated with harvesting autologous bone. Second, and in contrast to autograft bone, the volume of available allograft is essentially unlimited. Third, because cortical allografts can be selected from any bone (not just the iliac crest or tibial hemicortex), they provide the surgeon with access to grafts that have mechanical strength and options for shaping that are superior to any autograft site. Fourth, allograft bone can be preprocessed into a wide range of specialized physical forms (e.g., blocks, threaded or nonthreaded dowels, sized rings and wedges, chips, fibers, powder) prepared from cortical and/or cancellous bone. These preprocessed grafts provide the opportunity to customize and precertify the physical form and architectural properties (shape, size, mechanical strength, surface area, porosity) of a graft matrix to an individual site.

The method of sterilization and preparation of allograft tissue has a significant impact on osteoconductive, osteoinductive, and mechanical properties, as well as immunogenicity.[101,205–208] Donor cells and cell fragments are the most immunogenic material in allogeneic bone. Processing of allograft bone therefore includes steps that attempt to remove as many cells as possible from the graft. Immunogenicity is further reduced, although not eliminated, by freezing to –20° C.[209–217] Freeze-drying is even more effective at reducing the immunogenicity of allogeneic bone, but at the price of reducing mechanical strength by 50%.[211,218]

Using contemporary processing and storage techniques, clinical evidence of overt immunologic reaction against the graft is rare. Even so, histologic evidence of a low-grade inflammatory reaction can be found around essentially all allografts. This reaction probably slows the incorporation of many allografts and may contribute to the failure of some, as suggested by several canine studies that have documented improved biologic behavior in antigen-matched allografts.[206,207,218,219] Antigen matching is not currently considered practical in the clinical setting, however. The relatively high current success rates for allografts makes the large cost of antigen matching not feasible and is probably unwarranted in general practice.[220]

Sterility of frozen allografts is ensured through expedient postmortem harvesting using sterile surgical technique and careful monitoring using surface cultures and polymerase chain reaction screening for bacterial and viral genome fragments. The American Association of Tissue Banks (www.aatb.org) requires screening tests of all allografts as well as screening of patients' medical histories. Musculoskeletal allografts are tested for hepatitis B virus, hepatitis C virus, human T-lymphotrophic virus types I and II, and syphilis (*Treponema pallidum*).[221] It is difficult to determine exact risks of transmission, particularly in spinal surgery patients, who often have multiple comorbidities and may have had blood transfusions in addition to receiving tissue allografts. Differences in reporting and investigating these infections may also prevent precise determination of incidences of these events. Allograft transmission rates are estimated by risks of blood transmission of these viruses. The risk of transmission of hepatitis B virus in fresh-frozen allograft is estimated to be 1 in 63,000. Risk of transmission of hepatitis C virus is 1 in 1,000,000. The risk of transmission of HIV is between 1 in 1,000,000 and 1 in 1,600,000 for fresh-frozen allograft bone.[221–226]

A variety of secondary sterilization procedures have been designed and may be used, depending on the source of the allograft. Ethylene oxide sterilization was evaluated by Cornell,[227] who found a 70% decrease in bone induction by demineralized bone powder in rats. Other authors have reported variable changes in inductive capacity of ethylene oxide sterilized matrix.[228–231] Heating or autoclaving bone tissue is generally avoided due to their disruption of matrix proteins. Some processing techniques, such as high-dose irradiation, compromise both the biologic potential of bone matrix, reducing bone formation and union rates,[232,233] and also alter the mechanical properties of the graft.[234–242] For example, irradiation to 2.5 mrad or freeze-dried processing may reduce the torsional strength of the cortical allograft by as much as 50%.[218] Islam et al.[242] showed that, in contrast to the previously documented two- to threefold decreases in strength, Young's modulus, and ductility determined with monotonic tests, by their group and others,[237,238,243] gamma irradiation induces a more than 15-fold reduction in the high-cycle fatigue life of cortical bone at physiologically relevant stress levels.

Results from other clinical and experimental studies using allograft bone alone in spinal fusions have been mixed. Some investigators have found allograft to be significantly inferior to autogenous bone grafting when compared with other distinctive preparation methods,[53,55,235,244–256] whereas others find little or no difference between them.[53,114,256–270]

Angevine et al.[271] documented similar cost-effectiveness ratios between iliac crest autograft bone and allograft bone for single-level anterior cervical decompression and fusion (ACDF) for patients with cervical spondylosis.

Allograft bone appears to be particularly valuable in settings that require the graft to serve a significant mechanical function, such as struts or ring allografts for anterior lumbar interbody fusions (ALIF)[272–276] or as struts or bone–wire fixation constructs in the upper cervical spine.[277–286] In these settings, allografts have essentially replaced the use of autografts from rib, fibula, tricortical iliac crest, and tibial hemicortex grafts, which are all associated with significant donor site morbidity.

Several synthetic materials have expanded the options for structural support. These include interbody fusion cages comprised of titanium, carbon fiber–reinforced polymers, and polyetheretherketone (PEEK).[286–295] These materials provide the structural function that is necessary to maintain the height and stability of the interbody site. These cages and wedges lack some of the osteoconductive capacity of allograft bone. Furthermore, they lack the capacity of allograft bone to be biologically incorporated into the fusion mass and remodeled, remaining in the site essentially as a permanent foreign body. Metal cages create artifacts on magnetic resonance imaging and computed tomography, which makes radiographic assessment of fusion difficult. However, in comparison with allograft, synthetic materials offer the advantage of more consistent material properties, specifically strength and fracture

resistance. Recent studies have begun to evaluate absorbable designs, such as polylactic acid–polyglycolic acid copolymers, as well as poly(L-lactide-coD,L-lactide). However, the current data regarding the latter and former is insufficient to support broad clinical use at this time.[295]

Regardless of material used for structural support, there is general consensus that in order to achieve optimal rates of spinal fusion, the environment within and around these structural allografts or cages should be further supplemented with other osteogenic, osteoconductive, and/or osteoinductive graft materials. Autogenous cancellous bone, bone marrow aspirate,[296] processed bone marrow–derived cells,[174] processed nonstructural allograft materials, and BMPs[3,297] are most commonly considered.

Demineralized Allograft Bone Matrix

Demineralization is one means by which the biologic activity of allograft bone can be modified. In settings in which mechanical properties are not critical to the graft application, demineralization may enhance the osteoinductive activity of the allograft matrix by making growth factors embedded in the matrix more available. Several preparations of demineralized bone matrix (DBM) are available; however, these materials may vary in biologic activity, as discussed later.

The history of demineralization as a means to enhance allograft performance is richly linked to many of the recent biologic insights into bone biology and bone healing. It was more than a century ago, in 1889, that Senn reported the repair of long bone and cranial defects in patients with chronic osteomyelitis using hydrochloric acid–treated decalcified heterologous bone implants.[121] Although his primary motive was to promote antisepsis within the bone cavities, Senn observed rapid substitution of the demineralized tissue with new bone formation invading from the perimeter of the defects. However, several of Senn's contemporaries obtained equivocal results and clinical efforts over the next 70 years were minimal.[277,298–300]

Reddi and Huggins[301,302] revived this concept when they reported on their observation that demineralized matrix induced bone formation in rats. Marshall Urist went on to demonstrate bone induction using a variety of demineralized matrix preparations in muscular pouches of rabbits, rats, mice, and guinea pigs.[303] Subsequently, matrix-induced heterotopic bone formation was documented at many soft tissue sites, including muscle, tendon, and fascia,[301,303–305] as well as in the thymus[125] and soft connective tissue of visceral organs.[306] Nathanson also observed the differentiation of neonatal embryonic skeletal tissue into cartilage when cultured on demineralized bone matrix substratum and suggested that the tissue transformation of bone induction was analogous to embryonic bone tissue differentiation.[307–309]

Reddi subsequently characterized the inductive phenomenon of bone matrix as a cascade of events parallel to those occurring in endochondral ossification and postulated that the process was the result of stimulation by a series of soluble matrix factors that potentiated events along the cascade.[310–312] In this paradigm, bioactive factors in bone matrix stimulate activation and migration of osteogenic stem cells and progenitor cells. Mitogenic factors promote cell proliferation. Angiogenic factors promote local revascularization, and osteoinductive factors promote osteoblastic differentiation. Subsequently, bone matrix has been shown to contain a rich variety of growth factors and other bioactive molecules in concentrations that are bioactive.[313,314]

Sato and Urist[315] showed that demineralized bone matrix was both inductive and was synergistic with bone marrow–derived cells in healing of rat femoral defects. They went on to provide a clinical outlet for these discoveries by developing a "chemosterilized, autolyzed, antigen-extracted allogeneic bone (AAA)," prepared using chloroform-methanol extraction, 0.6 N hydrochloric acid extraction of soluble proteins with partial demineralization, and neutral phosphate autodigestion.[316–319] This preparation appeared to reduce the immunogenicity of the allograft matrix without loss of inductive properties. Using this preparation, Urist and Dawson reported on 40 patients undergoing posterolateral lumbar spinal fusion with an 80% success rate and a pseudarthrosis rate of 12%.[320]

The value of a variety of DBM preparations (chips, fibers, powders) has subsequently been described in a number of settings by a series of authors. Glowacki et al.[321–323] were among the first to report successful repair of craniofacial defects. Tiedeman et al.[144] and Wilkins et al.[324] both reported clinical efficacy in long bone defects. Other reports have also shown efficacy for DBM in spine fusion models.[325,326] Some studies have reported a benefit of adding DBM to autograft or ceramic matrices in animal spine fusion models.[142,327–330] There is also recent evidence that some DBM preparations can be used as a substrate for selective attachment and concentration of bone marrow–derived osteogenic stem cells and progenitors.[174,331]

Because demineralized bone preparations do not have mechanical properties sufficient to resist external forces, they can easily be dislodged from a graft site. The use of these materials is therefore primarily restricted to grafting of contained defects or graft sites that are protected by rigid internal fixation or to settings in which demineralized matrix is combined with other allograft or synthetic materials that resist displacement or compression.

Of recent clinical concern is evidence that suggests that the biologic efficacy of commercially available preparations of DBM materials can vary significantly, depending on the method of processing, the individual batch of bone that is processed, or the donor of the bone that is used. This variation has raised questions about the possible value of implementing generalized standards for either in vitro or in vivo biologic assays for bone from each batch and donor in order to limit the potential for biologically deficient materials from compromising the performance of clinical grafting procedures. At present,[204,225,332] without evidence that failed graft procedures cluster around individual donors or batches of demineralized bone and that these failures can be predicted by any of the available assays, the clinical value and cost-effectiveness of biologic assays is uncertain. Regardless, some providers of demineralized bone have elected to implement some form of bioassay and use these data to exclude some bone from use

and to make claims of superior or more reliable performance in the marketplace.

Deproteinated Heterologous Bone

In contrast to allograft bone, heterologous bone (xenograft) fails to induce osseous repair due to its high level of antigenicity. Partially deproteinated and partially defatted heterologous bone (Kiel bone or Oswestry bone) does exhibit greatly reduced antigenicity and therefore evokes a minimal immune response.[333] The denaturing process, however, also destroys osteoinductive matrix proteins. Accordingly, implantation of such materials in bone defects and muscular compartments has failed to generate bone formation.[150]

The impregnation of this material with cells capable of osteogenic activity, however, has been studied. Salama et al.[150] and Plenk et al.[334] demonstrated that deproteinated xenograft bone supplemented with autologous marrow assisted osteogenesis in both experimental animals and humans. In these experiments, deproteinated bone served as an osteoconductive scaffolding, providing a stable mechanical environment for revascularization and proliferation and differentiation of osteogenic cells. Salama and Weissman[151] reported satisfactory results in clinical attempts to use composite xenograft/autograft (Kiel bone/marrow) in a variety of bone defects. More recently, Rawlinson et al.[335] reported poor results using bovine-derived Cloward grafts. Due to the wide availability of more effective allograft matrix materials in the United States at similar costs, xenograft materials are not currently used.

Synthetic Bioactive Bone Graft Materials

Recent years have seen an explosion of new information about the cellular and molecular events involved in the bone healing response (see Fig. 66.1) and has increased the potential for clinical applications of growth factors with and without traditional bone grafts and bone graft substitutes. Purified human recombinant growth factors are becoming available. Many are active in multiple events in the bone healing process and are therefore candidates as potential therapeutic agents. In addition, developments in porous ceramic materials and bioerodible polymers of biologic and synthetic polymers enable the design of customized matrix materials that can be used both as osteoconductive scaffolds and as delivery systems for bioactive molecules. These converging events are now producing an army of first-generation and second-generation biosynthetic bone grafting materials. One of the prototype materials designed used in combination with bone marrow aspirate (BMA) is a matrix comprised of type I bovine collagen fiber coated with hydroxyapatite. Several studies compared BMA-collagen-ceramic composite to ICBG in transforaminal lumbar interbody fusion (TLIF), posterior lumbar interbody fusion (PLIF), and posterolateral spine fusion, finding similar outcomes but a lower radiographic fusion rate.[336–339] It is beyond the scope of this chapter to comprehensively review any one of these areas. Several recent reviews are available.[15,205,340–342] The following is intended as an overview of some of the ongoing developments in this area, specifically the application of growth factors, collagen matrices, and ceramics in synthetic bone grafting materials.

Bone Morphogenetic Proteins

A major advance occurred in 1978, when Urist et al.[343] reported the isolation of a hydrophobic, low-molecular-weight protein fraction from insoluble bone matrix gelatin that was responsible for osteoinductive activity.[344] Further characterization of this inductive factor, BMP, was made possible by quantitative extraction accomplished by differential precipitation in a buffer containing 4M guanidine hydrochloride.[345] Lovell and Dawson went on to report the success of a partly purified BMP preparation on polylactic acid strips in a canine segmental spinal fusion model.[346]

After an extensive search for the protein responsible for the inductive activity of bone matrix extract, Wozney et al.[347] identified and characterized three proteins isolated from a highly purified preparation from bovine bone in 1988, each capable of inducing bone formation in a rat subcutaneous bioassay. Human complementary DNA clones for each peptide were isolated and expressed as recombinant human proteins. Two of the encoded proteins were homologous and described as members of the TGF-β super gene family, whereas the third appeared to be a novel polypeptide (BMP-1). BMP-1 has turned out not to be a growth factor at all. Rather, this molecule has been characterized as a procollagen C-proteinase, which may have a biologic function in the activation of TGF-β–like molecules, including the BMPs.[348,349]

At least 17 BMPs have been identified, but only BMP-2, BMP-4, BMP-6, BMP-7, and BMP-9 have been documented to have significant osteogenic properties.[347,350–352] The BMP family are homologous proteins with molecular weight of 12 to 14 kD that are posttranscriptionally modified by glycosylation and are secreted as homodimers or heterodimers linked by one disulfide bond (≈30 kD).[347,353,354] In vivo, these proteins are secreted as soluble factors that have autocrine and paracrine effects. BMP-7 (OP-1) can also be found in systemic circulation and may also have effects on kidney function.[355,356] BMPs are present in bone matrix, both as homodimers and as heterodimers at a concentration of roughly 1 mg/kg of bone, where they are believed to play a role in bone remodeling and the coupling of osteoclastic and osteoblastic activity. BMP-3 is the most abundant BMP in demineralized bone, comprising as much as 65% of the BMP in bone matrix. However, BMP-3 is a negative regulator of bone formation, antagonizing the effects of BMP-2[357] and increasing levels of chondrogenic markers, such as aggrecan and type II collagen.[358] Daluiski et al. found that BMP-3 knockout mice have twice as much trabecular bone as controls.[359]

There are four subfamilies of BMP ligands based on their degree of sequence similarity and functions[360,361]: subfamily (I), containing BMP-2 and BMP-4; subfamily (II), containing BMP-5, BMP-6, BMP-7, BMP-8a, and BMP-8b; subfamily (III), containing BMP-9 and BMP-10; and subfamily (IV), containing BMP-3, BMP-3b, BMP-11, BMP-13, BMP-14, BMP-15, and BMP-16. BMP-3 (as stated earlier)[357–359] and BMP-13[361,362]

BMP-1	Procollagen C-proteinase		
BMP-2	BMP-2a		
BMP-3	Osteogenin		
BMP-4	BMP-2b		
BMP-5			
BMP-6	VgR1		
BMP-7	OP-1		
BMP-8	OP-2		
BMP-9		GDF-2	
BMP-10			
BMP-11		GDF-11	
BMP-12		GDF-7	CDMP-3
BMP-13		GDF-6	CDMP-2
BMP-14	MP53	GDF-5	CDMP-1
BMP-15		GDF-9	

FIG. 66.2 The bone morphogenetic protein (BMP) family of proteins. This figure lists the known members of the BMP family of proteins and some of the corresponding names that identify the same protein using other classification terminology. CDMP, cartilage-derived matrix protein; GDF, growth and differentiation factor.

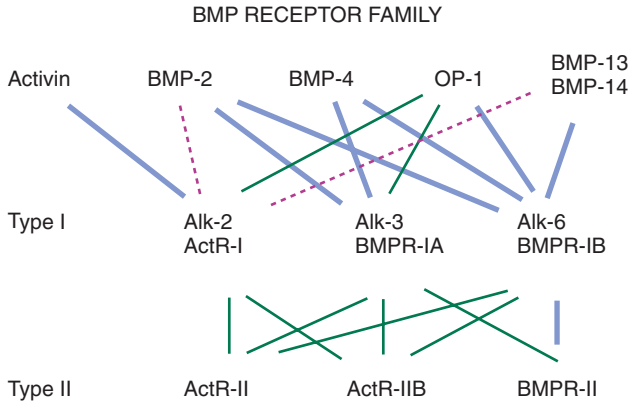

FIG. 66.3 The bone morphogenetic protein (BMP) receptor family. BMPs act on cells through interaction with a family of membrane-bound cell surface receptors. Cells must express one or more of the type I and the type II receptors in order to be responsive to BMPs. Some of the cross-reactivity between BMP-7, BMP-4, and another TGF-β superfamily member, Activin A, are illustrated. BMPs bind first to a type I receptor, including Alk-2, Alk-3, Alk-4, and Alk-6. The relative binding affinity of each BMP is reflected by the thickness of the connecting line. The BMP–type I receptor complex is then phosphorylated by a type II receptor protein to activate the signal transduction mechanism in the cell, which results in the BMP-induced response acting through the SMAD pathway.

have been shown to be inhibitory. Subfamily (IV) contains those BMPs that do not have osteogenic properties.

Fig. 66.2 summarizes these proteins along with synonyms or alternative names that are now, or have been, used for some of these molecules. There is RNA sequence homology within and between subgroups of the BMP protein family. Each of these proteins can interact with one or more of a family of cell surface receptors. Cells must express both type I and type II receptors (serine/threonine kinases) in order to be responsive to BMPs because a type I and type II receptor must interact in the presence of a BMP to mediate a cellular response. To date, three type I and three type II BMP receptors have been identified. BMPR-IA binds only BMPs. BMPR-IB binds BMPs and müllerian inhibitory substance. ALK-2 (also a type I receptor) binds BMPs and activin. BMPR-II binds only BMPs, and the activin type II receptors, ActR-IIA and ActR-IIB, bind both BMPs and activin.[363] In vitro, BMPs demonstrate dose-responsive modulation in responsive cells, both in primary osteogenic cells and in cell lines, in the range of 1 to 100 ng/mL, but each BMP demonstrates a unique and variable binding pattern for the individual receptors, as illustrated in Fig. 66.3. These genes are independently regulated in both space and time in embryonic development and in bone healing settings, but a great deal of functional redundancy and promiscuity between these proteins and receptors is present. Expression of specific inhibitors of BMP function (e.g., noggin, chordin, connective tissue growth factor, follistatin) also plays a role.[353,364–369]

Binding of BMP homodimers to type I and type II receptors can also be modulated by three families of co-receptors[361]: (1) betaglycan or type III TGF-β receptor[370] and Endoglin (aka CD105)[371]; (2) the EGF-CFC family (which includes Cripto)[372]; and (3) the glycosyl-phosphatidylinositol-linked family of repulsive guidance molecules (RGM),[373,374] which includes RGMa, TGMb or DRAGON, RGMc or hemojuvelin, and RGMd.[375] This complex system of activators, inhibitors, receptors, and modulators creates a rich field of potential therapeutic targets for purposed modulation. Spine fusion has been at the heart of both development and controversy in the rapidly evolving and promising field of targeted delivery of potent bioactive agents for tissue regeneration and repair.

Among the BMP homodimers that are most active in bone induction in vivo are BMP-2 (i.e., INFUSE), BMP-4, BMP-6, BMP-7 (i.e., osteogenic protein-1, or OP-1), and BMP-9. BMP-2 and BMP-7 have both been developed for clinical applications in bone grafting and skeletal reconstruction. BMP-13 (aka, GDF-6, CDMP-2) and BMP-14 (aka, GDF-5, CDMP-1) have been investigated.[358,361,376,377] BMP-14 (GDF-5) is present in varying levels in nucleus pulposus and anulus fibrosus of both normal and degenerative intervertebral disc tissue from patients with lumbar intervertebral disc disease, and it has been proposed that BMP-14 (GDF-5) may play an inhibitory role in progression of intervertebral disc disease.[378] At present, only BMP-2 has been approved by the US Food and Drug Administration (FDA) for use in spinal fusion. This approval is specifically limited to use in an absorbable collagen sponge (ACS) carrier (INFUSE Bone Graft, Medtronic) with a metallic lumbar tapered fusion device (INFUSE Bone Graft/LT-Cage Lumbar Tapered Fusion Device; Medtronic) in the setting of single-level ALIF from L2 to S1 for degenerative disc disease.[379] BMP-2 is also approved for use in open tibial shaft fractures stabilized with an intramedullary nail and treated within 14 days of initial injury.[380,381] BMP-7 (OP-1) received FDA approval under a humanitarian device exemption as an alternative to autograft in patients who have failed a previous spinal fusion surgery and are not able to provide their own bone or bone marrow for grafting because of a condition such as osteoporosis, diabetes, or smoking.[178] BMP-7–based products (OP-1 IMPLANT, OP-1 PUTTY, BioEZE, and BioVERSE) were removed from the US market in 2014.

A large number of animal studies have demonstrated the promise and relative safety for these proteins as powerful stimulants of a local bone-healing response in rodents, sheep,

canines, and nonhuman primates, using various carrier matrices and a dosage range of 100 to 10,000 μg/mL.[354,383–411]

Several of the early prospective clinical trials strongly supported the value of BMPs (particularly BMP-2) in the setting of spinal fusion, reporting fusion rates that were comparable with autogenous cancellous bone between 80% and 99%.[412–421]

In a prospective, consecutive patient enrollment with a minimum 24-month follow-up, 30 patients underwent anterior interbody allografts alone and 45 patients underwent anterior interbody allograft filled with rhBMP-2. All cases had posterior pedicle screw instrumentation. A total of 165 surgical levels (62 allograft alone; 103 allograft + BMP) were included. In the allograft-rhBMP-2 group, fusion rates were 94%, 100%, and 100% at 6, 12, and 24 months, respectively, after surgery. In the allograft-only group, fusion rates were 66%, 84%, and 89%, respectively, at the same time intervals. Clinical outcomes were significantly improved in the rhBMP-2 group when compared with the allograft group at 6 months. There were no revisions in the rhBMP-2 group and four revision fusion surgeries (13%) in the allograft group.[422] In a randomized, controlled trial in patients older than 60 years, Glassman et al.[423] also found that rhBMP-2/ACS (INFUSE Bone Graft) is a viable ICBG replacement in older patients in terms of safety, clinical efficacy, and cost-effectiveness.

Taking advantage of the clinical availability of BMP-2, several investigators began evaluating the use of BMPs for expanded off-label indications. One of the first areas was anterior cervical spine surgery.[424–426] Anterior cervical discectomy and fusion performed with rhBMP-2 (0.9 mg BMP per level) allograft was found to be as effective as iliac bone graft in terms of patient outcomes and fusion rates. However, safety concerns were raised related to neck swelling in the BMP group.[425] Vaidya et al.[304] compared 22 patients treated with rhBMP-2 and PEEK cages with 24 patients in whom allograft spacers and DBM was used. Radiographic examination following surgery revealed endplate resorption in all patients in whom rhBMP-2 was used, followed by a period of new bone formation commencing at 6 weeks. In contrast, allograft patients showed a progressive fusion. Dysphagia was a common complication; it was significantly more frequent and more severe at 1 and 6 weeks in patients in whom rhBMP-2 was used. There was no significant difference in the clinical outcome of patients in the two groups at 2 years. The authors concluded that, despite good fusion rates, they abandoned using rhBMP-2 and PEEK cages for anterior cervical fusion, due to side effects, high cost, and the availability of a suitable alternative. Shields et al.[427] reviewed 151 patients who underwent either an anterior cervical discectomy and fusion (n = 138) or anterior cervical vertebrectomy and fusion (n = 13) augmented with high-dose BMP-2 and found a 23% complication rate attributable to BMP-2. The authors concluded that an inflammatory effect involving adjacent critical structures led to increased postoperative morbidity.[427] Smucker et al.[428] and Crawford et al.[429] also reported similar findings.

Although BMPs clearly provide valuable tools for use in stimulation of spinal fusion, the next set of challenges is to optimize their use in a broader range of applications. This includes defining those clinical settings in which the current formulation of BMPs does or does not provide optimally effective biologic effects. This includes identification of patient groups or settings in which clinical performance may be limited even for on-label applications (e.g., high-risk patients—diabetes, steroid use, tobacco use, pseudarthrosis). It also includes identification of potential value settings that are currently off label, such as posterolateral lumbar fusion and applications in the cervical spine. These must be assessed through prospective trials or carefully selected and documented clinical experience. Until data regarding the use of BMPs in these settings become available, surgeons must remain cautious to avoid overoptimism or wishful thinking that may result in the use of these products in settings in which their performance is still to be proven. The following discussion regarding published complications associated with the clinical use of BMPs brings to light the importance of this vigilance on the part of surgeons to avoid being "overwhelmed by their enthusiasm of using recombinant human bone morphogenetic protein type 2."[430,431]

Risks and Adverse Events Associated With Use of Bone Morphogenetic Proteins in Spine Fusion

The initial clinical studies using BMPs reported few and often no complications.[93,94,412–414,430–434] However, this was not always the case. Lewandrowski et al.[435] reported vertebral osteolysis with the use of rhBMP-2 in PLIF with 5 out of 68 patients developing osteolysis within 4 months of surgery. Violation of the endplate during decortication was thought to be a contributing factor. This often resolves spontaneously. Similar observations were made in the cervical spine by Vaidya et al.[424]

As clinical experience expanded and BMP-2 was used in many settings beyond anterior lumbar spinal fusion, awareness of risks and adverse effects became more evident. This assessment began by a review of the concerns raised by Poynton and Lane (also discussed earlier) in 2002,[403] warning that "Safety issues associated with the use of bone morphogenetic proteins in spine applications include the possibility of bony overgrowth, interaction with exposed dura, cancer risk, systemic toxicity, reproductive toxicity, immunogenicity, local toxicity, osteoclastic activation, and effects on distal organs."

Despite initial reports of excellent outcomes, data first became available in 2006 citing adverse event rates between 20% and 70%, leading to the issue of a Public Health Notification by the FDA in June 2008[379] regarding life-threatening complications associated with the use of rhBMP-2. Despite initial reports of no adverse events regarding the use of rhBMP-2 for spinal fusions,[93,94,412,434,436] in 2011, Carragee et al.[431] systematically reviewed the published data on rhBMP-2, comparing results of early industry-funded studies with FDA reports and later independent reviews of outcomes and clinical trial data. In this review, concern was expressed regarding an increased risk of malignancy with high doses—specifically with use of AMPLIFY, developed by Medtronic, which is reported to have a dose (concentration × graft volume) 33% higher than INFUSE Bone Graft). There was also strong level 1 evidence demonstrating morbidity equal to or

greater than that in patients undergoing harvest of ICBG, specifically a two- to threefold increase in early back and leg pain (16–18% with INFUSE and 25–30% with AMPLIFY). The rate of wound complications was estimated to be two to five times the rate of those seen in patients not receiving rhBMP-2 (level 3 evidence). Carragee et al.[431] criticized the study design as having potentially biased clinical outcomes against the ICBG group, as the study protocols (1) limited the quantities of ICBG that could be used, (2) required discarding local bone graft, and (3) did not allow preparation of facets for arthrodesis, all changes from standard surgical procedures for PLIF.[431,437–439] In a more recent review of the literature, Walker et al.[297] concluded that rhBMP-2 might be useful in improving rates of radiographic arthrodesis in PLF, specifically in patients at high risk for pseudarthrosis, such as smokers.

Focusing on studies using rhBMP-2 for ALIF,[413,414,432,440,441] which previously had unreported complications, a later review on available FDA data and recent publications reported complications including osteolysis, subsidence, implant loosening, and migration at rates significantly greater than those in controls.[431] In addition, a statistical higher rate of retrograde ejaculation (RE) was seen in male patients (6–9%), two to four times greater than that in patients not receiving rhBMP-2. The rate of urogenital adverse events (described as mainly urinary retention) was twice that in controls (level 2 evidence). The rates of delayed infections in anterior and anteroposterior fusion procedures were significantly increased in patients receiving rhBMP-2, with the infection rate being as high as five times greater for delayed wound infections (level 2 evidence).[431]

In analysis that followed, Siemionow and Singh[442] advise caution in interpreting these findings, asserting that the current available evidence may be biased in favor of finding a correlation between rhBMP-2 and RE. However, they agreed with the prior assertion by Mroz et al.[443] that validated methods for preoperative and postoperative assessments of RE should be used in patients undergoing ALIF and that the lack of these standardized methods in the previous literature may have even contributed to previous underreporting.

Focusing on studies in which BMP-2 was used for PLIF despite initial reports of no adverse events, Carragee et al.[431] found that the morbidity in the patients receiving rhBMP-2 was the same as or greater than associated with harvest of ICBG (level 2 evidence). There was level 1 evidence of formation of ectopic bone into the spinal canal/foramen at a frequency six times that seen in patients not receiving rhBMP-2. In 50% to 70% of patients receiving rhBMP-2 for PLIF, complications included osteolysis, subsidence, implant migration, and/or loss of lordosis (level 1 and level 2 evidence). These problems usually do not resolve. Patients receiving rhBMP-2 for PLIF had poorer outcome scores: they were more dissatisfied with their surgery. The external validity of this finding was difficult to assess, as the RCT in question was discontinued prior to enrollment of a number of patients sufficient to provide statistical power to support further analysis of the data (level 2 evidence). Carragee et al.[431] criticized the use of ICBG as the source of autogenous bone in the PLIF trial. They asserted that prior to the publication of the industry-sponsored trial evaluating rhBMP-2 in PLIF,[430] the efficacy of local bone graft for PLIF had been established.[444] They argued that harvest of ICBG increased pain that would have been minimal or absent if local bone graft had been used alone or used to supplement the ICBG controls.[431] They proposed that the use of ICBG in controls may have unnecessarily handicapped the control group. More recent trials had confirmed the efficacy of local bone in single-level PLF,[445–447] and Carragee et al. emphasized that despite this handicap, no advantage was found for the use of rhBMP-2 in PLIF.[431] Haid et al.[430] later conceded, despite no discussion of adverse events in the initial reports, that the study was discontinued as a result of bony overgrowth into the spinal canal in patients receiving rhBMP-2.

Focusing on studies using rhBMP-2 in ACDF, despite initial reports of no device-related adverse events and claims of a 100% fusion rate with no significant morbidity in patients receiving rhBMP-2,[433,448] the Carragee et al.[431] review of later available FDA data and more recent publications revealed the following. There was increased perioperative mortality in the rhBMP-2 group (level 2 evidence). Perioperative wound complications, difficulty swallowing, and impaired vocalization were seen in rates 40% higher during the acute hospitalization in patients receiving rhBMP-2 (level 2 evidence). Patients in the rhBMP-2 group also experienced prolonged dysphagia requiring tube feeding even when a lower-dose formulation of rhBMP-2 was used (level 3 and level 4 evidence). Finally, endplate resorption, subsidence, and loss of alignment were seen in more than 50% of patients receiving rhBMP-2 for ACDF (level 3 evidence).

The findings of Carragee et al.[431] have been supported by more recent meta-analyses on the use of rhBMP-2 and rhBMP-7.[449,450] In addition to concerns regarding study design and the possible role of bias in reporting of the earlier industry-funded studies, Carragee et al.[431] drew attention to the importance of caution in large-scale clinical application of biologics that have known potential for safety concerns based on preclinical data, including intense inflammatory response and comprising neural elements.[403,410] These concerns, particularly regarding off-label use, were echoed by Epstein et al.[451]

In a prospective, randomized, controlled clinical and radiographic trial conducted in Belgium, Michielsen et al.[452] found no differences in clinical outcomes between use of rhBMP-2 and ICBG in patients undergoing single-level PLIF. Fusion was equally achieved between groups, but formation of trabecular bone was slower and interbody bone density was lower in the first year postoperatively in the rhBMP-2 group. The incidences of ectopic bone formation and osteolysis were high in the rhBMP-2 group. Because there was no evidence of ectopic bone formation, cystic formation, or osteolysis in the control group and because the ectopic bone extended posteriorly along the path of cage implantation, the authors concluded that these complications were directly related to use of rhBMP-2.

A cohort-controlled study confirmed previously published findings demonstrating a higher rate of RE in patients undergoing ALIF with rhBMP-2 at a single level (6.7%) when compared with control patients undergoing single-level (0%) and two-level (1.6%) ALIF without rhBMP-2.[453] Glassman

et al.[454] reported that use of rhBMP-2 in posterolateral fusion does not adversely affect postoperative leg pain to a clinically significant level in patients with dural tears specifically. There were no differences in leg pain scores or in any other health-related quality-of-life outcome measure between the group with dural tears and the group with no dural tears. However, the number of patients with neurologic deficits preoperatively was too small to determine whether or not there was a differential rate of recovery of neurologic function. Mannion et al.[455] reported on the use of rhBMP-2 with autograft for minimally invasive lumbar interbody fusion (PLIF or TLIF) performed at either one or two levels in 30 patients (36 levels). Using their technique of placement of a low dose of rhBMP-2 (1.4 mg) and locally harvested bone graft, almost all patients (33 of 36 levels) had evidence of fusion within 7.1 months. Complications related to rhBMP-2 occurred in 5 of 30 patients and included vertebral body osteolysis with nonunion (3.3%), heterotopic ossification in the neural foramen (6.6%), and cyst formation (6.6%). One patient required revision surgery. Practicing in the United Kingdom and Australia, they emphasized the importance of two potential obstacles to widespread use of rhBMP-2 in publicly funded health care systems: cost and adverse effects. They cautioned that, given that high rates of interbody fusion can be achieved with minimally invasive techniques without rhBMP-2,[456] the added cost and potential morbidity associated with use of this product should limit its applications to cases in which preexisting risks of nonunion are considerable.

In a retrospective study of patients undergoing TLIF with rhBMP-2, Helgeson et al.[457] reported that the incidence of osteolysis was high: 54% at 3 to 6 months postoperatively. While this decreased to 41% at 1 to 2 years, 76% of cases of osteolysis did not resolve. While this affected neither the rate of fusion nor the final outcome (overall union rate of 83%), a bony void was still present at the time of ultimate fusion. The authors noted that this patient population (at a military hospital) was younger, on average (38.2 years), than patients in other published studies.

Despite the fact that early studies documented little to no morbidity to the nervous system,[401] the incidences of back and leg adverse events were noted by the FDA to be markedly higher in the early postoperative period in patients undergoing PLF with both the INFUSE and AMPLIFY (Medtronic) rhBMP-2 formulations.[458] Concerns regarding the effects of rhBMP-2 in the setting of spinal cord injury led to in vivo studies in a rat model of penetrating spinal cord injury, in which Dmitriev et al.[459] performed PLF with or without rhBMP-2 at varying intervals after injury. They found significant intraparenchymal inflammatory changes with use of rhBMP-2 at all time points. Further studies with this model confirmed the presence of intraparenchymal inflammation at both early and late time points.[460] An unexpected finding was the difference in the need for treatment for self-mutilation behavior, a response to neuropathic pain in rats,[461] in the rhBMP-2–treated group (56%) compared with controls (31%). The authors proposed that these histochemical and clinical findings in rats correlated with clinical reports on early postoperative radiculitis in patients undergoing single-level TLIF with rhBMP-2.[462] This relative time interval (10 days in rats) is believed to correlate to several months in human patients.[463] This finding appears to be supported by FDA clinical data documenting the effects of radiculitis in these patients persisting for approximately 3 months postoperatively. The authors concluded that the mechanism of this observed allodynia is potentially via BMP-2–mediated inflammation in and around the dorsal root ganglion and emphasize the importance of careful consideration of risks associated with off-label use of rhBMP-2.[465]

In a meta-analysis of RCTs evaluating clinical outcomes of use of BMP versus ICBG for lumbar fusion in patients with degenerative disc disease, Noshchenko et al.[466] found significant improvements in the Oswestry Disability Index (ODI) and 36-Item Short Form Health Survey (SF-36) scores as well as in back and leg pain in both groups at 24 months. The rate of patient satisfaction was approximately 80% in both groups. The only difference in patient-reported clinical outcome measures between the two groups was a significantly greater improvement in the SF-36 (physical scale) scores in the BMP groups. However, the authors reported that the difference was heterogeneous, raising concerns regarding low levels of evidence.[466–468]

Malham et al.[469] reported results of a prospective study of 131 consecutive patients undergoing ALIF with a PEEK cage filled with rhBMP-2 and a separate anterior titanium plate, performed by a single spine surgeon and a single vascular surgeon with goal of prospectively evaluating complication rates, particularly RE. Of note, this patient population is closest in age (mean age, 45.3 years; range, 23–70 years) to that of Helgeson et al.[457] (mean age, 38.2 years; range, 23–81 years). Malham et al.[469] reported lower complication rates than those in the literature for ALIF patients, reported to be as high as 40%. Their total perioperative complication rate was 10.1%, with minor complications in 13.0% and major complications in 6.1%. Perhaps most noteworthy was that only 1 of 67 male patients in this series experienced RE (1.5%). This is in contrast to previous studies with published rates of RE of 7.9%,[470] 3.4%,[471] and 7.2%,[453] which led to conclusions that use of rhBMP-2 in lumbosacral ALIF was associated with an increased risk of RE. The overall fusion rate in this study (for ALIF and hybrid patients receiving rhBMP-2) was 96.9%. Only 4 of 131 patients had not experienced fusion at 12 months postoperatively. This was the 12-month fusion rate (12.9%) reported by Burkus et al.[414]

In the largest reported series of adult patients receiving high-dose rhBMP-2 (≥40 mg), Mesfin et al.[472] reported short- and long-term results in 502 adult patients at a single institution. The average length of follow-up was 42 months (range, 14–92 months). The majority of this caseload was comprised of adult spinal deformity cases, noted for having high complication rates, ranging from 35.9% to 46%.[473–475] Further, 47% of their cases were revisions, known to have a documented higher risk of major complications.[474] The authors stated that one of the main reasons they elected to use rhBMP-2 was the potential for decreasing the high risk for pseudarthrosis in this challenging patient population. Compared with a published pseudarthrosis rate of 17%,

cited in studies performed prior to the use of rhBMP-2, Mesfin et al.[476] reported a rate of 5%; 52% of their patients developing pseudarthrosis were patients undergoing revision procedures. In a patient population receiving an average dose of 115 mg of rhBMP-2 (range, 40–351 mg), with an average of 11.5 levels instrumented (range, 3–19 levels), these authors reported a lower prevalence of cancer in this patient group, when compared with the general population, and the dose of patients in this group who had cancer received a lower dose of rhBMP-2 than those in the noncancer group (although the dose was not significantly lower). At 1%, the rate of postoperative radiculopathy (in five patients, four undergoing TLIF) was also lower in this study than the rates of 5.4% to 11% reported in other studies evaluating rhBMP-2 in TLIF,[472,477,478] and the authors found no correlation between dose of rhBMP-2 and development of postoperative radiculopathy. These results challenge the findings in the literature regarding these complications and the associated discussions regarding potential for dose-related escalations in risk, particularly a study published at the same time by Carragee et al.[479] reporting on 463 patients with 86% follow-up at 2 years. In patients undergoing single-level instrumented posterolateral arthrodesis, at 2 years the incidence rate of cancer was 6.8-fold greater in the rhBMP-2 (40 mg) group in a compression-resistant matrix when compared with autogenous bone graft (control). In addition, fivefold more patients in the rhBMP-2/CRM group developed one or more cancers compared with the control group, also a statistically significant difference. The authors concluded that use of 40 mg of rhBMP-2/CRM was associated with an increased risk of new cancers.[479]

In a larger, population-based retrospective cohort study, Cooper et al.[480] compared the rate of new cancers in Medicare beneficiaries aged 67 years and older undergoing lumbar spinal fusion with rhBMP between 2003 and 2008 to patients who did not receive rhBMP. The authors identified 146,278 patients meeting these criteria. Mean duration of surveillance was 4.7 years. The authors used data from the Surveillance, Epidemiology, and End Results (SEER) Program[481] to determine whether the incidence of cancer was different from the general population. There was no association of administration of rhBMP with cancer incidence.

In response to concerns regarding the safety of INFUSE, Medtronic, Yale University, Oregon Health and Science University, the University of York in the United Kingdom, and Fu et al.,[482] via the Yale University Open Data Access (YODA) Project, conducted a meta-analysis of individual-patient data from 13 RCTs (12 sponsored by Medtronic and one by Norton Healthcare). The goals of this study were (1) to estimate the effectiveness and harm of rhBMP-2 in spinal fusion and (2) to assess reporting biases in published articles of industry-sponsored studies.[482] The authors found that the main sources of bias were lack of blinding of surgeons, patients, and outcome assessors. They concluded that there was no difference between the effectiveness of rhBMP-2 and ICBG when used in spinal fusion, specifically in ALIF and PLF. They found the evidence available insufficient to make conclusions regarding the effectiveness of rhBMP-2 compared with ICBG in other surgical approaches for spinal fusion.

In agreement with the findings (discussed earlier) by Carragee et al.,[431] Fu et al.[482] also concluded that use of rhBMP-2 in ACDF was associated with statistically significant increases in adverse events overall, wound complications, and dysphonia and dysphagia. They found that adverse events were common with the use of both rhBMP-2 and ICBG for lumbar fusion, with both on-label and off-label use. The authors stated that although this review did raise concerns regarding the possibility of increased risks of RE, urinary retention, and ectopic bone formation with rhBMP-2, the data on these events were sparse and "the quality of ascertainment was often poor," leading them to conclude that there was insufficient evidence regarding the risks of these complications in patients receiving rhBMP-2.

Fu et al.[482] also found that, consistent with previous findings, rhBMP-2 was associated with an increased risk for cancer through 24 months of follow-up but recommended caution in interpretation of this finding, as cancer cases were found to be heterogeneous and were underreported. They agreed with Carragee et al.[431] that publications of data reporting both on-label and off-label use of rhBMP-2 in journals favored the reporting of results favoring rhBMP-2 over ICBG and that adverse events of five trials were, in fact, underreported. They conceded that results were not previously made available to the public.

In another publication funded by the YODA Project, Simmonds et al.[484] evaluated individual-participant data in a meta-analysis of 11 Medtronic RCTs and one additional RCT comparing effectiveness of rhBMP-2 to ICBG. The authors concluded that rhBMP-2 improves rates of fusion compared with ICBG. However, they noted that inconsistency across trials was high. They also found that rhBMP-2 improves back pain and quality of life (based on ODI or SF-36 scores) between 6 and 24 months postoperatively, but that these improvements in pain were not clinically significant. They noted the limitation that patients were not blinded regarding treatment and, as such, may have been biased toward reporting better function and less pain if they were in the rhBMP-2 treatment group. This study also found increased pain in the immediate postoperative period in the rhBMP-2 group, but concluded that rhBMP-2 reduced pain in the longer term. This study reported an increase in the risk of cancer associated with rhBMP-2 administration, with this treatment group having almost twice the incidence of new cancer cases when compared with patients in the ICBG group, consistent with previously reported concerns regarding cancer risks.[485] However, they note that the overall absolute cancer risk in both groups is low and question whether this increased risk is genuine. This is not consistent with the increased risk of malignancy reported by the FDA with use of AMPLIFY, in which a 3.8% incidence of new malignancies was found when compared with 0.89% in controls. This difference was statistically significant, with the statistical analysis performed reporting a 90% to 95% probability that this association was genuine.[431,458] Regarding concerns about increases in formation of heterotopic bone, osteolysis, radiculitis, and RE,[485] Simmonds et al.[484]

advised that these findings should be interpreted with caution, as they were based on less extensive and less detailed clinical data than that in the YODA Project. Analysis of YODA studies found no difference in effectiveness (based on ODI/SF-36 scores, safety, or cancer risk between patients receiving the licensed INFUSE product and the unlicensed AMPLIFY preparation (which contained a higher concentration of rhBMP-2). However, the authors did concede that, overall, rhBMP-2 may lead to an increase in incidence of cancer and that this is a finding important for clinicians to discuss with patients when facilitating informed decision making. Regardless of the low published risks, Tannoury and An[486] advise that the observed increases in cancer incidence associated with use of rhBMP-2 should remain a critically important concern to clinicians based on longer-term reviews of the literature.[487]

Hustedt and Blizzard[178] subsequently expanded on the findings of the YODA studies, clarifying the rationale and logistics of the collaboration between Medtronic and Yale University. They summarized the findings resulting from all studies in the YODA Project as follows:

- There were no differences in fusion rates between rhBMP-2 and autograft ICBG.
- Both rhBMP-2 and ICBG are associated with similar rates of RE and neurologic complications when used in ALIF or PLF.
- There is clear evidence that use of rhBMP-2 leads to high complication rates in anterior cervical spine procedures and high rates of formation of ectopic bone in posterior lumbar interbody procedures.
- While there is a slight increase in the risk of cancer with use of rhBMP-2, the absolute risk remains very small and is therefore most likely clinically insignificant.

They also summarized the current recommendations for the use of rhBMP-2 based on the results of YODA analyses, as shown in Table 66.1.

TABLE 66.1 Recommendations for Use of rhBMP-2, per YODA[178,482,484] Analyses

Procedure	Recommendation
ALIF	There is no difference between rhBMP-2 and ICBG. However, ICBG requires an additional surgical site. When autograft bone is not available or harvest/use of autograft is not desired, rhBMP-2 is a reliable alternative to ICBG. RE and neurologic complications in patients treated with rhBMP-2 and ICBG were equal.
Anterior cervical fusion	The FDA has issued a warning stating that rhBMP-2 should not be used in the anterior cervical spine due to inflammation causing severe dysphagia and airway compromise.
PLF	There is no difference between rhBMP-2 and ICBG. However, ICBG harvest requires an additional surgical site. When autograft bone is not available or the harvest procedure is not desired, rhBMP-2 is a reliable alternative.
PLIF	Use of rhBMP-2 is associated with high rates of ectopic bone formation leading to neurologic compromise. ICBG is preferred.
TLIF	Use of rhBMP-2 is associated with seroma formation and neurologic compromise. Further evidence is needed. Judicious use of rhBMP-2 is advised based on reported complications.

ALIF, anterior lumbar interbody fusion; FDA, US Food and Drug Administration; ICBG, iliac crest bone graft; PLF, posterolateral fusion; PLIF, posterior lumbar interbody fusion; RE, retrograde ejaculation; rhBMP, recombinant human bone morphogenetic protein; TLIF, transforaminal lumbar interbody fusion; YODA, Yale University Open Data Access.

Cahill et al.[488] reviewed and summarized the findings of both YODA meta-analyses[482,484] and articles in the English language meeting their criteria of being published studies with at least 1 year of follow-up,[472,479] which included three large population-based studies.[480,489,490] With the addition of the population-based analyses, the advantages of the inclusion of massive data sets (MarketScan,[490] Medicare Beneficiary Data,[480] and PearlDiver[489] Medicare Data), the authors noted the clear advantages of larger sample sizes in risk assessment regarding postoperative carcinogenesis in patients receiving rhBMP-2 for spine fusion procedures. In combining these sources, Cahill et al.[488] concluded that the overall risk of cancer development is low and that there is no clear association between postoperative cancer formation and use of rhBMP-2 in spinal fusion.

In a meta-analysis of studies reporting on spinal fusion with rhBMP-2 in human patients, Vavken et al.[491] identified 26 studies with outcomes on a total of 184,324 patients (28,815 experimental patients and 155,509 controls) with a mean age of 51.1 ± 1.8 years. Using random-effects modeling to calculate pooled odds ratios (ORs), they found significantly higher risks of the following in patients receiving rhBMP-2 compared with ICBG: general complications (OR, 1.78), heterotopic ossification (OR, 5.57), RE (OR, 3.31), and cervical swelling (OR, 4.72). The pooled OR for new onset of tumor was slightly higher (OR, 1.35) for patients receiving rhBMP-2, but did not differ significantly between groups.

Favorable long-term outcomes of use of rhBMPs in spinal surgery were recently reported by Malham et al.[492] in a retrospective cohort study of patients in the state of Victoria, Australia. In 527 patients undergoing anterior, lateral, posterior, or posterolateral lumbar fusion performed by two spine surgeons between 2002 and 2012 with either rhBMP-2 (INFUSE) or rhBMP-7 (OP-1), with a mean follow-up period of 4.4 years (range, 1.8–11.5 years) and a mean age of 58.4 years (range, 21.3–93.0 years), fusion rates were similar (90.1% for rhBMP-2 and 91.9% for rhBMP-7). The success rate of interbody fusion was 93.5% at 12 months with no difference found between rhBMP-2 and rhBMP-7. The authors commented that they have not harvested ICBG since initiating the use of rhBMP in their practice in 2002. Reporting of cancer diagnoses in the state of Victoria, Australia to the Victorian Cancer Registry is mandated by law. The authors used this database to identify new cancers occurring during the duration of patient follow-up (2002–13) and compared this to the incidence of cancer in the population of Victoria. There was no significant difference in the incidence of cancer in their patient cohort when compared with age- and sex-specific rates for the population of Victoria. The authors noted that while their analysis criteria were more strict, these estimates of risk in their patient cohort are similar to those reported by Cooper and Kou.[480] They also cited that their findings differed from those of Fu et al.,[482] Simmonds et al.,[484] and Carragee et al.,[479]

all of whom reported increased cancer risks in patients who underwent spinal surgery utilizing rhBMP-2.

Opportunities for Improving or Refining the Use of BMPs and Other Bioactive Molecules

The mechanism of action of BMPs provides many opportunities for further advancement and refinement, including modification of dose, formulation, delivery systems, changes in molecular structure, and means of optimizing the environment into which these agents are placed. One of the principal requirements for optimal BMP activity is the presence of a local population of target cells that are responsive to the protein (i.e., they express appropriate receptors). In order for a BMP to be optimally effective, these target cells must be both available and activated in sufficient numbers to produce the desired result. If an optimal number of responsive cells are not present within the tissue volume that is exposed to the protein, the biologic response will inevitably be reduced and the implantation of a BMP (or any agent) may be completely ineffective. Variation in the concentration or biologic potential of target cell populations in bone, bone marrow, periosteum, and other tissues (e.g., muscle, fat) may explain much of the apparent variation in the magnitude and type of response seen to BMPs and other growth factors from site to site and individual to individual.[156,157,493,494]

Preclinical evaluation of BMPs in a series of animal models from rats to rabbits to dogs to nonhuman primates demonstrated the need for delivery of dramatically high concentrations of BMP to graft sites in higher animals.[386] In fact, the formulation of BMP currently available delivers an amount of BMP that is roughly 50 times greater than the total amount of BMP that is present in an entire human skeleton. INFUSE delivers BMP-2 in solution at a concentration of 1.5 mg/mL to be combined with a collagen carrier, resulting in an implanted concentration of slightly less than 1 mg/mL. The reason for this escalation of dose has not been clearly established, though several factors are likely to contribute. Species-specific differences in dose response may exist at the target cell level, though this has not been a consistent finding in in vitro culture of primary osteogenic cells. However, individual species do demonstrate significant differences in the concentration and prevalence of responsive target cells in local tissues and consistently lower numbers in higher animals. The geometry involved in delivery of BMP to a sufficient volume of a responsive target population of cells in larger graft sites increases with the cube of the dimension, which also contributes. A huge dose may be necessary to provide a burst of BMP delivery that is sufficiently large that the BMP diffusing away from the graft site will penetrate into regional tissues to a sufficient depth at a sufficiently large concentration to activate enough stem cells and progenitors or the graft site becomes larger. Similarly, if the concentration and prevalence of target cells in regional tissues decrease, as they do in higher animals, activation of a similar number of cells will require even deeper tissue penetration. These factors likely contribute to the seemingly exponential increase in dose that is necessary in larger animals.[15] A second possible explanation for the massive dose relates to the issue of BMP retention at the graft site. A massive initial dose may also ensure that a sufficient, though perhaps small, quantity of BMP will remain at the site long enough to result in activation of target cells that may not enter the graft site until several days after implantation, with the associated inflammatory response or angiogenic response following the surgical trauma. These issues in BMP delivery and function in a graft site suggest a number of options that could be used to increase the exposure of BMP to an appropriate target population of cells, thereby improving its performance. Direct delivery or supplementation of the target cell population in the graft site is one option. Evidence is provided by a number of studies that addition of a target population (e.g., bone marrow–derived cells) to a site of BMP implantation will significantly improve bone healing.[147,493,494] Another possible method for enhancing the performance of BMPs is to refine the method and rate of BMP delivery into the graft site. The chemical surface of the matrix may influence the protein binding, its conformation, and stability. In some cases, BMP binding to matrix can actually enhance the biologic performance.[495–497] The four major categories of BMP carrier materials are natural polymers, such as collagen, hyaluronans, fibrin, chitosan, silk, alginate, and agarose; inorganic materials such as low- and high-temperature calcium orthophosphates (calcium phosphate cements and sintered ceramics) and calcium sulfate cements; poly(α-hydroxy acid) synthetic polymers such as polylactic acid, polyglycolide (PLG); and their copolymers (poly[D,L-lactide-co-glycolide]) (PLGA).[498] Furthermore, the carrier (collagen, ceramic, polymer) may have its own biologic effects associated with the release of ions or other degradation products.[15] Currently INFUSE uses an absorbable type I bovine collagen sponge (ACS) as the carrier, on which BMP-2 is reversibly absorbed. A recent study in canines suggested that if BMP-2 is implanted in an environment containing $CaPO_4$ ceramic, BMP-2 and BMP-2–associated bone formation will concentrate around the ceramic.[172] Other options include controlled release from degradable polymers, liposomes, collagen-hydroxyapatite microspheres, and potentially an osteogenic and antiadipogenic molecule known as Oxy133 (recently evaluated in rodent and rabbit models).[499–502] Tethering BMP or other bioactive agents to the surface of a substrate using covalent linkage or a matrix-specific binding peptide is also being explored.[503]

Yet another option for enhancing the performance of BMPs is to prolong the period of time that effective concentrations of the protein are present in the graft site. Residence time of bioactive protein in a graft site is a complex function of the rate of delivery (e.g., release or solubilization); the rate of consumption within the graft site (e.g., degradation, inactivation, binding to inhibitors); and the rate of clearance from the graft site (e.g., diffusion, convection). With the current BMP preparations, release kinetics is relatively rapid. BMP diffuses rapidly out of the immediate graft site and appears at low concentrations, in systemic circulation, where it is rapidly cleared. Fifty percent of the rhBMP-2 is cleared from the site in 48 hours and less than 1% is remaining at 2 weeks.[504] Approximately 50% is excreted in the urine.[494]

Longer residence time within the site is associated with improved efficacy at lower protein concentration.[505] Residence time is influenced by the affinity of the protein to the carrier.[506,507] Residence time can also be increased by modifying the BMP protein itself to reduce its solubility and therefore its rate of diffusion out of the implant.[508] Prolonged residence time within the graft site may have two effects. It may allow the initial gradient of protein concentration around the site to be maintained for a longer period, which may positively influence chemotactic effects that may be mediated by the protein and draw more activated progenitors and other cells into the defect. Prolonged residence may also serve to maintain a functional concentration of protein in the graft site for a longer time, providing the opportunity for additional stem cells and progenitors to migrate into the graft site where they may become activated.

Other Growth Factors

A large number of peptide growth factors and hormones are known to have important effects on the recruitment, proliferation, and differentiation of osteoblastic progenitors, which may have potential therapeutic importance.[509,510] EGF and PDGF are both capable of inducing colony formation by osteoblastic progenitors in vitro,[33] and local injection of PDGF has been shown to result in induction of new bone formation when applied close to a bone surface. A PDGF product has been introduced for use in ankle fusion but has no current indication or data related to spine fusion.[511,512] Basic fibroblast growth factor (FGF; also called bFGF or FGF-2) will also increase proliferation of human osteoblastic progenitors and reversibly inhibit the expression of alkaline phosphatase and matrix synthesis in addition to its known potent angiogenic effects. FGF has been evaluated in preclinical studies using a hyaluronic acid delivery system and has been shown to increase local bone formation and union rates.[513]

VEGFs are a family of proteins that function as dimers. They have a structure similar to PDGF and interact with transmembrane receptors Flt-1, Flk-1, and Flt-4 to activate a tyrosine kinase signaling cascade. VEGFs play several important roles in angiogenesis, osteoclast migration, and osteoblastic activity.[514,515] VEGFs do not induce bone directly but, in addition to angiogenic effects, VEGF delivery has been shown to upregulate BMP activity in fracture healing and distraction osteogensis.[516,517] When used in combination, VEGFs may enhance the performance of BMPs.[518,519]

Transforming growth factor beta (TGF-β) is another potent osteotropic factor. Of the five known isoforms of TGF-β, two—TGF-β1 and TGF-β2—are synthesized by bone cells. In fact, bone matrix deposited by osteoblasts is the largest source of TGF-β and is mostly present in a latent form that is released during bone remodeling.[520,521] TGF-β has effects on bone formation and remodeling. It will induce new bone formation, but only when implanted or injected in close proximity to bone, suggesting that its bone formation effects are mediated primarily by trabecular or periosteal cells, a different or more limited target cell population than the BMPs.[522] For example, Joyce et al.[523] showed that subperiosteal injection of TGF-β can produce a marked periosteal response resulting in rapid formation of a cartilage tissue mass and bone formation via endochondral ossification. IGF-I and IGF-II potentiate a mature osteoblastic phenotype in culture.[58,524,525] Both TGF-β and IGF-I have been shown to promote spine fusion in a sheep model.[526,527]

Collagen

The major components of organic matrix of bone are type I collagen (90% dry weight), a large number of noncollagenous matrix proteins, at least two proteoglycans (biglycan and decorin), and several minor collagens (mostly types III and X). These proteins contribute an osteoconductive substrate for cell attachment and migration and are necessary elements of new bone formation and mineralization. The precise contribution of each element of organic bone matrix is not known. Nor is it understood how the structural organization of the various components within the matrix influences the biologic function of these proteins, making the engineering of synthetic matrices that mimic specific functional relationships between these proteins difficult.

Type I collagen has been the focus of many efforts to develop optimal tissue engineering scaffolds. Most of the noncollagenous proteins in bone matrix can be solubilized using 4 M guanidine. However, the majority of type I collagen in bone matrix is heavily interconnected by covalent pyridinium cross-links. This makes native collagen I insoluble and virtually impossible to manipulate as a reagent to create new structures. In addition, demineralized extracted collagen matrix is only modestly effective as osteoconductive material, though it has been used effectively as a delivery vehicle for purified proteins and extracts of bone matrix.

In contrast, fibrillar collagen (uncross-linked collagen) is soluble and can be extracted from bone and skin. Fibrillar collagen can be engineered to produce a variety of matrices, such as gels, sponges, and filaments. These are often secondarily cross-linked to stabilize their structure using a variety of chemical methods. Again, few of these engineered collagen matrices are effective by themselves in strongly promoting bone formation. Some formulations have appeared to actually compromise the efficacy of autograft in a graft site.[162] However, in general, collagen matrices have been effective as delivery systems for bone marrow–derived cells[146] and for growth factors. Both BMP-2 and OP-1 used collagen I as their delivery vehicle when introduced. Interconnected porous meshes of purified bovine collagen (pore size ≈50 μm) with a coating of hydroxyapatite precipitated on its surface have also been specifically developed and marketed as a delivery system for bone marrow harvested by aspiration.[339,528]

Noncollagenous Matrix Proteins

Bone matrix contains many proteins other than collagens and growth factors.[155,313,529–531] These proteins may serve a role in organization of the collagenous matrix and other proteins into higher-ordered structures. They may provide attachment sites for cells or binding sites for growth factors. They may serve as

regulators of mineralization, as in the case of bone and dentin phosphoproteins, bone sialoprotein, osteonectin, and osteocalcin.[532–534] They may also provide a source for release of locally active growth factors and other bioactive molecules during the process of matrix turnover and remodeling, as previously discussed.

Other than growth factors that are embedded in bone matrix, it is difficult to ascribe any one factor with exceptional function in the setting of bone grafting or a high potential for future clinical application. However, some may be relevant and deserve mention. For example, osteoblasts and osteoblastic cell lines appear to express integrins that bind selectively to both fibronectin and vitronectin[535–537] and possibly osteopontin, bone sialoprotein, and laminin. In addition, osteocalcin appears to be chemotactic for osteoclasts and monocytes,[538] critical elements of normal bone remodeling. Although these proteins are not likely to be exploited in terms of recombinant manufacturing processes used for BMPs, it is possible that these functions may be localized to specific functional domains of these proteins. This knowledge may be used to design specific low-molecular-weight surrogates that may be applied to tissue engineering constructs.

Ceramics

Calcium phosphate biomaterials fused at their crystal grain boundaries into polycrystalline ceramics by high-temperature sintering confer stability to these minerals and reduce bioresorbability.[539] A variety of ceramics are currently being evaluated, most of which are composed of either hydroxyapatite (HA) or tricalcium phosphate (TCP). Ceramics may be prepared as porous three-dimensional implants, dense block implants, granular particles (usually 0.5–3 mm in size), or thin surface coatings. Almost all calcium phosphate ceramics have a high degree of biocompatibility,[330,540] and some have already been extensively used in dentistry and maxillofacial surgery.[330,341,540–547]

The minimal macropore size in porous ceramics needed for effective ingrowth of bone is approximately 100 μm.[548,549] Most porous ceramics currently being manufactured contain interconnecting macropores ranging from 100 to 400 μm. The various calcium phosphate ceramics generally differ with regard to their bioresorbability characteristics. A number of investigators have reported that ceramic HA that does not exhibit bioresorption is essentially inert.[539,540,550,551] Conversely, there is unequivocal evidence that ceramic TCP undergoes biodegradation.[330,473,539,540,550]

Early studies of ceramics suggested that they may be capable of osteogenic stimulation.[552] In fact, one can often find new bone formation in an HA ceramic implant placed at heterotopic sites in the absence of other stimuli. This occurs only after several months and would not be likely to contribute to the early success of a bone graft. The role of ceramics, therefore, is primarily that of osteoconduction.[553] One possible mechanism for this apparent late osteoinductive property of HA ceramics is that an implanted HA implant will selectively bind proteins to its surface on the basis of their relative affinity to HA. This may result in the accumulation of some protein growth factors, such as BMPs, TGF-βs, and insulin-like binding protein-5, which have strong affinity to HA. Accumulation of these low-abundance proteins and their presentation on a stable surface may secondarily create a local growth factor environment on the ceramic surface that is capable of recruiting local osteoblastic progenitors and inducing bone formation. This affinity of many osteotropic growth factors for the highly charged surface of HA may also make HA ceramics an effective delivery system for growth factors as composite synthetic bone grafting materials are developed.[554]

The stability of a bone-ceramic interface and preparation of local bone are also important. Cameron et al.[555] demonstrated that ceramic implants placed against an unprepared bony cortex do not exhibit bone ingrowth and simply resorb over time. However, when placed subperiosteally and immobilized on a scarified cortex, bone ingrowth readily takes place. The sensitivity of these materials to micromotion likely results from magnification of the mechanical strain within the graft site at the interface between local tissues and the surface of a rigid ceramic block. Similar magnification of strain will occur in the regions of tissue between adjoining ceramic granules, inhibiting bone formation. As a result, the optimal settings for use of these materials may be limited to settings in which mechanical micromotion can be well controlled.

Another drawback of ceramic implants is that they are brittle and have low impact and fracture resistance.[556] Furthermore, the limited solubility and remodeling capacity of highly crystalline HA ceramics may retard late stages of bone healing and remodeling and may compromise late mechanical properties of the bone formed in a fusion site.[539,556] This concern has been reduced by the work of Ohgushi et al.,[557] which showed that ceramic combined with bone marrow exhibited greater biomechanical properties following implantation with marrow cells as a result of new bone formation in the implant. In addition, Muschler et al.[161,162,557] have performed a series of spinal fusion experiments evaluating composites of collagen and ceramic granules (60% hydroxyapatite, 40% TCP). Although these studies found that all composites tested had a significantly higher nonunion rate than autogenous cancellous bone graft, the mechanical properties of successful unions achieved with the collagen ceramic composites were comparable with the mechanical properties of unions resulting from autogenous bone graft, despite the presence of unresorbed granules in the fusion mass.

A modest volume of clinical literature is available related to ceramic materials in spine fusion. Several injectable ceramic preparations that crystallize at body temperature have also been described. Resorption rates vary significantly, from weeks to months. These may provide means for improving the initial mechanical fixation for acute fractures, though they do not seem well conceived for achieving long-term fixation. These injectable setting ceramics may also have potential utility in providing extended local delivery for bioactive proteins.[558] In a prospective, randomized study with 3-year follow-up, Dai et al.[559] compared beta-tricalcium phosphate versus autograft in patients undergoing single-level instrumented posterolateral fusion of lumbar spine with beta-tricalcium phosphate versus autograft. The authors reported

similar clinical outcomes and fusion rates and suggested that beta-TCP as bone graft substitute may eliminate the need for bone graft harvesting from the ilium.[559] In a different prospective study, Chen et al.[560] placed autologous iliac crest bone graft in one posterolateral gutter; on the other side, an equal quantity of autogenous laminectomy bone supplemented with calcium sulfate was placed. In a prospective, matched, and controlled study, Acharya et al.[561] evaluated HA-bioactive glass ceramic composite as a stand-alone graft substitute for posterolateral fusion of lumbar spine by placing it in the left intertransverse bed. The autograft was placed in the right intertransverse bed. At the end of 1 year, excellent radiologic outcome was seen on the right side (autogenous graft) in all the cases, whereas 95% (21 of 22) of the cases had poor consolidation on the left side (HA composite). Epstein[562] found a 15% pseudarthrosis rate following multilevel laminectomy and one- to two-level noninstrumented posterolateral fusion using lamina autograft/β-TCP. Enriched bone-marrow–derived mesenchymal stem cells were combined with porous beta-tricalcium phosphate in 41 patients undergoing posterior spinal fusion.[563] After 34.5 months, 95.1% of cases had good spinal fusion results.

Nickoli et al.[564] reported an overall fusion rate for all ceramic products as a bone graft extender in the lumbar spine to be 86.4% and that ceramics used in combination with local autograft resulted in significantly higher fusion rates. Kaiser et al.[565] provided an evidence-based guideline for performance of fusion procedures for degenerative disease of the lumbar spine, using HA/calcium extenders. β-tricalcium phosphate (β-TCP)/local autograft can substitute for autologous ICBG for single-level instrumented posterolateral fusion (one level 2 study). HA with local bone autograft/bone marrow aspirate (BMA) can be a substitute for ICBG in instrumented posterolateral fusion (one level 2 study). Use of HA can be a bone graft extender when mixed with ICBG for instrumented posterolateral fusions (multiple level 5 studies). Use of calcium sulfate preparations mixed with local autograft can be a substitute for ICBG in instrumented posterolateral fusions (one level 4 study and several level 5 studies). Finally, there is insufficient evidence to recommend an HA-glass/BMA composite as a substitute for autograft for posterolateral fusion.

Systemic/Patient-Specific Factors Influencing Bone Healing in Spine Fusion

Many systemic factors have been shown to influence bone healing in the laboratory. Clinically, these factors are also likely to play an important role. A list of systemic factors and their relative effects on bone healing is shown in Table 66.2. Given the complexity of various factors in the clinical setting, it is difficult to demonstrate on a case-by-case basis or in a clinical series that each of these factors results in significant alterations of fracture healing or the success of spinal fusion procedures. Nevertheless, the surgeon should optimize each factor whenever possible.

Nutritional status has been shown to affect the clinical outcome of surgical procedures generally[566] and on bone healing specifically.[567] Identification of a nutritional deficit using anthropomorphic measurements, serum albumin levels, lymphocyte count, skin antigen testing, and nitrogen balance studies can be important in selected patients. Recent weight loss, anergy in skin testing, serum albumin levels less than 3.4 mg/dL, or a total lymphocyte count of less than 1500 are clinical red flags indicating the need for a careful nutritional evaluation and a possible need for nutritional support.[568] Lenke et al.[569] documented that patients undergoing multiple-level spinal fusion procedures may take 6 to 12 weeks to recover from the perioperative nutritional insult and suggested more aggressive nutritional assessment in these patients. Because most evidence suggests that the critical period in determining the success of a fusion attempt occurs in the first 3 to 7 days of healing, manipulation of systemic factors should be carefully controlled during this time period, especially the administration of radiation,[570] chemotherapeutic agents,[571] nonsteroidal antiinflammatory drugs,[43,44] and corticosteroids. Tobacco use, specifically nicotine, is a clinical factor that is both reversible and most strongly associated with negative results.[406,572–577]

TABLE 66.2 Systemic Factors Influencing Bone Healing

Positive Factors	Negative Factors
Insulin	Corticosteroids
Insulin-like growth factor and other somatomedins	Vitamin A intoxication
Testosterone	Vitamin D deficiency
Estrogen	Vitamin D intoxication
Growth hormone	Iron deficiency anemia
Thyroxine	Negative nitrogen balance
Parathyroid hormone	Calcium deficiency
Calcitonin	Nonsteroidal antiinflammatory drugs
Vitamin A	Adriamycin
Vitamin D	Methotrexate
Anabolic steroids	Rheumatoid arthritis
Vitamin C	Syndrome of inappropriate antidiuretic hormone
	Castration
	Tobacco
	Sepsis

Local Factors Influencing Bone Healing in Spine Fusion

Many local factors also influence bone healing; a partial list of these is shown in Table 66.3. In some cases, these factors are unavoidable. In other cases, rational methods can be employed to limit the negative effects. Osteoporosis is generally assumed to be an undesirable factor in fracture healing, but this is without direct clinical evidence. This is probably true but could relate to both mechanical and biologic factors. The quality of internal fixation is significantly affected by bone mass and is an important variable in the outcome of spinal fusions. Furthermore, it has been reported that the quality of local bone marrow and other regional tissues in terms of the concentration, prevalence, and biologic potential of local osteogenic stem cells and progenitors may be reduced in the elderly patient, particularly patients with low rates of bone

TABLE 66.3 Local Factors Influencing Bone Healing

Positive Factors	Negative Factors
Increased surface area (bone and viable local tissue)	Osteoporosis
Local stem cell sources (e.g., bone marrow, periosteum)	Radiation scar
Osteoconductive scaffold (e.g., fibrin clot or other matrix material)	Radiation
Mechanical stability	Denervation
Mechanical loading	Tumor
Factors promoting recruitment, activation, and proliferation of osteoblastic stem cells (e.g., platelet degranulation products including PDGF, EGF)	Marrow-packing disorder
Osteoinductive factors (e.g., BMPs)	Infection
Factors promoting angiogenesis (e.g., FGF, EGF, VEGF)	Local bone disease
Electrical stimulation	Mechanical motion
	Bone wax (other materials inducing foreign body reaction)

BMPs, bone morphogenetic proteins; EGF, epidermal growth factor; FGF, fibroblast growth factor; PDGF, platelet-derived growth factor; VEGF, vascular endothelial growth factor.

remodeling.[15,62,578,579] These age-related changes may or may not be directly related to the pathophysiology of osteoporosis but likely have a negative impact on the biology of the graft site for spinal arthrodesis. These effects may be partly reversed by strategies that allow concentration of osteogenic cells from bone marrow or other tissues. The use of antiresorptive agents that inhibit osteoclasts would theoretically reduce bone formation and remodeling. Antiresorption medications affect bone remodeling, which is a central part of graft incorporation and fusion. In a recent review, Lubelski et al. concluded that although there have been numerous animal studies, there is limited clinical evidence on the use of antiresorptive medication and spinal fusion. Further clinical data are needed to understand the relative advantages/disadvantages of antiresorptive compared to anabolic agents and the impact of administration of these medications before or after fusion surgery.[578]

The mechanical stability of the graft site is generally a factor that the surgeon can control. Solid internal fixation increases the chances of achieving a successful fusion. The anatomic site, patient's weight, patient's activity level, and use of external immobilization are additional variables. The generally higher union rates seen in patients with spinal muscular atrophy[580] and Duchenne muscular dystrophy[581,582] may be the result of decreased voluntary motion and improved local mechanics despite the presence of osteopenia.

Local tumor invasion can replace normal marrow and weaken bone, and it may directly invade the fusion site. These problems may be partly overcome by the use of special fixation techniques[583] and adjuvant radiation and chemotherapy depending on the individual tumor. Use of autologous bone or bone marrow is desirable, but harvest must be performed in a separate surgical field to prevent tumor seeding in the donor site.

Marrow-packing disorders, such as thalassemia major, may decrease the osteogenic potential of marrow by overgrowth of normal marrow cells, altering the marrow growth factor environment and/or crowding out osteogenic stem cells. Similarly, local bone disease, such as Paget disease or fibrous dysplasia, can replace the population of normal osteogenic cells with abnormal cells, preventing or eroding into a successful fusion mass.

Radiation is an adverse factor for bone healing, especially when administered perioperatively. This may be a function of its direct cytotoxic effects on proliferating cells or the intense vasculitis induced by radiation injury. Long after the acute phase, radiation-induced osteonecrosis and the dense hypovascular scar left in the radiation bed may leave a poor environment for fusion. In some cases, therefore, it may be advantageous to use free vascularized grafts and donor vessels outside the area of previous radiation to enhance the vascular supply of local tissues and the likelihood of a successful fusion. Emery et al.[584–586] have shown that the timing of radiation after a spine fusion procedure has a significant effect on outcome and that radiation has the least adverse effect if given at least 3 weeks after grafting. Radiation was best timed to be performed either preoperatively or in the late postoperative period, avoiding the early postoperative period when vascular invasion of the graft site and proliferating osteogenic progenitors would be most vulnerable. Settings of marrow replacement or regional scarring secondary to radiation or other causes are perhaps most likely to benefit from methods designed to supplement or replace the local population of osteogenic cells. However, their value is as yet unproven in clinical trials.

Ma et al.[587] reported on a series of 22 consecutive patients with giant cell tumor of the cervical spine. Of these, 18 received postoperative radiation therapy 4 to 6 weeks following either subtotal resection or en bloc resection with total spondylectomy, with reconstruction with titanium plate and titanium mesh with autogenous bone graft for anterior reconstruction and pedicle screw placement for posterior reconstruction. While the authors caution that radiation myelopathy and radiation-induced sarcoma remain legitimate clinical concerns in any patients undergoing radiation therapy of the spine, their patients in this series experienced neither of these complications (with a follow-up period ranging from 36 to 124 months).

Electrical stimulation has been shown to be of potential benefit in the treatment of nonunions,[588,589] failed arthrodeses,[590–592] and congenital pseudarthroses,[590] consistent with spinal fusions in animal models.[593–595] Nonetheless, firm conclusions about efficacy are difficult to establish because of inconsistencies in both determining a reliable, reproducible endpoint for fusion and in incorporating the effect of patient parameters.[596]

Several of these clinical studies have been small series, often without a randomized control population.[594,597–599] A recent double-blind clinical trial in 201 evaluable patients found a benefit of electrical stimulation following uninstrumented posterolateral lumbar fusions but only in women.[600] Another randomized trial in 179 patients with both instrumented and uninstrumented posterolateral fusions found a union score of 85% among treated patients compared with

65% in placebo controls.[601] Application of extracorporeal shock wave treatment to enhance spinal fusion is another promising technique.[602,603]

Future Considerations

Advances that have already been made in the strategies and graft materials available for spinal fusion in the past several years have not yet eliminated the need for harvest of cortical or cancellous bone autografts, sparing patients the significant morbidity and cost of these procedures and their complications.

The potential for further advancement in the area of spinal fusion and tissue repair and regeneration in the spine is tremendous. Advances in stem cell biology, biomaterials, manufacture and purification of growth factors and other biomolecules, and the delivery of these agents is proceeding rapidly. In addition, methods for clinical evaluation and surgical and anesthetic techniques will offer surgeons and patients ever increasing reliable options, safer methods, and potentially entirely new strategies for repair and regeneration of bone and other tissues in the spine.

The clinically effective preparations of purified recombinantly manufactured protein growth factors are available. However, the efficacy and risks of these agents vary significantly with dose, carrier, and anatomic site. Clinical trials to date demonstrate clinical efficacy only for the limited indication of interbody lumbar fusion instrumented using a cage and, even then, only in carefully selected patients. Prudence and caution are indicated until additional data become available demonstrating that these materials or future materials will be effective in other settings and in less selected populations to minimize the chance of exposing patients to potentially ineffective treatment without the benefit of systematic controls or means of generalizable analysis.

Optimizing the use of current and future grafting materials will increasingly require a detailed understanding of the cell biology, materials science, and engineering principles upon which tissue engineering strategies are based.[15,60,62,63,205,415,604] Central to this process is the recognition that stem cell and progenitor populations that are capable of proliferating and differentiating to form new tissues are the direct or indirect target cells for all implantable osteoconductive biomaterials, all bioactive or osteoinductive proteins, and all methods for biophysical physical intervention (i.e., mechanical or electrical stimulation).

Future strategies will use the rapidly evolving knowledge and capabilities of many converging fields. We will design more efficient, more effective, and less invasive methods for surgical exposure, manipulation, and mechanical control over spinal segments and tissues. We will define methods to characterize and optimize the stem cell and progenitor populations in our spinal fusion sites, especially in settings where these essential target cells may be deficient in number or biologic potential. This will include the harvest, concentration, selection, and transplantation of osteogenic stem and progenitor cells when needed. We will develop more efficient and more effective methods for delivery of bioactive factors to responsive target cells. Finally, advances in biomaterials will also allow us to design and provide a milieu in which the conditions necessary for the activation, migration, proliferation, differentiation, and survival of osteogenic cells (and other cells that are essential to the bone healing response) can be customized to the unique biologic situation presented by each clinical setting and each graft site.

KEY POINTS

1. Graft site preparation is of paramount importance in fusion procedures regardless of whether or not biologics are used. Care needs to be taken to ensure that all of the soft tissues have been removed and that the bone surfaces are decorticated.
2. Host factors—such as diabetes, immunosuppression, nutritional depletion, and tobacco—play an important role in bone fusion; effort should be made to optimize reversible factors before undergoing elective spinal procedures.
3. Knowledge of the cell biology of spinal fusion and the attributes and synergies of available materials for bone grafting as well as clinical literature is essential for optimal selection of surgical techniques and graft materials.
4. BMP-2 is a powerful and potentially effective agent in enhancing bone regeneration. However, use of BMP-2 must be balanced by increased awareness of potential adverse effects and cost.

   Aspirates were obtained from two depths within the vertebral body and were quantified relative to matched, bilateral aspirates from the iliac crest that were obtained from the same patient at the same time and served as a control. Aspirates of vertebral marrow demonstrated comparable or greater concentrations of progenitor cells compared with matched controls from the iliac crest. The authors concluded that the vertebral body is a suitable site for aspiration of bone marrow for graft augmentation during spinal arthrodesis.
2. Vaccaro AR, Whang PG, Patel T, et al. The safety and efficacy of OP-1 (rhBMP-7) as a replacement for iliac crest autograft for posterolateral lumbar arthrodesis: minimum 4-year follow-up of a pilot study. *Spine J*. 2008;8:457-465.
   Thirty-six patients undergoing decompressive laminectomy and single-level uninstrumented fusion for degenerative spondylolisthesis and symptomatic spinal stenosis were randomized in a 2:1 fashion to receive either OP-1 Putty (24 patients) or autogenous iliac crest bone graft (12 patients). At the 48-month time point, complete radiographic and clinical data were available for 22 of 36 patients (16 OP-1 Putty and six autograft) and 25 of 36 patients (18 OP-1 Putty and seven autograft), respectively. Radiographic evidence of a solid arthrodesis was present in 11 of 16 OP-1 Putty patients (68.8%) and 3 of 6 autograft patients (50%). Clinically successful outcomes defined as at least a 20% improvement in preoperative Oswestry scores were experienced by 14 of 19 OP-1 Putty patients (73.7%) and 4 of 7 autograft patients (57.1%); these clinical findings were corroborated by similar increases in SF-36 scores. The respective overall success rates of the OP-1 Putty and autograft group were 62.5% and 33.3%. In this study, there were no incidents of local or systemic toxicity, ectopic bone production, or other adverse events directly related to the use of OP-1 Putty.

3. Shields LB, Raque GH, Glassman SD, et al. Adverse effects associated with high-dose recombinant human bone morphogenetic protein-2 use in anterior cervical spine fusion. *Spine*. 2006;31:542-547.
The authors reviewed 151 patients who underwent either anterior cervical discectomy and fusion (n = 138) or anterior cervical vertebrectomy and fusion (n = 13) augmented with high-dose INFUSE. They found a high morbidity rate with a total of 35 (23.2%) patients having complications that the authors thought were attributable to the use of high-dose INFUSE in the cervical spine. Fifteen patients were diagnosed with a hematoma, including 11 on postoperative day 4 or 5, eight of whom were surgically evacuated. Thirteen individuals had either a prolonged hospital stay (>48 hours) or hospital readmission because of swallowing/breathing difficulties or dramatic swelling without hematoma. The authors concluded that putative inflammatory effect that contributes to the effectiveness of INFUSE in inducing fusion may spread to adjacent critical structures and lead to increased postoperative morbidity.

This review highlights the current state of cell-based tissue engineering and the central engineering principles and strategies involved in the design and use of cell-based tools and strategies, particularly the challenges of mass transport and the influence of cell biology on the design and development of biologic osteoconductive scaffold materials.

5. Burkus JK, Gornet MF, Dickman CA, et al. Anterior lumbar interbody fusion using rhBMP-2 with tapered interbody cages. *J Spinal Disord Tech*. 2002;15:337-349.
The authors presented results of a multicenter, prospective, randomized, nonblinded study of patients with degenerative lumbar disc disease undergoing interbody fusion using two tapered, threaded fusion cages. The investigational group (143 patients) received rhBMP-2 on an absorbable collagen sponge. A control group (136 patients) received autogenous iliac crest bone grafts. At 24 months the BMP-2 group's fusion rate was 94.5% and the control group's was 88.7%.

67 CHAPTER Bone Substitutes: Basic Science and Clinical Applications

Jeffrey C. Wang
Zorica Buser

Spine disorders are one of the most common medical problems worldwide, with low back and cervical pain being among the top contributors to high disability rates.[1] Choosing the right treatment is very challenging due to the complexity of degenerative changes, patient comorbidities, and psychosocial factors. Spinal fusion is a common treatment for various conditions, including deformity, trauma, and degenerative disc disease with instability. Nonetheless, significant rates of pseudarthrosis (up to 26%) have been reported in the literature.[2] Advances in surgical techniques and instrumentation, a variety of biologics, and better knowledge of fusion biology have increased fusion rates, but symptomatic pseudarthrosis still occurs in 10% to 15% of cases.[3–7] Nonunion may result in poor clinical outcomes and extensive medical expenditure. New bone formation is essential to arthrodesis of the spine and is heavily influenced by the local bone environment and grafting substitutes.

Successful grafting materials require three essential components: an osteogenic potential capable of directly providing mature osteoblasts and stem cells that will drive new bone formation, osteoinductive factors that are able to signal the osteoblastic differentiation of osteoprogenitor stem cells, and an osteoconductive scaffold that assists neovascularization and supports the ingrowth of bone. In addition to these properties, the ideal bone substitute should be without risks of disease transmission. Autologous bone grafts are the only grafting materials that possess all three properties; they can provide immediate and long-term mechanical stability, and are therefore considered the standard. Autogenous grafts can be divided into two groups: local bone (laminae, spinous processes, or facet joints) and extraspinal material (iliac crest bone graft [ICBG]). Local bone is a cortical bone graft in which cell migration is decreased due to small pore size. ICBG, on the other hand, is cancellous bone that provides a great environment for rapid new bone formation but lacks the ability to withstand compressive loading. Both grafting materials have similar fusion rates in single-level fusions; however, it has been shown that ICBG outperforms local autograft for multilevel fusions.[8] The main challenges with both grafting materials are bone quality, particularly in older patients, and the amount of autograft needed for long-segment fusions or revision surgeries. Furthermore, ICBG harvesting is associated with considerable donor site morbidity, increased operative time, and increased blood loss.[9] Up to 30% of all patients undergoing the harvesting of ICBG will experience significant postoperative pain or complications including infection, hematoma, nerve or vascular injury, fracture, persistent pain, abdominal herniation, or pelvic instability.[4,5,10–23] Some older studies report autologous bone graft harvest to be associated with major complications in 8.6% of patients and minor complications in 20.6%.[19] For these reasons, other grafting materials were developed to augment, expand, or substitute for autogenous bone grafts.

In order to avoid morbidity associated with harvesting autogenous graft and to optimize bone formation for fusion, several classes of bone substitutes have been developed. These include allografts, ceramics, demineralized bone matrices (DBMs), osteoinductive factors and bone marrow aspirates (BMAs), autogenous platelet concentrate, mesenchymal stem cells, and gene therapy (Table 67.1). Although bone substitutes do not provide the same osteogenic, osteoinductive, and osteoconductive properties as autografts, various grafting materials have demonstrated efficiency for bone formation in basic science and clinical studies. Furthermore, advances in the understanding of bone remodeling, the development of osteoinductive proteins and small molecules, and the synthesis of new osteoconductive carriers hold a promising future for biologic treatments of spinal conditions.

Allografts

Allografts are composed of cadaveric bone and have been employed traditionally as bone graft extenders. Allografts have good osteoconductive and minimal osteoinductive properties; however, they lack growth factors and osteogenic cells due to the processing that they undergo in order to decrease their antigenicity. Allograft bone may be applied to the graft bed in a crushed particulate form or can be formulated to create structural spacers. Cortical allografts offer substantial structural

stability and are best suited for interbody arthrodesis but suffer from increased graft resorption and slow bone remodeling. Corticocancellous allografts initially impart little mechanical support to the fusion site but, because of its relatively large surface area, are integrated more rapidly than cortical bone.[24,25] Genetic incompatibility between donor and recipient has been found to be associated with increased resorption of the allograft and histologic evidence of rejection.[26]

After the harvest, allograft bone undergoes debridement of soft tissue, removal of bacteria and viruses, and antibiotic bath. Preservation is achieved through freezing or freeze-drying in order to decrease its antigenicity and permit storage for extended periods of time.[27] Frozen allografts may be stored for up to 1 year. Freeze-drying reduces immunogenicity even more than freezing, but on rehydration, these grafts may lose up to 50% of their mechanical strength.[28] Other sterilization techniques, such as ethylene oxide or irradiation, may compromise the material properties and osteoinductive capacity or leave toxic residues behind.

Disease transmission is one of the main concerns with allografts, particularly viral diseases, such as human immunodeficiency virus and hepatitis. Nevertheless, there have been only two documented cases of human immunodeficiency virus transmission from allograft bone, both of which involved unprocessed grafts.[29] The combination of rigorous donor screening and tissue processing has lowered the risk of infection to less than one per million transplants.[30] A retrospective review of US Food and Drug Administration (FDA) data from 1994 to July 2007 found that 96.5% of all recalled allografts were musculoskeletal. Most were recalled between 2006 and 2007 because of improper donor evaluation.[31] Other complications observed after the implantation of structural allografts include nonunion and fracture of the graft due to the slower rates of incorporation.[32,33]

Structural allografts have been used extensively for anterior cervical discectomy and fusion (ACDF). Studies evaluating patients undergoing single-level ACDF with either allograft or autogenous bone have demonstrated similar fusion rates.[34,35] Furthermore, Jagannathan and colleagues reported 94% fusion rates for single-level ACDF with freeze-dried cortical allograft without plate fixation or postoperative rigid cervical collar.[35a] For two-level ACDFs, several studies reported higher fusion and lower nonunion rates with autografts compared to allografts.[36,37] Advances in plate fixation have increased the fusion rates in both single-level and multilevel ACDFs. Samartzis et al. noted similar fusion rates between allografts (94.3%) and autografts (100%) in two- and three-level ACDFs.[38]

In the posterior lumbar spine, autogenous bone graft appears to be superior to allograft for promoting posterolateral arthrodesis. Jorgenson and colleagues[39] conducted a prospective analysis of autografts versus allografts in posterolateral lumbar fusion in the same patient and concluded that ethylene oxide–treated allograft is inferior to autograft and should not be used for posterior lumbar fusions. Another prospective study of adult posterolateral lumbar spinal fusion reported that autografts alone or combined with allograft resulted in solid fusion in 80% and 50% of the cases, respectively. Freeze-dried allograft produced no solid fusions, and frozen allograft led to partial fusion in only 40% of the cases.[40] While allografts alone were not able to achieve a sufficient fusion rate for posterior spinal fusion, they contributed to solid fusion as bone extenders in adolescent idiopathic scoliosis. Jones and colleagues conducted a retrospective review of long-segment spinal fusion with cancellous freeze-dried allograft in patients with pediatric idiopathic scoliosis. They reported a 92.7% fusion rate and an average of 3.4 degrees of loss of curve correction at 39 months' follow-up.[41] A multicenter retrospective study with 111 patients undergoing spinal fusion for adolescent idiopathic scoliosis reported a 2.7% pseudarthrosis rate and 5.9 degrees loss of correction when freeze-dried allograft and autograft were used together.[42]

Additional studies have reported excellent outcomes with the use of femoral ring allografts in the anterior lumbar spine,

with freeze-dried allografts having higher risk of nonunion compared to frozen allograft.[43–45] In cases involving revision anterior lumbar fusions, one study found that the results obtained with tricortical allograft may be comparable with those obtained with autogenous bone graft taken from the iliac crest.[46] Overall, these studies suggest that allografts may be efficacious alone or as graft extenders in anterior cervical and lumbar fusions and in patients with scoliosis deformities.

Ceramics

Ceramics are osteoconductive bone substitutes without cells and growth factors.[47] The most commonly used ceramic scaffolds for spinal fusion are calcium sulfates, silicate-substituted calcium phosphate, calcium phosphates (hydroxyapatite [HA], β-tricalcium phosphate [β-TCP]), or a combination of these materials. Ceramics are favorable bone substitutes because they are biodegradable, nontoxic, nonimmunogenic, easy to sterilize, and available in virtually unlimited supply without donor site morbidity or infection risk. The bioresorbability of a ceramic is influenced by the shape, density, and chemical composition of the material. HA is a relatively inert substance that is retained in vivo for prolonged periods of time, whereas the more porous tricalcium phosphate typically biodegrades in about 6 weeks.[48] When loaded with a source of osteogenic cells, such as autogenous bone or bone marrow, ceramic scaffolds assist cellular adhesion, support vascular ingrowth, and promote new bone formation.[49] Disadvantages of ceramic structures are their brittle structure and reduced shear strength and resistance to fracture. Because they offer minimal mechanical stability in the immediate postoperative period, ceramics are commonly used in conjunction with rigid internal fixation and must be protected from loading forces until they are incorporated into the surrounding bone.

With rigid instrumentation, several studies have reported that ceramic scaffolds are efficient bone graft extenders when used with the local bone in posterolateral spinal fusion.[50–52] In a prospective single-center study, patients underwent posterior lumbar interbody fusion (PLIF) or posterior lumbar fusion (PLF) with laminectomized bone chips and HA or ICBG.[53] At 12 months, the fusion rates were 86.7% in the HA group and 88.9% in the autograft group, with the average fusion mass volume being greater in the HA/local graft group. In a prospective PLF study done by Korovessis et al.,[54] patients were divided into three groups based on the grafting material: ICBG bilaterally, ICBG on one side and HA plus BMA and local autograft on the other side, and HA plus BMA plus local bone bilaterally. Solid intertransverse and posterior fusion was observed only in the ICBG group, deeming HA inappropriate as a stand-alone grafting material. Similar results were reported by Thalgott and colleagues,[55–57] who retrospectively evaluated the efficacy of coralline HA as a bone replacement in anterior interbody fusion in both the cervical and lumbar spine. Yoshii et al.[57a] reported positive results for HA as bone extender in ACDF. HA and percutaneously harvested trephine chips led to similar fusion rates as ICBG, had lower blood loss, and no donor site complications or fragmentation of the HA graft.

On the other hand, successful results have been reported for the implantation of ceramic scaffolds for posterior spinal fusion in scoliosis cases, which require extensive bone graft.[58–60] Ransford and colleagues[59] conducted a prospective randomized study to evaluate the use of a synthetic porous ceramic as a bone graft substitute in posterior spinal fusion for idiopathic scoliosis; they concluded that porous ceramic is a safe and effective bone substitute. Lerner and coworkers reported similar results with the use of β-TCP as a local bone extender in the posterior correction of adult idiopathic scoliosis.[60] They reported loss of correction for the β-TCP group of 2.6 degrees compared to 4.2 degrees in the ICBG group. Furthermore, β-TCP was shown to be a good bone extender in posterior lumbar fusion, achieving 100% fusion rates, as with ICBG at a 3-year follow-up.[61]

Calcium sulfate is another synthetic graft substitute. It was initially used as filler for traumatic bone defects or as an antibiotic carrier. It has been linked to increased wound and infection rates, however.[62] Furthermore, Niu et al. reported low fusion rates in patients on the side treated with calcium sulfate and BMA (41%) compared to the side treated with ICBG (91%).[63] Silicate-substituted calcium phosphate (SiCaP) has been shown to contain some osteogenic properties in addition to osteoconduction. However, data on the success of SiCaP in fusion is inconclusive. In a randomized clinical trial, SiCaP led to 100% fusion rates in patients undergoing PLIF for degenerative disc disease. The authors also reported that patients with SiCaP showed reduced back pain at 6 weeks and better quality-of-life measurements at 6 months compared to a recombinant human bone morphogenetic protein 2 (rhBMP2) group.[64] On the other hand, Nandyala and colleagues reported poor outcomes with SiCaP in minimally invasive transforaminal lumbar interbody fusion (TLIF). They recorded lower fusion rates (65%) and higher pseudarthosis rates (35%) with SiCaP when compared to rhBMP2.[65]

Ceramic carriers may also function as effective vehicles for the delivery of osteoinductive growth factors.

Demineralized Bone Matrices

DBMs are derived from allograft bone by removing the mineralized component and antigenic markers, thereby reducing its immunogenicity. DBMs have osteoconductive and some osteoinductive properties. The osteoconductive matrix consists of type I collagen, glycoproteins, calcium sulfate, and debris. The osteoinductive properties of DBMs were first recognized by Urist[66] in 1965, when he reported that the introduction of decalcified bone brought about the formation of heterotopic bone in rodents. The bone morphogenetic proteins (BMPs) represent less than 0.1% of all bone proteins by weight,[67] but these growth factors are essential to the process of osteoinduction, initiating a cascade of cellular events leading to bone formation. Other growth factors include bone sialoprotein, osteopontin, transforming growth factor-β (TGF-β), and insulin-like growth factor-1.[68] With aging, the levels of BMPs decrease; however, TGF-β and insulin-like growth factor-1 levels are not affected and extend

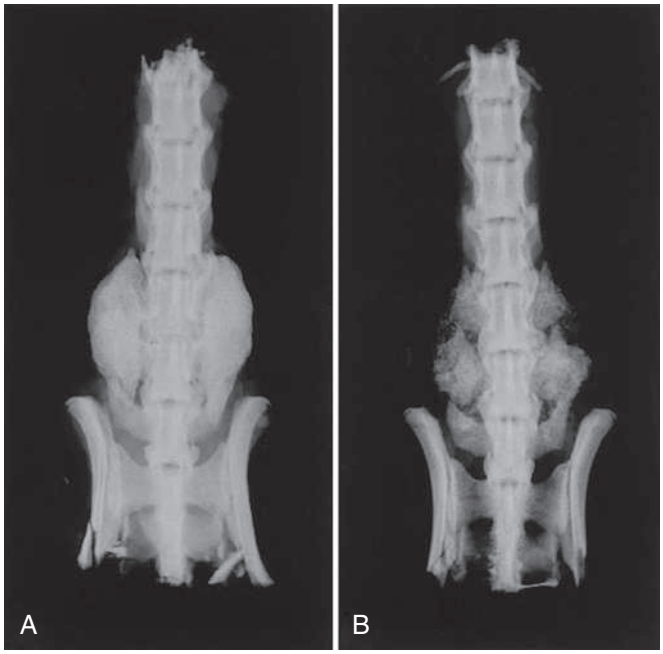

FIG. 67.1 Demineralized bone matrix (DBM) preparations possess variable osteoinductive activities. (A) Implantation of DBM induces an intertransverse spinal fusion in a rat model. (B) Implantation of another DBM does not result in a solid fusion, suggesting that there are significant differences in the osteoinductive potentials of commercially available DBM products.

osteoinduction via interaction with BMP proteins.[69] Commercially available DBMs have demonstrated marked variability in osteoinductive potential that may reflect differences in their BMP content in rat spinal fusion models (Fig. 67.1).[70–72]

Rabbit, dog, and nonhuman primate models of posterolateral spinal fusion have demonstrated good results with DBMs alone or in conjunction with autograft.[73–76] Clinical studies also support the efficacy of DBMs as bone graft extenders for posterolateral spinal fusion.[77,78] A composite consisting of DBM putty and aspirated bone marrow offers similar performance to autograft in posterolateral spinal fusion. A multicenter prospective study that compared the effectiveness of Grafton (Osteotech) DBM gel composite with iliac crest autograft in posterolateral spinal fusion demonstrated that Grafton DBM could extend a volume of autograft that was less than that normally required to achieve a solid spinal fusion.[79] DBM and bone marrow composite has been successful for posterior spinal fusion in scoliosis surgeries as well, and the fusion rates have been reported to be comparable with those of autograft.[80] One case series of anterior lumbar interbody fusions (ALIFs) with DBM composites consisting of titanium mesh cages, coralline HA, and DBM concluded that the DBM composite was effective for anterior interbody fusion of the lumbar spine when used as part of a rigidly instrumented circumferential fusion.[56] On the other hand, An and colleagues[81] prospectively compared the fusion rates of an allograft-DBM composite with autograft in anterior cervical fusion and concluded that the allograft-DBM construct resulted in a higher rate of graft collapse and pseudarthrosis than autograft alone. The low fusion rates reported in that study have prompted surgeons to look for an alternative in DBM delivery. Several studies conducted prospective evaluations of DBM with or without autograft packed into polyether-ether ketone (PEEK) cages.[82,83] Park et al. observed 97% fusion rates in ACDF patients with DBM and local autograft packed in PEEK cages.[82] Moon and colleagues reported fusion in 77.8% of patients at a mean 25.5-months' follow-up in two-level ACDFs with PEEK cages packed with Grafton DBM without plate fixation. Regional alignment and cervical global alignment were improved postoperatively; however, 84% of the patients had some subsidence of the cages.[83]

In a direct comparison of multiple formulations of the same DBM, the putty and flexible sheet forms enhanced spinal fusion to a greater extent than a gel, most likely because the former are fiber-based preparations and exhibit improved handling characteristics over the gel form.[84] Apart from bone extenders, DBM was tested as a delivery vehicle for growth factors, cells, and antibiotics. In a rat PLF model, DBM with adenovirus carrying a *Nell-1* gene was implanted at L4–L5; at 6 weeks postoperatively, micro-CT demonstrated a 70% fusion rate.[85] High doses of Grafton DBM had a nephrotoxic effect in a rat model but not in human studies.[86]

Osteoinductive Growth Factors

Numerous growth factors capable of signaling cell-surface receptors and directing cellular activities are involved in the regeneration of bone tissue. In 1965, Urist[66] first observed that DBM possessed osteoinductive ability; subsequently, the osteoinductive BMPs were isolated and characterized. BMPs are members of the TGF-β superfamily. By binding to specific receptors present on the surface of the osteogenic progenitor, intracellular cascades that recapitulate endochondral ossification are activated. BMPs also stimulate mesenchymal stem cells to differentiate. Initially, BMPs were extracted from large amounts of bone: 10 kg of cortical bone yielded less than 20 g of osteoinductive protein.[87] In addition, these crude preparations contained a heterogeneous collection of growth factors, including several different types of BMPs, as well as other biologically inactive proteins.

With advantages in molecular biology, the genes encoding the BMP proteins were sequenced and subsequently cloned (recombinant DNA), allowing for the mass production of single BMPs, including BMP-2 and BMP-7 (also known as osteogenic protein-1 [OP-1]).[88] Because they are available in almost unlimited quantities, BMP-2 and BMP-7 have become the most widely used recombinant BMPs for animal studies and are the only BMPs currently being evaluated in human clinical trials. In contrast to purified extracts, recombinant growth factors are free of impurities and do not elicit a host immune response. Recombinant human BMPs (rhBMPs) are soluble factors that tend to diffuse away from the fusion site when used alone, resulting in attenuation of their osteoinductive capacity. For this reason, before implantation, these factors are combined with a carrier matrix that serves to restrict their movement, confine them to the location where they are needed, and allow them to release consistently over

time. Current osteoinductive carriers used to deliver rhBMPs include autogenous bone graft, DBMs, collagen, ceramics, and polylactic acid.[88–100] Depending on the specific clinical application and the location into which the growth factors will be introduced, some carriers might be superior to others. Minamide et al. demonstrated in their rabbit lumbar fusion model that rhBMP-2 delivered onto bone cement coated with type I collagen had better fusion rates and more mature bone with higher tensile strength and stiffness than rhBMP-2 delivered onto a type I collagen sheet.[101] Multiple animal studies, many of which were performed in nonhuman primates, have established that the implantation of BMP-2 and BMP-7 in the posterior spine results in fusion rates equivalent to or superior to those obtained with autogenous bone graft. Furthermore, they may generate fusion masses with improved biomechanical properties that may obviate the need for decortication of the posterior elements, a procedure that is normally required to provide endogenous growth factors that are essential for successful posterolateral spine arthrodesis.[102] Boden and colleagues[103] conducted one of the first prospective randomized clinical pilot studies on the use of rhBMP-2 for posterolateral fusion in humans. In that study, the authors randomly divided the enrolled patients into three treatment groups, as follows: autograft with instrumentation, rhBMP-2/ceramic granules with instrumentation, and rhBMP-2/ceramic granules without instrumentation. They reported that the fusion rate of the rhBMP-2/ceramic granules without instrumentation group was 100%, which was superior to the autograft with instrumentation group (40%).[103] Following this pilot study, Dimar and colleagues[104] conducted a prospective randomized study comparing the use of ICBG to rhBMP-2 combined with a carrier (bovine collagen and tricalcium/HA) for single-level posterolateral fusions. Those authors reported that the rhBMP-2 group demonstrated increased fusion rates (91%) as compared with the autograft group (73%).[104] In another study, Boden and colleagues[105] described the human pilot trial of the use of rhBMP-2/collagen inside lumbar interbody spinal fusion cages. Although the number of patients enrolled in that study was small, they reported at the 2-year follow-up that fusion occurred more reliably in patients treated with rhBMP-2-filled cages than in controls treated with autogenous bone graft.[105] Burkus and colleagues also conducted a prospective study on the use of rhBMP-2/collagen sponge with allograft dowels or tapered cylindrical fusion devices in ALIF and concluded that the use of those rhBMP-2 composites showed promise in assisting anterior intervertebral spinal fusion.[106–108] Slosar and colleagues,[109] in a prospective study on ALIFs, compared patients treated with allografts, either with or without the addition of rhBMP-2, with posterior instrumentation and demonstrated excellent results with the use of rhBMP-2. These reports supported the use of rhBMP-2 for ALIF and contributed to approval by the FDA in 2002. Because of its high fusion rates in ALIF, rhBMP-2 use was extended "off-label" to PLIF, TLIF, and cervical fusion. An increase in the number of procedures with rhBMP-2 has generated a large body of literature on adverse events and complications. Resorption of an implanted graft before osteoinduction and interbody fusion occurs was associated with the rhBMP-2 use. McClellan and colleagues[110] retrospectively investigated cases with a TLIF with BMP and reported a high rate of bone resorption, thereby assuming that the osseous remodeling potential of rhBMP-2 may lead to bone resorption within the vertebral body. In another TLIF study, 7.4% of the patients who received rhBMP-2 developed vertebral osteolysis within 4 months postoperatively.[111] Pradhan and colleagues[112] reported that the pseudarthrosis rate among patients who received femoral ring allografts with rhBMP-2 was higher than that in patients who received femoral ring allografts with autogenous iliac bone. They concluded that this appeared to be caused by the aggressive resorptive phase of allograft incorporation, which occurs before the osteoinduction phase.[112] These results suggested that caution must be exercised in deciding between autograft and rhBMP-2 for anterior lumbar interbody fusion and that further clinical studies were warranted. In a canine lumbar spine fusion model, the placement of OP-1 (BMP-7) over a dural tear stimulated new bone formation in the subarachnoid space, resulting in mild spinal stenosis at the site of dural decompression.[113] Several other rhBMP-2 complications have been documented in the lumbar spine including heterotopic/ectopic bone formation, radiculitis, and wound infections.[114–117] In a minimally invasive TLIF and PLIF study, 21% of the patients with rhBMP-2 presented with heterotopic bone formation; however, they were not associated with any further adverse events.[116] The rate of radiculitis in patients undergoing minimally invasive TLIF with rhBMP-2 was 11% within the first few days postoperatively.[117] Vaccaro and coworkers reported wound infections in 4 out of 24 patients (16.7%) who had single-level uninstrumented fusion with OP-1.[118] A recent meta-analysis reported that the overall data on the benefits and harms of BMP are underreported and often industry biased, making their accuracy inconclusive.[119,120]

It appears that the osteoinductive activity of the BMPs may compensate for the inhibitory effects of nicotine and nonsteroidal antiinflammatory drugs, two agents implicated in hindering spinal fusion in humans.[121–124] As noted previously, recombinant growth factors have been used in conjunction with intervertebral fusion devices in an attempt to achieve arthrodesis of the anterior spinal column. Titanium cages or cortical allograft dowels loaded with rhBMPs proved to be more efficacious than similar devices carrying autogenous bone for stimulating interbody fusion in a number of different animal models, a finding that was consistent whether these composite grafts were implanted in the cervical, thoracic, or lumbar spine.[123–125] These encouraging results were corroborated by a prospective, randomized clinical trial in which patients with degenerative disc disease limited to a single level of the lumbar spine were treated with a threaded cylindrical cage filled with either rhBMP-2 protein or autograft.[126] After 24 months, all 11 patients who had received rhBMP-2 exhibited radiographic evidence of solid fusion, compared with only two of the three control patients who were implanted with interbody devices containing their own iliac crest bone. Patients in the rhBMP-2 group initially experienced a more rapid resolution of their original symptoms, although at 6 months both groups demonstrated similar levels of clinical improvement. In addition, no complications were reported

with the use of rhBMP-2. These studies have confirmed that partially purified BMP extracts and recombinant growth factors are able to induce spinal fusion in animals and humans. In all of these studies, however, the concentration of BMP necessary to bring about adequate bone formation in this environment was several magnitudes of order greater than normal physiologic levels, an observation that raised potential safety concerns. Furthermore, a recent meta-analysis summarized rhBMP-2 concentrations for various spinal procedures, and found poor study quality and large discrepancies in BMP doses within each procedure.[127]

In contrast to anterior lumbar fusion, there are studies that caution against the use of high-dose rhBMP-2 for cervical anterior spinal fusion. Shields and colleagues[128] reported a retrospective review of patients who underwent anterior cervical fusion using high-dose rhBMP-2/collagen sponge. The authors reported that 23.2% of patients suffered complications, such as hematomas, dysphagia, and excessive edema. Vaidya and colleagues[129] also reported that complications were associated with anterior cervical spinal fusion using rhBMP-2, including dysphagia, which was shown to be significantly more frequent and more severe in patients in whom rhBMP-2 was used. As a consequence, in July 2009, the FDA issued a Public Health Notification citing serious adverse effects with use of BMP in the cervical spine. Several systematic reviews looked at rhBMP-2 complications in the cervical spine. Tannoury and colleagues reported that the most common complications were dysphagia and neck swelling, hematoma, vertebral edema, osteolysis, and wound infections.[114] In order to minimize the quantities of BMP required for a successful fusion and outcome, it will be important to establish the appropriate dose for each spinal application and develop efficient carrier systems to deliver these osteoinductive factors.

New adjuvant agents such as bone morphogenetic binding peptide (BBP), which may enhance the efficiency of BMP, are under investigation in animal and in vitro studies. BBP is a BMP-specific binding protein that was isolated on the basis of the early work of Urist. BBP binds rhBMP-2 with an intermediate affinity, which makes it an ideal "slow release" agent.[129] As such, BBP may reduce the time to fusion and more thoroughly control the distribution of bone healing in spinal fusion.

Autologous Platelet Concentrate

Platelet degranulation is part of the normal cascade of bone healing with release of several growth factors, such as platelet-derived growth factor and TGF-β. These growth factors promote chemotaxis and proliferation of mesenchymal stem cells and osteoblasts and enhance bone healing.[130,131] By concentrating these platelet factors as autologous growth factor (AGF) concentrate, one may enhance the formation of new bone in lumbar spinal fusion when used in combination with autografts.[132] In the autologous platelet gel systems currently in development, platelet-rich plasma is separated from a sample of the patient's blood and concentrated in a fibrinogen matrix. This fibrinogen preparation is combined with thrombin, forming a fibrin clot that can be administered with an osteoconductive scaffold or a source of osteogenic cells to form a composite bone graft. However, AGFs have several disadvantages: blood draw, platelet processing, and longer surgery time. Recently, several reports have addressed in detail the efficacy of AGF for spinal fusion.[133–136] Weiner and colleagues[134] retrospectively compared autograft alone with an autograft with AGF in posterolateral spinal fusion; the authors reported that the use of AGF resulted in inferior rates of fusion compared with those of autograft alone. Hee and colleagues[135] conducted a prospective study on AGF in instrumented TLIF and concluded that the use of AGF in TLIF procedures did not increase overall fusion rates, although it might promote a faster rate of fusion. Carreon and colleagues[136] retrospectively investigated the effectiveness of platelet gel in instrumented posterolateral fusion and reported that platelet gel failed to enhance the fusion rate when added to autograft. On the other hand, Jenis et al. reported similar fusion rates between ICBG (85%) and autograft supplemented with AGF (89%) in one- or two-level lumbar interbody fusion with posterior fixation.[137] In current systems, autologous platelet concentrate has not been conclusively shown to enhance fusion; thus, further investigation may be warranted.

Mesenchymal Stem Cells

Mesenchymal stem cells (MSCs) are self-renewing and pluripotent cells and have been identified in a variety of tissues, including bone marrow,[138] muscle,[139,140] periosteum,[141] and adipose tissue.[142] In a variety of animal models, bone marrow–derived MSCs have demonstrated an efficacy in spinal fusion. Minamide and colleagues[143] cultured MSCs derived from bone marrow and implanted these cells onto the posterolateral lumbar transverse process with an HA-granule carrier in a rabbit model; five of seven rabbits in the high-number cultured cell group were deemed to be fused using manual palpation. The authors demonstrated that these cells acted as a substitute for the autograft in spinal fusion.[140] Using a rhesus monkey model, Wang and colleagues[144] expanded autologous MSCs derived from bone marrow in culture, stimulated them with osteogenic supplements, and constructed calcium phosphate ceramic composites with MSCs. They demonstrated that autologous MSC composites could enhance bone regeneration and achieve osseous spinal fusion in an anterior interbody fusion model. Clinically, Gan and colleagues[145] used bone marrow–derived MSCs combined with porous β-TCP for posterior spinal fusion and reported 95.1% spinal fusion.

Unfractionated bone marrow (BMA) has osteoinductive (growth factors) and some osteogenic potential. The bone marrow of healthy adults contains only one MSC for every 50,000 nucleated cells; this population is even further diminished in older patients and those with metabolic diseases such as osteoporosis.[143–145] Moreover, as bone marrow is aspirated from the iliac crest, it undergoes extensive dilution with peripheral blood, further decreasing the concentration of MSCs. Amplification or concentration of BMA may improve the yield of osteogenic MSCs from bone marrow. BMA is

always combined with a carrier (DBM or collagen I sponge) to supplement mechanical properties. Taghavi and colleagues retrospectively reviewed a cohort of patients undergoing instrumented revision PLF with at least 24 months' follow-up.[146] Patients were divided into three groups: autograft only, BMA and autograft, and rhBMP-2 on a collagen sponge. They found that all grafting options achieved solid single-level fusion (100%). However, the multilevel BMA group had only a 63.6% fusion rate, while the other two groups had 100%. Clinical outcomes in all three groups were similar at 2 years, leading to the conclusion that BMA is a viable option for single-level procedures. Another single-level PLF study showed good fusion rates with BMA and autogenous bone chips (85.7%) similar to ICBG alone (90.5%). However, the calcium sulfate and BMA group had only a 45.5% fusion rate compared to the control side that received ICBG (90.9% fusion).[63] In a systematic review, Khashan et al. reported several PLF studies comparing local bone graft to BMA with various carriers (ceramics, DBM, or collagen). All of them showed similar fusion rates between BMA and ICBG groups, but the overall level of evidence was weak.[147] At the same time, multiple studies have confirmed that the amplification of osteoprogenitor cells that occurs after the culture expansion of MSCs results in greater bone formation than the use of unfractionated bone marrow, which demonstrates a relative paucity of osteogenic cells.[148,149] The introduction of culture-expanded MSCs has also been shown to be superior to bone marrow for eliciting the repair of critical-sized skeletal defects in an animal model.[150] While MSCs can play an important role in replacing the autogenous bone graft for spinal fusion, there are significant limitations, such as in vitro expansion, potential contamination, and revision surgery.

Gene Therapy

Gene therapy involves the delivery of a vector with a specific DNA sequence, or gene, to target cells that subsequently express the therapeutic protein. Recombinant BMPs have been used successfully to stimulate fusion in several clinical trials.[103,105,151–156] The advantages of gene therapy are that it can provide longer release of osteogenic proteins at levels more closely resembling physiologic levels than the administration of a single large dose of recombinant proteins. Delivery vehicles include viral and nonviral vectors that can be delivered in vivo (nonspecific and can elicit host immune response) or ex vivo (transfection of isolated autologous cell). Nonviral vectors are easier to produce, they are more stable, less antigenic, and are theoretically safer than viral vectors. Common nonviral vectors include naked DNA, liposomes, or polyplexes (DNA embedded into lipids or polymers). Nevertheless, viral vectors are often favored over nonviral strategies because of their superior transduction efficiencies. Replication-deficient adenoviral vectors have been successful in animal experiments. Lu and colleagues[85] tested a new osteoinductive factor, Nell-1 (Nel-like molecule-1) with DBM carrier, for in vivo gene therapy in the posterior rat spinal fusion model and reported 70% fusion rates at 6 weeks. However, there are several drawbacks

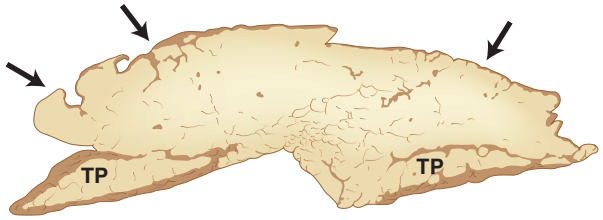

FIG. 67.2 Ex vivo gene therapy using rat bone marrow cells transduced with the bone morphogenic protein-2 gene successfully induces spinal fusion in rats. A sagittal section through the posterolateral spine demonstrates a solid fusion mass (*arrows*) spanning two adjoining transverse processes (TP).

with adenoviral vectors. Although these vectors transfect both dividing and nondividing cells, they cannot integrate into the host genome, thereby limiting protein production to several weeks.[157] Furthermore, adenoviral vectors generally retain their ability to synthesize adenoviral proteins, which stimulate the host immune response.[158,159] Recently, in order to compensate for the disadvantage of adenoviral vectors, various other viral vectors, such as adeno-associated viral vector and lentiviral vector, have been tested[160–162] and improvements have been implemented to ensure safety.[162–164]

Using cells, in particular stem cells, as a delivery vehicle in gene therapy could potentially hold a two-fold benefit for spine fusion by providing both osteogenic and osteoinductive characteristics. This bone grafting technique has been implemented in several animal models for spinal arthrodesis.[161,165–171] Wang and colleagues[168] employed ex vivo gene therapy to promote posterolateral spinal fusions in rats. Rat bone marrow cells transduced with the *BMP-2* gene were combined with a guanidine-extracted DBM and implanted in the posterolateral spine. Treatment with BMP-2-producing marrow cells generated solid fusion masses comparable with those resulting from the use of recombinant BMP-2 protein (Fig. 67.2). Even though high rates of fusion were observed, there are several safety concerns with use of viral vectors in humans. Furthermore, cells have to be isolated, expanded, and successfully transfected. Focusing on one or a combination of two BMPs is only capturing a certain stage of bone remodeling and might not provide long-term results. To overcome some of these obstacles, several studies looked at the markers of early bone pathway. Boden and colleagues[169] achieved single-level posterior fusions of the lumbar and thoracic spines in rats by supplying bone marrow cells with the gene encoding the LIM mineralization protein (LMP-1), a signaling protein that stimulates the expression of multiple osteoinductive growth factors. Consistent fusions were obtained in all of the animals receiving bone marrow cells containing the LMP-1 DNA sequence, whereas no bone formation was observed in those implanted with cells carrying an inactive copy of the gene. Another study on LIM-1 looked at the transfection dose response in vitro and the fusion rates in vivo using buffycoat cells derived from either bone marrow or peripheral blood.[170] After being infected for only 10 minutes with an adenoviral vector bearing the *LIM-1* gene, these cells were placed in the posterolateral spine in conjunction with an osteoconductive

carrier. Radiographic, biomechanical, and histologic findings noted fusion in all of the animals that had been treated with these transduced cells. Although gene therapy has been validated by preclinical studies as an effective technique for enhancing bone formation and may be a viable bone graft substitute for spinal fusion, significant concerns remain regarding its safety in humans, especially the potential risks related to the use of viruses. Although these viruses are unable to replicate, it is still conceivable that they may regain the ability to propagate and trigger an uncontrollable infection. Some viruses insert randomly into the DNA of target cells, raising the possibility of malignant transformation. In addition, the cost-effectiveness of gene transfer methods has not been definitively established. These safety and economic issues may ultimately determine whether gene therapy is viewed as an acceptable alternative to autogenous bone graft for augmenting spinal fusion.

Conclusion

There is a wide array of bone substitutes for spinal fusion. Despite the existing literature on each of those graft substitutes, a strong level of clinical evidence is still absent. Most of the grafting materials do not require FDA approvals and thus lack preclinical research. At the same time, there are ample clinical studies on local autograft, bone morphogenetic proteins, and bone marrow aspirates. Unlike autogenous bone, which remains the gold standard because it contributes osteogenic cells, osteoinductive factors, and an osteoconductive matrix, none of the other individual bone substitutes provides all three components required for bone regeneration. As such, optimal use of bone substitutes may combine several techniques to construct a composite graft with an even greater capacity to enhance spinal arthrodesis. Understanding the biology and specificity of each bone substitute is critical for achieving successful spinal fusion. Expanding the number of clinical studies on each grafting substitute is warranted.

KEY POINTS

1. Bone substitutes can act as graft extenders (combined with autologous bone in order to reduce the amount of needed autograft), enhancers (combined with autograft to enhance fusion), or substitutes.
2. Autogenous bone graft, usually harvested from the iliac crest, is the only graft that possesses all components needed for bone formation: osteoconductive matrix, osteoinductive proteins, and osteogenic cells. The optimal bone substitute may be a composite of materials to share some of these properties.
3. Autogenous bone graft may be limited in quantity, and its harvest is associated with complications.
4. Potential forms of bone substitutes include allograft bone, DBM, ceramics, osteoinductive proteins, autologous platelet concentrate, mesenchymal stem cells, bone marrow aspirates, and gene delivery systems.
5. Each bone graft carries risks and benefits; the right choice strongly depends on the medical condition of the patient and the type of surgery.

CHAPTER 68

Electrical Stimulation for Spinal Fusion

SECTION IX

Ilyas S. Aleem
Paul Glazer
Mohit Bhandari

Achieving a consistently successful fusion continues to be a challenge in spinal surgery.[1] Approximately 25% to 81% of lumbar fusion procedures fail to solidly fuse[2] and may require further operative or nonoperative intervention. Numerous factors affect fusion rates, including patient age, smoking status, medical comorbidities, graft source, and levels of fusion.[3–5] Electrical stimulation is a limited-risk adjunctive therapy that has been advocated to promote spinal fusion. Three types of electrical stimulation are currently employed: direct current (DC), capacitive coupling (CC), and inductive coupling (IC). IC includes the mechanisms of pulsed electromagnetic fields (PEMFs) and combined magnetic fields (CMFs).[6–8] Clinical data have demonstrated an enhancement in bone healing rates with electrical stimulation even before the true mechanisms of action of these technologies were well understood. Recent evidence provides support for the use of electrical stimulation for decreasing pain and radiographic nonunion rates.[9] This chapter reviews the history of electrical stimulation, the types of electrical stimulation and their mechanism of action, and the quality of the evidence behind the use of electrical stimulators for bone healing.

History of Electrical Stimulation

The role of bone electrical potential is increasingly being recognized as an important component in bone healing.[10,11] The earliest use of electrical currents was in 1841, when Hartshorne reported its use on a patient with a tibial nonunion.[12] In 1850, Lente reported successful use of galvanic current in the treatment of patients with delayed union or nonunions.[13] In 1957, Fukada and Yasuda[14] subsequently developed the concept of piezoelectric fields on bone healing, suggesting that electrical potentials of bone are altered in response to compression and tension. The authors reported that the areas of bone under compression were electronegative and those under tension were electropositive. In 1974, Dwyer and Wickham advanced this concept to spinal fusion, first reporting the use of electrical stimulation as an adjunct to lumbar spinal fusion.[15] The mechanism of action of electrical stimulation therapy is not clearly understood but is generally thought to work by stimulating the calcium-calmodulin pathway secondary to the upregulation of bone morphogenetic proteins (BMPs), transforming growth factor-β, and other cytokines.[16–21]

Methods of Electrical Stimulation

Three types of electrical stimulation have received US Food and Drug Administration approval for treating spinal fusions. These technologies include DC electrical stimulation, CC stimulation, and IC stimulation, such as PEMFs and CMFs. DC stimulation requires implantation of the device at the surgical site, whereas IC and CC methods are used noninvasively.

Direct Current Electrical Stimulation

DC stimulation involves the surgical implantation of electrodes connected to a battery. The cathodes are in direct contact with the exposed fusion bed. The cathode's effective stimulation distance is 5 to 8 mm. The batteries deliver a constant DC for a total of 6 to 9 months. The surgical implantation of the device obviates the need for patient compliance. However, there are disadvantages to the placement of the device because the manufacturer recommends removing the battery in 6 to 9 months, which entails a second surgical procedure. Also, there is a rare but reported risk of seeding the battery from systemic infection.

Direct Current Stimulation: Mechanism of Action

DC stimulation enhances the production of a number of osteoinductive factors that are normal regulators of bone matrix formation. This mechanism of action was discovered using Boden's animal model of spinal fusion,[17] which uses a New Zealand White rabbit intertransverse process fusion model for spinal fusion using autogenous bone graft. The model involves a surgical procedure similar to that performed in humans and has a similar nonunion rate to that of autograft.[17] Morone and colleagues[22] studied this model further

and showed that within the developing fusion mass, there is a distinct temporal and anatomic location for the production of BMPs and other factors that are necessary to achieve a solid fusion.

Fredericks and colleagues[23] used this animal model to study the effects of DC on the temporal expression of growth factors in the developing fusion mass. They demonstrated that there was an upregulation in the production of BMP-2, BMP-6, and BMP-7 relative to controls. In addition, the use of DC stimulation avoided the potential complications seen with the application of a single high dose of growth factor to achieve fusion. Complications of ectopic bone formation, bone resorption, or antibody formation against the single growth factor have been reported with the application of a single growth factor.[23]

The use of DC stimulation creates an electrochemical reaction at the cathode. This creates a faradic reaction, lower oxygen concentration, increased pH, and hydrogen peroxide production. Decreased oxygen concentration has been shown to increase the activity of osteoblasts. An increase in local pH decreases the activity of osteoclasts and enhances the activity of osteoblasts. Furthermore, the elevation in pH can stimulate the release of vascular endothelial growth factor (VEGF) from local macrophages. VEGF has been shown to be another factor involved in enhancing vascular ingrowth and stimulating bone formation.

Direct Current Stimulation: Clinical Application

The clinical use of DC current stimulation began as early as 1974 by Dwyer, who demonstrated clinical success in 11 out of 12 patients who received an implanted bone stimulator.[15,24] Kane reported the results of a multicenter trial involving 84 patients who had an implantable DC current stimulator.[25] This group was compared with a historical control group of 159 patients. The experimental group using the DC current stimulator had a higher percentage of patients who had previous surgery and nonunion. Despite this bias favoring the control group, there was a significant increase in successful fusion in the DC-stimulated group: 91% versus 83% in controls. In 1988, Kane published an additional study of "difficult" patients undergoing posterior spinal fusion.[25] These patients were deemed difficult because they (1) had one or more previous failed spinal fusions; (2) had grade II or worse spondylolisthesis; (3) required extensive bone grafting necessary for a multilevel fusion; or (4) had other risk factors, such as obesity. He found that there was a statistically significant improvement in fusion rate of 81% in the electrically stimulated group versus 54% in controls.

In 1994, Meril reported a 93% fusion rate in patients who had undergone anterior lumbar or posterior lumbar interbody fusion with DC current stimulation compared with a 75% fusion rate in the control group.[2] In 1996, Rogozinski published a study that analyzed the use of DC stimulation in patients undergoing posterior lumbar spinal fusion with pedicle screw instrumentation and autograft.[26] The electrical stimulation group had a 96% successful fusion rate as compared with 85% in the control group. The higher rate of fusion in the Rogozinski study as compared with that in the Kane study may be related to the use of spinal instrumentation.

Kucharzyk[27] reported the outcome of a controlled prospective study in a high-risk fusion population. The study involved two groups, each with 65 patients with similar diagnoses. All patients underwent posterolateral fusions with pedicle screw instrumentation and the use of autologous bone graft. They were divided into two groups: those with or without the use of DC electrical stimulation. The average follow-up was 3.8 years. That study reported a 95% successful fusion in the stimulated group versus 79% in the control group.[27]

In 1996, Tejano and colleagues[28] evaluated a series of patients undergoing posterolateral intertransverse process fusion and facet fusions, either as a primary procedure or as a pseudarthrosis repair. They reported a 91.5% fusion rate in the primary surgery group and an 80% fusion in the pseudarthrosis group.

Capacitive Coupling Electrical Stimulation

CC is a noninvasive electrical stimulation technology used to enhance spinal fusions. This device consists of electrodes placed directly on the skin, over the area of the spine undergoing fusion. The pair of external plates produce electric fields when an electric current is applied by the alternating-current signal generator. The device is worn continuously for 6 to 9 months. The success of this technology, however, depends heavily on patient compliance. Brighton first reported CC electrical stimulation to treat recalcitrant nonunions in 1985.[29]

Capacitive Coupling Stimulation: Mechanism of Action

CC perturbs bone cell membrane potentials, which then activate membrane proteins and affect healing. Osteopromotive factors are upregulated by CC electrical stimulation. Using Boden's rabbit model for posterolateral spinal fusions,[17] Fredericks and colleagues[23] found that the normal physiologic expression of the following growth factors is upregulated by CC stimulation: BMP-2, BMP-4, BMP-6, BMP-7, transforming growth factor-β, fibroblast growth factor 2, and VEGF.

Lorich and colleagues[30] studied the response of bone cells to CC. They found that CC stimulation involves transmembrane calcium translocation using voltage-gated calcium channels. This mechanism increased intracellular calcium concentration and calmodulin activation, which has been shown to enhance bone cell proliferation. Zhuang and colleagues[31] further documented that this enhancement of calcium and calmodulin also promotes the synthesis of transforming growth factor-β. Brighton and colleagues[32] studied the signal transduction in electrically stimulated bone cells using CC. These studies demonstrated a dose-response effect, showing increased cell proliferation with longer treatment times.[32]

Capacitive Coupling Stimulation: Clinical Application

Goodwin and colleagues[33] performed a multicenter, randomized double-blind study of CC stimulation. Patients underwent

either anterior interbody or posterolateral lumbar fusions. Clinical and radiographic results were assessed, and CC stimulation had a higher success rate of 84.7% versus 64.9% for the control group, although the surgeries varied in terms of use of instrumentation and type of bone graft material.

Inductive Coupling Electrical Stimulation

IC stimulation includes the mechanism of PEMF and CMF. The PEMF device is a noninvasive technology consisting of external current-carrying coils, driven by a signal generator. The CMF device differs from that of the PEMF device in that it involves a time-varying magnetic field superimposed on a static magnetic field. Bone generates a biphasic electrical potential when stress is applied. These electrical potentials are thought to be the signal for bone degradation and formation. The biochemical pathway mediating the effects of CMF may involve an increase in osteoblast responsiveness to insulin-like growth factor II by modulating receptor availability.

The PEMF coils must be worn across the area of the spinal fusion for approximately 6 to 8 hours daily for 3 to 6 months. Many clinical trials have shown that PEMF devices may help heal nonunions.[34] As with CC stimulation, however, patient compliance is essential.

Pulsed Electromagnetic Fields: Mechanism of Action

The mechanism of action of the PEMF is not well understood and its effect on enhancement of spinal fusion is not as conclusive as with DC electrical stimulation. Several animal studies show no significant differences with PEMF-treated groups and controls. In rabbits, there was an increase in stiffness, area under the load displacement, and load to failure of the fusion mass in the stimulated group versus controls. There are no in vivo animal studies using CMF for spinal fusions.

Clinical Studies of Pulsed Electromagnetic Fields

In one study, 13 patients with documented pseudarthrosis following posterior lumbar interbody fusion procedures achieved fusion after being treated with PEMF. Lee reported a 67% success rate for treatment of posterior pseudarthrosis with PEMF.[35] Mooney[36] reported a randomized, sham-controlled double-blind trial of 195 patients comparing PEMF versus placebo using a brace containing PEMF to induce an electromagnetic field in patients undergoing interbody fusion. They reported a 92% fusion with PEMF compared with 65% fusion in controls.[36]

Electrical Stimulators: Quality of the Evidence

In 2013, Tian et al. conducted a meta-analysis looking at the efficacy of various types of electrical stimulation on spinal fusion.[37] A total of 21 articles with 1381 patients were evaluated. The pooled fusion rate for all studies was found to be 85% (95% confidence interval [CI], 79–90%). No statistical difference was found between the three electrical stimulation methods. Further, subgroup analysis suggested that various patient and surgical factors—such as age, sex, smoking status, surgery type, fusion levels, implant use, and graft type—did not significantly influence the fusion rate.[37] However, although the authors compared DC, CC, and IC, the specific question of stimulation versus no stimulation was not addressed. Furthermore, there were several major limitations of that study,[38] including combining randomized trials with observational studies, no adjudication of the confidence in the effect estimates, no exploration of heterogeneity, no risk of bias assessment, and no presentation of results in a clinically applicable format (number needed to treat or minimal clinically important difference). Park et al.[39] performed the most recent systematic review of electrical stimulation following lumbar spinal fusion procedures; a statistical meta-analysis, however, was not performed by the authors.

A number of factors limit the quality of the evidence in studies assessing adjuvants to bone healing. First, in keeping with other orthopaedic studies of fracture healing, the definition of radiographic union has proved troublesome and inconsistent.[40–42] Static anteroposterior and lateral radiographs or computed tomography scans are generally the most common method for assessing bony union. Although use of standardized checklists can improve agreement,[40,43] none of the trials described used these checklists. Multiple, independent blinded assessors would also increase the reliability of union assessment. Second, most studies reported only surrogate endpoints; similar to other studies on orthopaedic adjunct devices, larger effects are typically reported for surrogates compared with direct measures of function.[44] In addition, patient-reported outcomes are inconsistently utilized in fusion studies. Finally, certain disadvantages of electrical stimulation—such as cost, patient inconvenience, and self-limited local conditions (e.g., skin irritation or superficial hematoma)—were rarely assessed.[33,45] Given the potential benefit in preventing nonunion, however, it is unlikely that these disadvantages would be a significant deciding factor for patients or clinicians. An economic evaluation by Wu et al.[46] demonstrated that electrical stimulation for bone healing is a more cost-effective fracture nonunion treatment when compared to either ultrasound or no stimulation and that patients receiving electrical stimulation had lower total health care resource use and overall costs.

In order to address many of the methodological limitations of previous studies, a rigorous meta-analysis of sham-controlled randomized trials was recently reported.[9] The study involved 15 sham-controlled randomized clinical trials that included 1247 patients total. The authors identified all trials randomizing patients to electrical or sham stimulation for bone healing and included acute fractures, nonunion/delayed unions, osteotomy, and spinal fusions. The assumption that electrical stimulation has a similar effect on all bone healing was hypothesized based on the consistency of the biologic process across all bone healing[47–50] This hypothesis was then tested using the interaction test, which found no evidence to support a difference in treatment effect due to treatment indication. The authors found moderate-quality evidence supporting that electrical stimulation decreased pain ($P = .02$)

and radiographic nonunion rates by 35% (95% CI, 19–47%). A subgroup analysis assessing only spinal fusions found an even greater effect of electrical stimulation with a nonunion risk reduction of 38% (95% CI, 45–84%).[9]

Conclusions and Future Direction

The clinical benefits of electrical stimulation in spinal fusion surgery have been well recognized and evidence supporting the use of electrical stimulators for spinal fusion continues to grow. Numerous studies demonstrate a consistent enhancement of successful fusion with electrical stimulation. Recent studies further show that electrical stimulation not only decreases rates of nonunion, but also improves patient-reported outcomes, such as pain.[9]

Future large, rigorously designed trials using an intention-to-treat analysis with clear reporting of methodologic quality are warranted.[51] Furthermore, future investigation into the use of electrical stimulators in higher-risk populations—such as smokers, those undergoing multilevel procedures, or those with reoperations—may allow clinicians to determine who may benefit most from this intervention. Additionally, although union is a continuous process and there is no commonly accepted radiographic definition, a consistent and valid method for defining union should be considered in future trials.[52] Finally, high-quality randomized trials assessing patient-important outcomes, such as function, are warranted.[9]

KEY POINTS

1. Three types of electrical stimulation are described for spinal fusion: direct current, capacitive coupling, and inductive coupling.
2. The mechanism of action of electrical stimulation therapy is not clearly understood but is generally thought to work by stimulating the calcium-calmodulin pathway secondary to the upregulation of bone morphogenetic proteins, transforming growth factor-β, and other cytokines.
3. The clinical benefits of electrical stimulation in spinal fusion surgery have been well recognized and evidence supporting the use of electrical stimulators for spinal fusion continues to grow.

CHAPTER 69

Cervical Instrumentation: Anterior and Posterior

SECTION IX

Eeric Truumees

Introduction and Overview

In the late 1890s, B.E. Hadra of Galveston, Texas, stabilized a cervical fracture-dislocation in the first modern report of spine instrumentation.[1] Hadra later used this technique in Pott disease.[2] For the next hundred years, cervical instrumentation remained limited to various posterior wiring schemes, of which Rogers' technique was the most frequently used.[3] In the 1980s, wiring patterns began to include corticocancellous bone struts for added extension stiffness.[4] In the last 2 decades rigid, segmental fixation, including lateral mass and pedicle screws, has dominated.

Anterior instrumentation could not be considered until Smith and Robinson popularized the anteromedial approach.[5] Even then, the simple plating systems carried over from appendicular stabilization were fraught with loosening, back-out, and other devastating soft tissue consequences. Dedicated anterior cervical plating systems were first described in the 1970s. Bicortical purchase decreased screw back-out and instrumentation failure rates but added canal penetration and cord injury risk. In the 1980s, locking mechanisms enabled safe unicortical purchase while preventing screw migration.[6]

Cervical instrumentation continues to evolve with new disc replacement systems, dynamic and low-profile anterior plates, cervical cages, and resorbable implants. While promising, some of these newer technologies have been incorporated into clinical practice without evidence of added benefit. Since the last edition of this textbook, interest in resorbable implants has waxed and waned.

Before recommending an implant system, American surgeons must consider its Food and Drug Administration (FDA) status. Often a device will be cleared for some, but not all, of its common indications. The reasoning is usually obscure and bureaucratic and does not always reflect safety or efficacy. Read the device's package inserts and direct questions to the manufacturer's legal counsel or to the FDA (800-638-2041).

The FDA is not empowered to dictate patient care. Off-label use of cervical instrumentation may occur in two settings, each establishing different demands on the physician. The practice of medicine includes use of FDA-cleared, marketed devices for indications not listed on the FDA approved labeling. When the indication or intended patient population lies outside the device's labeling, surgeons may still legally use the device per their best judgment but must be able to support the decision with reliable scientific evidence. It is prudent, though not specifically required, to discuss the proposed implant's FDA status and rationale with the patient. No investigational device exemption (IDE) or institutional review board (IRB) review is needed in practice of medicine cases. The second off-label implant setting involves experimental or investigational devices. If the FDA has not cleared the device for market for any indication, clinical use requires an IDE. Even then, the implant may be used only in accordance to the approved protocol's plan of investigation. A separate, formal informed consent must be obtained from the patient. Physicians involved in the study may not share the device with other physicians.

Since the last edition of this text, placement of screws in the posterior elements of the cervical spine, including pedicle and lateral mass screws, has received FDA labeling for most common indications. That said, several implants, such as some expandable cages, remain off-label when used in the cervical spine.[7-9]

Cervical spine implants are used in wide-ranging indications, including trauma, tumor, deformity, infection, and degenerative disease. In each group, the goals are the same; implants can reduce deformity, provide stability, and share loads with host and graft tissues until healing occurs. Most of these devices aim to support the fusion process. Some laminoplasty plates, for example, are approved as "bone graft containment devices." Newer devices seek to improve on their predecessors by emphasizing previously ancillary goals: minimization of adjacent-segment degeneration, surgical morbidity, iatrogenic neurologic deficits, and unintended-level fusion. For example, interest in motion-preserving devices is increasing. This chapter is written to assist spine surgeons in rational selection of implants by discussing their evolution, biomechanics, indications, outcomes, and complications.

Relevant Anatomy for Spinal Instrumentation

For the purposes of reconstruction, the cervical spine is divided into three regions: the cervicocranium, mid-cervical spine, and cervicothoracic junction. Each region's unique

anatomic and biomechanical considerations influence the instrumentation chosen.

The cervicocranium includes the skull base, atlas, and axis. The cervicocranial joints' size, shape, and location allow more motion than those in the subaxial spine and render arthrodesis particularly challenging.[10,11] The bony elements of the cervicocranium, beginning with the occiput, are unique. The clivus ends in the basion, the anterior border of the foramen magnum. The opisthion refers to its dorsal border. From the foramen magnum, the occipital squama curves 90 degrees cranially toward the inion (or external occipital protuberance [EOP]).

Embryologically, the C1 vertebral body is absorbed into the dens. The absence of a C1 vertebral body means there is no disc between the occiput and C1 or between C1 and C2. The posterior C1 arch forms two-thirds of the ring. There is no spinous process, but rather a posterior tubercle to which the rectus minor and suboccipital membrane attaches. Critically, the vertebral artery runs along a groove on the cranial surface of the posterior ring. More than 1.5 cm from the midline, the groove becomes very shallow. Exposure of the ring's superior aspect risks vertebral artery injury. C1 has a lateral mass on each side, but no pedicle or laminae. While the arches are thin, the lateral masses are heavy, thick structures, each with concave superior articulating surface.

The occiput–C1 articulation includes convex occipital condyles lateral to the foramen magnum articulating with the concave C1 lateral masses. Normal occipitocervical extension is limited to 21 degrees when the occiput abuts the C1 posterior arch.[12,13] More than 8 degrees of rotation between the occiput and C1 is pathologic. In children, the flatter occiput–C1 joints are less able to restrict motion, predisposing them to injury.[14]

Atlantoaxial motion occurs through two sets of two joints. First, the slightly convex inferior facets of the axis meet the slightly convex superior facets of the atlas. These joints are oriented in the horizontal plane and have no interlocking bone to prevent subluxation. They allow 43 degrees of rotation, nearly half of normal cervical rotation.[15] The second set of atlantoaxial joints arises from the cranial projection of the odontoid projecting into axis ring. The dens acts as the focal point of a network of ligaments providing resistance to translation, flexion, extension, and rotation. Dens resection leads to vertical and atlantoaxial instability.[16]

The axis, the largest and heaviest cervical vertebra, bears a large, bifid spinous process. The bony isthmus between the facets is often called the pedicle. Technically, this represents the C2 pars and is a large dense structure that projects medially at 30 degrees and superiorly at 20 degrees. The short, stout, nearly horizontal C2 pedicle lies between the C1–C2 facet and the vertebral body.

The lower cervicocranium (C2–C3) transitions into the more homogeneous subaxial patterns.[17,18] The C3–C6 vertebrae exhibit a uniform configuration but increase gradually in size. The vertebral bodies are roughly twice as wide as they are deep. Each contains a body, paired pedicles and articular masses, laminae, and a single, bifid spinous process. The transverse process projects laterally from the superolateral aspect of the body and anterior surface of the articular mass and contains the foramen transversarium. The transverse process ends in anterior and posterior tubercles. At C6, the prominent anterior (carotid) tubercle can be palpated for intraoperative localization.

Morphometric data from 100 CT studies revealed mean vertebral body widths of 24.6 and 23.0 mm wide in males and females, respectively.[19] The narrowest measured 17 and 14 mm, respectively. In the midsagittal plane, the average anteroposterior (AP) diameter was 18 mm in males (smallest, 13 mm) and 16 mm in females (smallest, 10 mm). A morphometric analysis of critical cervical pedicle dimensions recorded a wide range of values and only fair interobserver correlation.[20] Transverse angulation was constant at 40 degrees. Relative to the lateral mass axis, the C3 and C4 pedicles were oriented superiorly, whereas C6 and C7 were oriented inferiorly. The dorsal entry point of the pedicle on the lateral mass defined by transverse and sagittal offset had similar mean values with wide ranges and variable topography. Sufficient variation exists to preclude safe instrumentation with topographic landmarks alone. Ludwig and colleagues recommended laminoforaminotomy or image guidance to place these screws.[20]

Because bony element size varies considerably, preoperative planning with axial and sagittal images decreases the risk of screw placement. For example, verify that the C2 isthmus is large enough to accommodate a 3.5 mm screw. If bony element size is questionable on magnetic resonance imaging (MRI), a 2-mm computed tomographic (CT) slice limited to the levels of surgical interest should be obtained. Request that the CT gantry be reangled to parallel the endplate at each disc level. Clear preoperative measurements of the bony elements allow larger screws to be used. Otherwise, smaller screws with lower pullout and fatigue strength characteristics are used. Similarly, preoperative planning allows improved screw trajectory to incorporate better triangulation and subchondral bone purchase. Upper cervical anterior plating may benefit from coronal CT or MRI images above C3 because anatomic variation is considerable and makes this technique inadvisable in up to 20% of cases.[21]

The uncinate process projects cephalad from the inferior mid-cervical vertebral endplates. The immediately superior vertebral endplate receives the uncinate via a contiguous lateral indentation. Together, the process and indentation form the synovial uncovertebral joint (of Luschka). Biomechanically, the uncovertebral joints regulate extension and lateral bending. The posterior uncovertebral joint has a secondary role in torsional control.[22,23]

Posterior midline cervical approaches first encounter the spinous process. The bifid process may be taller on one side or the other. The surgeon must therefore pay critical attention to the midline. Deep in the subperiosteal plane, no sharp demarcation exists between the spinous process and the lamina. Spinous process wiring techniques therefore require great care to avoid inadvertent spinal canal entry. Working laterally, an inferior notch at the junction between the lateral mass and the lamina is typically encountered. At the medial boundary of the lateral mass, this notch serves as an excellent landmark both for lateral mass fixation and en bloc decompression procedures. The articular masses (or pillars) are

dense, heavy, rhomboid structures formed by junction of the superior and inferior articular processes. Average facet inclination is 35 degrees from vertical.

Successful cervical instrumentation requires a detailed understanding of vascular anatomy. First, placement of occipital screws risks dural sinus injury. Venous sinus injury is especially likely with screw placement within 1 cm of the EOP.[24] The internal carotid artery (ICA) runs a mean 2.9 mm from the anterior C1 lateral mass and is therefore at risk with Magerl and Harms screw constructs.[25] ICA injury could lead to life-threatening hemorrhage and stroke, but only one clinical report has, as yet, emerged.[26] In this case, a 60-year-old man presented with an 8-month history of recurrent cerebral infarcts more than 3 years after atlantoaxial stabilization with transarticular screws. The screw tip impinged the ICA, leading to both high-grade arterial stenosis and a pseudoaneurysm. On the other hand, in a retrospective review of 50 random contrast CTs of the head and neck, the artery's course would place it at risk during C1 lateral mass screw placement in 58% of cases.[27] Medial screw angulation decreases risk.

Vertebral artery injury may occur with both anterior and posterior cervical procedures. Although clinically evident injuries are rare, catastrophic consequences include fistula, pseudoaneurysm, cerebral ischemia, and death.[28,29] Because the vertebral arteries are paired, injury to one rarely results in significant neurologic deficit. If intraoperative vertebral artery injury is suspected, do not attempt exposure or screw placement on the contralateral side. In anterior procedures, dissection lateral to the vertebral body puts the vertebral artery at risk.[29] On approach, carefully mark the midline. Previously, with both anterior and posterior vertebral artery injury, attempts were made to tie off the vessel. Posteriorly, the vertebral arteries are vulnerable to injury during insertion of Magerl and C2 pars and pedicle screws because the drill bit traverses the C2 body. Especially in rheumatoid patients, a high rate of erratic and variable arterial courses has been reported and may preclude safe screw placement in 20% of sides (Fig. 69.1)[28,30,31] Thus, with any significant cervical reconstruction procedure, preoperative investigation of the artery's course is mandatory.[32] Although recommendations today vary, the advent of endovascular repair has prompted many spine surgeons to request an intraoperative vascular surgery consultation. For many of these injuries, local bleeding is controlled and the patient is taken to the vascular suite for stent placement. Consider permanent occlusion or ligation only if the contralateral vertebral artery provides adequate collateral circulation.

Less frequently, a variable course of the posterior inferior cerebellar artery could pass through the skull into the upper cervical spine, where it is vulnerable to C1 lateral mass screw placement.[33]

Another major anatomic factor limiting safe cervical spine instrumentation is individual variation. In children, for example, standard implant sizes may be too large. Because their fusion potential is so high, onlay bone grafts alone are a good option in most children. However, in children with neuromuscular disorders or greater degrees of instability, rigid stabilization should be considered.[34]

In one study of 28 children with skeletal dysplasia, nonrigid implants with postoperative halo immobilization were compared with rigid implants. Nonunion was seen in nine of 14 nonrigid cases and one of 14 rigid cases. That said, two of the children in whom rigid implant placement was attempted had intraoperative vertebral artery injuries. No new neurologic deficits were seen in either group, however.[35]

Recent anatomic studies have suggested that, in children as young as 2 years, the occipital keel, C1 lateral mass, and C2 lamina offer adequate space for 3.5 mm screw placement in "almost all cases."[36] Transarticular screw placement was not considered safe in the majority of these younger patients. Successful use of C2 laminar screws in children was recently reported.[37] Caution is certainly advised for patients younger than 6 years.[38-40] Other implants modified for use in small children, including craniofacial miniplates, have been described.[40]

Body habitus also affects instrumentation choices. For example, obtaining a shallow trajectory for dens screw placement in barrel-chested patients is difficult. A preoperative CT

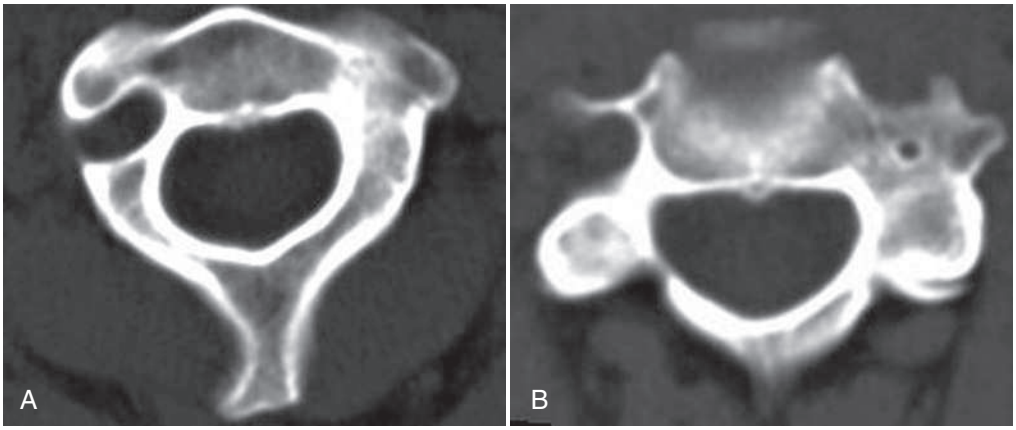

FIG. 69.1 Asymmetric course of right vertebral artery at (A) C2 and (B) C6. Risks of screw placement vary significantly from right to left sides.

topogram should be used to assess this option. Similarly, transarticular screw placement is more challenging in patients with marked thoracic kyphosis. If the topogram does not include enough of the patient's frame, check the screw's inclination angle by holding a guide wire alongside the neck and obtaining lateral fluoroscopic images. Adjusting the patient's position often allows the case to go forward. Failure to make these changes before incision adds significantly to the time, risk, and complexity of the procedure. Occasionally, coronal images are useful. Structures at risk include the vertebral artery and the hypoglossal nerve. Note the size and caudal extent of the jawline, which may limit anterior upper cervical instrumentation angulation options.

Significant interindividual variability also affects reconstruction options at the cervicothoracic junction. Typically, the Southwick and Robinson anteromedial exposure is difficult below T1–T2.[41] Even in cases in which the disc space can be safely reached, orthogonal screw placement is affected by the manubrium.[42] In Sharan's study of 106 consecutive MRIs, while T3 was often cranial to the sternal notch, a straight trajectory was limited to the T1–T2 disc space.[43] Transmanubrial or transsternal approaches increase exposure to T3 but are associated with significant morbidity.[44] Below T4, a formal thoracotomy is often required. In one study, the size of the thoracic outlet, as measured by the instrument manubrial thoracic distance, served as a key guide to the optimal anterior approach.[45] Still, marked interindividual variability of the cervicothoracic angle and the cranial extent (and cervical level) of the superior manubrium (i.e., short- and long-necked patients) greatly affects selection, ease, and safety of anterior approaches.[43,46]

Although cervical instrumentation relies on standard spinal approaches, a wider exposure than that for simple decompression or uninstrumented fusion procedures is often needed. Small incisions with tight fascial constraints may force suboptimal screw trajectories. Because rigid implants "lock in" segmental alignment, careful attention to positioning is mandatory.

Percutaneous placement of cervical instrumentation from both anterior and posterior approaches is being reported with increasing frequency in the literature.[47] For example, to protect the midline tension band, lateral mass screw constructs have been implanted via tubular retractor systems.[48] In posterior cervical reconstruction, smaller, midline open approaches may complement percutaneous screw delivery.

The fluoroscope should be set up so that AP and lateral images can be easily obtained. For technically challenging cases such as dens or Magerl screw fixation, simultaneous AP and lateral fluoroscopy may be helpful. Prior to draping, check the alignment fluoroscopically. While certain pathologies reduce better in flexion, others align with extension.

Fluoroscopy and Navigation for Cervical Spine Instrumentation

Safe instrumentation of the cervical spine requires avoidance of vascular and neurologic structures that are often not exposed for implant placement. Historically, intraoperative fluoroscopy has been used to confirm level localization, optimize spinal alignment, and assess screw trajectory. Fluoroscopy can be used in real time to guide entry point selection or after placement to confirm acceptable positioning. Some techniques, such as cervical disc arthroplasty, require a real-time approach to ensure proper implant centering and alignment. Other indications for continuous or pulsed live imaging include cervical vertebroplasty and debridement of distant structures (Fig. 69.2).[49,50]

At the occipitocervical and cervicothoracic junctions, overlying bony structures such as the jaw and shoulders frustrate fluoroscopy.[51] Other limitations of fluoroscopy include increased surgical time, possible sterile field contamination, and radiation exposure.[52] Delineation of which cases intraoperative fluoroscopy is "necessary" remains controversial.[53-55] In one study of 419 cervical pedicle screws, 17 were malpositioned.[53] Given the risks associated with malposition, the authors concluded that pedicle axis/en face views improved safety. Even with intraoperative imaging, malposition rates from 2.7% to 34% are reported.[54,56-58]

In another series, the accuracy of intraoperative AP fluoroscopy was compared with use of bony landmarks (the uncovertebral joints) when centering a cervical disc prosthesis.[59] Postoperative CT scan demonstrated acceptable accuracy with anatomic alignment alone. A variety of intraoperative guides to improve aim and placement have been devised but have gained only limited popularity.[60]

Overlapping anatomic structures, difficulty imaging the cervicothoracic junction, and the desire for intraoperative axial images have fostered increased interest in "three-dimensional" fluoroscopy.[51] The reconstructed axial images are not real CT slices, but intraoperative CT simulation was found to have 100% concordance with postoperative CT.[61] The bulk and radiation required limit the utility of these systems in real-time imaging applications. Typically, they are used at the end of the procedure to document appropriate implant

FIG. 69.2 Intraoperative image using O-Arm navigation (Medtronic) in a complex cervical reconstruction.

positioning or as part of a frameless stereotactic guidance system.[62] Although these systems continue to rapidly evolve, significant controversy remains as to their accuracy in cervical applications.[63,64] Ludwig and others found computer guidance more accurate than topographic landmarks or a laminoforaminotomy in accurate cervical pedicle screw placement.[20]

Beyond improving safety of screw insertion, computer-aided spinal navigation has fostered enthusiasm for smaller incisions and less soft tissue mobilization.[65]

Use of image guidance to place C2 pedicle screws in a minimally invasive manner was compared with standard open placement. Accuracy rates were similar but time and blood loss were lower in the minimally invasive group.[66] Another recent study of eight children with failed wiring for atlantoaxial instability underwent successful, rigid stabilization using CT navigation.[67] Most conclude that navigation improves, but does not eliminate, the risk of critical screw malpositioning. Computer guidance systems may be particularly helpful in patients with previous surgery, deformity, or destructive processes that obliterate landmarks.[68-70]

Limitations of computer navigation include displacement with drilling forces, cervical mobility requiring frequent reregistration, small structure size at the limits of device accuracy, and steep trajectories outside device pathways.[71] The surgeon must understand the principles of the tracking system to prevent misinterpretation of computer-generated information.[72] Navigation systems should only be used by experienced surgeons who can, if necessary, continue the procedure with conventional techniques.

Selecting the Biomechanically Correct Implant

The most common preventable cause of instrumentation failure arises from surgical judgment errors. Although modern implants are overengineered for their designated function, their success requires understanding of their biomechanical function.[73-75] Direct failure of the implant is most often due to improper selection or fatigue. The average spine cycles 3 million times per year.[76,77] If bone healing fails to occur, the implant will ultimately fail, either at its anchor points in the bone or in the material itself. The novelty and technical challenge of safe implant placement should not divert the surgeon's attention from meticulous preparation of the fusion bed and grafting technique. Occasionally, misplaced implants fail. However, careful surgical exposure and intraoperative radiographic confirmation reduces misplacement (Box 69.1). More typically, failure occurs when the surgeon fails to fully understand one of four things: (1) the forces to which the spine will be subjected, (2) the planes in which the spine is unstable, (3) how the implants are meant to counteract these forces, and (4) how instrumentation affects forces passing through structural grafts.

Unlike typical fracture healing, which passes through Hunter's stages of bone repair (inflammation, soft callus, hard callus, and remodeling), most modern cervical implants seek primary healing in which osteon cutting heads directly cross segmental gaps.[78,79] This approach requires near-anatomic alignment and rigid stabilization. Excessive strain or poor bone-to-bone contact stimulates fibrous tissue deposition and, ultimately, construct failure. The importance of restoration of proper spinal alignment in reducing stresses on the construct and graft has become increasingly clearer.[80]

BOX 69.1 Important Factors in Selection of Cervical Implants

- Pathoanatomy: mechanism of injury and direction of instability
  - Mode of failure (in trauma, direction and magnitude of injury vector)
  - Direction of instability
  - Degree of instability
  - Compromised stabilizing structures:
    - Number of levels
    - Number of spinal columns per level
    - Bone vs. ligament (anticipated healing)
- Host bone quality
- Graft bone quality
- Expected level of patient loading
- Availability of postoperative immobilization
- Surgeon familiarity with techniques
- Availability of implants

No clear line divides the "stable" from the "unstable" spine. In serial sectioning studies, White and Panjabi concluded that more than 11 degrees of sagittal angulation and 3.5 mm of sagittal plane translation represented instability.[75] These values are most helpful in the acute trauma setting but are less meaningful with chronic destruction, such as with infection. In many cases cervical instrumentation is not meant to correct any innate spinal instability, but rather to reverse the iatrogenic instability associated with decompression. Because each structure contributes to normal stability and kinematics, minimizing disruption of intact structures during decompression is key.[82] For example, a two-level cervical anterior approach is less destabilizing than a one-level corpectomy.[83] Another classic example of iatrogenic spinal destabilization is postlaminectomy kyphosis.[84] The difficulty in treating this condition fostered interest in laminoplasty.

The surgeon must ask: what is unstable, which planes are affected, and how badly? In trauma, for example, identifying the primary plane or mode of failure is critical. For example, a transverse atlantal ligament rupture leads to flexion instability, whereas posteriorly displaced dens fractures are unstable in extension as well. Posterior C1–C2 wiring is mechanically more rational for transverse acetabular ligament rupture than for displaced dens fracture.

Account for patient-specific factors when planning cervical instrumentation. Children's excellent healing potential may require less rigid fixation.[85] On the other hand, even with excellent graft carpentry and implant placement, osteoporosis increases segmental motion and decreases construct pullout and fatigue strength.[86] Other physiologic factors, such as the challenged healing environments in diabetics and smokers and after chemotherapy and radiation, as well as in larger or poorly compliant patients, may require a more aggressive, rigid implant strategy.[87]

Increase the strength of any spinal construct with added fixation points, triangulated placement, or the goal of aiming

for the dense subchondral bone of the vertebral endplate. Alternatively, extend postoperative immobilization.[88] For cervical bone screw placement, insertional torque, pullout strength, and bone mineral density are highly correlated.[89,90] Bone mineral density has a greater impact on pullout strength than bicortical purchase,[91] yet the relative merits of unicortical versus bicortical screw purchase continue to be debated.[92] In both anterior and posterior applications, bicortical screws exhibit significantly greater holding power in terms of both immediate pullout strength and fatigue resistance.[84,93-95] Yet even in the trauma setting, unicortical fixation maintains reduction and confers high fusion rates.[96] The advantages of bicortical purchase are magnified in osteoporosis, wide decompression, multilevel procedures, and when the available fixation points are limited.[89,97-99]

Adding polymethylmethacrylate (PMMA) to the screw tract significantly increases the screw's torque and pullout strength.[100,101] Bone loss may affect pedicle screws because they engage cortical bone rather than the lateral mass's cancellous bone, later and to a lesser degree.[63] Other physiologic factors, such as challenged healing environments after chemotherapy and radiation, may mitigate for more rigid fixation.

Once the surgeon has delineated the "personality" of the pathology, implant options should be considered. Ideally, the surgeon should be facile with a wide array of implants and techniques to tailor the treatment to the patient's needs. That is, having decided which issues the implant is meant to address, the surgeon should review the available options while noting each implant's limitations and risks. Implantation risks vary and decrease with experience. Each institution may offer a variety of tools, such as fluoroscopy, navigation systems, and intraoperative monitoring, that may improve safety.

Early attempts at surgical fixation were complicated by infection, devascularization, inadequate metallurgy, and metal allergy. Better antisepsis, soft tissue handling, and materials evolved. Then, a limited understanding of the bone biology and mechanics resulted in poorly conceived implants and techniques. Over time, biomechanical studies have improved implant design. Unfortunately, these studies underestimate the importance of soft tissue and muscular tension. Most biomechanical research is limited by its ex vivo nature. Cadaveric, animal, or plastic spines are tested in laboratory settings with various pure or complex loads, but these studies do not take into account the importance of muscle forces, tissue healing, or the possibility of gradual ligamentous relaxation (creep).[102,103]

The surgeon should seek to optimize the healing environment by limiting unnecessary exposure, denervation, and devascularization of the paraspinal muscles. Compromised extensor musculature allows collapse into kyphosis above or below the instrumentation.[48] Increasingly, surgeons are exploring midline sparing, less-invasive approaches to the placement of cervical implants, even in anatomically challenging regions such as the C2 pedicle.[104] Careful muscular repair may protect the construct.[105] In the posterior cervical spine, a multilayered closure, including the suboccipital triangle and ligamentum nuchae, improves balance and decreases eccentric implant loading.[48,106]

Biomechanical Principles and Functional Modes

Most cervical spine implants are made of stainless steel, pure titanium or, most commonly, titanium-aluminum-vanadium alloy. Steel implants usually have cobalt chrome and molybdenum to enhance corrosion resistance and have a modulus of elasticity 12 times that of normal bone. That means that steel is significantly stiffer than bone. Titanium alloys tend to have greater native biocompatibility and corrosion resistance. Furthermore, titanium has a modulus only six times greater than bone. Use of titanium alloys is increasing because of their high strength/weight ratio, enhanced ductility, and increased fatigue life.

The material's ultimate tensile strength refers to the area under its stress-strain curve up to the point where elastic deformation becomes plastic deformation. That is, ultimate tensile strength is the maximum stress a material can sustain without changing shape. This value is different for different materials and ranges from 50 MPa for trabecular bone to 650 MPa for titanium.[74] Ultimate tensile strength of a material may become altered during surgery. Compromise of the implant's integrity by repeatedly bending and unbending is common. Titanium is especially sensitive to notching. The implant's material properties are also affected by manufacturing elements such as drill holes, structural imperfections, and surface irregularities. Hardness is a surface characteristic referring to the material's ability to resist plastic deformation. Hardness can be enhanced with surface coating, but improper handling may destroy the surface coating and compromise implant hardness.

During the 1950s, Danis and Müller refined the principles of internal fixation.[107] Stable internal fixation fulfills the spine's local biomechanical demands without concomitant external immobilization. Fixation strategies can be subdivided by implant constraint. A constrained system's locking mechanism rigidly binds the individual components (e.g., the screw and plate). The surgeon should achieve maximum rigidity by segmental fixation of each vertebra to a constrained system. A nonconstrained construct is fixed only at the ends of a multilevel construct or includes nonrigid connections between the screws and longitudinal member.

Spinal implants function in one or more modes (Box 69.2). The principal mode is defined by the device's location on either the spine's flexion or extension side and by the principal mechanism of loading. The degree to which a stabilization mode is "needed" depends on the spine's mechanical deficits. For example, an anterior cervical plate's role varies depending on the quality of the interbody grafting. When the spine

remains unable to sustain compressive forces, a strong, rigid, bridging implant, applied to either the anterior or posterior columns, serves as the weight-bearing column. The most common cervical bridging implants are multilevel, segmental, rigid posterior screw-rod systems compensating for multilevel anterior metastatic disease or difficult-to-reach, anterior cervicothoracic or occipitocervical lesions.[108] Posterior lateral mass plates or rods are more typically used in neutralization mode. To decrease strains across bone healing surfaces, the neutralization implant shields flexion and axial loading forces while minimizing torsional bending and shearing loads.

The buttress principle is designed to prevent axial deformity. In the appendicular skeleton, a buttress plate holds impacted or depressed fragments once they have been elevated back into anatomic position. Anterior cervical surgery often includes restoration of disc height with an interbody device. Here, the plate, placed on the side of load application, "buttresses" the spine, minimizing compression, torque and shear forces. The buttress effect requires close surface contact between the implant and the bone surface. The implant and bone surface should be carefully contoured before fixation. Any osteophytes that cause the plate to "ride up" should be resected. In buttress mode, the middle screws should be inserted first, moving away afterward in both directions.

A tension band is also applied to the extensor side but requires competent load-bearing ability. A typical example is posterior wiring used to encourage fusion in anterior cervical discectomy and fusion (ACDF) with delayed union. This wire resists tensile and bending forces only if the anterior spinal column can bear weight. In the pseudarthrosis setting, this limitation confers an advantage because it encourages fusion by dynamically compressing the anterior weight-bearing column. In most cases, additional posterior bone graft is not required.

Only 36% of cervical axial loads are borne anteriorly while 32% is borne by each of the posterior articular pillars.[109] Despite the relative importance of the articular pillars, the mobility and heavy weight of the head relative to the small size of the cervical bony elements underscores the anterior column's critical role in construct stability. When comparing "loose" with "tight" grafts, graft status predicted overall construct stability and plate effectiveness.[110] On the other hand, excessive anterior distraction decreases posterior column load transmission and thereby subjects the anterior graft and vertebral bodies to excessive loads.[111,112] In trauma cases, for stability, cover at least 30% of the endplate area.[113] Similarly, endplate preparation affects graft support and axial loads.[114,115]

Cervical stabilization is achieved with bone screws used independently or with plates, rods, or cages. Name screws by describing their major diameters, intended bone type and thread proportion (partially or fully threaded), thread pitch, lead, and length. A screw's minor (root or shaft) diameter determines its tensile strength and breakage resistance. The distance between adjacent threads is a screw's pitch. Increasing pitch increases bone between threads but decreases number of threads over the length of the screw. Pullout strength is determined by its root area and the host bone's composition. Root area, the total surface of thread contact to bone, is primarily determined by the screw's major (outside or thread) diameter.

Cortical screws typically exhibit a smaller major diameter, decreased pitch, and a shallower thread than cancellous screws. Pretapping the hole prior to screw insertion reduces thread-bone interface microfracture and improves holding power, but requires an extra step. Self-tapping cortical screws confer similar holding power and have become standard.[101,116] However, the cutting flute at the screw's tip limits thread contact and may require 1-2 mm increased depth of penetration. Cancellous screws, on the other hand, provide more surface area for bone purchase by increasing major diameter and pitch. As insertion compacts trabecular bone, cancellous screws are not tapped.

Torque applied through the screwdriver rotates the screw clockwise, advancing it along its predrilled path. Screw advancement creates an axial compression force against the cortex or plate. On average, insertion applies 2500 to 3000 N.[117] Over time, living bone remodels, slowly decreasing compressive force. External forces magnify this innate loss of holding power.

Individual screws may also be placed in one of several "modes." Positional or neutralization screws hold the implant, such as an anterior plate, to the spine via compressive forces. For neutralization screws, use a centering guide to drill a pilot hole of equal diameter to its root. Lag screws provide compression across two surfaces. Overdrill the proximal bone to the screw's outer diameter. The distal piece is drilled to the inner diameter. The torque differential pulls the distal bone to the proximal. Cervical cages with predrilled screw paths utilize this principle. Lag techniques offer little protection against axial loading and rotation. Thus, in the spine, they are best used with cages or plates.

In rigid, locking plates, the screw head is locked to the plate through either secondary metal-on-metal threads, a Morse taper, or an external blocking system. In that these screws function mechanically more like a bolt than a screw implies that the axial force generated during insertion is not critical. The simplest of these designs act like internal external fixators.[93,118] Longer screws improve fixation.[119]

Anterior Spinal Instrumentation

Unlike the posterior cervical spine, all anterior implants are constrained by limited purchase sites, sagittal profile concerns, and the limited extensibility of most surgical approaches. Anterior fixation points are limited to the vertebral body and endplates. Anterior cervical pedicle and occipital condyle screws have been described, but are technically challenging and infrequently performed.[21] Bulky implants may cause swallowing difficulty or respiratory compromise. Currently, anterior reconstruction options can be divided into direct dens fracture fixation, anterior load-bearing implants, and plates. Load bearing implants, including disc replacements, bone struts and cages, reconstruct defects created by discectomy and corpectomy procedures.

Anterior Screw Stabilization of the Upper Cervical Spine

In the cervical spine, stand-alone screw fixation is used most frequently to provide rigid internal fixation of unstable dens fractures while preserving C1–C2 motion and avoiding extensor muscle dissection and graft harvest morbidity. Dens screw fixation is indicated mainly in widely displaced type II fractures.[120] Before C1 lateral mass fixation, dens screw fixation was specifically recommended in patients with concomitant C1 ring fractures to avoid posterior fusion to the occiput. Direct anterior stabilization is associated with decreased blood loss, postoperative pain, and morbidity relative to posterior fusion operations.[121] In patients with incomplete reduction from traction, an attempt at direct, open anterior reduction may be undertaken. These maneuvers are performed with fluoroscopic guidance from an entry point significantly caudal to the injury. This technical challenge sways surgeons with only limited anterior open reduction internal fixation (ORIF) experience to treat incompletely reduced fractures posteriorly.

Contraindications to dens screw fixation include transverse atlantal ligament (TAL) disruption and fractures more than 18 months old.[120,122-124] Horizontal and posterior oblique fracture lines are much more likely to heal in anatomic position than anterior oblique.[120] Some "high" type III fractures have enough bone in the body inferiorly to maintain purchase of the base of the screw. But, in "low" type III dens fractures, the screws may break out of the inferior aspect of the C2 body.

The utility of stand-alone dens screw fixation in osteoporotic and elderly patients continues to be controversial.[125] In one retrospective study, 102 of 110 achieved fracture healing.[126] The nonunion rate was 4% and 12% in those under and over age 65, respectively. However, in a comparison study of 29 odontoid fracture patients older than age 65, all posteriorly fused patients healed uneventfully. Only 8 of the 11 dens screw patients healed. Interestingly, 7 of the 10 treated nonoperatively healed and only after long and complicated courses. The authors concluded that, in the elderly, posterior C1–C2 fusion was superior to both anterior fixation and nonoperative treatment.[88]

Dens screws are placed using an anteromedial approach. Before surgery, reduce the fracture with traction. The transverse incision is made just above the level of the cricoid cartilage. Split the platysma muscle longitudinally and the carotid sheath is identified. Blunt dissection extends the approach cranially. The prevertebral fascia and anterior longitudinal ligament (ALL) are split in the midline over the axis. Expose the fracture site only if open reduction is needed.[121] Once the fracture is reduced, place two 2.0 mm K-wires into the anterior inferior C2 body with biplanar fluoroscopy guidance. Optimal access typically requires resection of the anterior anulus of the C2-C3 disc space. One maintains rotational stability as the other is tapped. A 3.5-mm cortical screw is placed after which the second wire is removed. Some surgeons continue to recommend dual-screw placement. Recently, percutaneous dens screw fixation has been reported using a cannulated system.[127]

Dens screws average 40 mm in length. While single screw fixation is sufficient, the tip of the screw must penetrate the apical cortex. Postoperative immobilization regimens vary among surgeons from either soft collar to halo vest immobilization for 2 months. Direct osteosynthesis of acute dens fractures is associated with an 88% union rate as soon as 6 weeks postoperatively.[120,121] Remote fractures healed at a significantly lower rate of fusion (25%). Overall, hardware failure occurs in 10%.

Other anterior screw fixation techniques into axis and occiput have also been described. [21,128] Early, anatomic feasibility studies of an endoscopic, endonasal approach to atlantoaxial transarticular screw fixation have been reported.[129] To date, these techniques appear to be used rarely in clinical situations in which posterior fixation techniques are not possible or have already failed. Here, anterior screw fixation may add stability to augment continued attempts at posterior arthrodesis.

Anterior Cervical Plating

In the early 1990s, as cervical plates became safer and easier to implant, their use exploded in tandem with interbody allograft over structural autograft.[130,131] Benefits include decreased rates of: pseudarthrosis, graft extrusion, and graft subsidence (Fig. 69.3).[132] Plating allows the patient to avoid postoperative bracing and begin early rehabilitation.[113,133] While the benefits of plating may justify application, this does not imply that a plate is "needed" in most degenerative conditions. Good outcomes have been reported without instrumentation and there is little proof that routine anterior cervical plating improves surgical outcomes.[5,134-137] With proper graft carpentry and immobilization, even unplated corpectomies heal.[138] Yet, one series of 97 tricortical autogenous iliac crest ACDFs reported pseudarthrosis rates of 11% and 28% in one- and two-level cases, respectively, despite 2 months of collar immobilization.[139] The reduction in pseudarthrosis and graft extrusion rates associated with plating justifies multilevel anterior procedures.[6,133,135,140-142]

The drawbacks of cervical plating include implant cost and bulk and the possibility of late soft tissue injury. Previous concerns over stress shielding of the plated bone and graft appear to have minimal clinical relevance.[143-145] Esophageal erosion secondary to screw or plate loosening, while rare, may be fatal.[146] Additionally, if adjacent-segment surgery is indicated, the approach may require a more extensive dissection to remove the old plate. "Extension" plates and all-in-one screw-cage designs may allow previous implant retention without significant biomechanical compromise.[147,148]

The least controversial indications for anterior cervical plating include stabilization after major anterior bone resections after corpectomy for tumor or fracture. Anterior plates are also used, with or without supplementary, posterior instrumentation in:

- Multilevel discectomy
- Most cervical corpectomy procedures
- Irreducible locked facets with cervical disc herniation
- Anterior cervical pseudarthrosis
- Trauma with loss of anterior load-bearing ability

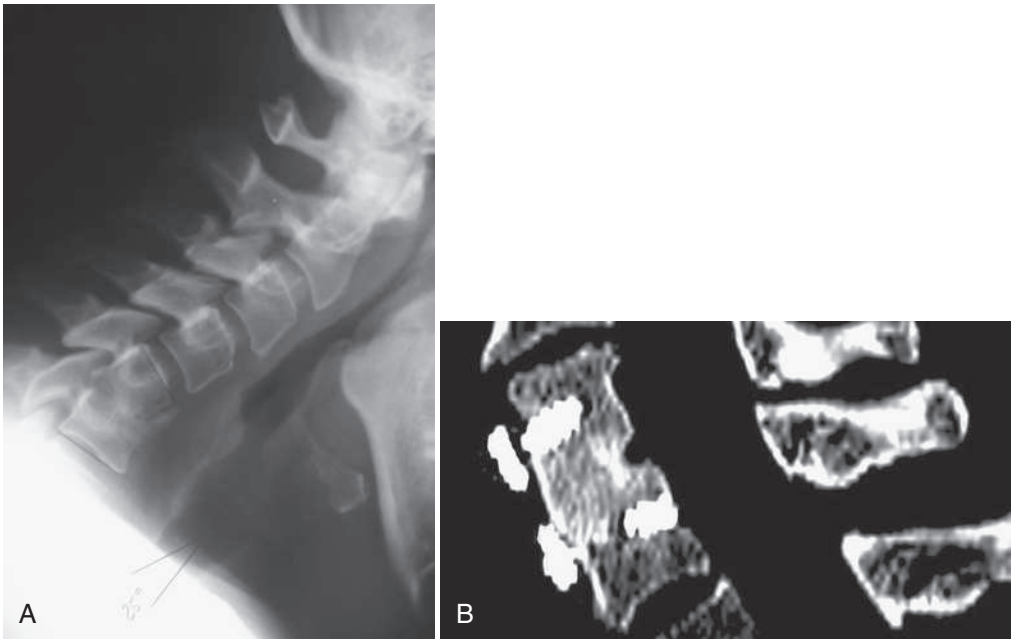

FIG. 69.3 (A) Lateral radiograph of patient with painful C5–C6 pseudarthrosis after uninstrumented anterior cervical discectomy and fusion. (B) After revision with a plate, the bone graft healed, as confirmed by sagittal computed tomography. Note plate prominence proximally.

After posterior instrumentation, anterior plating does not appear to confer additional mechanical benefits.[149-151] Thus, if an immediate posterior approach with screw and rod placement is to be performed, anterior grafting or cages are helpful, but the plate is probably not needed.

Evolution and Mechanics of Anterior Cervical Plates

Most anterior cervical plates are placed in a buttress mode. As such, they do not eliminate all motion. The more levels included in the construct, the more motion, including plate bending and screw-bone and screw-plate interface toggling is expected.[152] In many loading modes, anterior plating is inferior to a rigid, posterior construct. As a stabilization method, therefore, it fills a role somewhere between "too stable to need an implant" and "too unstable to survive plating alone."

Without a plate, spinal flexion loads the graft, and extension unloads it. With a rigid anterior plate, these forces reverse. Flexion unloads the graft and extension loads the strut more than similar degrees of flexion in the unplated state.[153] Taller grafts magnify this effect by disc space distraction and diminished posterior column loading.[111]

Initially, small fragment appendicular plating was used. The Caspar plate was among the first specifically for the cervical spine. Its parallel screw slots allowed settling, making the Caspar also the first axially dynamic plate. At that time, settling was considered undesirable and plate was modified by replacing half of its slots with round holes. These screws were not locked to the plate. After cycling, all unlocked unicortical constructs lose significant rigidity.[93] Bicortical purchase was required to decrease back-out.

Second-generation cervical plating systems, such as the Cervical Spine Locking Plate (CSLP, Synthes, Inc.), added rigidity and locking mechanisms. Many of these plates force a medial screw convergence to resist pullout through the triangulation effect. Advantages of locking the screw-plate interface:

- allows unicortical fixation
- prevent screw back-out
- improve fatigue life (loss of rigidity after cycling)

Typically, differences in grafting technique yield greater differences in overall construct rigidity than plate choice.[154] For most degenerative indications, nonrigid plates are mechanically similar to locking plates.[155] In multilevel and more unstable constructs, however, failures, including plate and screw fracture, construct pullout, and delayed or nonunions were reported even with second-generation plates.[133,135,140,142] Designers responded with thicker and stronger implants.

Even with highly rigid third-generation plates, pseudarthroses continued to occur. Benzel and others observed fracture of rigid plates in patients with solid arthrodesis and hypothesized that plate failure allowed construct dynamization similar to a sliding hip screw.[156] Sliding hip-nail constructs permit deformation along the femoral neck axis, subjecting the fracture to optimal compression forces. Several cervical plates seek to control subsidence and bone graft load sharing.

Today, cervical plates can be placed into three groups. *Rigid* plates remain popular. Recent mechanical studies, often in destabilized cadaveric models, continue to support their use over nonlocking and dynamic implants.[157,158] *Dynamic* plates could allow oversettling, resulting in kyphosis, foraminal narrowing, and lower fusion rates.[159-161] Dynamic plate advocates argue that late rigid plate nonunions are under-recognized.[156,162] *Intermediate* designs allow variable screw angulation in an otherwise rigid plate. Some plates offer both fixed and variable screw insertion methods. Interestingly, variable screw plates

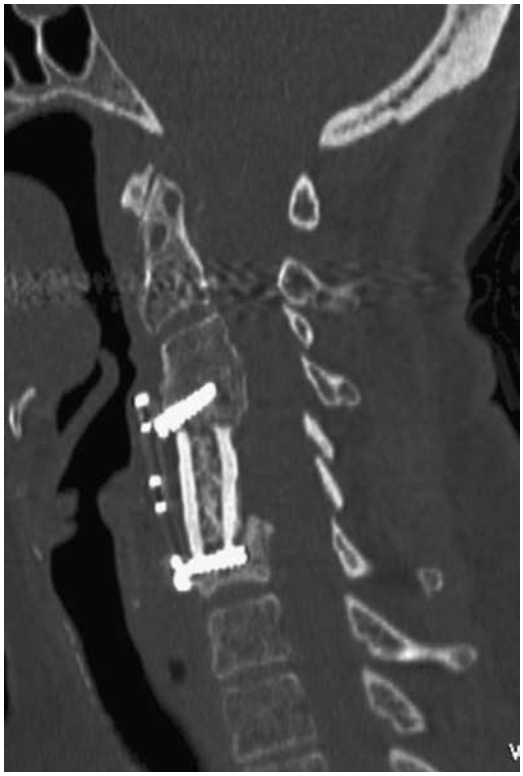

FIG. 69.4 Sagittal postoperative computed tomographic image showing subsidence of a fibular strut after anterior cervical corpectomy. Note the dynamization of plate with telescoping superiorly and the near absence of the normal vertebral body trabecular pattern. The loss of horizontal trabeculae should alert the surgeon to osteoporosis and a higher risk of implant failure, especially with fixation in the anterior, mostly cancellous spine.

FIG. 69.5 Anterior cervical dynamic plate (Ant-Cer Plate) allowing controlled collapse. (Courtesy Zimmer Biomet, Warsaw, IN.)

have detractors from both the rigid and "fully" dynamic camps. One mechanical study found that variable-angled plates had more favorable pullout characteristics no matter what angle for screw insertion was used.[163]

In general, locked cervical plates and dynamic plates are similar in flexion-extension, lateral bending, and torsional stiffness. All plates effectively share load with a full-length graft. As normal graft resorption occurs, a rigid anterior cervical plate may prevent graft load sharing by maintaining a gap between the graft and the host bone.[164] However, if graft subsidence (or controlled impaction) occurs, dynamic plates share load more effectively than locked plates (Fig. 69.4).[165-168] The degree of load shielding engendered by rigid plating is controversial.[169,170] Another cadaveric study reported that dynamic and static plates offered similar overall stabilization, but the dynamic plate performed better in extension and after endplate removal.[171] Whether dynamic plates are appropriate in trauma and other highly unstable situations continues to be debated.[157,171]

Dynamic systems offer significant design variability, but typically incorporate implant telescoping features or movement along the spine itself. For example, the ABC slotted plate design allows up to 10 mm each of cephalad and caudad plate migration. While telescoping implants may be more elegant, one study found them less stiff than slotted designs.[165] Some allow graft preloading (Fig. 69.5).[112,167]

While several studies have been released over the last 15 years, no clear clinical evidence of the superiority of one plate over another has been identified. In a series of 34 DOC plate system cases, 85% of plates subsided and 61% impacted more than 3 mm but mean lordosis changed only 0.4 degree.[142] Anterior cervical reconstruction employing dense cancellous grafts and dynamic plates reported a 1-year fusion rate of 96%.[172] Average subsidence for single-level and two-level fusions were 2.0 and 3.2 mm, respectively. In a prospective analysis of 50 consecutive patients, either a rigid or a load-sharing plate (Orion and Premier, respectively) was placed.[173] After 12 to 35 months, there was no difference in the fusion rates. Interestingly, significant differences in pain and functional impairment favored the load-sharing system. Other studies have reported similar or lower fusion rates with dynamic plates (16% vs. 5% with the static plate).[160,174]

At the time of the last edition of this text, anterior cervical plates constructed from bioresorbable polymers had been introduced.[175,176] Their rationale was function as graft containment devices while reducing or eliminating complications such as implant migration and failure, imaging degradation, and stress shielding of the fusion mass. The implants theoretically dissolve after their mechanical function has been fulfilled and before long-term problems occur. Ultimately, however, the mixed quality of fixation offered (with early, dramatic failures), the variable speed to resorption, and the occurrence of inflammatory reactions led to a marked decline in investigations in that direction.[177,178]

Similarly, while still available, the popularity of plates with single screw fixation per level has waned. These devices were

produced to reduce thickness and operating room time; however, few appreciable benefits were realized and higher pseudarthrosis rates encountered.[179]

Cervical Plating: Indications and Rationale

After multilevel reconstruction and high-energy trauma, stand-alone anterior plating is controversial. After multilevel strut grafting, anterior plates significantly increased global spinal stiffness and decreased segmental motion.[153] However, while excellent radiographic outcomes are reported after single- or two-level plated constructs, with additional levels, the risk of graft failure increases substantially, even with a plate.[134,180]

However, ongoing screw-vertebral motion is seen after three-level corpectomy and 4 level discectomy cases.[150] While two motion segment constructs are acceptably immobilized, lateral mass screw systems are significantly more rigid in longer constructs.[149,170,181,182] After cycling, range of motion at the lower end of the construct increased 171% in flexion, 164% in extension, 153% in lateral bending, and 115% in axial rotation. This fatigue failure explains caudal loosening of long anterior plate constructs.[150] In multilevel reconstructions, consider longer and larger diameter screws, or supplementary, posterior instrumentation.[183]

Rather than perform multilevel corpectomies, many surgeons prefer hybrid corpectomy/discectomy decompressions to allow improved restoration of lordosis and additional, mid-construct anchors. Whether the spared ligamentous and bony interconnections justify the additional time and fusion surfaces that must heal remains unclear.[110,184-187] In a cadaveric study segmental fixation afforded by three-level discectomy and hybrid discectomy and corpectomy yielded significantly more flexion-extension and lateral bending stiffness than the two-level corpectomy.[188] In two small studies of four- and five-level hybrid anterior reconstructions, all patients ultimately fused.[189,190] The authors concluded that adjunctive, posterior stabilization was not needed when hybrid techniques are used.

Historically, stabilization of the traumatized cervical spine required either posterior stabilization or halo immobilization.[191] More recently, in patients with a flexion-distraction injury and disc herniations, anterior plate fixation was reported to obviate a posterior approach.[192] Some recommend this approach only in patients with good bone quality, utilizing wedged grafts and external immobilization until radiographic fusion is evident.[193] In a mechanical study, anterior fixation was "adequate" to stabilize the traumatized segment, but lateral mass plating was even more effective.[194]

Failure rates increase with age and medical comorbidities.[195] In that front-back surgeries are difficult to recommend to older, sicker patients, halo bracing has been tried instead. Unfortunately, halo-vests poorly immobilize the lower cervical segments at most risk for construct failure. Halos confer additional pulmonary and other medical morbidity.[196] As such, formal anterior-posterior reconstructions must be considered. After posterior instrumentation, anterior plating does not confer additional mechanical benefits.[149-151]

Cervical Plating: Technique

Anterior plates are typically applied through a standard anteromedial approach. A transverse incision generally suffices. In some cases, a longitudinal incision along the anterior border of the sternocleidomastoid is required. Optimal screw trajectories may be limited by tension from the midline viscera, especially in males with a large thyroid cartilage. In this setting, adequate fascial release improves implant alignment and decreases retractor pressure.[146] Inadequate exposure risks aberrant screw trajectories into the adjacent (usually superior) disc space. Some authors recommend intraoperative fluoroscopy or K-wire placement into adjacent disc spaces to guide subsequent plate and screw trajectory planning.[197] On the other hand, unnecessary dissection or incorrect needle localization may increase adjacent-segment degeneration (ASD) risk.[198]

Select a plate of appropriate size. Depending on the intended screw angulation, the plate should extend no further than the midportions of the superior and inferior vertebrae. Adjacent-level ossification disorder (ALOD), an early form of ASD, increases with plate impingement on the cranial adjacent segment. In one series of 330 ACDFs, Caspar pins, plate impingement, and ALL stripping were all risk factors for ALOD, which was seen in the 6 to 12 months after surgery.[199]

With longer constructs holding pins maintain plate alignment while drilling the screw tracts. Otherwise, drilling may dislodge or rotate the plate. In long constructs, malangulation may translate into poor fixation at the opposite end of the construct. On the other hand, in a series of 200 patients undergoing one-, two-, and three-level ACDFs, frontal plane angulation and lateral displacement were not significantly associated with outcomes.[200]

Close plate contouring increases effective buttressing, may decrease swallowing difficulties, and increases the number of screw threads in the vertebral body.[201] Overcontouring may risk plate fracture.[202] Prior to plate application, ensure proper alignment, especially neck rotation and remove any externally applied traction.

Many surgeons universally use 14 mm screws. Optimally, base screw depth on the anterior-posterior depth of the adjacent intact vertebrae should be 12 to 20 mm. If measuring from CT, confirm that the gantry angle simulates the ultimate screw trajectory. Consider bicortical purchase in osteoporotic bone or more unstable situations.[89] Bicortical screws may better "lever" the spine into lordosis, but may also decrease graft-plate alignment prevent load sharing, and increase force on the bone-implant interface.[156,201] The biggest disadvantage to bicortical screw fixation lies in the danger of cord or root injury.[118,170] If bicortical screws are to be placed, use a screw-tap method under image intensification control. Palpate the posterior cortex with a thin, blunt K-wire or ball-tipped probe.

Some plates strictly fix the screw trajectory. Others allow a "cone" of variable screw placement. Variable angle plates have been recommended as a means of "dynamizing" the construct.[158] Angulation may allow longer screws to be placed with triangulation to enhance pullout strength. Most commonly, an "up and in" trajectory is recommended. Others recommend the screws be angled into the dense, subchondral

bone plate. More recently, a trajectory 90 degrees to the plate has been recommended.[163] Proper screw placement in anterior cervical plating cases is often suboptimal if done without radiographic guidance.[203] When possible, redirect screws that enter adjacent disc spaces.

Typically, the plate supplements the more critical portions of the procedure. Emphasize any necessary canal and foraminal decompression, sagittal alignment correction, and subsequent grafting. Cervical plates will not compensate for poor grafting technique.[74,77] Traditionally, patients undergoing anterior cervical plating procedures were placed in rigid braces postoperatively. More recently, a strong trend toward soft collar or nonbracing has emerged. In a 257-patient randomized, multicenter trial, the nonbraced patients had a higher, but not statistically different, fusion rate.[204]

Cervical Plating: Outcomes and Complications

Anterior cervical plate outcomes and complications vary most by the underlying indication for placement. On the other hand, a general sense of these risks and benefits assists the surgeon when deciding what types of implants are rational in a given clinical situation.

Given that plating is often recommended to improve fusion rates, our limited ability to identify a solid fusion, "stable pseudarthrosis", or symptomatic nonunion must be clear. Plain films do not always reveal subtle clefts or inducible displacement on flexion and extension.[205] Fine-cut CT scans better define bridging trabecular bone, but with significant radiation exposure. Further, implants, particularly stainless steel plates or "trabecular metal" cages cause scatter.

The advantage of anterior plates for single-level cervical fusions continues to be debated.[139,206,207] When comparing reoperation rates before and after they began routinely plating ACDFs, Bose et al.[207] reported 48 unplated cases, in which three developed early graft extrusions and two had symptomatic pseudarthrosis. In comparison, one of the 35 plated one-level ACDFs developed displacement and three exhibited symptomatic pseudarthrosis.[207] Others found little advantage in outcomes or fusion rates after plating one-level cases.[140,208] Unplated patients more often drifted into kyphosis.[208] Another series of single-level discectomies reported pseudarthrosis rates of 4.5% and 8.3% with and without plate fixation, respectively.[134] Based on Odom's criteria, good or excellent results were reported in 91% and 88% of the plated and nonplated patients, respectively. Single-level plating is associated with few complications.[6,132] After one-level ACDF, routine radiographic assessment may not be warranted in asymptomatic patients.[209] Only 2% of the asymptomatic patients had construct abnormalities compared with 25% of the symptomatic patients.

Fusion rates decrease with increasing levels and the advantages of plating become more apparent. In a two-level ACDF cohort, pseudarthrosis rates were 0% for plated patients and 25% for those with no plating.[135] In three-level fusions, better clinical outcomes and an 18% pseudarthrosis rate were reported in the plated group versus a 37% pseudarthrosis rate in the nonplated group.[136]

After ACDF and corpectomy, bone graft collapse or settling into the adjacent endplates commonly results in a kyphotic deformity. Plating is superior to nonplating in maintenance of segmental lordosis, though the impact of that lordosis on long-term clinical outcomes continues to be debated.[210-213] In Wang et al.'s series, the 0.75 mm of graft collapse in plated patients compared with 1.5 mm for nonplated patients.[134] In 93 patients undergoing cervical corpectomy without instrumentation, there was a mean loss of 10.4 degrees of lordosis. Sagittal contour was not associated with neurologic decline or functional outcome.[211]

The complications of instrumented procedures include all of those associated with noninstrumented procedures, with the addition of:

- Metal sensitivity
- Disruption of imaging
- Bulk of instrumentation/soft tissue impingement
- Elimination of space for bone graft
- Late hematogenous seeding of infection
- Increased morbidity of any revision surgeries

A number of authors have reported that cervical plating is "permissive" and over the last 15 years, complications have become similar to those for nonplated fusions.[135,214,215] In large, society-wide reports, cervical instrumentation complications included a 2% to 3% neurologic injury rate, 3% to 45% reoperation rate for implant failure, and 5% to 10% infection rate.[216] Today, neurologic injuries and infections from plate application are rare.[215,217]

Unfortunately, implant failures are reported more frequently (1-4%) and may result from osteoporosis, multiple insertion attempts, inadequate postoperative immobilization, or excessive postoperative loading.[215,217] Often, the implant failure rate is proportional to the number of multilevel cases. Plate rigidity and bicortical screw fixation also impact failure rates.[95,170]

In osteoporotic patients, avoid Caspar pins (which may pull through the bone and disrupt plate anchorage), consider bicortical fixation, and, for those patients with significant cervical deformities, plan a back-front-back approach to serially release and correct alignment.[99] In one recent biomechanical investigation of 12 cadaveric spines, the addition of posterior screws and rods always increased stiffness and resistance to cyclic loading from the anterior plate alone. An especially large difference was noted for fixation of three or more levels.[218]

Unicortical screws may break their plate retention mechanism and back out, or may take the plate with them. Bicortical screws tend to fail in the middle from three-point bending loads after graft settling. When screws enter the neighboring disc space, they may accelerate ASD. The impact of well-performed ACDF on the incidence of degeneration at adjacent levels remains controversial. One cadaveric study found no difference in adjacent-segment motion or pressures between a grafted fusion with and without plate fixation.[219]

Screw displacement may cause esophageal injury.[220,221] Vascular complications arise from over-retraction on carotid sheath or direct injury to the vertebral artery.[29] Retraction is especially problematic in older patients with atherosclerosis

and may lead to strokes. Vertebral artery injury is rare with anterior procedures and is thought to occur with excessive lateral dissection.

Dysphonia and dysphagia have received more attention in the recent literature. While rates vary from 2% to 60% (which may depend on whether and how the question is asked), both are more common in women.[222-224] Rates increase with revision and more cranial levels.[222-224] The degree to which plate placement and thickness affect dysphagia remains controversial.[223,225,226] If there is a plating effect, it may arise from plate thickness, texture, or merely the increased exposure necessary to place one. One study compared final construct height with preoperative osteophyte height.[224] No differences in rates of dysphagia were noted. When comparing 156 consecutive patients undergoing ACDF with either the thinner, smoother Zephir plate or the thicker and rougher Atlantis plate, dysphagia gradually decreased over 2 years to 0% and 14% in the Zephir and Atlantis groups, respectively.[225] Plate removal improved dysphagia in 17 of 31 patients.[226] In those improving after plate removal, adhesions were found between the plate and surrounding fascial structures.

Anterior Cervical Cages

Along with plating, cervical cages have evolved as increasingly complex cervical reconstruction efforts were carried out anteriorly. Structural grafting historically required tricortical iliac crest or autologous fibula harvest. In some countries, allograft bone banks have obviated the morbid structural bone harvest. In other parts of the world, allograft is not readily available and axially stable implants were sought to eliminate structural graft harvest.[227]

Mechanics and Rationale

Initially, mesh cages were developed for corpectomy indications. Over time, cage materials and geometries have rapidly expanded. Now, there are interbody devices for ACDF procedures, struts to reconstruct corpectomy defects, expandable cages, and cages with built-in plating or screw-in mechanisms. Cage materials include machined allograft, titanium, polyetheretherketone (PEEK), carbon fiber, and trabecular metal (among others) (Fig. 69.6). The ideal cage provides the following benefits[228]:

- Immediate structural support to resist axial compression and maintain anterior column distraction
- An adequate "footprint" to resist subsidence
- Small enough size to prevent stress shielding of the graft material
- Decreased surgical morbidity by obviating structural autograft harvest
- Avoidance of structural allograft complications (interspecimen quality variability, microfracture, collapse, and the possibility of viral transmission)

Theoretical disadvantages of anterior cage placement include the following [229]:

- Variable modulus of elasticity mismatch with host bone (depending on cage material)
- Increased cost
- Sharp edges causing soft tissue injury with displacement (mainly titanium mesh)
- Difficulty with postoperative imaging and confirmation of fusion (metallic implants)
- Limited true fusion (spot welding of small graft area inside the cage to host bone)
- Limitations in "sculpting" of material after insertion

As with cervical plates, many design philosophies have evolved that attempt to maximize cage advantages while minimizing their limitations. As with other implants, no best cage has been identified. Some implants are better suited for some patients or indications than others.

Cervical cages come in two main geometries: vertical and horizontal. Typically, vertical implants fill corpectomy defects and horizontal implants reconstruct postdiscectomy gaps. For the latter group, the mechanical goal is of distraction-compression via restoration of annular tension.[230,231] Implantation technique varies but is not significantly different than bone graft placement. The metallic tines of vertical cages and threads or texturing of horizontal cages allow better torsion and displacement resistance than an equivalently sized, smooth bone graft.

Cages are further subdivided by shape and material. Horizontal cage designs, for example, include screw-in, box, or mesh. Screw-in cages are threaded cylinders (e.g., BAK/C; Zimmer Biomet). The use of these implants has declined since the last edition of this text due to the excessive endplate violation required for insertion. Box cages are rectangular with textured bearing surfaces. The titanium implants developed initially gave way to carbon fiber and then PEEK designs (Fig. 69.7). One recent comparative study found no difference in the mechanical properties or fusion potential of PEEK vs. titanium ACDF spacers.[232]

Several mechanical studies have been undertaken to better understand the relative merits of different cage materials and geometries. In one, multiple cage types and autologous iliac crest grafts were tested in flexion, extension, axial rotation, and lateral bending in 80 sheep spines. Compared with an intact segment, cages increased flexion but decreased rotational stiffness. Mesh designs provided greater extension and bending stiffness than screw-in designs.[233] When compared with standard Smith-Robinson ACDF, single BAK/C offered significantly lower stiffness and failure loads.[234] Cage size and placement in the disc space are more important than differences in pore size or materials.[235] A fully open cylinder transferred loads more effectively than a central pore in a box design.[236]

The mechanical benefits of cages over bone graft are small. A cage does not supplant the additional stability afforded by plating.[90,228,237-239] A finite element model compared four implantation methods and found that stand-alone cages offered the least stabilization. The cage with a locking plate was very stiff in all directions. Two dynamic plate configurations reduced flexibility in all directions compared with intact cage but left significant mobility.[240]

One disadvantage of cage implantation is difficulty assessing radiographic fusion status; radiolucent carbon fiber and PEEK interfere less.[229] Even more important is the expense;

FIG. 69.6 (A) Axial and (B) coronal computed tomographic (CT) scan of structural vertical mesh cage with autogenous bone graft placed inside cage. The cage was placed too far to the right (best seen in A), and the patient reported right-sided radicular symptoms. (C) Sagittal CT image of patient in whom reconstruction of a three-level corpectomy for ossification of the posterior longitudinal ligament was attempted with an expandable cage. Despite the presence of fusion with segmental instrumentation, cage subsidence into the T1 superior endplate led to anterior displacement. This cage was ultimately replaced with a custom-cut mesh cage.

in most cases, cages are used with, rather than in lieu of, plating.

As with traditional grafting, subsidence has been seen with cages, but less with wide endplate coverage.[238,241] For example, cylindrical implants subside significantly further than plate and graft or rectangular cage constructs.[228,242] Endplate preservation and graft pegging or limited endplate perforation for vascular ingrowth decrease subsidence.[114,243]

Expandable cages, initially used in tumor reconstruction cases, have recently received increased attention in reconstruction of the degenerative cervical spine. Proponents argue that traditional cages require segmental overdistraction to place the cage and achieve tight endplate contact.[244] Distraction in situ allows the cage to be precisely adjusted to the defect.

Thus, these cages may also be easier to place in anatomically challenging regions such as the occipitocervical and cervicothoracic junctions. Alternatively, more extensive jaw-splitting or submandibular approaches may be used to place mesh cages. Anterior occipitocervical implants continue to be described, typically for post–tumor resection cases and usually with posterior, rigid, adjunctive instrumentation. Recently, a biomechanical study of anterior mesh cage placement with screws into the clivus demonstrated stable fixation for reconstruction of extensive ventral upper cervical spine defects.[245]

In a retrospective review of 20 corpectomy patients reconstructed with a distractible cage with an attached plate, stability was achieved in all cases. One subsidence and 75% good or excellent outcomes were reported.[246] In anatomic regions with limited anterior access (e.g., cervicothoracic and occipitocervical junctions), formal anterior plating may be difficult. Custom cages decrease the need for perpendicular access to the spine.[247] Detractors argue that expandable cages limit bone graft area, add significant cost, and generate high forces that precipitate adjacent-segment fractures.[248]

Newer hybrid cage devices incorporate plates or screw recesses.[229,249] These anchored spacers integrate screws to provide immediate fixation while maintaining low implant profile. This approach may decrease procedure time and allow decreased morbidity of approach by limiting anterior soft tissue disruption, particularly for surgery adjacent to a previous fusion, in that it may obviate the need for plate removal. However, a stiff fusion mass may overtax the holding power of these devices. While one biomechanical comparison of an anchored spacer to predicate cage-plate constructs found no significant differences, the same authors more recently found

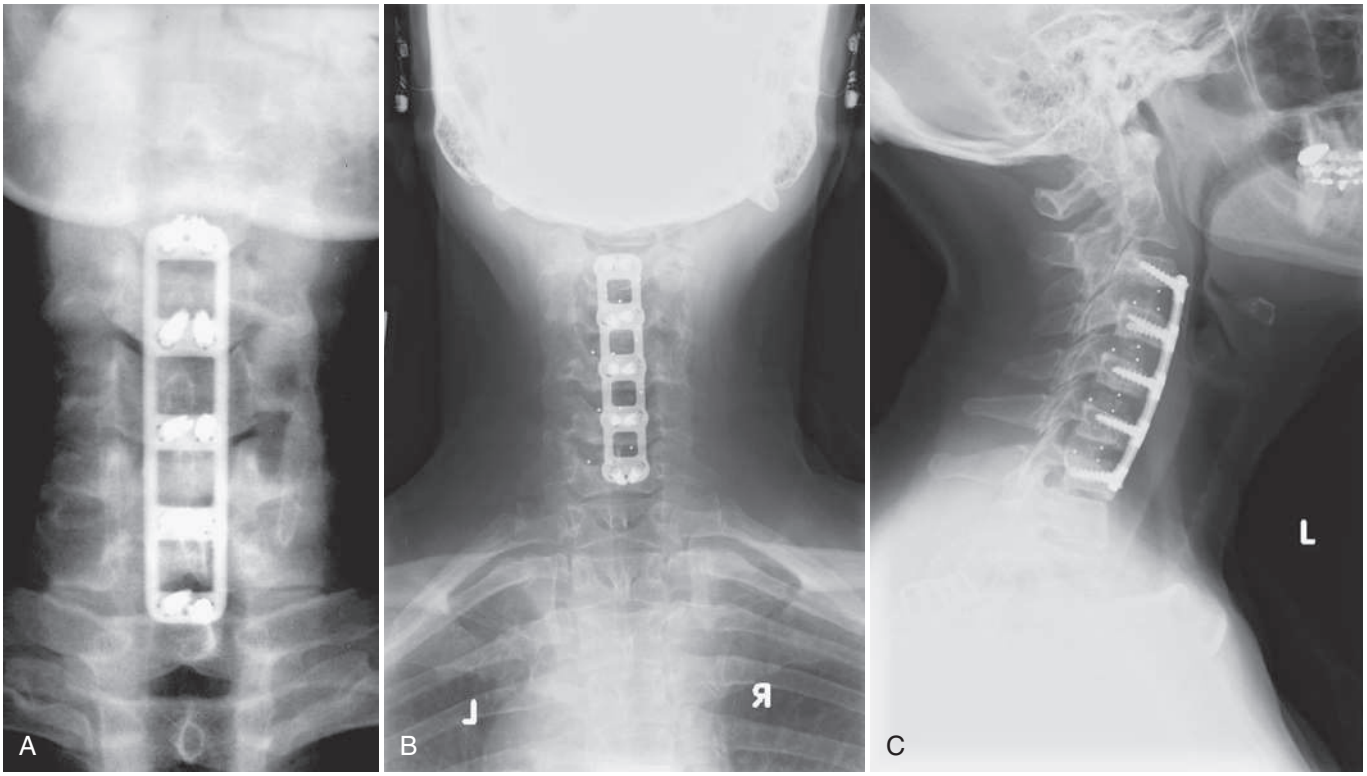

FIG. 69.7 (A–B) Anteroposterior and (C) lateral radiographs showing multilevel C3–C7 anterior-only reconstruction with anterior cervical plate. Local autograft was used to fill polyetheretherketone cages, and full healing was documented on computed tomography. The patient later reported painful subjacent degeneration at C7–T1.

that separate plate and graft constructs were stiffer than integrated devices in all testing modes.[148,250] The difference increased with the number of levels performed. On the other hand, one recent cadaveric biomechanical study concluded that the anchored spacer "showed stabilizing potential at the operated level statistically similar to that of the standard revision with a two-level plate."[251]

In a recent clinical study, 63 patients underwent either stand-alone cage or more typical cage-plate reconstruction.[252] At 1-year follow-up, similar overall clinical outcomes were achieved, but the stand-alone device was associated with a lower risk of dysphagia, procedure time, and estimated blood loss. Other small series have also reported good clinical results.[253]

As with anterior plating, interbody bioresorbable polymers have been studied. Results have been mixed.[76,177,254] At this point, these devices cannot be recommended for implantation outside of carefully controlled trials.

Implant Selection and Technique Notes

Cervical cages are used to reconstruct anterior spinal column defects. As such, they may be used after discectomy procedures or to fill in corpectomy defects after surgery for degenerative, traumatic, or neoplastic indications. Use of nonbiologic materials in the face of active infection remains controversial.[255] Allograft struts are just as susceptible to glycocalyx or biofilm formation as metal or PEEK implants.

Ideally, structural autograft would be used in patients with osteomyelitis. However, because the autograft harvest adds morbidity in already frail patients, several authors have used titanium and PEEK implants and have reported successful reconstructions.[255-257] At follow-up intervals of 20 to 54 months, these authors reported greater than 90% fusion rates and no recurrent infections. However, "radical" anterior debridement is recommended along with posterior screw-rod stabilization and 8 to 12 weeks of intravenous antibiotics. As an exception, one series reported two recurrences in a group of 36 patients with vertebral bone destruction treated with expandable cages caused by infections ranging from *Staphylococcus aureus* to tuberculosis.[258]

Restoration of stability may be more critical than avoiding implants. Full debridement of cervical osteomyelitis often requires two-level corpectomy. Typically, surgical indications include neurologic compromise, vertebral body destruction with kyphosis, segmental instability, failure of medical treatment, and epidural or paravertebral abscess.

As with plating, anterior cage procedures are mechanically most vulnerable when carried over multiple levels, risking extrusion and subsidence. Cage subsidence is associated with neck pain, plate failure, significantly lower Japanese Orthopedic Association score recovery, and late neurologic deterioration.[227] As with plating, hybrid approaches and multilevel discectomy are more stable than corpectomy.[259]

Stand-alone cages (e.g., without anterior plating or a posterior rod-screw construct) are also controversial. Typically,

good clinical outcomes and fusion rates (93.3–100%) are described despite high subsidence rates.[260,261] Subsidence and segmental kyphosis are worst at C6–C7.[262] In a comparison study, 44% of stand-alone cage segments lost more than 5 degrees of lordosis and subsided more than 3 mm, typically by 3 months after surgery.[263] Outcomes do not appear to be affected by these radiographic findings.[263,264] However, small series have reported successful use of stand-alone cages adjacent to previous ACDF constructs.[265]

Bone Graft Selection

Particularly in areas without allograft banks, cages provide structural support, thereby avoiding the chronic donor site pain seen in up to 31% of patients undergoing structural autograft harvest.[139,266-268]

Several graft options can be used with structural cages. Nonstructural (morcellized) iliac crest autograft, often collected percutaneously with reamers, may be placed in or around the cage.[269] Others recommend local bone from the decompression, which may be copious in disseminated idiopathic skeletal hyperostosis or spondylosis cases but limited in soft disc herniation cases. Morcellized allograft, demineralized bone matrix patties, and recombinant human bone morphogenetic protein 2 (BMP-2)–containing sponges have also been used. A few series report excellent results after implanting "empty" cages.[270–273]

Machined allograft cages may not require additional grafting and have compared favorably to autograft in one- and two-level anterior procedures.[274] A number of allograft options are available. For discectomy procedures, tricortical iliac crest wedges and small fibular rings predominate. Dense cancellous allograft (e.g., patellar wedge) has been recommended for its open-matrix structure. This structure imparts axial stability comparable to tricortical iliac crest and more fully cortical fibular grafts while maintaining a porous structure that promotes vascularization and cellular penetration.[275] In one series of 98 patients, dense cancellous allograft was used with one- and two-level dynamic plating. At 12 months, the fusion rate was 96%. While there were no allograft or hardware complications, mean subsidence was 2.0 and 3.2 mm for the single- and double-level constructs, respectively.[172]

In a multilevel ACDF study in alpine goats, threaded intervertebral fusion cages filled with BMP demonstrated a much higher arthrodesis rate and accelerated bone formation compared with either autogenous bone-filled BAK/C or autogenous bone grafts.[276] In humans, enthusiasm for anterior cervical BMP placement has been tempered by postoperative swallowing and breathing problems in nearly one-fourth of patients implanted.[277] BMPs may also stimulate the resorptive phase of bone healing, leading to endplate resorption and increased cage migration.[278] Another series of 200 retrospectively reviewed one- to three-level ACDF patients found a 100% fusion rate using CT and dynamic radiographs.[279] Soft tissue problems included 14 (7%) with clinically significant dysphagia and four (2%) who required repeated operation for hematoma or seroma. Outside of very low doses implanted for specialized circumstances, anterior cervical use of BMP is not recommended.

For either structural autograft or allograft, avoid placing screws into the graft itself as this increases the risk of graft fracture.[280,281] Some PEEK, carbon fiber, and metallic cages contain holes to allow fixation to an anterior cervical plate. The mechanical benefits of this additional fixation have not been convincingly demonstrated.

Cages constructed entirely of osteoconductive materials such as tricalcium phosphate or trabecular metal have come into use. The crystalline grafts may be more brittle, but they have better imaging characteristics than their metallic counterparts. Small studies using coralline interbody implants have reported variable clinical outcomes, fusion rates around 45%, and high rates of graft fragmentation and subsidence.[282-284] Tantalum interbody implants are far less brittle but add considerable scatter even with CT evaluation. A recent study randomized 61 patients to ACDF with a tantalum interbody implant or autologous iliac bone graft and plating.[285] Although 24-month radiologic and clinical outcomes were similar, complications were considerably higher in the autologous graft group. Some hybrid PEEK or metal cages incorporate osteoconductive cores of tricalcium phosphate, coralline hydroxyapatite, or similar materials.[286] Use of these implant types remains limited.

Technique

Wider endplate coverage allows the cage to better resist axial compression forces. Therefore, especially at lower cervical levels, choose the widest cage that will fit in the defect.[235,262,287] For some multilevel procedures, different cages may be optimal at different levels.[262] Some recommend anterior osteophytes be retained to increase load-bearing area.[261] It is unclear whether the axial load-bearing benefits of osteophyte retention exceed detrimental effects on plate prominence or buttressing.

To decrease extrusion rates, achieve a tight interference fit. Excessive traction unloads the articular pillars posteriorly.[112] Increasing cage height also increases segmental lordosis, but this may decrease adjacent-segment motion.[288] When selecting and implanting a cervical cage, observe the following:

- Maximize endplate coverage, especially at lower cervical levels
- Avoid excessive traction before insertion
- Avoid excessive endplate violation
- Add a plate for discectomies of more than one level and all corpectomies
- Consider supplementary posterior fixation for two or more level corpectomies

In the absence of specialized indications, avoid radiopaque and expensive, cylindrical, and poorly modulus-matched implants.

Outcomes and Complications

Several studies examine the impact of cages after anterior cervical reconstruction. Most typically, outcomes vary far more by the indications for surgery than by the implant

selected. On the other hand, some studies have compared various instrumentation types.

Initial favorable reports in 80 and 135 patients receiving BAK/C cage implants reported high fusion rates.[289,290] These initial reports were followed by prospective, randomized, FDA trials comparing BAK/C cages with uninstrumented ACDF in 344 radiculopathy patients. Virtually all outcome measures were similar in both groups and maintained over 2 years. The authors concluded that threaded fusion cage outcome are the same as those of a conventional uninstrumented ACDF with iliac crest autograft.[291] With longer, 4.8-year follow-up in 103 patents, 95% good-to-excellent outcomes were reported with a 98.9% fusion rate.[292] Lordosis was maintained in 93.8% and increased in 6.2%.

Other, smaller studies have compared rectangular carbon fiber and titanium cages with iliac crest autograft. High fusion rates and equivalent outcomes were reported in all groups. Significant donor site pain was reported in 20% to 33% of the structural autograft patients.[269,293,294] An economic comparison found that costs between mesh cages and autograft were not significantly different because of the iliac crest harvest morbidity.[267] Another prospective, randomized study of 42 cervical interbody fusions found similar results with either an autologous tricortical graft or a cage and that tricortical graft was cheaper.[295]

Fewer studies report cage outcomes after corpectomy surgery. Most are retrospective reports of 26 to 100 patients reporting titanium mesh or PEEK packed with local autograft or allograft chips.[256,296,297] Successful use of stand-alone cages in one-level corpectomies is reported, whereas three or more corpectomy levels use adjunctive posterior stabilization. Fusion rates from 97% to 100% are reported, but so too are occasional cage extrusions, kyphotic collapse, and postoperative radiculopathy. Most authors concluded that titanium cages provide immediate strong anterior column support with minimal hardware complications and avoid bone graft site morbidity.

Other prospective, randomized studies have been somewhat less enthusiastic about the cage outcomes. In three studies with approximately 100 patients randomized to ACDF with a carbon fiber cage or a traditional Cloward procedures, overall pain and disability were similar for both groups.[298-301] Although donor site pain was significantly less in the cage group, the fusion rate was significantly lower as well (85%, 86%, and 81% vs. 55%, 62%, and 74%, respectively). In both studies, patients with pseudarthrosis reported more severe neck pain than those solidly fused.

Anterior cervical reconstruction with cages conveys the same risks as surgery without cages.[238] Complications such as displacement or subsidence with foraminal stenosis occur more frequently in multilevel procedures (up to 33%) and in osteopenic or spastic patients. In these settings, adjunctive posterior stabilization should be considered. [302-304]

Cervical Disc Arthroplasty

As of this writing, only three cervical implant strategies seek to preserve segmental motion: direct screw osteosynthesis, laminoplasty with plates, and cervical disc replacement. Although there is longer clinical experience with lumbar disc arthroplasty, cervical total disc replacement (TDR) is more commonly offered in most countries.[305,306]

FIG. 69.8 Lateral radiograph of a patient who underwent cervical disc replacement at C6–C7 below a previous C5–C6 anterior cervical discectomy and fusion.

Relative to the lumbar spine, differences between fusion and nonfusion stabilization methods are more pronounced in cervical applications. The cervical lateral masses have a much larger role in axial load bearing than the lumbar posterior elements. The smaller cervical bony endplates challenge endplate fixation.[307] The anterior airway and posterior cord amplify the risks associated with cervical TDR relative to their lumbar counterparts (Fig. 69.8).

A wide variety of materials have been incorporated into TDR systems, including cobalt-chrome, titanium, and high-molecular-weight polyethylene; optimal biomaterials have not been identified.[308,309] The cobalt-chrome devices affect postoperative MRI imaging to a much greater degree than the titanium-based devices.[309] The likelihood and effects of wear debris do not appear to be significant concerns in early follow-up studies or in experimental models, but these particles clearly migrate into the periprosthetic and epidural spaces.[310] The long-term inflammatory potential of metal-on-metal appendicular prosthesis debris has led to the removal of both spinal and appendicular arthroplasty systems from the market.[311,312]

Even within material groups (e.g., metal-on-polyethylene), many design questions remain unanswered.[307,313] Some systems rely on a midline keel to achieve fixation; others use spikes or endplate texturing. Keels may risk sagittal split fractures,

especially in multilevel implantations.[314] These devices vary in terms of the constraint they place on normal segmental motion.[313] Typically, more constrained implants require more elaborate endplate fixation methods but may also offer more protection of the facets.[315] No current device fully restores normal segmental kinematics.[307,316] Even suitable device kinematics require perfect midline positioning and rotation to provide proper motion.

Unlike lumbar applications, cervical disc replacements have been implanted in the treatment of spondylotic radiculopathy and myelopathy, not axial pain syndromes.[317] Contraindications include active infection, osteoporosis, and radiographic evidence of mechanical instability or absent motion. The prevalence of contraindications in patients with cervical degenerative disease is lower than in similar lumbar cohorts.

Given the perception of traditional ACDF surgery as highly successful, expectations for implementation of expensive new technology such as disc arthroplasty have been very high.[317] First, in most younger and active patients, preservation of motion itself is a worthy goal and may be associated with decreased postoperative axial pain and improved function. More important, however, is the effort to decrease adjacent-segment degeneration.[318]

As of this writing, cervical arthroplasty continues to slowly gather proponents. Certainly, patient selection for arthroplasty is far more selective than for predicate anterior discectomy and fusion procedures.[317] Most randomized trials show outcomes that favor TDR; an analysis of outcome predictors shows that patient factors such as work status and pending litigation have a far greater impact on outcomes than the disc spacer utilized.[319,320] Most recent reports detail FDA trials of newer implants or two-level placement. For example, a recent report detailed the 4-year outcomes of a two-level implantation of the Mobi-C (Zimmer Biomet).[321] The device maintained motion, and no device failures were reported. In this study, and most others, arthroplasty patients had better outcomes in terms of Neck Disability Index and Short Form-12 scores while having a lower rate of secondary surgeries compared with ACDF. Favorable 10-year outcomes have been reported.[322,323] Interestingly, strong evidence favoring arthroplasty in terms of adjacent-segment degeneration has not yet emerged.[324,325]

Posterior Cervical Instrumentation

Posterior cervical instrumentation can be categorized by location into occipitocervical and subaxial implants. Functional categorization includes rigid segmental systems versus nonrigid wiring systems. Posterior implants may be used in a motion-sparing capacity when stabilizing a laminoplasty door. Recently, spacers have also been introduced for placement in the cervical facets.

Occipitocervical Instrumentation

As with other types of spinal instrumentation, nonrigid wire constructs have given way to screw-based rigid constructs. Still, the heterogeneous mix of pathologies and patient age requiring occipitocervical stabilization ensure the older methods remain relevant.

Nonrigid Occipitocervical Systems

Initially, occipitocervical stabilization involved onlay fusion with morcellized graft followed by prolonged halo immobilization.[34,326] Fusion rates from 75% to 89% were reported. Subsequently, to allow early mobilization without a halo, occipitocervical stabilization using sublaminar wires and PMMA was reported.[327] Although excellent clinical results were reported, fusion rates were not and this technique has been largely abandoned.

Wertheim and Bohlman reported good results using a structural bone grafting technique with sublaminar wires.[328] To improve stiffness, subsequent authors incorporated bent Steinmann pins, Kirschner wires, curved rods, and malleable loops and rods into sublaminar wire or cable constructs.[329-334] These constructs often use cancellous rather than structural autograft. While these rods confer additional stability over wired structural bone, they are semirigid and typically require halo immobilization.[335-337] Fusion rates vary from 90% to 100%.[328,337]

Typically, semirigid constructs achieve occipital fixation with burr holes. Segmental spinal fixation is obtained with interspinous or sublaminar wires. Interspinous wires decrease risk to neurovascular structures and offer less-restrictive placement options. Wire-graft and wire-loop constructs have disadvantages, including limited utility in patients requiring decompression, decreased fatigue life, and the need for postoperative immobilization. Rods wired to the bone may piston through the wires, reducing vertical stability.[338-341] In patients with poor healing potential, the increased fatigue susceptibility of wired constructs favors rigid fixation.[342] Similarly, rigid stabilization should be considered when bulky external bracing is contraindicated, as in spinal cord or pulmonary-injured patients, or when compliance may be limited.[331] Luque rectangle and two rigid plating systems conferred similar compression and flexion stiffness in one study, but the plates were far more stiff against extension and torsion.[341]

Sublaminar and suboccipital wire passage can be technically challenging, especially in patients with axial collapse or stenosis. These difficulties stimulated interest in rigid systems, which evolved from contoured appendicular trauma reconstruction plates. These implants stabilize without canal incursion or postoperative halo immobilization.[337,339] Whether wiring or screws offer better fixation in the osteoporotic cervicocranium remains controversial.[329,330]

Rigid systems are recommended in cases of deformity correction or with multiplanar, particularly vertical, instability.[339] Specifically, screw-rod constructs are indicated in patients undergoing decompressive laminectomy, dens resection, or multiple-level fixation from the occiput to the lower cervical spine.[343] Ostensibly, rigid stabilization allows shorter constructs, saving fusion levels.[337,339] Historically, occipitocervical fusion was utilized in dens fracture malunion or nonunion.[344] Today, C1 lateral mass screw fixation avoids extension to the occiput in many cases.

There are no specific contraindications to occipitocervical fusion. In fact, for patients with clear occipitocervical instability, few alternatives exist. In some patients, medical issues provide a relative contraindication. Unfortunately, external stabilization is relatively ineffective in patients with higher degrees of instability. Typically, contraindications imply safety of one technique over another. Aberrance in vertebral artery anatomy, for example, increases risks of C2 pars fixation.

Autogenous iliac crest bone grafting remains standard for occipitocervical fusions. If possible, cable a strut down to bridge the bleeding surfaces of the host bone.[345] Allograft bone has been less successful.[346] BMP has been used and results have varied, but they may approach autograft.[347] Complications, including neurologic decline, have been reported.[348]

Occipitocervical fusion requires rigid head control with either a Mayfield head clamp or an open halo ring. The articulation's large flexion and extension arc requires careful attention to alignment. On lateral fluoroscopy, assess the occipitocervical angle.[349,350] In neutral, the intersection of McRae's line and a line through the superior endplate of C3 should be 44 degrees. Of three techniques used to measure occipitocervical alignment, McGregor's line was more reproducible and reliable than Chamberlain's and McRae's lines.[351] Improper alignment may increase subsequent subaxial degeneration.[352] Shallow postoperative occiput–C2 angles, which decrease oropharynx cross-sectional area, predict postoperative dyspnea and dysphagia.[349,352]

Until the 1990s, the semirigid Wertheim and Bohlman technique was the most common form of occipitocervical fusion.[328] Expose the posterior elements from the EOP to C4. Create a trough on both sides of the EOP 2 cm above the foramen magnum with a high-speed burr. Use a towel clip to create a hole in the ridge and pass an 18-gauge wire through the hole. Twist the wire over the ridge. Then, pass a second, sublaminar loop around the C1 arch. Pass a third loop through and around the base of the C2 spinous process. Harvest a thick, 3×5 cm corticocancellous graft from the posterior iliac crest. Divide the graft longitudinally into two parts and drill three evenly spaced holes into each graft. Decorticate the occiput, C1 ring, and C2 laminae. Thread the more lateral arm of the wire at each level through the corresponding holes. Maneuver the graft down the wires until it is apposed to the decorticated bone. Bring the second arm of each wire medially around the graft and tighten the wires sequentially. Pack additional cancellous bone between the two grafts. If fixation is secure and bone quality is good, use a skull-occiput-mandibular immobilization or Minerva brace postoperatively. If fixation is poor, maintain the patient in a halo vest for 6 to 12 weeks.

Alternatively, obtain safe bicortical wire passage by enlarging the foramen magnum and thinning the occiput with a burr in a 5- to 7-mm semicircle. Then resect the remaining inner table piecemeal with a 2-mm Kerrison rongeur to remove the posterior lip of the foramen magnum. Create two to four occipital holes with a 4-mm burr approximately 1 cm lateral to the inion and approximately 7 mm cranial to the foramen magnum. Elevate the dura off the inner table toward the burr holes and from the foramen magnum with a 4-0 curved curette. Pass a looped, double-twisted, 24-gauge wire or braided cables through the holes on both sides. If a C1 laminectomy has been performed, drill a small hole through the remnant of the lamina on either side, if there is sufficient remaining bone, and pass a single 24-gauge wire through.

In the presence of neurologic compression, do not attempt sublaminar wire passage. Instead, pass a wire through the C2 spinous process by drilling transversely approximately one-third of the length up the spinous process. On each side, perforate the cortex with a 2-mm burr and connect those holes with a towel clip. Then pass a 20-gauge wire through the hole, loop it under the spinous process, and pass it a second time.

Occipitocervical fusion with a Luque or Ransford loop uses similar wiring positions and requires a template and fluoroscopy to ensure appropriate rod contouring. The rod profile must exactly match the skull and cervical laminae to prevent wire or cable cut-through. The wires are used to hold both the rod and the bone graft, or the rod alone, with nonstructural bone graft placed around the rod.

Rigid Occipitocervical Instrumentation

Rigid occipital fixation has been achieved with unicortical and bicortical 3.5-mm screws, inside-out, and screw-nut techniques.[353-355] The original, rigid, longitudinal connectors between the cervical spine and skull were dual pelvic reconstruction plates extending laterally from cervical spine lateral masses to lateral positions on the occiput.[356,357] Because the occiput is thickest and pullout strength greatest at the EOP, Y-plates, utilizing the stronger midline occipital keel, were developed (Table 69.1).[358] Histologically, this 9.7 to 15.1 mm thick, dense bone is ideal for screw fixation but decreases radially from the inion.[359,360] The midline bone between the inion and the foramen magnum remains thicker than laterally. Newer modular systems with occiput-specific plates optimize skull fixation by placing screws in the thick, midline keel.[361]

In some children or when adequate bone anchorage is not available in the midline keel, hooks may be placed in the occipital squama.[362] Alternatively, occipital screws may be placed into the condyles instead. The clinical and mechanical pros and cons of this technique have not yet been elucidated.[363]

The mobile locking mechanisms found in newer systems require less meticulous rod contouring, but all are technically demanding and require a thorough knowledge of occipitocervical anatomy.[356] These rod-plate hybrids allow more room for bone graft and increased intraoperative flexibility with no fixed hole-to-hole distances but are more expensive.[364] Many of these plates allow additional perimedian screw placement to improve rotational control.[365]

The various occipital constructs can be combined with a variety of cervical fixation methods. Most commonly, C1 lateral mass screws alone or with C2 pedicle screws, C2 pedicle screws alone, or C1–C2 transarticular screws are described.[108] When plated to six occipital screws, C1–C2 transarticular screws are either the most rigid form of occipitocervical fusion or are equivalent to C2 pedicle screws.[330,366-368] Occiput–C1 transarticular screws have been described but are technically demanding to place and require additional Magerl screw

stabilization. These screws may not be appropriate in patients with distracting injuries.[369]

At surgery, place the distal anchoring screws first. With the cervical fixation in place, template the skull. Match both contour and the cervical screws' position. The need for coronal and sagittal plane contouring has increased the popularity of rod-plate hybrids. Occipital fixation should be as close to midline as possible and close to, but not over, the EOP. Plating over the inion causes painful occipital prominence. Caudally, avoid the foramen magnum because the bone is thin and the trajectory difficult. Screw lengths range from 6 to 14 mm, average 10 mm, and become longer toward the EOP. Use a set-depth drill bit at 8 to 10 mm. Drill, palpate the inner cortex, deepen the depth setting 1 to 2 mm, and redrill until the cortex is breached. Because the occipital bone is hard, these screws should be tapped. The smaller threads on self-tapping screws may not be adequate in younger patients with good bone stock. Constructs incorporating a bone strut with the plate allow longer screws to be used but add construct bulk.

The weakness of the skull's inner table and the proximity of the venous sinuses argue for unicortical fixation.[24,359,370] Bicortical screw pullout strength is 50% greater than unicortical screws, whose holding power is similar to wiring.[360] Usually, bicortical purchase is recommended because unicortical screws strip on contact with the inner cortex. Vascular injury and dural leak can be avoided with a careful drill-tapping technique. In older patients, the dura may be adherent to the skull's inner surface. Stop the ensuing cerebrospinal fluid leak by placing the screw.[330,356]

Once the plate is in place, fashion a corticocancellous graft to lie between the two plates. Notch the graft to straddle the C2 spinous process and cover the posterior arch of C1 and the occiput. Hold the graft in place using heavy suture or wire. Alternatively, place a screw in the midline of the skull and wrap wire or cable around the screw, then over the graft and around the C2 spinous process. Denuding the C1–C2 facet joint cartilage allows additional bone to be packed directly. Immobilize rigidly stabilized patients in a collar for 4 to 12 weeks. Before discharge from care, verify union with flexion-extension radiographs.

Outcomes and Complications

Occipitocervical fusion patients are often acutely ill from high-energy trauma, neoplasm, systemic infection, or advanced rheumatoid arthritis. Modern anesthetic and perioperative management has reduced the mortality rate from 10% to 1.7%.[326,371,372] Complication rates vary widely based on underlying comorbidities. For example, perioperative complications were historically common with occipitocervical fusion in rheumatoid patients.[373,374] Complication rates decrease when patients are treated earlier in the disease.[375] Children have rarer but still significant complication rates. Although some series describe "minimal" complications using contoured plating systems, others report complication rates up to 30%, including transient quadriplegia, pneumonia, hydrocephalus, cerebrospinal fluid leak, and traumatic fusion fracture.[326,333,356,376]

Irrespective of the construct used, with autograft occipitocervical arthrodesis rates are high, at 85% to 100%.[108,328,337,377,378] However, one study reported 100% failure of seven fusions performed with cadaveric bone. Subsequent autogenous iliac crest graft achieved fusion in all seven.[346] In children, 100% fusion rates have been reported without internal fixation.[379] Even rheumatoid patients, perceived as poor healers, demonstrated 94% to 100% fusion rates with rigid occipitocervical fixation.[326,339,380,381]

The construct failure rate, with loss of fixation and recurrence of deformity, is proportional to the fusion rate. The rate and mode of failure depend on the surgical technique and postoperative immobilization. Wiring constructs fail by cut-through of the wire through the bone or by fatigue failure of the wires themselves. Rigid systems fail by fracture through the inferior lateral mass or pedicle.[341] Construct failures also increase in patients with osteoporosis and neuromuscular disorders. With constructs ranging from the Ransford loop to modern, rigid systems, failure rates of 0% to 5% are reported.[337,357,372,382-386] In a recent study using CT assessment of final fusion, 27 occipitocervical fusion patients were assessed at a mean 7.2 years.[387] In this series, failures were seen at a mean of 31.2 months. The authors emphasized the importance of "sufficient bone grafting, proper decortication of the bone bed, use of thicker and high stiffness rods, and ultra-high molecular weight polyethylene tape" reinforcement to minimize implant failure.

Of course, successful osteointegration does not guarantee a favorable clinical outcome. Occipitocervical fusion limits postoperative motion, an effect compounded by postoperative halo. In one report, neck stiffness caused half the patients to make lifestyle changes.[383] A series of cancer patients reported 75% excellent or good outcomes.[377] Children exhibit far less range-of-motion loss after occipitocervical fusion and have overall favorable outcomes.[379,388]

In children, the possibility of an occipitocervical "crankshaft" phenomenon remains controversial.[389] In children younger than 6 years, postoperative increases in occipitocervical junction lordosis have been reported. Fixation in a neutral or slight flexion may counteract this increase.[382] Spontaneous fusion extension occurs in adults but is more common, at up to 38%, in younger patients.[333,390] In a 17-year follow-up study, 90% of children and adolescent patients had reported excellent or good results with a low complication rate despite an overall increase in osteoarthritis changes in unfused segments and a decrease in mobility.[390] In another study, the rate of adjacent-level degeneration at 5 years was 7%.[326] Late subaxial subluxations can occur in any patient group but are more common in patients with active rheumatoid arthritis.[384]

The subcutaneous nature of the occiput also risks wound infection and dehiscence, especially in rheumatoid, less-mobile, and older patients.[384] In a heterogeneous patient population, a 5% wound infection rate was recorded.[326] Older series report pin site infections and skin breakdown under the halo vest.[333] Even patients immobilized by collars should be observed closely for occipital ulcerations, especially those with greater occipital nerve anesthesia.

While more rigid constructs have higher theoretical risk of neurovascular injury, the reported rate of these injuries has been low.[356,376] In a series by Sasso and colleagues, a total of 78 occipital screws were placed. No patient deteriorated neurologically and no complications resulted from any of these screws.[381] Abumi and colleagues' series included subaxial pedicle screws, and no neurovascular complications were seen.[391]

In most series, the risk of postoperative neurologic deterioration and the prognosis for recovery are inversely proportional preoperative deficits.[392] In a Ransford loop study by Malcolm and colleagues, of seven patients who deteriorated neurologically after surgery, none had been neurologically normal.[383] In rheumatoid patients, more severe neurologic involvement is associated with lower recovery rates.[372,393] In most series, surgical intervention reliably prevents further neurologic decline.[372,385,393-395] The literature demonstrates less reliability in neurologic improvement.[372,385,393] In Huckell and colleagues' series, for example, no patients experienced neurologic decline, and average neurologic improvement was one Nurick grade.[378] In a Dutch series, 35% improved dramatically—one whole Nurick grade.[396]

Atlantoaxial Instrumentation

Atlantoaxial instrumentation is indicated for segmental instability, often from trauma (e.g., transverse atlantal ligament rupture or dens fracture), rheumatoid arthritis, or congenital or metabolic anomalies.[397-399] Radiographically, abnormal C1–C2 motion is expressed as an increase in the anterior atlanto-dens interval (AADI). The AADI passes from the midposterior margin of the anterior ring of C1 to the anterior dens surface. In adults, the AADI is normally less than 3 mm; in children, it should be less than 4 mm. Acute increases in the interval usually signal instability. With chronic joint destruction, greater motion may be well tolerated.

Gallie and Brooks Techniques

Historically, the Gallie technique has been used to stabilize C1–C2.[372,400,401] This technique offers good resistance to flexion and is indicated in flexion-unstable situations such as transverse atlantal ligament rupture or, occasionally, dens fracture with anterior displacement. Gallie fusion requires C1 sublaminar wire passage and should be avoided in patients with arch fracture or cord swelling. At C2, the wire is simply passed around the spinous process. This wiring offers little rotational or extension stability and should therefore be avoided in posteriorly displaced dens fractures, for example. Despite its limitations, this technique or one of its many reported modifications is still routinely used because of ease and safety (Fig. 69.9).

Upper cervical stabilization requires rigid fixation to the operating frame. Immediately after positioning, assess the reduction and visibility of the upper cervical levels on open-mouth views. Next, make a midline incision from occiput to C3 and expose the tips of spinous processes. Carry a subperiosteal dissection along the C2 lamina, which preserves the suboccipital triangle muscular insertions for subsequent repair. Carry the subperiosteal dissection around the arch superiorly and inferiorly to allow passage of a doubled, U-shaped 18- to 20-gauge (1.2 mm) wire or equivalent titanium cable in a caudal to cranial direction. Harvest an H-shaped bone block from the iliac crest bone block and

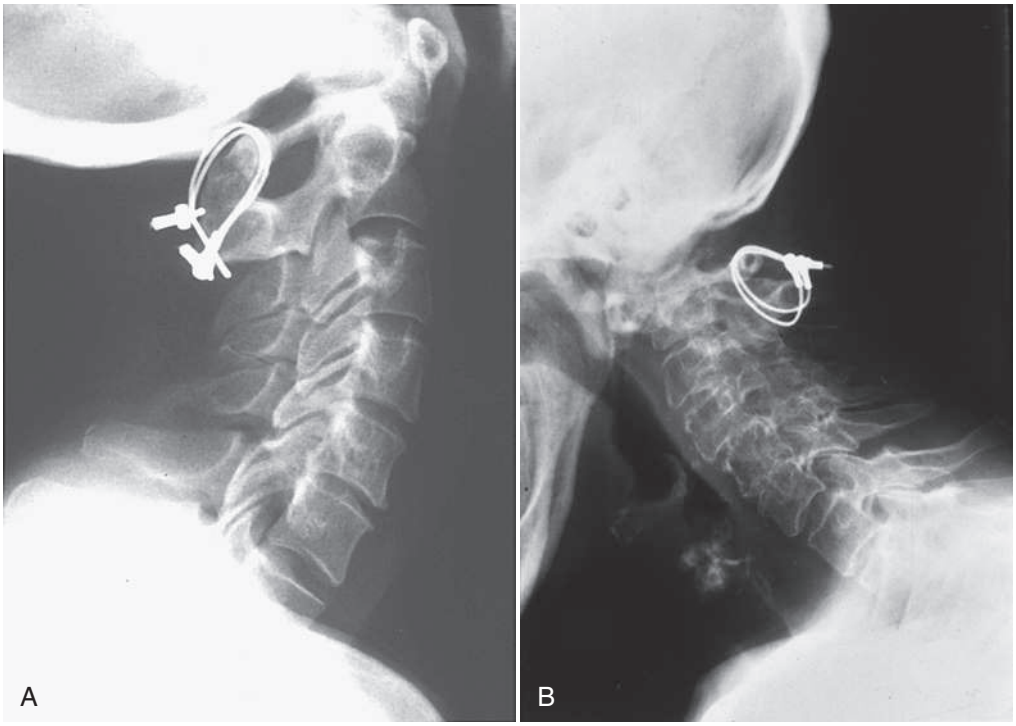

FIG. 69.9 Lateral radiographs of (A) Gallie and (B) Brooks posterior C1–C2 wiring constructs.

shape it to fit the C1–C2 laminae and interlaminar space. Notch the inferior part to fit over the C2 spinous process. Decorticate the posterior elements and pass the loop over the bone block and around the C2 spinous process. Pack open areas with cancellous graft.

One common Gallie modification is the wedge compression, or Brooks, technique.[402,403] With this method, bone blocks are fashioned to fit between the C1 arch and the C2 lamina, providing additional rotational and extension stability. Sublaminar wiring is undertaken at both levels. This technique cannot be used when the posterior elements have been compromised. Most authors recommend halo immobilization after Brooks fusion.

The indications for a Brooks fusion are like those for a Gallie. Gallie fusion is adequate for most flexion injuries. Consider Brooks technique for extension injuries and when more rigid fixation is deemed necessary.[137] A Brooks fusion is performed much as a Gallie but requires additional exposure of the inferior C2 lamina. Carefully preserve the atlantoaxial membrane. Doubled cables are passed under the C1 arch, then under the lamina of C2. Two rectangular iliac crest bone grafts approximately 1.25 × 3.5 cm are harvested and beveled to fit the interval between the C1 arch and the C2 lamina. The posterior elements are decorticated and the wires or cables are tightened to secure the grafts in position.

Various modifications to the Brooks method include passing the wires or cables through the grafts themselves. Avoid C2 sublaminar wire placement by passing two 18-gauge stainless-steel wires beneath the posterior arch of the atlas and around a threaded Steinmann pin, which is drilled through the base of the axis spinous process.[404]

Magerl Transarticular Screws

In 1987, Magerl described a rigid C1–C2 transarticular screw fixation technique. Intact posterior elements are required.[405] These screws offer greater rigidity, especially in rotation, and better maintenance of reduction than wired fusions.[403] On the other hand, screw placement is technically more challenging and risks vertebral and internal carotid artery injury.[27] Consider Magerl screws in acute or chronic atlantoaxial instability, when revising C1–C2 pseudarthroses, as part of occipitocervical stabilization, or in patients who cannot tolerate halo immobilization. Irreducible fractures and aberrant vertebral artery anatomy may contraindicate transarticular screws (Figs. 69.10 and 69.11).

To achieve the cranial trajectory required to place Magerl screws, extend a standard upper cervical midline approach more distally. Alternatively, augment a small C1–C2 incision with more distal stabs for drill placement. The screws enter C2 at its inferior aspect and exit at the posterior aspect of the upper articular process. On their way into the C1 lateral masses, the screws pass through the C1–C2 facet, which is considerably more anterior than C1–C2. Magerl recommends direct exposure of the C1–C2 facet joint. He uses Kirschner wires to retract the soft tissues containing the greater occipital

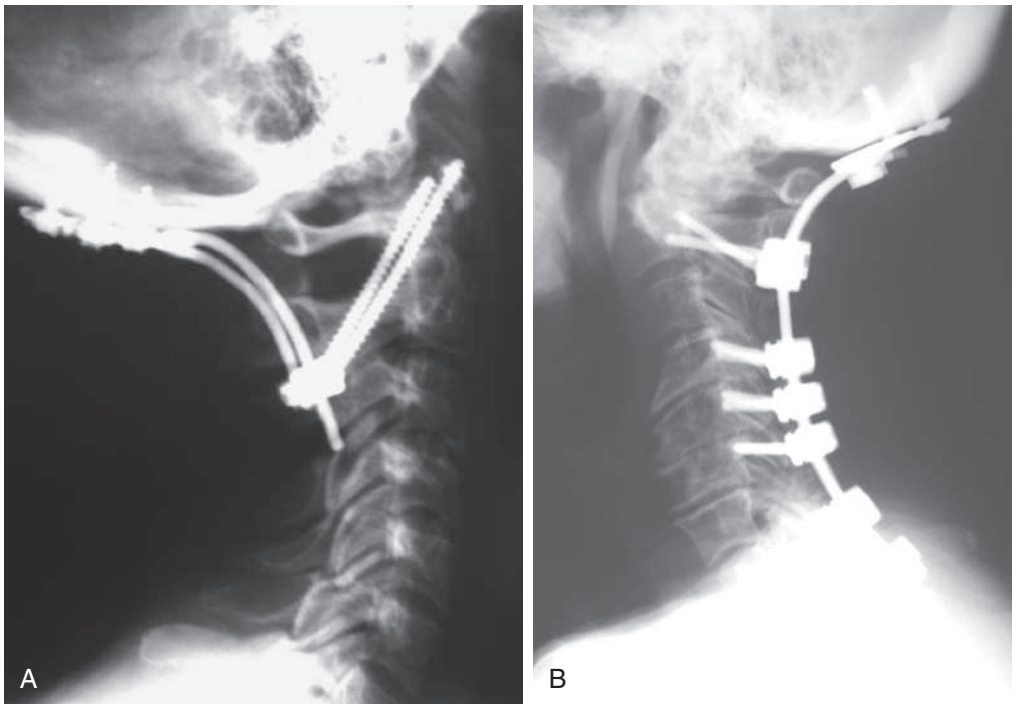

FIG. 69.10 Lateral postoperative images of two patients after occipitocervical fusion. (A) A young man underwent skull–C2 fixation after ejection from a motor vehicle led to traumatic occipitocervical dissociation. Magerl technique was used caudally. (B) A 72-year-old woman with long history of rheumatoid arthritis experienced basilar invagination, multilevel stenosis, and subaxial subluxation at C7–T1. She underwent an occiput–T2 decompression and fusion using a midline occipital keel plate, C2 pedicle fixation, C4–C6 lateral mass screws, and pedicle screws in T1 and T2.

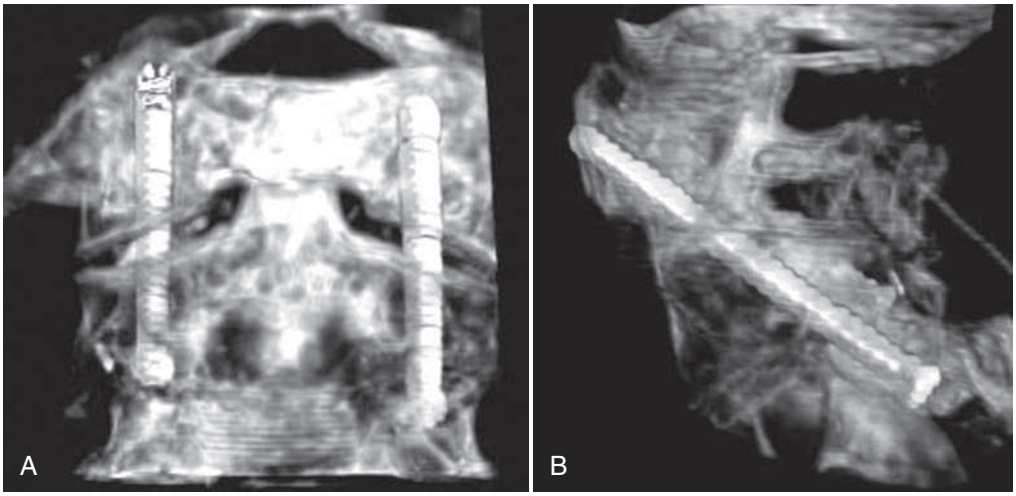

FIG. 69.11 This patient underwent Magerl transarticular C1–C2 screw fixation for atlantoaxial instability. (A) Anteroposterior and (B) lateral three-dimensional reconstructed images are presented.

nerve and its accompanying venous plexus.[405] As with the Harms technique described later, the plexus of thin-walled vessels lying on the C1–C2 facet capsule is typically injured with posterior exposure. The rich venous plexus can bleed profusely, and serial attempts to reach the joint with interval packing are often needed. The risk of these injuries can be reduced by bluntly dissecting the soft tissues in a caudal to rostral direction along the C2 pedicle. The consequences of plexus disruption are not significant.

Start the screw on the medial side of the inferior facet of the axis, aiming for the exposed isthmus cranially. Proceed toward the middle of the C1–C2 facet on the AP view and the anterior C1 ring on the lateral. To avoid the vertebral artery, direct the screws 25 degrees *toward* midline, and 25 degrees cranial. Navigation assistance decreases breach rates, but screw revisions were not required in unguided surgeries.[406] Some advocate cannulated drills to reposition the guide wire for optimal orientation. To stabilize the segment during the first screw's passage, place both guide wires before drilling. The hard subchondral bone at the joint level may deflect the guide wires. Tap past the facet joint to prevent screw deflection. The screws should just reach the inferior edge of the anterior C1 ring on the lateral view. Bicortical purchase is typically recommended but may not be necessary in all cases. In patients with satisfactory bone quality, no significant differences in pullout strength were seen.[407] Avoid overpenetration, which risks structures running vertically along the anterior C1 lateral mass, including the hypoglossal nerve and the internal carotid artery.[27,408]

With the C1–C2 facet exposed, decorticate the joint and impact bone graft. The rich venous plexus and anterior positioning of the joint have prompted many spine surgeons to skip this step, apparently without increased pseudarthrosis. Others, to restore segmental height, aggressively expose this area, sacrificing the greater occipital nerve and placing allograft shims in the joint.[409] Magerl augments the screws with Gallie wiring and fusion. In addition, a looped sublaminar wire at C1 improves reduction and allows motion segment stabilization during guide wires, drills, and screw passage. Others have reported 100% fusion rates without concomitant Gallie fusion.[410] Overall, transarticular screw fixation is associated fusion rates between 85% and 98%.[381,411] In comparative studies, transarticular screw fixation was associated with fewer complications and up to 21 times fewer nonunions than atlantoaxial wiring and halo.[412,413] Still, the advantages of Magerl screws must be weighed against the procedure's potential morbidity, particularly for surgeons who rarely perform C1–C2 posterior stabilization. If one vertebral artery is injured, do not attempt to place the opposite screw.

C1 Lateral Mass Screws and the Goel-Harms Technique

Beginning in 2000, screw fixation into the C1 lateral mass, described initially by Goel, was popularized by Harms.[414,415] Although Harms' technique shares indications with Magerl, over time it has become more frequently performed. This technique tolerates imperfect C1–C2 reduction and aberrant vertebral artery trajectories. Thus, the Harms technique is feasible in many cases that are inappropriate for Magerl screws.

Today, C1 lateral mass screws may be used as interval anchors in long occipitocervical constructs or end anchors in occiput–C1, C1–C2, or longer C1 to subaxial cervical constructs. Single-level implant placement without fusion to achieve fracture healing without necessitating later implant removal has long been described for C1 ring fractures using C1 lateral mass screws and transverse plating.[416]

The atlantoaxial complex is exposed posteriorly. The C2 dorsal primary ramus (greater occipital nerve) passes inferolateral to the joint and can be pulled sideways out of the C1 screw's trajectory. As with C1–C2 facet exposure, the rich venous plexus around the greater occipital nerve may require successive attempts at dissection with interval packing. Blood loss ranges widely from 50 to 1500 mL (mean, 540 mL).[417] Postoperative greater occipital nerve dysfunction is common.[418] Some authors routinely sacrifice this nerve to improve visualization and hemostasis.[409] The relative risks and benefits of resection of the C2 root have been debated.

FIG. 69.12 This patient shows healing of type II odontoid fracture after a Goel-Harms construct including screw fixation into lateral mass of C1 and pars of C2.

Resection of the root allows easier and more accurate placement of C1 screws. It also allows greater access to the C1–C2 facet for direct fusion or reconstruction of collapsed C1–C2 segments. One recent study found that preservation of the C2 root was associated with higher rates of occipital neuralgia (Fig. 69.12).[419]

Most begin just below the C1 posterior ring, "flushing" any overhanging bone with a burr or Kerrison rongeur. The large size of the atlanto-lateral mass makes screw placement forgiving.[420] Mean C1 lateral mass is 11.6 ± 1.4 mm wide and 12.7 ± 1.0 mm high.[418] The large size of the lateral mass and the variety of angulation options may allow this step to be skipped in up to 50% of cases.[421] If performed, be very careful laterally because the vertebral artery passes directly over an increasingly thin C1 ring.

Placement through the C1 posterior ring avoids the plexus around the C2 dorsal primary ramus but may risk injury to the vertebral artery. In one recent series, a starting point on the C1 arch was associated with fracture in one case, which was addressed with sublaminar wiring.[422] The authors concluded that the technique was justified but that careful review of the preoperative imaging was critical. A recent literature review assessed the impact of starting point on C1 lateral mass fixation. High success rates in terms of arthrodesis were reported with each of the reported entry points.[423]

Select the midpoint of the lateral mass by palpation or fluoroscopic control.[424] From this central starting point, straight-ahead and 10 to 15 degrees of medialized trajectories have been recommended. While medialization avoids the internal carotid artery laterally, avoid more than 25 degrees.[418,420,425] An anatomic study found that although optimal screw medialization was about 21 degrees, when there was variation in C1 lateral mass anatomy customized surgical planning was recommended.[426]

Craniocaudal angulation seeks to avoid the occiput–C1 and C1–C2 joints. Recommendations vary, but a safe zone surrounds a 20-degree superior inclination or the 20% to 40% point of the anterior C1 arch.[418,427] Preoperative planning with axial CT or MRI images helps select the safest angle. Look for an arcuate foramen, an anomaly seen in 15.5% of patients.[428] If present, the arcuate's posterior aspect (ponticulus posticus) is occasionally mistaken for the C1 screw entry point.

Use polyaxial screws with an average length within the lateral mass of 22 mm.[418,420] Most often 3.5-mm diameter screws have been reported, but 93% accommodate 4.0-mm screws.[421] To reach the posterior C1 ring, add a mean 11.4 mm (range, 6.9–17 mm) to the screw length outside the bone.[420] Partially unthreaded screw shanks may decrease greater occipital nerve irritation.[418] Even in children, less than 1% of atlases are unable to accommodate a 3.5-mm screw.[429] Screw depth averaged 20.3 mm and arch overhang 6.3 mm (range, 2.1–12.4 mm).

The 1800-N pullout force of C1 lateral mass screws is significantly lower than occipital screws but similar to C2 pedicle screws.[418] Both unicortical and bicortical C1 lateral mass screws are stronger than subaxial lateral mass screws.[430] Although bicortical screws are significantly stronger than unicortical, this additional holding power might not be needed. The C1 lateral mass screws, once locked to their inserting drivers, can be used to improve the reduction. When compared with Magerl screws, the Harms technique provides identical stabilization, except in extension.[431] If significant extension instability is encountered, consider an interspinous graft. Most reports have included 28 to 102 patients and concluded the Harms technique is safe and effective.[409,417,432] Fusion rates from 98% to 100% have been reported. Although screw protrusion into the vertebral artery canal is occasionally seen, no clinically significant neurovascular compromise has been reported.

A recent study of 26 patients reported 100% C1–C2 fusion rate for the Goel-Harms technique, even including previous nonunion of other treatment modalities. There were no neurovascular complications and the authors recommended that this approach be considered first.[433]

Elliott and others reported a meta-analysis comparing Magerl vs. Goel-Harms technique for C1–C2 rigid stabilization.[434,435] They examined 69 class III studies incorporating 3146 patients. They concluded the Goel-Harms technique was associated with higher fusion rates and lower vertebral artery injury rates.[434] The same authors found that the vertebral artery injury rate was higher with Magerl transarticular screws than with C2 pedicle screws.[435]

C2 Fixation Options

As an alternative to the Magerl technique, screws may be placed into C2 alone. C2 fixation includes true pedicle, pars,

FIG. 69.13 Axial computed tomographic cut showing crossed C2 translaminar screws. (From Wright NM. Posterior C2 fixation using bilateral, crossing C2 laminar screws: case series and technical note. *J Spinal Disord Tech.* 2004;17:158–162.)

and intralaminar screws. Most of what are commonly termed C2 pedicle screws are, in fact, pars screws. Only screws passing beyond the very anterior C1–C2 facet and into the small C2 vertebral body are true pedicle screws.

The relative vertebral artery and neurologic risks of C2 pedicle and Magerl screws continue to be debated.[436,437] In a retrospective analysis of 341 C2 pedicle screws placed in 181 patients, postoperative CT scans demonstrated a 17.3% breach rate.[437] Lateral breaches were more common than medial breaches. No neurologic sequelae resulted.

In most studies, C2 pedicle screws are mechanically equivalent to C1–C2 transarticular screws and are stronger than intralaminar screws, which are stronger than pars screws.[368,438,439] Intralaminar screws are less effective at reducing lateral bending range of motion and thus may be suboptimal in dens fractures (Fig. 69.13).

Occasionally C2 screws are described for direct osteosynthesis of C2 pars fractures (hangman's fracture). Most authors agree that hangman's fractures without significant angulation, translation, or C2–C3 disc injury do not require operative intervention. Therefore, isolated use of C2 pedicle screws for osteosynthesis is rare. On the other hand, temporary rigid C1–C2 instrumentation without fusion is increasingly common in Asia in patients with odontoid fractures not amenable to dens screw fixation.[440,441] The screws are removed once the fracture has healed.

Pars screws are inserted in a manner like that described for Magerl screws earlier. The same entry site is used. The screw is angled less cranially, and mediolateral angulation mimics the easily palpated pars angle. Typically, these screws are angled 10 to 15 degrees medially and 35 degrees superiorly to avoid injury to the vertebral artery. Start true C2 pedicle screws in a far lateral position on the C2 lateral mass, just superior to the C2–C3 facet. This lateral starting point and the 40- to 45-degree medial direction required to pass all the way into the body may require a percutaneous stab. Before placement, carefully assess preoperative axial images. About 20% of the time, local anatomic conditions preclude true pedicle screws.[409]

Crossed C2 laminar screws decrease vertebral artery injury risk and allow segmental C2 fixation in patients with a narrow isthmus.[442] Technique modifications include a bony window in the lateral lamina to ensure that the screws have not entered the canal.[443] Occasionally a deeply furrowed spinous process or underdeveloped C2 midline posterior ring mandates parallel, rather than crossing, screw placements.[444] Good clinical performance of this anchorage method continues to be reported.[445,446]

Other C1–C2 Stabilization Options

In the 1980s, Halifax clamps enjoyed a period of favor because canal intrusive instrumentation could be avoided.[447] These devices were easy to use and more rigid than the available alternatives. These devices were among the first titanium implants in the cervical spine and therefore offered less interference with postoperative MRI. Unfortunately, Halifax clamps were prone to arch fracture, implant slippage, difficulties with graft placement, and a nearly 25% pseudarthrosis rate.[448,449] PMMA has been recommended for patients with rheumatoid arthritis (due to the poor iliac crest bone quality) and for immediate stabilization in patients with metastases.[450] The long-term results of PMMA used with wiring or alone have been poor. More recently, some authors have recommended midline PMMA for immediate stability and lateral bone grafting for long-term stability.[451]

Posterior Subaxial Instrumentation

Mid-cervical posterior instrumentation offers an array of wiring and more rigid rod-screw techniques like that in the upper cervical spine. The merits of each approach in terms of ease of insertion, cost, and mechanics are analogous. The more homogeneous mid-cervical anatomy simplifies level-to-level fixation decisions.

Posterior Wiring

The oldest, and simplest, form of cervical instrumentation is spinous process wiring. A variety of wiring strategies have been reported. All function as a nonrigid tension band. As in the upper cervical spine, wiring affords good flexion stability but less stability in other planes of motion, especially extension and rotation. The degree to which wires stabilize the spine varies by route of wire passage, quality of bone against which the wires pull, and wire tension.

To resist flexion and extension, the wire must be tensioned to 22 N. At 50 N, rotation resistance begins. Unfortunately, augmented tension also increased the chance of cut-through.[452]

Previously, wiring techniques were used in the stabilization of facet dislocations, teardrop fractures, postlaminectomy instabilities, and neoplastic collapse. Today, routine wiring has given way to rigid, lateral mass fixation. Most frequently, posterior cervical wiring is used to treat anterior interbody fusion pseudarthroses. Still, wiring continues to offer spine surgeons a back-up to supplement or replace an inadequate lateral mass construct. Wiring remains a low-profile, cost-effective solution in cases of limited flexion instability.[453] Avoid wiring in patients with movement disorders or torsional or axial instability.[454] Over time, bone graft, Steinmann pins, or Luque rectangles have been added to increase extension stability.[455,456] Even these modified wiring techniques remain unstable to axial load.

As with all posterior spine procedures, prone positioning requires careful attention to alignment and ocular pressure. The skin and subcutaneous tissue are dissected down to the midline fascia. Subperiosteal dissection is then completed to expose the spinous processes, laminae, and facet joints at the level of interest. To prevent inadvertent fusion extension, limit dissection to the intended levels and protect adjacent facet capsules. Drill a 3-mm burr hole in the base of the spinous process on both sides. Aim the holes toward the proximal aspect of the cephalic spinous process and distal aspect of the caudal spine. Run a nerve hook along the inferior lamina border to identify the canal; low holes may injure the dura or posterior cord.

To create a tunnel for the wires, pass a towel clip gently through the holes. Pass a single 18- or 20-gauge wire through both spinous processes. In a single-level fusion, this wire can be tensioned and tightened. When fusing more than one level, incorporate intervening spinous processes with a figure-of-eight wiring pattern. To maintain tension, avoid wiring fractured posterior elements. A variation, the Dewar technique improves the wire's holding power by spooling it over Kirschner wires inserted through the spinous process bases.[457]

For most uses, the Bohlman triple wiring has supplanted the Rogers technique. This procedure begins with a simple wiring but adds second and third wires through the cephalic and caudal holes in the bases of the spinous processes, respectively. Carefully decorticate the laminae and facets with a burr. Harvest two corticocancellous grafts of appropriate length from the outer table of the iliac crest. The grafts are drilled for wire passage, ensuring firm contact with the underlying lamina. Place the graft's posterior cortical edge just under the spinous process to enhance stability and maximize graft-lamina contact. Simultaneously tighten the wires on each side of the spine (Fig. 69.14). Place additional cancellous chips on the exposed lamina or facets. As a function of construct stability and patient compliance, a cervicothoracic orthosis or halo vest may be used for 6 weeks. This technique has been shown to be safe, effective, and biomechanically superior to many other wired constructs.[458,459]

The smaller subaxial canal compounds risk associated with sublaminar wiring below C2. More typically, interfacet wiring and fusion are performed after laminectomy or when the spinous process is fractured.[460] Additionally, adding an oblique interfacet wire to a simple midline technique improves rotational stability.[461] To place an oblique wire, insert a Penfield No. 4 dissector into the facet joint. Direct a 2-mm drill inferiorly into the facet. For single-level fusion, pass a 20-gauge wire through this hole and loop it around the inferior spinous process. For multiple-level and postlaminectomy facet stabilization, extend facet wires to adjacent facets. Tie facet wires to structural bone grafts or metallic rods for additional stability.

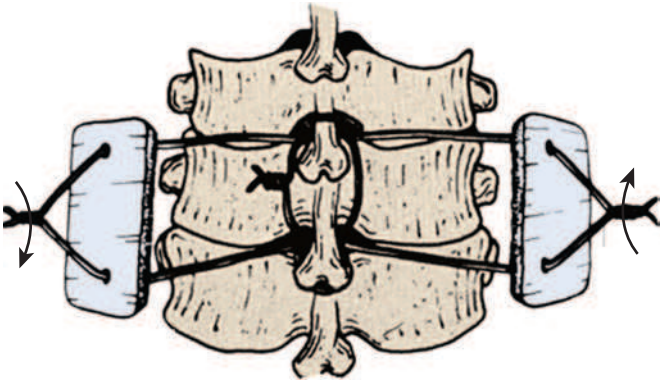

FIG. 69.14 Schematic showing Bohlman's triple-wire technique for posterior fixation of the subaxial cervical spine.

Multistrand, braided cables are stronger, more flexible, and more fatigue resistant than monofilament wire. Cable utilization increased after reports of frequent fatigue failure, loosening, and bone cut-through with monofilament wires.[452] On the other hand, cables are more expensive than wires and cable memory may lead to gradual loss of reduction or canal intrusion. If wires or cables break, the strands may penetrate the dura, leading to cerebrospinal fluid leak or direct neurologic injury.[462] Stainless steel, titanium, and polyethylene offer similar mechanical properties.[452,463] Titanium and polyethylene cables are more imaging friendly than stainless steel wires. Cable systems often come with sophisticated tensioners. These constructs lack sagittal axis control, and overtensioning may induce retrolisthesis. Recent outcome reports are limited but favorable for both wires and cables.[464,465]

Rigid Posterior Mid-Cervical Instrumentation

Rigid subaxial instrumentation options include hooks and lateral mass, pedicle, and transarticular screws. Rigid fixation implies both a tight interface with the host bone and a rigid locking mechanism between the anchor and the longitudinal member (a plate or rod). These systems more effectively maintain sagittal alignment than wiring and remain effective after laminectomy or posterior element fracture.[466,467]

Initially, reconstruction plates were used. Today, plates continue to be used because they are cheaper and lower profile than rod systems. On the other hand, interfacet distances vary widely among individuals (9–16 mm; mean, 13 mm), and a plate's hole spacing limits optimal screw placement.[468,469] Oblong holes better accommodate variable interfacet distances at the cost of rigid axial control of the screw. Rods are more easily contoured and allow greater freedom in lateral mass screw placement. Newer rod constructs offer rigid locking and cross-linking.[468] Screw-rod systems are more

easily extended to the occiput and across the cervicothoracic junction. Finally, screw-rod systems permit the application of compression, distraction, and reduction forces within the construct.[469] Both plating and rodding systems tend to fail with superior screw loosening and pullout. In cadaveric testing, plate failure occurred earlier and more likely fractured the superior lateral mass.[84] Posterior lateral mass constructs are more rigid than either anterior plating or posterior wiring systems.[470,471]

Cervical Hooks

Hooks, although not as rigid as screws, have relatively simple placement. There are several types: Halifax clamps (discussed earlier), laminar (canal intrusive) hooks, and the hybrid hook-plate. Cervical hooks were initially used at the cranial end of long deformity constructs. Other indications include tumors and upper thoracic trauma. The need to extend thoracic constructs into the low cervical spine has decreased with the increased utilization of thoracic pedicle screws. Utilization for cervical pathologies has decreased with improved lateral mass systems and dedicated cervicothoracic junction constructs. Hook-plates provide one-level stabilization in which the screw is placed into the superior lateral mass and the hook captures the inferior lamina. Hook-plate designs remain practical for C6–C7 instabilities because they avoid screw placement in the thin C7 lateral mass.[472] More commonly, C7 pedicle screws are placed.

Few outcome studies are available describing utilization of cervical hooks. Most describe atlantoaxial placement.[473] Particular risks of hooks include dural penetration, iatrogenic neurologic injury, or late hook disengagement.[474] Laminar hooks must be avoided at levels with cord edema canal stenosis. Biomechanical testing reveals that hook constructs are comparable to lateral mass screws in flexion and extension loading but less rigid in lateral bend and rotation.[475] All posterior systems resist lateral bending better than anterior plates.

Lateral Mass Screws

Most typically, rigid subaxial fixation relies on placement of lateral mass screws into C3–C6. Lateral mass screw fixation is indicated when more rigid fixation than wiring is necessary (Figs. 69.15 and 69.16). Polytrauma patients typically benefit from the earlier mobilization and decreased bracing engendered by rigid stabilization. More rigid fixation should be considered in any patient in whom healing may be delayed, compliance is suspect, or multilevel fusion is required.

Safe lateral mass screw placement requires familiarity with the articular pillar anatomy. Expose to the lateral edge of the pillar. Do not pass over the edge as bleeders in this region retract anteriorly and are difficult to control. Remove the osteophytes to better delineate the articular pillar's margins. Sagittal alignment of the neck varies with each case. Pass a Penfield No. 4 dissector into the facet to ascertain its angulation. Locate the center of the lateral mass by defining the notch between the lamina and the lateral mass. Several trajectories have been described. The Roy-Camille technique describes screw insertion at the apex of convexity of the lateral mass. Aim 10 degrees laterally to decrease the risk of nerve root injury. To decrease facet violation, Magerl recommended an entry point 2 to 3 mm medial and superior to the apex. He described a 25-degree lateral drill angle and a superior trajectory parallel to the facet (typically 45 degrees). Anderson,[472] An,[466] and others[469] have described variations of entry site and angulation. An and colleagues[137] suggested lateral mass entry 1 mm medial to its center. The drill is angled 30 degrees lateral and 15 degrees cranially.

When these trajectories were assessed in cadavers, the Roy-Camille technique frequently violated neurovascular structures below C3, especially, with more lateral screw angulation, the nerve root.[472] The Magerl technique was safe at the standard 25 degrees and modified positions of 20 degrees and 30 degrees. The Anderson technique was safe at 20- and 30-degree modified positions. At C7, only the modified Anderson technique (20–30 degrees of lateral angulation) was safe.

Bicortical penetration improves failure resistance by 20% but increases root injury risk. Consider bicortical screws in the presence of osteoporotic bone, few acceptable anchor points, unstable spines and, particularly, in those with anterior column collapse and decreased axial load-bearing capability. To place a bicortical screw, gradually increase the drill's set depth. Palpate the opposite cortex. To avoid stripping the threads, be sure to tap the full screw depth.

Lateral mass screw placement risks canal intrusion and vertebral artery or nerve root injury.[51,476] Typically, overly long screws or poor drilling technique precipitated the complication. Occasionally, poor plate or rod contouring compresses the root from foraminal stenosis engendered by a lag screw effect when the screw pulls the lateral mass up to the plate or rod. Adjacent facet joint violation may accelerate adjacent-segment degeneration.

Lateral mass screws have recently been reclassified and are now approved as adjuncts to cervical fusion. Despite their late reclassification, they remain among the safest implants in spine surgery.[477] In one series, despite coronal and sagittal plane deformities and lateral mass abnormalities, 212 lateral mass screws were safely implanted. There were no cord or vertebral artery injuries, cerebrospinal fluid leaks, screw malposition or back-out, loss of alignment, or implant failure.[469] Iatrogenic radiculopathy (usually transient) risk is less than 1.8% per screw, even in children as young as 6 years.[478,479] Unlike wiring, loss of fixation and reduction are rare, even when no formal autogenous grafting is performed.[480-482] Failure in kyphosis is occasionally seen in patients with incompetent anterior column load bearing (e.g., C5 burst fracture).[481] One study compared anterior or posterior stabilization in 52 patients with unstable cervical spine injuries and spinal cord injuries.[483] Neurologic improvement was seen in 70% and 57% of the anterior and posterior groups, respectively. There were two nonunions in the anterior group and none in the posterior. There were no statistically significant differences in fusion rates, alignment, neurologic recovery, or long-term pain complaints. A recent series of 2500 lateral mass screws placed in 430 patients found that only three patients needed revision for implant-related reasons.[484]

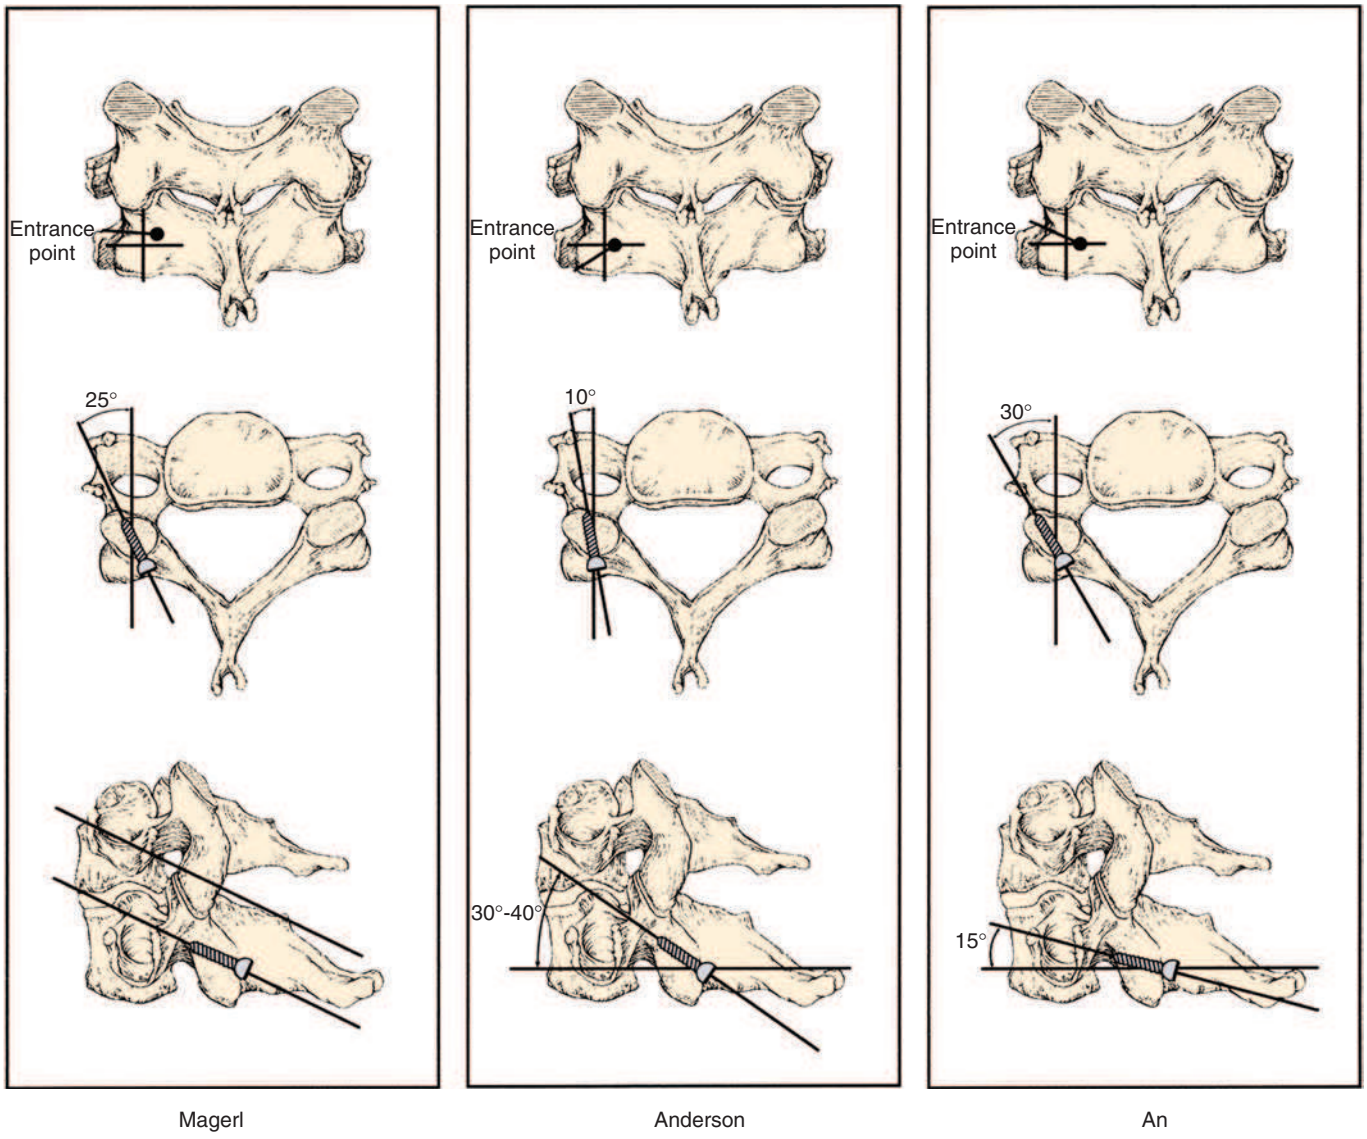

FIG. 69.15 Various lateral mass screw placement options. (From Xu R, Haman S, Ebraheim N, et al. The anatomic relation of lateral mass screws to the spinal nerves: a comparison of the Magerl, Anderson, and An techniques. *Spine [Phila Pa 1976].* 1999;24:2057.)

Ongoing concerns with lateral mass screw fixation include the muscle dissection required for insertion and the increased profile associated with polyaxial systems and rods. A number of systems have been introduced with decreased bulk and "favored angle" geometries to allow closer apposition to the bone.[485] The degree of constraint at the screw-rod interface varies between systems. Loose connections or flexible rods may allow a drift into kyphosis. On the other hand, overcorrection of kyphosis may increase postoperative nerve traction injury risk. One series reported that, in a series of myelopathy patients undergoing decompression, half of those instrumented with lateral mass screws and rods (five of 10) had a postoperative C5 palsy.[486] In five of 63 (8%) of the uninstrumented patients with C5 palsy, the deltoid weakness was not as severe as in the instrumented patients.

Increasingly, lateral mass screws are inserted through tubular retractors or percutaneous cannulated routes. These approaches preserve muscle and ligament integrity, thereby maintaining the posterior tension band. With most systems, up to two levels can be treated.[487] The real benefits of this approach are not yet clear.

Salvage of failed lateral mass screws can include 4.0-mm revision screws in the same trajectory, redirection to a Roy-Camille technique, and conversion to pedicle screw placement. In a cadaveric evaluation, no significant differences were seen between a larger Magerl lateral mass screw versus a Roy-Camille revision.[488] Pedicle screw revision offers significantly greater pullout strength (566 N) compared with either the Magerl (382 N) or Roy-Camille (351 N) revision. At the cranial and caudal ends of a decompression and fusion construct, or at intervening levels in nonlaminectomy cases, laminar hooks and transarticular and translaminar screws can also be considered.[489] One clinical study concluded translaminar screws were technically simpler and offered adequate stability.

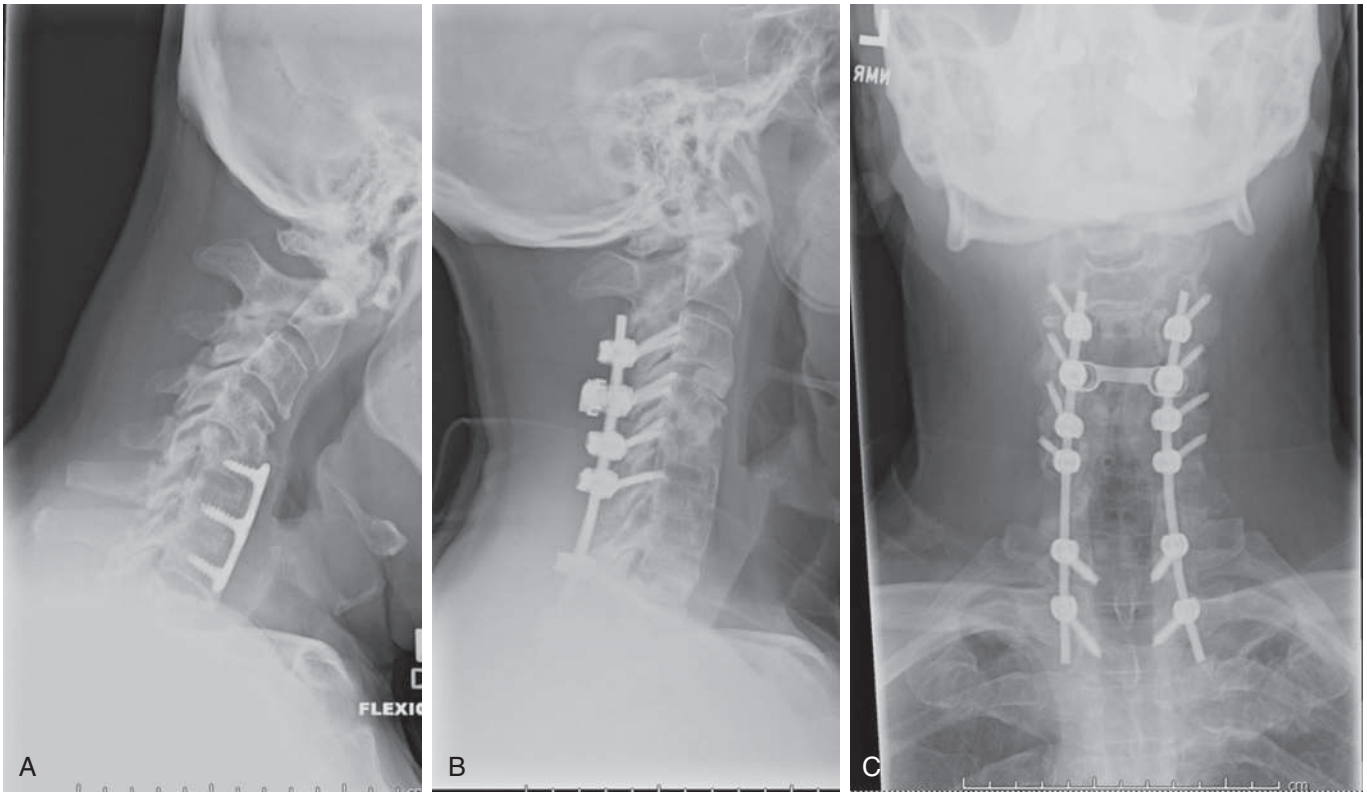

FIG. 69.16 (A) A 56-year-old man who had undergone previous C5–C7 anterior cervical discectomy and fusion (ACDF) presented with adjacen-segment (C4–C5) degeneration, kyphosis, stenosis, and increasing myelopathy. The anterior plate was removed and ACDF performed at C3–C4 and C4–C5, and a posterior stabilization was performed with lateral mass screws from C3 to C6 and pedicle screws at T1. Postoperative (B) lateral and (C) anteroposterior views are also shown.

Mid and Lower Cervical Pedicle Screws

Pedicle screws offer three-column fixation and have greater pullout strength than lateral mass screws.[22,117,490] A single C7 pedicle screw approximates the stability provided by lateral mass screws at both C6 and C7.[491] While single-screw pullout and fatigue resistance are higher with pedicle fixation, whole-construct strength differences may be minimal.[475] The small mid-cervical pedicles and the proximity of the cord, vertebral arteries, and nerve roots limit enthusiasm for routine screw fixation. Most frequently, C3–C6 pedicle screw placement is recommended in posterior-only corrections of markedly unstable three-column injury or maintenance of correction after cervical osteotomy or postlaminectomy kyphosis.

The standard pedicle screw placement method uses an entry point 3 mm below the superior facet joint (Fig. 69.17).[22] The drill is angled 45 degrees medially and advanced in a vertical line parallel to the endplate. Alternatively, a line parallel to the contralateral lamina provides a 3-mm safe corridor for sagittal plane angulation.[492] Alternatively, Abumi recommends burr removal of the lateral mass to provide a direct view of the pedicle introitus.[490] The pedicle is then probed and tapped and a 3.5-mm cortical screw inserted. Mean pullout resistances are similar. Unfortunately, standard angulations and entry points may be dangerous because, between C4 and C6, pedicle anatomy surface topography is highly variable.[64] Avoidance of pedicles smaller than 4.5 mm, a laminoforaminotomy technique to directly palpate the pedicle, and navigation assistance improve safety.[20] Some have reported safe placement with patient-specific, rapid-prototype drill guides.[493,494]

A number of studies report safe utilization of mid-cervical pedicle screws and cite high fusion rates and excellent correction of cervical deformity with this technique.[391,495] More recent series reported a 20% malposition rate with an 8% symptomatic breach rate and 3.4% vertebral artery injury rate.[496,497] Both groups concluded that mid-cervical pedicle screws posed significant additional risks and should be used by very experienced spine surgeons for destructive lesions only.

The large C7 pedicle size and absence of the vertebral artery in the foramen transversarium encourage more routine placement.[498,499] C7 pedicle screws can be inserted with any of the techniques described for mid-cervical screws. Close assessment of preoperative axial CT and MRI images is recommended to ensure that the foramen transversarium does not contain the vertebral artery, to measure the patient's medial angulation and pedicle diameter, and to familiarize the surgeon with the surface bone topography. Intraoperatively, a C6–C7 laminotomy allows direct palpation of the pedicle. Adequate fascial release prevents undermedialization.

With any posterior cervical screw placement, intraoperative electromyographic assessment may be helpful. To reduce scatter, test the screws before placing the connecting rod. Stimulation thresholds correlate with screw position, and

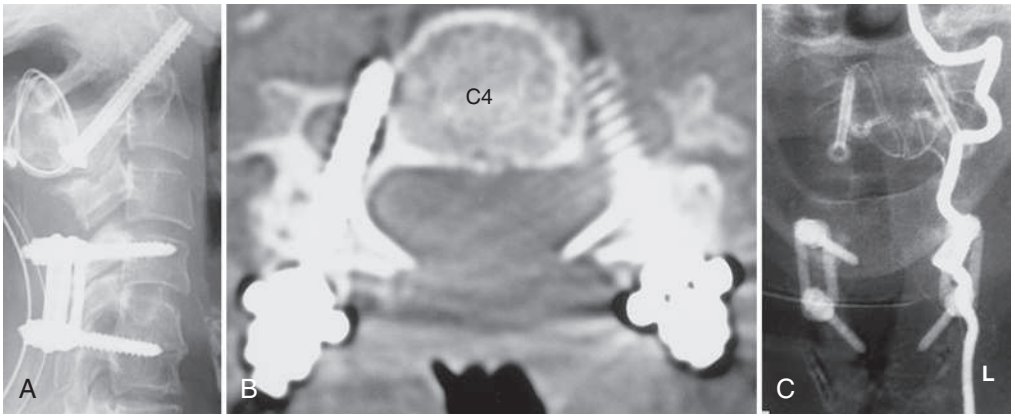

FIG. 69.17 (A) Lateral radiograph demonstrating placement of subaxial cervical pedicle screws during posterior cervical fusion. (B) Axial computed tomographic image of subaxial cervical pedicle screw within the foramen transversarium at C4. (C) Angiogram demonstrating flow through left vertebral artery with no flow on the right side. (From Abumi K, Shono Y, Ito M, et al. Complications of pedicle screw fixation in reconstructive surgery of the cervical spine. *Spine (Phila Pa 1976).* 2000;25:962–969.)

values greater than 15 mA reliably predict acceptable screw position.[51]

Lower Cervical Transarticular Screws

Subaxial transarticular screw fixation has been described both alone and with rods.[500] Unisegmental bone screws traverse four cortices for excellent holding power; their lack of polyaxial heads or rods reduces implant costs and profile. At C7, the limitations of fixation to the thin lateral mass and difficulty of pedicle screws favor 8- to 10-mm screws placed perpendicular to the facet.[501] Multilevel transfacet screw constructs compare favorably to the more typical lateral mass screw and rod technique.[502,503] One recent finite element model found that downward-angled, transarticular screws were stronger than either pedicle or lateral mass screws in the treatment of a three-column mid-cervical injury.[504]

In clinical studies, multilevel transfacet screw constructs compare favorably to the more typical lateral mass screw and rod technique.[500,502,503] A recent study compared direct sagittal placement with a 30-degree lateralized placement that would theoretically convey less risk to the cervical roots.[505] A total of 95 screws were placed in 18 consecutive patients. One complication, nerve root irritation due to screw malposition, was reported. Lateralized positioning was reported to significantly increase four-cortex placement and decrease loosening (29% vs. 5% and 24% vs. 2%, respectively). Although the authors supported the technique, they noted that "extensive cranial exposure is required to align the instruments in the proper sagittal trajectory." In fact, the occiput can block screw placement, especially in the upper cervical spine.

Posterior Cervical Rods and Cross-Links

A variety of "longitudinal members" are available for posterior cervical spine surgery. Titanium rods from 3.0 to 4.0 mm are the most frequently used. Stainless steel implants remain available and may be preferable when durability and deformity correction are sought. Overbending, especially in titanium rods, decreases fatigue life.[506] Customized rods have been developed for specific indications, including prebent occipitocervical implants thickened at the bend to improve fatigue life. Hinged rods were initially developed for cervical osteotomies to allow controlled osteoclasis.[507] Today, they also obviate hyperangulated bends in occipitocervical fixation, especially in patients with rheumatoid arthritis and occipitocervical impaction.

A variety of specialized cervical cross-links are available. With decompression procedures, the posterior cord drift may lead to cross-link impingement. Precurved cross-links arch over the canal. Cervical cross-links are indicated in the presence of coronal instability, to compensate for limited fixation points, and to contain structural grafts.[98] Also consider cross-links for increased torsional stability, to reconstruct axial bursting injuries, in longer constructs, and in osteoporotic bone.[508]

Facet Spacers

Spacers made of allograft bone, PEEK, and other materials, typically around 2 mm thick, have been described to restore alignment or improve foraminal volume. Many have a large osteoconductive surface. When implanted, compression across the implant may enhance the fusion process. One recent biomechanical study found that these spacers alone did not adequately reduce spinal motion, however, and adjunctive screw and rod fixation had to be used.[509] Another study found that the devices were easy to implant and did not increase kyphosis.[510]

Laminoplasty Implants

Laminoplasty implants seek to contain hinge bone grafts and to prevent closure. A wide variety of implants support the many described laminoplasty techniques. Most common are sutures, spacers, precut bone grafts and miniplates for the Hirabayashi open-door technique. Because the facet capsules are often thinned or stripped during exposure, 2-mm metallic

TABLE 69.1 Occipital Bone Thickness

Skull Location	Midline (mm)	1 cm off Midline (mm)	2 cm off Midline (mm)
EOP	10–15	9–11	7.5–9
1 cm below EOP	9–11	5–7	4.5–6
2 cm below EOP	8–9	4–6	3.5–4.5
3 cm below EOP	6–7	4–5	3.5–4.5

EOP, external occipital protuberance.

suture anchors inserted along the standard lateral mass screw trajectory augment the initially described suture.[511,512] In two series of 15 and 42 patients, respectively, low complication rates, ease of use, and closure avoidance were reported.[513,514] Over the last few years, laminoplasty miniplates have been offered to more rigidly stabilize the hinge and to allow more aggressive decompression. These devices are FDA approved only as graft containment systems. Custom-shaped allograft plugs further assist in "propping" the laminoplasty door and offer biologic healing over time. Late displacement leading to tetraparesis has been reported.[515] A recent study compared laminoplasty plates with suture suspension fixation. The authors concluded that "miniplate fixation preserved more cervical range of motion and better cervical alignment, maintained cervical spine canal expansive stability, and effectively avoided lamina reclosure" than suture fixation.[516]

Conclusions

Cervical instrumentation options are rapidly evolving. On one hand, the explosion in the number and variety of implants available offers the spinal surgeon choices heretofore never imagined. On the other, choosing the optimal approach for the patient has become increasingly difficult.

As both more sophisticated stabilization and fusion devices and motion-sparing techniques evolve, the surgeon will require a clear understanding of cervical spine biomechanics. Appropriate surgical strategies will arise from the patient's specific anatomic and pathomechanical needs.

Today, the wealth of conflicting data points out limits of our current mechanical models. Aside from the most common procedures (e.g., ACDF), there are very few direct comparisons of available techniques. However, large database studies may help us.

Since the last edition of this text, lateral mass screw placement in the posterior cervical spine has been approved for most common indications. This labeling change, and increasing attention on sagittal spinal balance, has continued to push rigid segmental instrumentation in the cervical spine. Cervical disc replacement has become more commonplace, but utilization varies significantly and it is likely appropriate only in a fraction of patients for whom anterior cervical fusion techniques can be considered.

The pressure for surgeons to consider the costs of implant choices has only increased. New "bundling" models of reimbursement are on the horizon that will require surgeons to more clearly delineate how much surgery is "enough." A clear understanding of spinal biomechanics and reconstruction options will allow the surgeon to decrease immediate costs through pragmatic implant selection as well as long-term costs through a reduction in surgical failure and revision. The patient will benefit in several ways, not least of which is the avoidance of the morbidity of excessive reconstruction. Anterior cervical implantation of BMP has proven to be an example of this phenomenon.

KEY POINTS

1. Patient positioning:
   - Intraoperative alignment is critical, especially in long fusions.
   - Appropriate alignment allows safer placement of the implants.
   - If in doubt, check radiographs and examine rotation (midline spinous processes).
2. Adequate exposure:
   - Accurate placement requires clear delineation of the relevant anatomy.
   - In anterior procedures, release fascia, undercut platysma, remove retractors regularly, and decrease endotracheal cuff pressure to decrease soft tissue complications.
3. Closely inspect the preoperative imaging studies; individual anatomy varies widely.
4. Preoperative planning: list the types and sizes of implants required before scrubbing in.
5. Have a back-up plan; familiarity with multiple techniques is useful if a screw backs out or proves difficult to place.
6. New products: carefully evaluate the data yourself; there is little advantage to the patient for their surgeon to be the "first on the block."

   This short, well-illustrated text provides an excellent overview of the mechanical principles that inform rational implant selection and placement. This book describes the various stabilization modes in greater detail than this chapter allows.
2. White AA 3rd, Panjabi M. *Clinical Biomechanics of the Spine.* Philadelphia: Lippincott; 1990.
   This short text describes normal and pathologic mechanics of the spine. Without a solid understanding of how disease disrupts normal spinal stability, instrumentation becomes a rote or knee-jerk process. Instead, the surgeon should consider the deficiencies and postoperative needs of the individual patient when planning reconstruction.
3. Steinmetz MP, Benzel EC, Apfelbaum RI. Axially dynamic implants for stabilization of the cervical spine. *Neurosurgery.* 2006;59(4 suppl 2):ONS378-ONS388.
   This article provides an excellent overview of the evolution of anterior plates. Although the overt bias here favors axially dynamic implants, given the frequency with which anterior cervical plates are used, the surgeon should have a clear understanding of the relative merits of different design philosophies.
4. Dvorak MF, Pitzen T, Zhu Q, et al. Anterior cervical plate fixation: a biomechanical study to evaluate the effects of plate design, endplate preparation, and bone mineral density. *Spine.* 2005;30:294-301.
   This well-done biomechanical study addresses some of the challenges to anterior cervical plate fixation. Spinal surgeons

increasingly are encountering patients with osteoporosis, for example. The authors describe the positive and negative effects of varied endplate preparation methods and plate designs.

5. Wang JC, McDonough PW, Kanim LE, et al. Increased fusion rates with cervical plating for three-level anterior cervical discectomy and fusion. *Spine*. 2001;26:643-646.
This is one of a series of articles published from 1999 to 2001 outlining the University of California–Los Angeles experience with anterior cervical discectomy and fusion procedures. Fusion rates and other radiographic parameters were assessed with and without plating in one-, two-, and three-level procedures. Plates offer increasing advantages over nonplated constructs with increasing number of levels treated. Failure rates increase with additional levels of surgery, however, even with plates.

6. Wertheim SB, Bohlman HH. Occipitocervical fusion: indications, technique, and long-term results in thirteen patients. *J Bone Joint Surg Am*. 1987;69:833-836.
This classic article details Bohlman's modification of cervical wiring. In the occipitocervical and the subaxial applications, additional wires were used to apply structural grafts to the spine. These structural grafts increased extension stiffness over previous simple wiring. Although rigid fixation is currently more common, variable bone quality and anatomy continue to make these approaches relevant.

This is one of several key anatomic studies assessing occipital bone thickness and the proximity of the cranial sinuses. These studies and clinical experience led to a gradual migration away from off-midline plates to modular designs that fix to the thick midline keel.

8. Harms J, Melcher RP. Posterior C1-C2 fusion with polyaxial screw and rod fixation. *Spine*. 2001;26:2467-2471.
Use of upper cervical fixation techniques has changed markedly since Harms' popularization of C1 lateral mass screw placement. With rigid C1 fixation, extension of cervical fusions to the occiput has been limited to the rare, true occipitocervical instability only. This procedure is technically simpler than Magerl's transarticular screw fixation and is not as limited by incomplete reductions and anatomic abnormalities. As a result, more surgeons have chosen to exploit this approach than either transarticular screws or wiring. Increased use of C2 crossed laminar screws has furthered this trend.

70 CHAPTER Thoracic and Lumbar Instrumentation: Anterior and Posterior

Eeric Truumees*

Introduction

The spinal column functions mechanically to support the load of the body, allow controlled motion, and protect the neural elements. Diseases of the spinal column affect its performance and ability to function normally. A vertebral body tumor disrupts the load-bearing capability, and aggressive decompression for stenosis can lead to instability and kyphotic collapse.

In most cases, spinal implants are combined with segmental fusion as part of a treatment strategy to restore the mechanical functions disrupted by trauma, tumor, deformity, infection, or degenerative disease or by the surgical management of these disorders. In each etiologic subgroup, the particular indications for thoracolumbar instrumentation may be different, but the goals remain the same: to increase or maintain stability, prevent or reduce deformity, help bear the loads of the spine, and encourage the healing of bone graft.

Thoracolumbar implant constructs are used to prevent further collapse by neutralizing a deforming force or by holding the spine in a mechanically more favorable position. In some cases, deformity correction may be beneficial and may decompress the canal. Either way, an understanding of spinal pathomechanics is crucial. In addition, spine surgeons must be aware of the available implants and how they can be best used to optimize treatment, help ensure a good surgical outcome, and minimize the risks associated with surgery.

Overview and History

Internal fixation of the thoracolumbar spine has been used for the past century.[1] Many implants were developed to treat specific spinal conditions in specific populations, with use broadening later. For example, the "Hong Kong procedure" gave rise to modern anterior thoracolumbar surgery in an effort to treat the deformity associated with spinal tuberculosis.[2]

In other cases, the concepts behind new spinal implants were borrowed from other fields. Artificial disc replacement arose from low-friction total knee arthroplasty designs. Kyphoplasty to treat painful osteoporotic fractures evolved from angioplasty balloons.[3,4]

From their initial incarnations, each generation of implants evolves to broaden applications, reduce the difficulty of application, or address unintended consequences of previous procedures. One of the most dramatic examples of this iterative phenomenon is the development of segmental instrumentation in the correction of spinal deformity and its role in preventing the flat back deformity engendered by previous hook-rod constructs.

When considering an implant, the spine surgeon needs to understand its US Food and Drug Administration (FDA) status. Although the FDA may not dictate or interfere with medical care, they do place medical devices into one of three categories (Box 70.1).

In early 2017, the FDA announced the results of a 2-year review process of thoracolumbosacral pedicle screw systems. Although individual companies still need to apply to downgrade their implant's classification, overall rigid pedicle screw systems have been downgraded from class III to class II.

Off-label use of thoracolumbar instrumentation occurs in two settings, each of which makes different demands on the physician. First, the common practice of using a device for an indication other than that for which it was assessed by the FDA is termed "practice of medicine." The second off-label use involves experimental or investigational devices. On a practical level, these devices have been used widely for years. However, the downgrade allows expanded, company-directed education efforts and decreases the regulatory burden associated with system development.

For a commercially available and marketed device, the physician is legally allowed to use the device in any manner, according to his or her best knowledge and judgment. When the treatment regimen is not included in labeling, however, the physician should be able to document device efficacy from the scientific literature. Outside of individual hospital rules, no investigational device exemption or institutional review board review is needed.

*The editors sincerely thank Dr. Truumees for his work on this chapter in the sixth edition of this text, for which he was not credited.

BOX 70.1 US Food and Drug Administration (FDA) Medical Device Classifications

Class I: Neither Standard nor Premarket Approval Warranted

- Present little risk to public
- General controls sufficient to ensure safety and efficacy
- Subject to minimal FDA regulation

Examples: cast materials, crutches, wheelchairs

Class II: Higher Risk, General Regulatory Controls *Not* Sufficient

- Enough data exist to develop a performance standard
- May present some additional risk to public
- Individual performance standards developed by FDA

Examples: intramedullary nails, bone screws, plates, cemented total hip arthroplasty

Class III: Highest Risk, Requires FDA Premarket Approval

- Not enough information exists to ensure safety and efficacy or to establish a performance standard
- May present a substantial risk to the public
- Not enough information to establish performance standard
- Not cleared for marketing for a particular purpose by FDA

A device that has not received market approval for any indication is deemed experimental. Experimental devices may be used only in accordance with an approved protocol derived from an investigational device exemption submission. It is unreliable to depend on a textbook or sales representative for this changing classification. Instead, it is prudent to review the product's labeling on the FDA's website (www.fda.gov).

The emphasis in this chapter is on currently available thoracolumbar instrumentation systems used to maintain alignment and to decrease motion while awaiting solid bony fusion of the treated spinal segments. Implants used for direct fracture repair are rarely used in thoracolumbar spine surgery. One exception is for direct repair of spondylolysis without segmental fusion.

Implants developed to improve segmental stability without fusion, such as physeal staples, disc arthroplasty, and interspinous process devices, are briefly discussed. Dynamic pedicle screw systems are now included in an FDA subtype of semirigid systems, including polyetheretherketone (PEEK) rods. These systems were also downgraded to class II, but only as an adjunct to fusion.

Relevant Anatomy

A firm grasp of thoracolumbar anatomy is required to understand the implications of disease on anatomy and allow safe placement of implants.

The thoracolumbar spine can be divided into five regions: the cervicothoracic junction, the mid-thoracic spine, the thoracolumbar junction, the mid-lumbar spine, and the lumbosacral junction. Each region has distinct anatomic and biomechanical characteristics that must be considered when planning reconstructive and instrumentation surgery. The anatomy typically serves the biomechanics. For example, facet orientation predicts motion segment direction and range of motion. Facet orientation also "couples" motion so that flexion necessitates translation.[5]

Surgical approaches and implant placement affect the local spinal anatomy directly or indirectly. Direct anterior lumbar interbody approaches require sacrifice of the anterior longitudinal ligament. In disc replacement procedures, to achieve more parallel distraction, the posterior longitudinal ligament may need to be resected.

The thoracic spine's articulation with the rib cage increases its rigidity.[6] Before proceeding with a transthoracic approach and spinal reconstruction, the surgeon must be familiar with the articulations between the rib and vertebral body. There are two sets of demifacets: one at the disc level and the other at the transverse process. Radiate ligaments stabilize the articulation further. The rib attaches to the transverse process and the superior aspect of the same-number vertebra (at the level of the pedicle). For example, to reach the T9–T10 disc, one can follow the T10 rib to the superior aspect of the T10 body.

The rib–pedicle–transverse process junction is critical in posterior approaches as well. Because the pedicles of the mid-thoracic spine are quite narrow, some authors have recommended an in-out-in approach for pedicle screw insertion. With this technique, the pedicle screw trajectory begins dorsally, but as the pedicle narrows, the screw passes laterally into the space between the rib and the pedicle. This space, containing only ligamentous tissues, does not jeopardize neurologic structures or the lung parenchyma.[7]

The thoracolumbar junction represents a straight segment and a mechanical transition zone between the lordosis of the mobile, lumbar spine and the kyphosis of the more rigid, thoracic spine. As such, it is vulnerable to injury and loss of fixation with externally applied forces.

The lumbar spine permits significant flexion and extension across all levels. There is a sharp increase in the amount of lateral bending exhibited at L3–L4. There is less lateral bending at L2–L3 and L4–L5. In the lumbar spine, axial rotation is limited by the vertical orientation of the facets.

Successful spinal fixation requires a stable bone-implant interface. The proximity of the neural elements limits the bone surfaces available for spinal instrumentation. In addition, the bone's size and shape influence which implants can be used. For example, larger pedicles accommodate larger screws. Larger screws increase the stability of fixation and increase holding strength.

There is significant anatomic variation among patients. Modern imaging systems allow preoperative measures of optimal screw length and diameter.

The spinal cord typically ends at the L1–L2 disc space. Below the conus, the nerve roots pass from the central thecal sac through the neuroforamen into the pelvis. Several cadaveric and imaging studies have described the proximity of the bony elements to nearby neural structures. One cadaveric study measured the average distance from lumbar pedicle to the dural sac medially. From cranial to caudal in the lumbar canal, the range was 1.29 to 1.56 mm; clinically, this means that a medical pedicle breach greater than 1.29 mm has a significant chance of contacting or injuring the dura.[8]

It is important to understand the relationship of the pedicle and the exiting nerve root. In the thoracolumbar spine, a given root exits the central canal into the foramen just below the

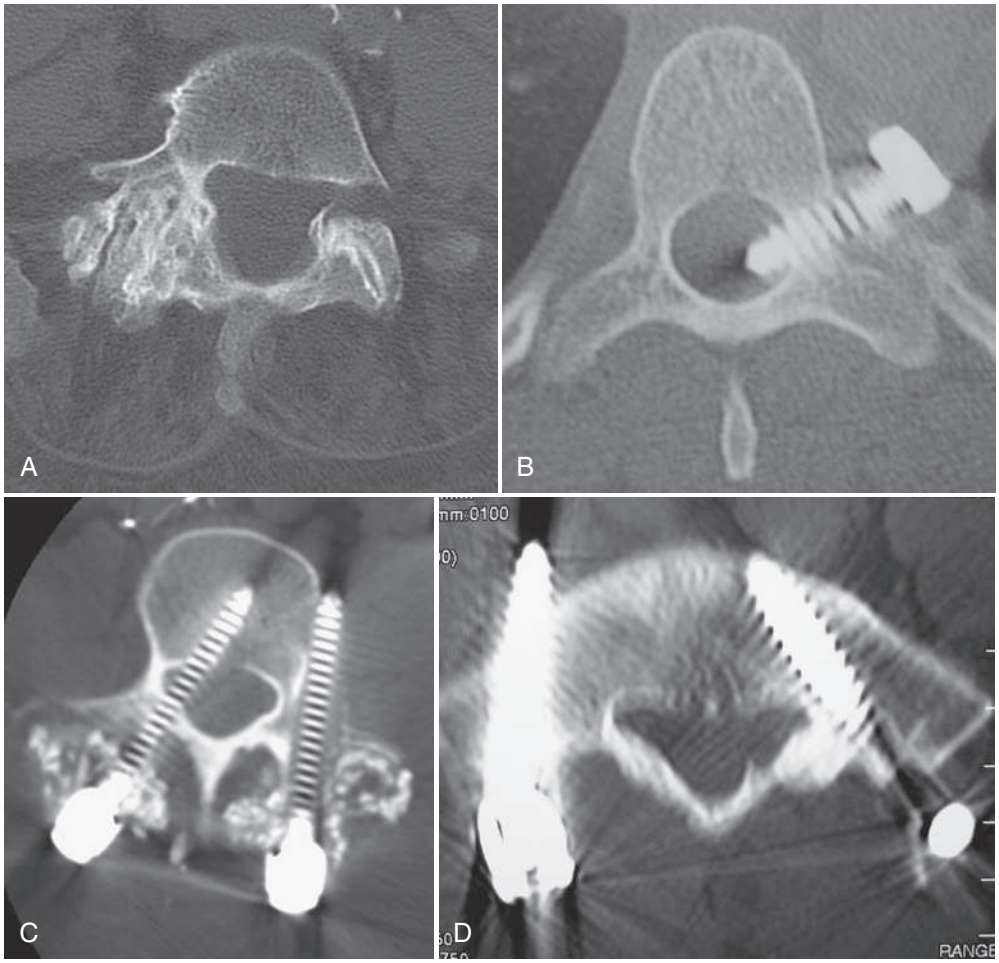

FIG. 70.1 Importance of good exposure. (A) Axial computed tomographic (CT) scan of a patient with marked facet hypertrophy. In most cases, complete takedown of the soft tissue around the lateral pars and medial transverse process provides enough anatomic clues for appropriate positioning of the pedicle probe. In cases such as this, resection of the facet osteophytes significantly improves identification of normal anatomic landmarks, improving pedicle screw placement accuracy. (B) Anteriorly, soft tissues must be reflected posteriorly enough to palpate the posterior vertebral body margin. This gives the surgeon a markedly improved three-dimensional sense of the position of the spine in space and can avoid inadvertent penetration of the spinal canal with a screw, as shown here. Proper positioning of the patient is critical. If the patient is rotated, the surgeon's orientation to the spine may be confused. That may have contributed to the misplacement shown here. (C) Adequate exposure also requires adequate soft tissue release. Particularly in patients with a narrow pelvis, if the thoracodorsal fascia remains tight, the surgeon has to struggle to achieve proper medialization of the screws. (D) Postoperative axial CT scan shows S1 screws. The left-sided screw is in acceptable position, whereas the trajectory of the right-sided screw is not medialized enough. The screw penetrates the anterior sacrum and impinges on the L5 root anteriorly.

pedicle of the same numbered vertebra. For example, at the T11–T12 level, the T11 root exits beneath the 11th pedicle. After the L5 nerve root exits the neuroforamen, it travels anterior to the sacral ala. An S1 pedicle screw that is placed too far lateral or is too long places the L5 nerve root at risk for injury. The pedicle is farther from the superior nerve root at 4.12 to 5.52 mm but closer to the inferior root, where distances ranged from 1.10 to 1.06 mm. The nerve roots and dura are statistically further from the L5 pedicle than from other pedicles, making the L5 pedicle safer than other lumbar pedicles for screw insertion (Fig. 70.1).

Knowledge of the intimate relationship of the major vessels to the spine is crucial to avoid life-threatening complications during anterior and posterior thoracolumbar instrumentation. The surgical goals, local anatomic realities, and implant size and mechanical features must be considered together. For example, when addressed anteriorly, a scoliotic curve is typically approached from its convexity to allow a more complete release. However, in the upper thoracic spine, the approach is typically from the right to avoid the arch of the aorta.

The lumbar spine is typically approached from the left for several reasons. First, the liver is on the right and is more difficult to mobilize. Second, a left-sided approach brings the surgeon into contact with the aorta before the vena cava. The aorta is more easily recognized and is more durable. This decreases the risk of sudden, catastrophic blood loss (Fig. 70.2).

Placing anterior thoracolumbar implants requires preoperative evaluation of the vascular structures and detection of

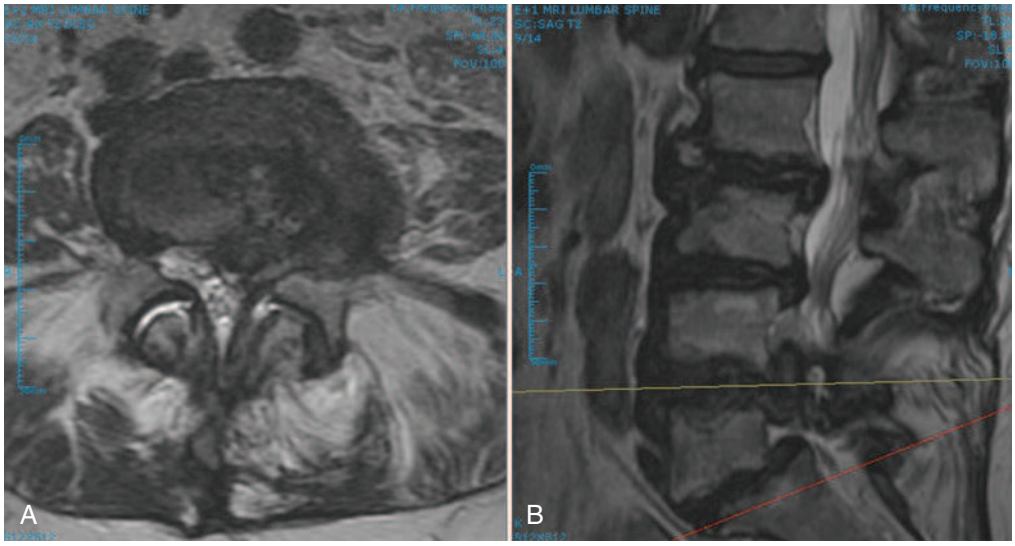

FIG. 70.2 Preoperative planning is crucial when selecting the implants or the angle of the approach to the spine. In certain cases, one implant may suit a patient better than another. (A) Cross-sectional and (B) parasagittal magnetic resonance images of L4–L5 disc space. Note the right iliac vessels are more lateral than expected. This type of anatomy may preclude the use of a transpsoas approach.

potential vascular anomalies. Vascular calcifications in an older patient may limit retraction of the vessels and may be a contraindication to anterior surgery. In addition, any patient with previous abdominal or hernia surgery must be carefully evaluated because scar tissue may be a contraindication to abdominal surgery.

In posterior approaches, the heart-shaped thoracic vertebral bodies allow thoracic pedicle screws to breach the vertebral cortex and endanger the aorta. This distance can vary with scoliosis but may be as little as 2 mm.[9] Placement of interbody devices from a posterior approach may also endanger the anterior vascular structures.

BOX 70.2 Important Factors in the Selection of Thoracolumbar Implants

Pathoanatomy: mechanism of injury and direction of instability
Mode of failure (e.g., in trauma, direction, and magnitude of injury vector)
Direction of instability
Degree of instability
Compromised stabilizing structure
Number of levels
Number of spinal columns per level
Bone vs. ligament (anticipated healing)
Host bone quality
Graft bone quality
Expected level of patient loading
Availability of postoperative immobilization
Surgeon familiarity with techniques
Availability of implants

Biomechanics of Thoracolumbar Instrumentation

Understanding disease state pathomechanics and implant biomechanics is crucial to successful construct design. Occasionally, implants fail because they are misplaced. More commonly, implants fail due to a judgment error (Box 70.2). Typically, the surgeon fails to understand fully one or more of the following factors:

1. Forces to which the spine is subjected
2. How the implants counteract those forces
3. Planes in which the spine is unstable
4. How instrumentation affects forces passing through structural grafts
5. Destabilizing effects of the operative procedure itself
6. Nature and extent of postoperative muscular forces
7. Time course of bone and soft tissue healing

The third factor, that of instability, remains controversial and difficult to predict. In trauma, understanding the mechanism of injury and direction of instability allows the surgeon to attempt to reverse that direction and those forces to affect a reduction and provide stability. Although not always clear in trauma, these factors become more opaque with etiologies such as inflammatory, neoplastic, and degenerative disease. Overestimation of the degree of instability present may lead to unnecessarily large surgeries or, in some cases, surgery without an indication. On the other hand, failure to appreciate clinically relevant instability may lead to inadequate treatment.

In general, the degree of anatomic disruption, as depicted by magnetic resonance imaging (MRI) or by abnormal angulation or translation on plain radiographs, should direct the surgeon toward the type of stabilization.

Implants are used to exert forces on the spine (e.g., to effect a reduction or scoliosis correction) or to resist forces (e.g., to prevent postoperative kyphosis). To select spinal implants properly, the surgeon must understand the size and direction of the forces to be applied. The surgeon must have an idea of how well the bone and soft tissue elements of the spine would respond to these forces (e.g., would the screws hold).

TABLE 70.1 Factors Used to Select Thoracolumbar Instrumentation Strategy

Internal Factors	External Factors
Compromised stabilizing structures (e.g., an injured anterolateral ligament may render the spine less able to resist extension forces)	Anticipated stresses exerted by the patient
Tissue type of the compromised stabilizer (healing time will vary)	Appropriateness and effectiveness of postoperative immobilization (e.g., external bracing may do little to shield the lumbosacral junction; patients with spinal cord injury may not be the best candidates for postoperative bracing)
Number of levels involved	Surgeon familiarity with relevant technique
Number of spinal columns involved	Availability of implants
Biologic and biomechanical quality of the host bone; consider preoperative dual-energy x-ray absorptiometry scan in at-risk patients	Effect of the surgery on adjacent levels
Biologic and biomechanical quality of the bone graft used. Because allograft will have longer incorporation times than autograft, a construct with greater fatigue resistance may be required.	Morbidity of the approach

Finally, the change in these forces during healing, including the effects of bone fusion, muscle healing, and implant fatigue, should be considered to minimize the risk of late implant failure. The more completely the surgeon understands these factors, the better able he or she is to choose the appropriate type of implant, appropriate implant material, optimal number and position of anchor points, and duration of postoperative immobilization.

Regardless of the etiology, delineating a few characteristics of the disease state is always useful (Table 70.1).

Implant Materials and Fusion Characteristics

Most posterior thoracolumbar fixation systems are made of stainless steel, pure titanium or, most commonly, titanium-aluminum-vanadium alloy. Metallic implants are also used in anterior column surgery as both screw-plate/screw-rod systems as well as rigid structural spacers to maintain or restore anterior load-carrying capacity.

Surgical stainless steel is very strong, with yield strength of 700 MPa. It is also stiff, having a modulus of elasticity 12 times that of normal bone. Steel implants usually have cobalt-chromium alloy and molybdenum to enhance corrosion resistance. Titanium alloys tend to have greater native biocompatibility and corrosion resistance. Titanium has a modulus of elasticity only six times greater than bone, which makes it easier to bend and insert than steel. These characteristics allow titanium-based devices to transfer load effectively to the vertebral body, partly shielding the implant from some stresses.

Two types of titanium are typically used. Pure titanium is recommended only when very low strength is needed because it has a low yield strength of only 170 to 485 MPa. More typically, a titanium-aluminum-vanadium alloy, with yield strength of 800 MPa, is used. Its greater strength does not change the favorable modulus of pure titanium (110 GPa).[10]

Cobalt-chrome rods are often used in deformity surgery, where some reports suggest long fatigue life and better maintenance of coronal plane correction.[11,12] However, one recent series reported a significantly higher rod fracture rate when cobalt-chrome rods were used to stabilize pedicle subtraction osteotomies.[13]

A reduction in stress shielding allows bone grafts to respond to more load appropriately. Use of titanium alloys has increased because of improved imaging characteristics, high strength/weight ratio, enhanced ductility, and increased fatigue life. Even with titanium, one of the disadvantages of metal cage implantation lies in plain radiographic assessment of fusion.[14]

Increasingly, nonmetallic implant materials have been used in thoracolumbar implants. Common materials include machined allograft bone, carbon fiber, or PEEK. Typically, these materials are used as cages, spacers, and graft containment systems rather than as fixation systems. Advantages of radiolucent materials such as PEEK include easier radiographic assessment of graft integration. For some nonmetallic implants, the modulus of elasticity is closer to that of host bone, allowing greater load sharing.[15] Mechanical testing showed acceptable mechanical and fatigue characteristics for PEEK as a load-bearing implant material.

Rods made of PEEK were briefly used for similar load-sharing reasons. Cadaveric tests compared the impact of PEEK versus titanium rods on adjacent-segment motion and intradiscal pressure.[16] No significant benefits of PEEK rod placement were noted. Furthermore, high failure and implant mobility rates have diminished their popularity.[17,18]

Although allograft bone spacers may be used alone, similar to their metal counterparts, they are typically filled with bone graft or bone morphogenetic protein. Radiographic assessment of bone healing may be improved when nonmetallic biomaterials are used. Even with radiolucent cages, differentiation of bone adherence versus through-growth (true fusion) is difficult, however. Bridging bone anterior (sentinel sign) or lateral to the cage is often used to signal fusion.

In a biologic environment, fretting and corrosion can occur between the modular components of a spine construct. Kirkpatrick and colleagues[19] subjected 48 spinal implant constructs to surface analysis stereomicroscopy. Titanium alloy implants ($n = 25$) showed no significant corrosion, but three of the constructs showed fatigue failure of the anchoring screws. The cobalt alloy construct showed no evidence of corrosion. Semirigid stainless steel implants had mild surface alteration, whereas rigid constructs showed moderate to severe corrosion. Based on their findings, the authors recommended avoiding rigid stainless steel implants or constructs with different surface finishes between rods and connectors.

The surgeon must use caution when combining implants made of different metals.[20] Mixing stainless steel with titanium could lead to a galvanic response and early corrosion, although titanium has been used with cobalt-chromium alloy without significant corrosion or complications.

In the early 2000s, there was quite of bit of interest in resorbable spine implants. At that time, numerous absorbable polymers, such as polylactic acid, were undergoing testing. With resorbable cages, the graft is gradually loaded to a greater and greater degree as the cage is enzymatically digested.[21,22] Each interbody device had different mechanical characteristics, such as modulus of elasticity and different resorption times. Implant failures and heterogeneity in implant performance in different patients have curbed enthusiasm, although new materials may revitalize this area of research.

The material properties of implants are also affected by manufacturing variables, such as drill holes, structural imperfections, and surface irregularities. Ultimate tensile strength—the maximum stress a material can sustain without changing shape—may be altered during surgery. Titanium rods are particularly sensitive to notching. If a complex rod contour is required, a template should be used to minimize the amount of rod bending. In some patients with rigid dual-curve deformities, it may be more effective to use separate rods in the thoracic and lumbar spine, employing rod-to-rod connectors ("dominoes") to complete the construct.

Implant fatigue is an important cause of failure. The average spine cycles 3 million times per year.[23-25] Current implants are overengineered for their designated function; therefore implant failure is more likely to occur from improper selection than from mechanical properties.[26] If bone healing is delayed or incomplete, the implant or construct ultimately fails, so meticulous attention to bone grafting technique is imperative.

Although newer rod materials, such as Ti6Al-4V alloy, allow better deformity correction with lower rod fracture rates, notch sensitivity continues to be reported.[27,28] Recently, nitinol rods have shown improved wear resistance compared with titanium and similar wear resistance to cobalt-chrome.[29]

Spinal implants are designed to provide segmental stability to facilitate bone healing. However, the type of fusion also affects the construct selected. For example, improved spinal implants have fostered a trend away from autogenous bone graft to allograft. Although allograft requires longer incorporation times, rigid instrumentation increases the rate of maturation.

A number of factors may impact the rate of bone healing and the chance of nonunion. For example, postoperative wound infections may affect fusion rates, especially in areas vulnerable to cyclic loading.[30] Other factors include motion, loading, muscle status, medical comorbidities, nutritional status, and tobacco use.

For fusions expected to heal slowly, more robust forms of instrumentation, possibly with additional anchor points, should be used. For example, lower fusion rates in smokers may justify instrumentation in settings in which in situ fusion would otherwise be appropriate. When clinical or mechanical circumstances increase the risk of pseudarthrosis, use of bone morphogenetic protein (BMP), on the other hand, may accelerate healing and may permit use of less fatigue-resistant constructs.[13] Other steps, such as addition of L5–S1 interbody fusion below a long posterolateral fusion, can be considered.[31]

Along the same lines, the anticipation of increased postoperative loading, poor patient compliance, or inadequate postoperative immobilization may warrant more rigid forms of operative stabilization. Examples include patients with neurologic or motion disorders who are subject to increased spinal loads and patients with spinal cord injury or a colostomy for whom brace immobilization is impractical.

The type of fusion achieved has implications on regional spinal mechanics as well and the advisability of subsequent implant removal. Historically, the most common fusion technique was the posterior fusion. The primary advantage of this approach was easy surgical access to the midline posterior elements (spinous processes and lamina). Disadvantages included its limited utility in laminectomy patients. Also, the graft material lies distant from the center of rotation and experiences significant tensile forces with spine flexion. This distance increases tensile stress and motion on the graft that could lead to migration, excessive motion, or graft resorption and ultimate nonunion.

Over time, direct posterior fusion was replaced by intertransverse fusion. For an intertransverse (posterolateral) fusion, the facet joints, lateral pars, and transverse processes are decorticated and grafted, leaving the lamina accessible for decompression. Intertransverse graft material is closer to the center of vertebral rotation. The disadvantage is a poor vascular bed and a decreased area for fusion.

Interbody fusion provides significant mechanical advantages in terms of graft compression and a large, well-vascularized fusion surface. The anterior column fusion spans the neutral zone and, when healed, represents the strongest mechanical block to segmental motion.[32,33] Even a solid intertransverse fusion may fracture or elongate if excessive or repeated load is placed across the motion segment.

The stability of this type of fusion has implications on subsequent implant removal. A report of 75 patients who underwent implant removal for late operative site pain, infection, or hardware failure, with a minimum of 2-year follow-up, found that the average loss of curve correction was 23.1 degrees.[34] Only 40% of those with operative site pain reported postoperative relief, and indolent infections were found in 37%.

Thoracolumbar implants share applied loads with the spine until a stable fusion occurs. If a construct bears most of the load, stress shielding of the spine results and may lead to device-related osteopenia.[35,36] The clinical sequelae of this shielding theoretically include graft resorption and possible implant failure, although emphasis on this phenomenon has declined over the last few years.

Temporary screw-and-rod fixation of spinal fractures to allow near-anatomic healing without arthrodesis have increasingly been described.[37] In a recent series, a cohort of 45 consecutive trauma patients who underwent implant removal after fracture healing were compared with 45 patients whose implants were retained. In most cases, a long-segment instrumentation and short-segment fusion had been performed. At 2-year follow-up, the implant removal group was found to have better visual analog pain scale and Oswestry Disability Index (OSI) scores as well as better range of motion.[38] A recent retrospective study of 104 patients found that minimally invasive surgery (MIS) with these principles was as effective

as open surgery, while reducing procedure time and hospital stay.[39] Successful use in patients with ankylosing spondylitis and disseminated idiopathic skeletal hyperostosis has also been reported.[40]

In addition, temporary percutaneous stabilization of thoracolumbar trauma in patients with other major systemic injuries has been reported. In this setting, the initial construct is converted to formal fusion when the patient has stabilized medically. Mechanically, this damage control approach was evaluated in five cadavers. At least two levels of fixation above and below the level of injury were required to restore adequate rotational stability for log-rolling and sitting up.[41]

Demand Matching, Improving Fixation, and the Implications of Osteoporosis

The number of fixation points required of a spine construct depends on the demand placed on the construct, the fixation strength of the anchor, and the time required for bone healing. The most common, and increasing, challenge to thoracolumbar fixation comes from osteoporosis. Osteoporosis is the most common metabolic bone disorder and results from loss of both the crystalline (inorganic) and collagenous (organic) portions of bone.[42] Similar difficulties may be encountered in patients with spinal neoplasia or inflammatory arthritides.[43]

Throughout life, the body constantly remodels bone by removing old bone and creating new bone. Osteoporosis occurs when the rate of bone resorption exceeds the rate of bone formation. Lower rates of bone formation result in a decline in overall mineral density of bone. Unbalanced osteoclast activity results in disruption of the normal connectivity between bony trabeculae. Osteoporotic bone is weakened in the material and architectural sense.[42]

At least 40 million people are at risk for osteoporosis in North America. With the aging of the population, this number is likely to triple over the next 3 decades. Management of spinal disorders in an osteoporotic spine will thus be an increasing challenge. These bone quality issues are also noteworthy when treating patients with metastatic disease or inflammatory spinal arthritides.[44]

Implant failure in osteoporotic bone is common. Even if healing occurs uneventfully, patients with osteoporosis are at risk for compression fractures and spondylolisthesis adjacent to rigid constructs.[45]

For many patients, the diagnosis of osteoporosis and initiation of appropriate management are delayed. Because the consequences of the failure to recognize osteoporosis are so high, the spine surgeon must screen at-risk patients. Because at least 30% bone mass loss is needed to identify osteopenia reliably on plain radiographs, dual-energy x-ray absorptiometry (DEXA) and serum vitamin D levels are better screening tools.[46,47]

Results of DEXA scans are given in T and Z scores. The T score compares the patient's bone mineral density (BMD) with mean values for healthy, same-gender young adults. For each standard deviation below the norm, fracture risk increases 1.5- to 3-fold. A T score of –1 implies a 30% chance of fracture. As the T score decreases from –1 to –2, the risk of instrumentation failure increases significantly. The Z score compares BMD with age-matched controls. A Z score less than –1.5 warrants a more extensive workup for osteomalacia or neoplasm. DEXA values are falsely increased with scoliosis, compression fractures, spondylosis, extraosseous calcification, and vascular disease. In many spine patients, the T score at the femoral neck hip may be more predictive of implant holding power than the spine value.[48]

Depending on the patient's activity level, the nature of the intended surgery, and the severity of the osteoporosis, preoperative initiation of antiosteoporotic management and delay of elective spine procedures may be warranted.[42] Bisphosphonates dramatically suppress bone resorption and decrease hip and spine fractures. These agents inhibit osteoclast activity and directly stabilize the bone crystal, making it more resistant to osteoclastic bone resorption. Parathyroid hormone (Forteo) is anabolic to bone and leads to early, dramatic increases in bone mass. Preoperative Forteo programs, typically for 6 months, have been increasingly reported and may accelerate spinal fusion as well.[49]

When planning a spinal reconstruction procedure in an osteoporotic patient, it is important to recognize the differing vulnerabilities of various spinal structures. Trabecular bone represents 20% of the total bone mass and comprises the larger part of the vertebral body. Because trabecular bone exhibits eight times greater metabolic activity than cortical bone, osteoporosis affects trabecular bone earlier and to a greater degree than cortical bone.[50] The threshold BMD for successful anterior spinal instrumentation has been reported at 0.22 g/cm (as measured by quantitative computed tomography [CT]).[51]

The cortical bone of the pedicle and laminae is preserved longer in patients with early or moderate osteoporosis. As a result, posterior fixation is typically recommended. Initially, the relative holding power of pedicle screws versus infralaminar pedicle hooks was debated. While the pullout strength of hooks appears to be less sensitive to osteoporosis than screws, screws still offer greater fixation strength.[52]

Because of the difficulty achieving a stable anterior column reconstruction in an osteoporotic patient, combined anterior and posterior surgeries are often recommended to achieve adequate fixation. Other strategies to improve fixation in this patient population include augmentation of screw tracts with polymethylmethacrylate (PMMA), use of laminar hooks to protect inferior pedicle screws, expansion of screw designs, triangulated screw placement, increased use of transverse connectors, and bicortical vertebral body purchase.

BMD is linearly related to screw insertion torque and pullout strength.[53] The surgeon's tactile sense of purchase when placing the screw relates to construct strength. On the other hand, a recent study measured screw placement force and torque in 76 cadaveric pedicles.[54] Proper cannulation axial force was a mean 48 N. Medial and lateral breach required 129 and 86 N, respectively. The authors noted that "A large range of cannulation and breach forces and torques were measured due to variations in bone quality and geometry."

PMMA may be added to screw tracts to increase pullout strength (Fig. 70.3).

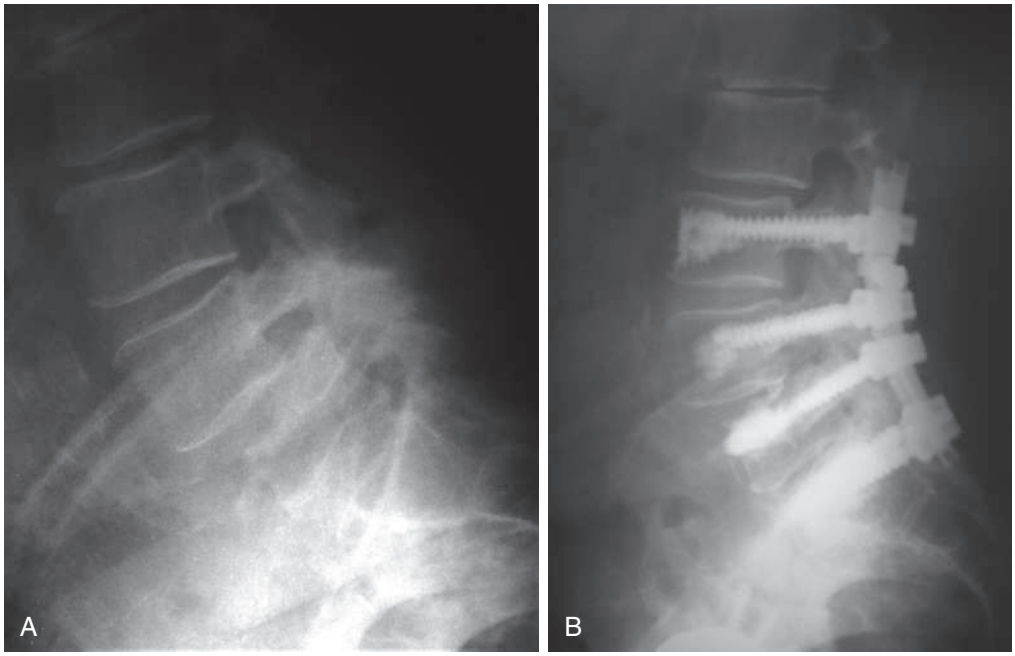

FIG. 70.3 (A) Preoperative and (B) postoperative lateral lumbar radiographs demonstrate the surgical strategy used in an osteoporotic patient with long-standing spinal stenosis associated with an L4–L5 spondylolisthesis as well as back pain from a nonhealing L5 superior endplate compression fracture. A facet-sparing laminectomy was performed as well as a three-level fusion from L3–S1. To improve fixation in the osteoporotic bone, cement augmentation (vertebroplasty) of the anterior cancellous bone was performed before screw insertion. At L5, balloon-assisted augmentation was undertaken to improve anterior load-bearing capacity. Additional fixation points, including L3 and L5, were also used.

Use of calcium sulfate and PMMA augmentation of the vertebral body continues to be reported to restore anterior column stability in combination with posterior transpedicular screw placement in trauma, tumor, and other indications. Typically, good outcomes with minimal cement leak rates and without associated complications are reported.[55,56] In addition to kyphoplasty and vertebroplasty techniques, a vertebral body stenting approach has also been described.[57]

Cannulated screws with ports for PMMA injection have been reported with reasonable results. Other surgeons simply place the PMMA before placing the screw, arguing that a doughier PMMA can be placed if not requiring extrusion through small holes in the screw.[58] PMMA augmentation has also been used in the reconstruction of pathologic fractures from neoplastic disease, including those in which the pedicle itself has been compromised.[59]

Although bicortical purchase increases the screw's pullout strength and resistance to cyclic loading, BMD has an overall greater impact.[60] Improved unicortical screw strength can be achieved with triangulated and subchondral placement.[61-63]

If bilateral screws are placed in a triangulated pattern, use of a transverse or cross connector further increases fixation strength. Mechanically, stability is improved by the presence of bone between the screws rather than merely by the bone within the threads of each screw individually. Avoid parallelogram (four-bar linkage) constructs in which the screws and longitudinal members form a perfect square or rectangle. These constructs resist lateral loads less well than a triangulated pedicle screw placement.[64] In anterior dual-rod constructs, a trapezoidal short-short/long-long construct is typically recommended.

Screw length is linearly related to pullout strength. Little difference is seen between self-drilling or self-tapping designs; if tapping is performed, undertapping by 1 mm leads to greater pullout strength than undertapping by 0.5 mm.[65,66] For sacral screws, especially in long constructs, bicortical screws improve holding power and sagittal plane correction. Some authors have recommended aiming the screw upward into the disc space or through the sacral promontory.[67,68]

Another option lies in transdiscal screw placement. Here, lumbar pedicle screws are aimed cranially through the superior endplate, across the disc space, and into the vertebral body above. Most typically, this approach has been used in spondylolisthesis. Depending on pedicle size, this can add holding power to screws across even sagittally aligned segments.[69]

The implants themselves may also be modified to address a given patient's clinical needs. For example, maximizing the diameter of typical pedicle screws improves pullout strength and decreases the risk of fatigue failure of the screw. Other, newer approaches include hydroxyapatite (HA) screw coatings to improve screw-bone integration. One recent study found that the HA shank prevented triggered electromyographic responses.[70] Increasingly, surface roughness and nanostructural surfaces are being studied to improve osseointegration of screws and other spine implants.[71] Drug- and chemotherapy-eluting implants have recently been devised for specific clinical situations. One recent study described successful use

of pedicle screws with iodine surfaces to decrease concerns about bacterial adherence and biofilm formation.[72]

Posterior Thoracolumbar Instrumentation

Modern, posterior, rigid, segmental spine stabilization systems arose in response to kyphoscoliosis deformity occurring in patients surviving polio and tuberculosis.[73] Internal stabilization began in the early 1900s by Lange, but it was not until the 1950s and 1960s that Harrington, Moe, and others developed the first generation of modern spinal instrumentation.[74] In the 1980s, Cotrel and Dubousset first popularized rigid, segmental hook-based fixation.[75]

Currently, rigid, segmental, posterior transpedicular constructs represent the most common form of thoracolumbar instrumentation. Despite the dominance and versatility of transpedicular constructs, instrumentation failure is by no means rare. The implants below are orgnanized by the bone elements to which they anchor.

The midline posterior approach remains the most common access route for placement of thoracolumbar instrumentation. This extensile approach is applicable from the occiput to the sacrum. Below L2–L3, the dural sac may be safely retracted to afford enough exposure to the posterior disc space for performance of a posterior lumbar interbody fusion. In the upper lumbar spine, the risk of neural injury with dural retraction increases, and more oblique approaches to the disc space, such as transforaminal lumbar interbody fusion (TLIF), are safer. Practically, however, these oblique posterior approaches to the thoracolumbar disc space have become more common at every level.

In the thoracic spine, a midline posterior approach is considered dangerous for decompression of anterior compressive pathology. The lateral extracavitary or costotransversectomy approach allows access to thoracic vertebral bodies from a posterior approach without violation of the pleura or takedown of the diaphragm.[76] While this approach allows a one-step approach to decompression and long, rigid, posterior stabilization, anterior column visualization and access are inferior to that afforded by a transthoracic approach. Significantly more bone resection (including the rib, costotransverse joint, facets, and pedicle) is required to achieve that visualization. Costotransversectomy is associated with increased blood loss, longer operative time, increased paraspinal muscle disruption, and chest wall numbness from intercostal nerve resection. Occasionally, anterolateral cord compression can be addressed with a compromise approach between a standard laminectomy and a formal costotransversectomy. These transpedicular decompressions are known by various names, such as pediculofacetectomy, and are particularly useful in patients with tumors in whom the neoplasm has already destroyed most of the pedicle.[77,78] In this case, the decompression is mainly soft tissue removal, and the anterior compressive elements can be removed indirectly by pulling them away. Although this approach confers limited visualization, even relative to costotransversectomy, it reduces operative time, blood loss, and iatrogenic destabilization. An angled microscope or 70-degree endoscope may improve visualization of the anatomy anterior to the dura.[79]

Most thoracolumbar instrumentation requires a relatively wide exposure beyond the facet and out into the transverse process. The powerful retractor systems affording this wide exposure create extremely high levels of intramuscular pressure.[80] Over time, this pressure can cause muscle necrosis similar to a compartment syndrome. For longer cases, the retractors should be removed every 2 hours to allow muscle recovery. This recovery time is particularly important because preoperative muscle abnormalities may exist in some conditions, which can be accentuated by the trauma of extended muscle retraction.

Over time, a variety of less invasive approaches to the posterolateral lumbar spine have evolved. For example, the Wiltse paramedian approach, although initially described for resection of far-lateral disc herniations, has been used for interbody and posterolateral fusions.[81] A bilateral paramedian trajectory in the intermuscular plane between the longissimus and multifidus muscles is best when no midline decompression is needed. In addition, this approach could be considered for posterolateral pseudarthrosis revision to avoid midline scar. A variant of the Wiltse paramedian approach is used in most MIS fusions using tubular retractors, microscopic dissection, and fluoroscopic guidance. Iatrogenic muscle injury can result from denervation of the primary motor branch of the dorsal primary ramus when the muscle is stripped from the midline beyond the facets.[82]

Interspinous Process Stabilization

A variety of interspinous process devices have been introduced for varying indications. Most share a minimally invasive concept in that they can be inserted with the patient under local or limited anesthesia through small incisions. However, some devices require formal, open exposure of the posterior elements to attach or wrap "artificial ligaments" or other outriggers.

In North America, the most familiar of these interspinous process devices is the X-STOP (Medtronic). Marketed as a less-invasive alternative to laminectomy, the X-STOP is used to distract the spinous processes in patients with symptomatic spinal stenosis. Subtle segmental flexion or prevention of extension is said to increase canal diameter and relieve neural compression.

In 2005, a randomized, controlled, prospective, multicenter trial of 191 patients with neurogenic claudication compared outcomes of patients treated with X-STOP with outcomes of patients receiving nonoperative care. At 2 years, the symptom severity score of patients treated with X-STOP improved by 45.4% over mean baseline. The control group had only 7.4% improvement. Physical function improved 44.3% in the X-STOP group but declined in the controls. The authors concluded that the X-STOP provided effective treatment for patients with spinal stenosis (Fig. 70.4).[83]

Subsequently, studies have compared less-invasive decompression with X-STOP surgery. Similar clinical outcomes were achieved, but the interspinous process device has a higher rate

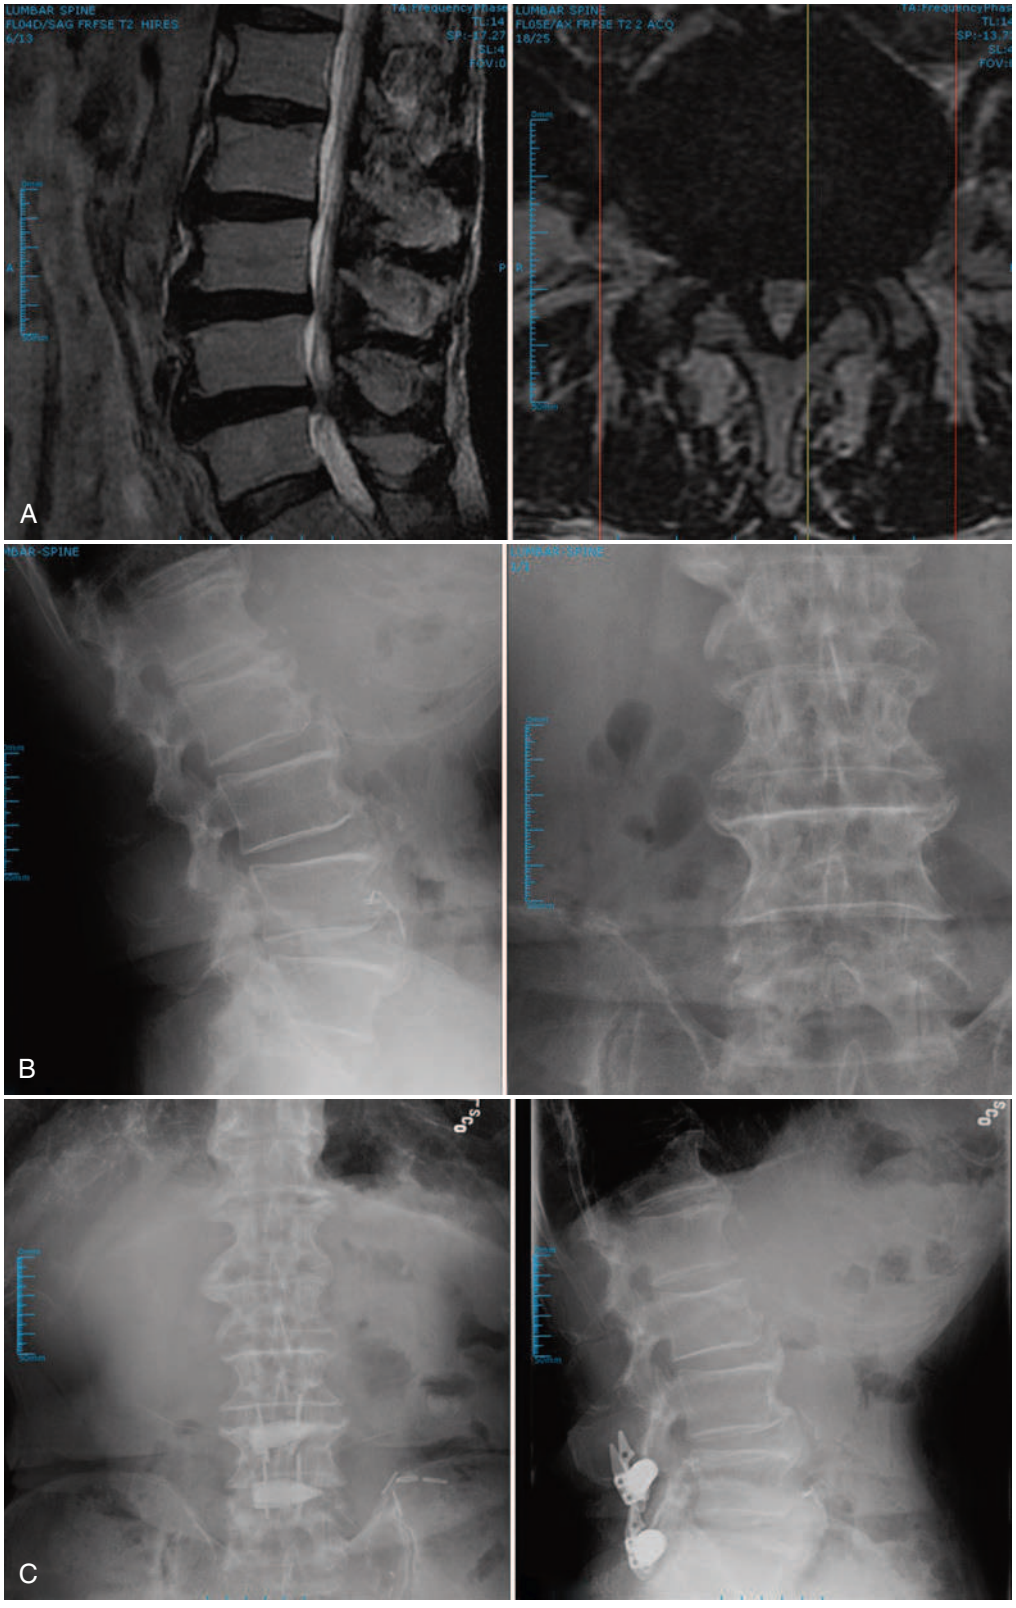

FIG. 70.4 As a less-invasive alternative to laminectomy, an interspinous spacer is used to distract the spinous processes in patients with symptomatic spinal stenosis. Subtle segmental flexion or prevention of extension is said to increase canal diameter and relieve neural compression. (A) Preoperative magnetic resonance image showing multilevel stenosis. (B) Preoperative radiographs. (C) Postoperative radiographs showing placement of interspinous spacers placed at L4–L5 and L3–L4.

of secondary surgery and a much higher cost of care.[84,85] Use of this device appears to be declining, however, and reasonable outcomes with newer study devices have been reported.[86,87]

Other interspinous process devices are used to stabilize the segment rather than decompress the canal. Some of these are meant to be used after decompression and in lieu of or as a means of achieving segmental fusion.[88]

One of the devices intended to treat mechanical low back pain through either distraction or restriction of motion was the Wallis implant (Zimmer Biomet), in which a semielastic blocker dampens forces passing through the posterior elements while decreasing the neutral zone.[89] The first-generation implant, with a titanium blocker and an artificial ligament made of Dacron, was developed in 1986. More than 300 patients were implanted from 1988 to 1993. Subsequently, a PEEK version of the Wallis implant was developed. Without permanent fixation into the vertebral bone, the "floating" design of the Wallis and similar implants seeks to avoid the risk of loosening encountered with pedicle screw–based and facet replacement–based dynamic stabilization systems. According to a more recent review of the Wallis implant, significant improvements in back pain were seen "without serious complications." The Wallis system was recommended for (1) discectomy when massive fragment leads to substantial loss of disc material, (2) first disc herniation recurrence, (3) discectomy for herniation of a transitional disc with sacralization of L5, (4) degenerative disc disease at a level adjacent to a previous fusion, and (5) isolated endplate lesions leading to chronic low back pain.

A recent study reported 2-year outcomes of posterior tension band placement after laminectomy and in lieu of fusion in patients with degenerative stenosis and spondylolisthesis. Good clinical outcomes, no progressive instability, and only one reoperation were reported.[90]

Spinous process fixation may also be used during fusion procedures as a posterior tension band. Because of the limited stability afforded by the spinous process, these devices were initially recommended to "back up" anterior lumbar interbody fusion (ALIF) procedures. Recently, a biomechanical study was undertaken to compare the utility of such a device with transpedicular instrumentation in stabilizing the spine after insertion of a lateral interbody cage in six cadavers.[91] The authors found that posterior supplementary fixation increased stability but that pedicle screws offered additional coronal plane stability. At this point, little long-term data or biomechanical data under multiple load cycles are available. In another biomechanical study, the interspinous process device improved flexion-extension stability compared with ALIF alone, but demonstrated little lateral bending or rotational stability when compared with a bilateral pedicle screw construct.[92]

One recent review concluded that although the wide variety of designs and materials for interspinous process devices was generally safe, the clinical benefits declined over the long term.[93] Spinous process–based devices have limited utility at L5–S1 due to the small size of the S1 spinous process. A recent study found that the sacral spines were highly variable in their morphology but had a similar load to failure of lumbar spinous processes.[94] In addition, spinous process erosion or fracture can occur with either the motion-preserving or fusion devices.

Facet-Based Stabilization

Numerous methods of facet fixation have been proposed. Historically, small screws were placed directly through the facet joint. Although these screws were able to lock the facets, their short length produced too small of a lever arm to counteract the forces to which the lumbar facet is exposed, and many of these implants failed. Techniques at the present time are exploring additional methods of bony purchase. The most common of these is the Magerl technique, in which 4.5-mm, fully threaded cortical screws, usually 50 to 60 mm in length, are passed from the opposite side of the spinous process through the ipsilateral lamina and across the facet.[95] The Boucher technique is similar but incorporates a greater degree of pedicle penetration.[96] In both of these techniques, the screws are not placed in lag mode.

These translaminar facet screws are indicated for one- or two-level fixation when reduction is not needed. Most often, they have been used as posterior column stabilization after ALIF procedures. The advantages of these screws include minimally invasive insertion via a 4-cm percutaneous approach. Translaminar facet screws are much less expensive than transpedicular constructs and offer less impingement on surrounding musculature.

Using contemporary techniques, fusion rates are high and cases of screw failure are rare. Recently, facet screws were compared with pedicle screws in 62 patients undergoing circumferential single-level lumbar fusion.[97] Facet screw utilization was associated with less blood loss, cost and, at long-term follow-up, less back pain and adjacent-segment degeneration than pedicle screw placement.

Disadvantages to translaminar facet fixation include absence of the three-column purchase afforded by transpedicular instrumentation. Patients may therefore need postoperative immobilization. Contraindications to translaminar facet screws include absence of adequate lamina or facet joints. These screws may be placed after laminotomy procedures but not typically after full laminectomy.

Recently, focus on direct facet and translaminar facet screws has declined due to increased use of spinous process fixation and cortical screws. That said, as a means of posterior tension band reconstruction after ALIF, though, they continue to have a longer track record than the newer techniques mentioned.[98]

Over the last 10 years, a number of percutaneously placed allograft dowels and other facet joint implants have been marketed as adjuncts to fusion. Reports of clinical effectiveness remain sparse. A recent biomechanical study of six cadaveric specimens compared two facet bone dowels.[99] One offered little stability at any time point. The other did restrict flexion-extension motion but lost fixation after 5000 cycles. The authors concluded that these devices were not mechanically effective and warned that "considerable magnitudes of device migration were detected."

When the previous edition of this text was published, study of facet arthroplasty systems was underway. These systems

were not intended to treat facet-mediated axial low back pain, but rather to restore stability after laminectomy without necessitating spinal fusion. They fit into a narrow treatment window between clearly unstable spines (e.g., spines with scoliosis or a dynamic spondylolisthesis) that require concomitant fusion and cases in which a narrow decompression can be performed that would not jeopardize postoperative stability.

Creation of a functional facet replacement system is a complex undertaking. Four main components, the superior and inferior right and left facets, have to be sized to the individual. Different designs rely on varying forms of attachment, but fixation through the pedicle is generally required. Various outriggers, cross-links, or other devices hold the system together and balance tension to maintain stability while maintaining segmental motion. Although a 7-year follow-up study of 10 patients treated internationally for spinal stenosis and spondylosis revealed reasonable results, it appears that clinical study of these devices in North America has been abandoned.[100]

Laminar Wires, Ribbons, and Hooks

Posterior thoracolumbar instrumentation has traditionally been divided into rigid and nonrigid implants. The earliest constructs incorporated the spinous processes or other posterior elements alone or with slabs of structural iliac crest autograft. Although simple wiring techniques are no longer used in the thoracolumbar spine, many wire-rod techniques continue to be routinely used. The most common technique—Luque wiring—uses sublaminar wires as anchors. These wires are wrapped around rods to form a segmental, nonrigid spine construct. Such techniques are nonrigid because they allow "pistoning" of the spine in a craniocaudal direction. Luque's construct was the first segmental system that used multiple wire attachment points.[73,101]

In North America, Luque constructs are currently preferentially used in the thoracic spine. Common indications include neuromuscular scoliosis, scoliosis with thoracic lordosis, and occasional cases of idiopathic scoliosis. Hybrid constructs using Luque wires with pedicle screws and other bone anchors are more commonly used. Contraindications to sublaminar fixation include absence of laminae. In addition, there is a danger of passing the wire through the spinal canal, particularly in patients with kyphosis or canal stenosis.[102] Because wiring techniques do not provide axial stability, they are a poor choice for stabilization of pathologic processes with anterior column insufficiency. For example, sublaminar wires should not be used as primary fixation in patients with vertebral fractures or tumors.

In response to the risk of sublaminar wire passage, Drummond proposed a technique, commonly referred to as the Wisconsin method, in which the rod is wired to the spinous processes.[103,104] This method has been used with Harrington rods and other rod systems to provide additional stability by segmental fixation.[105] A button may be used to decrease wire cut-through of the spinous process. Although this technique is rarely used alone anymore, it may be useful in hybrid constructs, particularly when limitations of bony anatomy or breakout of prior instrumentation renders the pedicles and other posterior elements unusable.

The next evolutionary step after wiring in thoracolumbar instrumentation came with simple, hook-based distraction devices intended to assist in the correction of scoliosis. After Harrington's initial ground-breaking design, several other modified designs were developed. Harrington rods were used in thoracic curves and for thoracolumbar burst fractures.[106] In trauma cases, the Harrington system provided quick and easy stabilization compared with the earlier devices. This construct could be combined with a rod sleeve to provide a three-point fixation and was particularly advantageous in polytrauma patients. Because Harrington rods produced distraction, they often led to flat back deformities that resulted in persistent pain and fatigue. When the importance of sagittal plane balance was understood, and as newer, more powerful systems became available, Harrington rods fell out of use.

Early hook-based segmental thoracolumbar spine constructs allowed lordosis to be contoured into the rod and held with segmental bone anchorage. These constructs were significantly more rigid than their predecessors. This increased rigidity improved fusion rates and sometimes obviated the need for postoperative bracing or cast immobilization. This was particularly advantageous for children and adolescents undergoing surgical correction of idiopathic scoliosis.

Disadvantages of this construct, as with rigid implants elsewhere, included the effect of fusion on adjacent segments. In contrast to pedicle screw constructs, which use the concept of three-column spine fixation, hooks anchor to the posterior elements alone and do not have the same power to reduce scoliosis.[107] Although misplaced pedicle screws can produce catastrophic neurologic or vascular injury, hooks by their very nature are canal intrusive. Volumetric studies suggest that mildly misplaced screws produce less canal encroachment than hooks.[108]

In a comparison of pullout strength, thoracic pedicle screws were found to be significantly stronger than hooks and were recommended for rigid curves.[109] Another study, in children with idiopathic scoliosis, found no differences in operative time or curve correction achieved with hook or screw constructs.[110]

Various hooks with different characteristics are available. Each of these is suited to a particular mode of placement and loading. Pedicle hooks, resting on the lamina of the instrumented vertebra and the superior articular process of the next distal vertebra, are the strongest. They are always directed cephalad so that their U-shaped tip captures the pedicle and provides maximal stability for rotation and translation maneuvers. Because of their configuration and their dependence on facet joint anatomy, these implants can be placed from T1 to T10 or T11.[111] There are subtle variations in hook shape, including short-throated and long-throated configurations and straight or offset collars. Contemporary anatomic hook designs give better bony contact.

Laminar hooks are available in various designs. Variation in blade width and style and the relationship of the blade to the body of the hook allow for optimal hook-bone interface. Between T3–T10 or T11, lamina hooks may also be placed on

the superior surface of the transverse process. Here the transverse process hook is combined with a pedicle hook to yield a pedicle-transverse grip or "claw." Although such claws may be constructed over one or two levels, two-level claws are easier to insert and mechanically stronger.[112] Claws are used mainly at the ends of a construct. Above T3, the transverse process becomes more horizontal, and transverse process hooks do not align with the pedicle hook. The claws must be pedicle–supralaminar hook combinations.

A supralaminar hook enters the spinal canal in a cranial to caudal direction and, while providing the second strongest anchorage, risks iatrogenic cord injury if the hook pistons in and out of the canal during rod manipulation. Thus, careful selection of the hook shape is mandatory. Moreover, one should consider avoiding periapical placement or utilization of supralaminar hooks in the correction of hyperkyphosis. Finally, infralaminar hooks are placed in a cephalad direction. These anchors are rarely necessary in the thoracic spine because pedicle hooks provide proximally directed forces. Usually, these implants are used inferiorly, along with pedicle screws in hybrid constructs. Occasionally, they are added to transpedicular constructs to protect the screws from pullout.[113]

In younger patients with painful pars defects and minimal segmental degeneration, a screw-hook combination can be used for direct osteosynthesis of the spondylolysis.[114]

While wired, semirigid constructs are no longer frequently used as a stand-alone in lumbar spine surgery, these tools are occasionally used in osteoporotic patients or in deformity or trauma surgery to improve reduction or provide temporary or adjunctive fixation before transpedicular implants are used.[115]

For some indications, sublaminar wires have given way to polyester bands. The possible advantages of these bands include their radiolucency and the wider surface area through which to grip osteoporotic bone (which may mean less cut-through compared with sublaminar wires).[116] Sublaminar and transverse process polyester band fixation has been reported to successfully aid the reduction of scoliosis.[117]

A recent report of 115 neuromuscular scoliosis cases included 29 patients treated with a hybrid pedicle screw, polyester clamp and band technique.[118] At a mean of 29 months' follow-up, a 69% correction had been achieved and sagittal balance was corrected to within 2 cm of the C7 plumb line in 97% of the patients. The authors believed these results compared favorably to sublaminar wire and all pedicle screw cases. In particular, they wrote "Sublaminar bands utilized in a hybrid construct appear to be safe, can achieve corrections equivalent to all-pedicle screw constructs, and may decrease the potential complications associated with every level transpedicular fixation in the patient with a highly dysmorphic and osteoporotic spine."

Unfortunately, sublaminar implant passage may still subject the patient to iatrogenic neurologic injury. In one recent series of 21 patients with neuromuscular scoliosis, two neurologic injuries occurred.[116] Although successful radiographic outcomes were achieved, the authors suggested tempered enthusiasm for this technique.

Although these bands are typically placed in a sublaminar trajectory, subtransverse bands have also been reported.[119] Superelastic cables have recently been tested under the theory that they would provide constant stabilization during various loading modes.[120]

Pedicle Screws

Pedicle screws continue to offer the only three-column fixation available in the thoracolumbar spine. Because they are inserted from the posterior elements into the vertebral body, they allow the surgeon to apply distraction, compression, lordosis, rotation, or translatory forces selectively.[121]

Pedicle screw systems have been studied in Europe since the early 1980s. Modern attempts at pedicle fixation were popularized in North America by Steffee. Their use temporarily declined after a series of television exposés and high-profile lawsuits. Subsequently, many of the available systems received FDA class II status. This approval stopped many of the lawsuits and led to a rapid escalation in the number of systems available and the extent of their use.[122] Advantages of transpedicular fixation spine include:

- Rigid segmental fixation
- Improved fusion rates
- Reduction of deformity and maintenance of correction
- Earlier rehabilitation
- Minimized use of postoperative bracing

Disadvantages and complications of pedicular screw fixation include:

- Increased operative time and risk of infection
- Increased cost
- Risk of pedicle fracture
- Increased complication rates, particularly with regard to implant soft tissue impingement and screw malposition
- Dural tear
- Nerve toot or spinal cord injury
- Anterior vascular injury
- Stress shielding and device-related osteopenia
- Risk of adjacent-level degeneration

Adjacent-segment degeneration issues continue to plague lumbar fusion patients. Park and colleagues found that pedicle screw placement, more than the actual number of levels fused, was the strongest predictor of adjacent-segment degeneration.[123] This review reported a 12.2% to 18.5% incidence of symptomatic adjacent-segment degeneration during the follow-up period compared with a 5.2% to 5.6% rate in patients fused with other forms of instrumentation or no instrumentation. Damage to the adjacent unfused facet by the screw was thought to be a potentially significant factor producing adjacent-level degeneration. Unintended adjacent-level fusion may also be encountered more frequently in patients undergoing transpedicular instrumentation. One prospective, randomized trial of 130 patients undergoing either instrumented or uninstrumented fusion found that inadvertent fusion had occurred in 19 cases (14%). There was a higher risk of unintended fusion with pedicle screw instrumentation, although functional outcomes were not affected.[124]

The role of stress shielding in patient outcomes is controversial. The concept was introduced by McAfee and colleagues in 1991.[125] Subsequent studies have failed to show osteoporotic

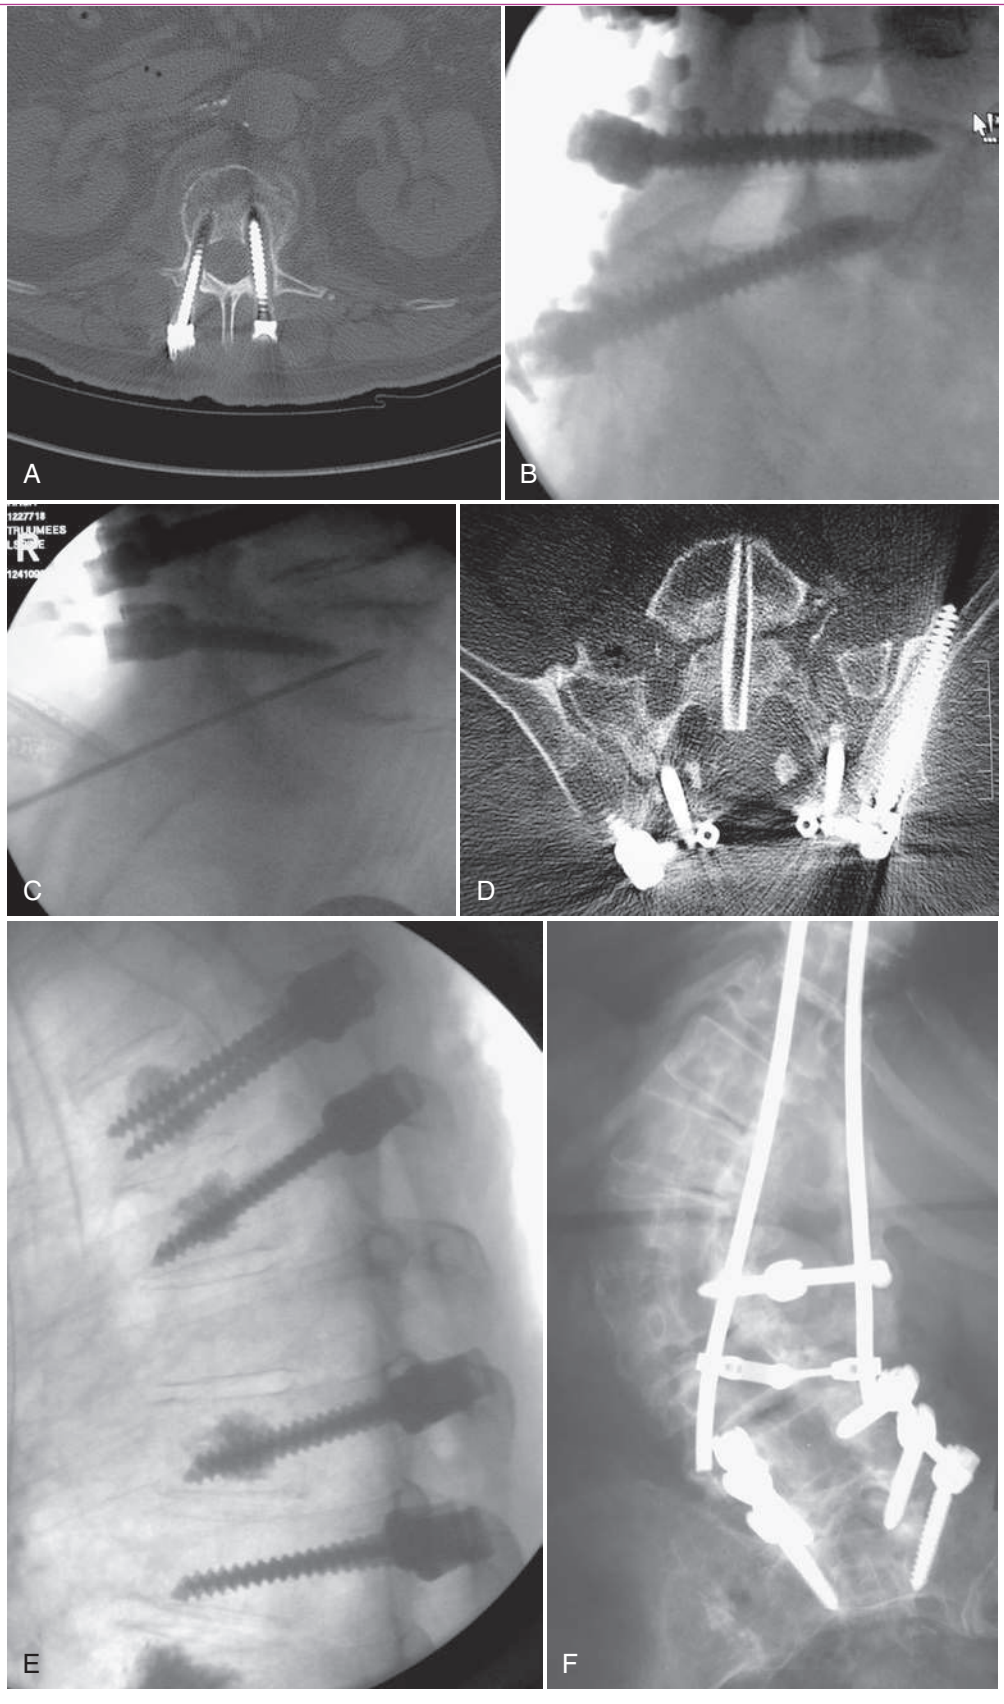
collapse within a fusion construct. Transpedicular screw fixation does not affect the postoperative reduction of fusion mass.[126] The indications for and contraindications to pedicle screw placement remain controversial. Pedicle screw constructs are widely indicated in cases with clearly defined instability, particularly in the setting of trauma and tumor. In particular, they provide stability where prior laminectomy has been performed.

Pedicle screw systems may also be divided by the type of longitudinal member or the connection between the anchor and the longitudinal member. Plating systems are one such system and are generally less expensive than modular, polyaxial screw-and-rod systems. Typically, plate-screw systems require that the screws function as bolts that are rigidly affixed to the plates with nuts and washers. Contemporary polyaxial systems have a U-shaped saddle in the head of the screw into which the rod can be secured. Polyaxial systems fare better under static and cyclic compressive loads. Because higher rod manipulation forces are possible, these connections serve to increase stresses at the end levels of the construct. Although theoretically their increased freedom of motion should make polyaxial screw constructs less stiff, this has not been borne out in cadaveric testing.[127] Rods are discussed in greater detail below.

Clinical failure of transpedicular constructs occurs in one of two ways: through loosening with fixation failure or through failure to fuse. Loosening occurs as repetitive loading persists beyond the tolerance of bone. This is usually the result of delayed union or motion at a screw-bone interface, often from excessive activity. The screw is exposed to a combination of cantilever bending and axial pullout loads (Fig. 70.5).

Subacute or acute bending failure and implant breakage result from cantilever bending loads in excess of the yield point of the screws. Even severely degenerated and collapsed discs undergo cyclic axial displacement during axial loading. These cyclic displacements may lead to significant cantilever loads and bending moments. These are most pronounced around the screw hub, inside the pedicle.

This effect is multiplied when the screw-rod construct operates in a bridging mode and bears most or all of the anterior column axial loads, as with burst fractures. If a deformity reduction maneuver is performed during surgery, this subjects the screws to increased load. Typically, the end vertebrae are affected. Various techniques for correction, such as derotation maneuvers, have been described. A strategy that emphasizes correction in the middle segments of the construct with decreased corrective force at the terminal levels is associated with good reduction, while limiting axial tensile forces at the cranial end screw.[128,129] After bony healing, fatigue failure of the implants may still theoretically occur but should no longer be of clinical concern.



A number of studies sought to retrospectively quantify pedicle screw–related complications. Significant variability was seen among studies, with overall complications of varying severity reported up to 54%. Rates of deep infections, screw misplacement, and screw breakage ranged from 5% to 10% but appeared to be decreasing in more recent studies.[130-133]

Spondylolisthesis may be stabilized with or without an attempt at slip reduction. Reduction maneuvers include rod contouring with an additional cranial fixation point with screws with an extended head into which the rod can be forcibly delivered, translating the slipped segment posteriorly.[134,135] Some screw-rod systems have been designed solely for slip reduction. With reduction of an L5–S1 spondylolisthesis, there is increased risk of a postoperative L5 root palsy.[136] Although slip reduction has not been shown to improve outcomes, more recent series also report very low rates of L5 root injury.[137,138] Pedicle screw constructs are also routinely used to increase the likelihood of fusion in the surgical management of junctional stenosis, degenerative spondylolisthesis or scoliosis, isthmic spondylolisthesis, prior pseudarthrosis, and more than a three-level fusion (Fig. 70.6).

Typically, pedicle screw fixation is avoided in the presence of overt infection, but it may be considered in cases of significant instability. Relative contraindications to pedicle screw fixation include very small pedicles, marked osteoporosis, and inadequate anterior column support.

The question of when to add pedicle screw fixation remains unanswered. Although pedicle screw instrumentation enhances the rate of spinal fusion in degenerative

FIG. 70.5 When posterior thoracolumbar instrumentation fails, it is usually at the screw-bone interface. (A) If fusion fails to occur, the screws may loosen, as demonstrated by the lucency around the pedicle screws. Various techniques have been reported to improve screw pullout strength of the construct. (B) One technique uses screw insertion into the endplate of the level above for additional purchase. (C–D) This elderly, osteoporotic patient had had a previous long fusion to L5. Subsequently he developed an isthmic spondylolisthesis at L5–S1 with a progressive slip. He returned to the operating room for extension of fusion to the pelvis. The Bohlman technique of posterior fibular strut placement from S1 to L5 was undertaken using a reamer over the guide wire shown in the (C) lateral fluoroscopic image. (D) Postoperative axial computed tomographic image shows the fibular strut in good position. Short iliac screws were also placed. (E) In patients with poor bone quality, polymethylmethacrylate may be used in the vertebral body to improve screw pullout strength. Another concern is the appropriate number of fixation points; the more unstable the spine or the poorer the quality of the patient's bone, the more fixation points are required for a successful construct. (F) Failure of a long scoliosis construct presumably because too much force was concentrated at the base, where all the inferior anchors were crowded together.

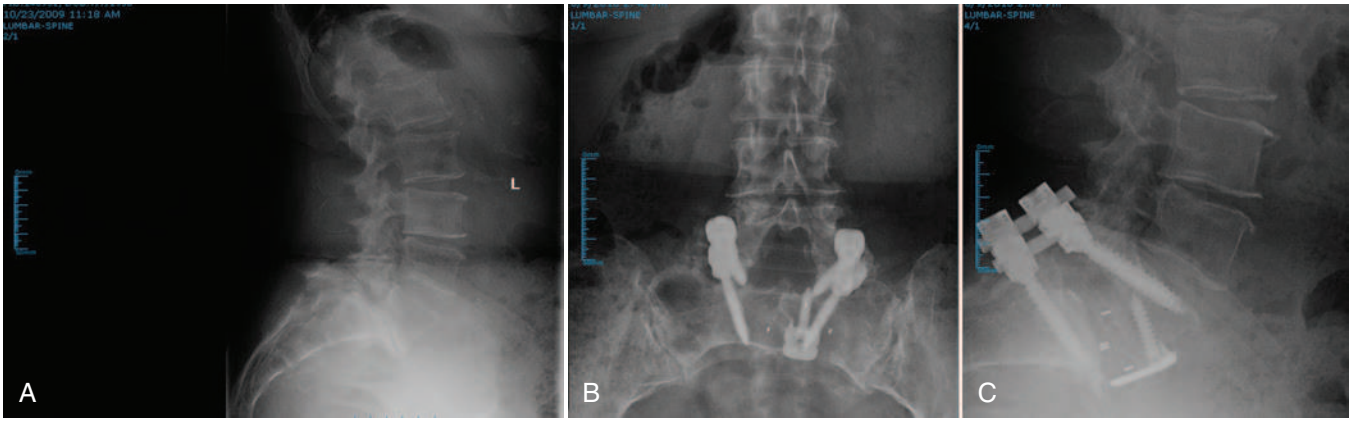

FIG. 70.6 A 65-year-old woman with L5–S1 isthmic spondylolisthesis who underwent anterior L5–S1 anterior lumbar interbody fusion with instrumentation followed by posterior instrumentation and fusion. (A) Lateral preoperative standing radiograph. Postoperative (B) anteroposterior and (C) lateral standing radiographs.

conditions of the lumbar spine, such fusion does not always correlate with clinical outcomes. Conversely, patients may report excellent symptomatic improvement even in the setting of radiographic pseudarthrosis.[139]

One prospective, randomized, controlled trial of 130 patients evaluated supplementary pedicle screw fixation in posterolateral lumbar spinal fusion and found that fusion rates were not significantly different between instrumented and uninstrumented groups. Although functional outcome, as assessed by the Dallas Pain Questionnaire, improved significantly in uninstrumented and instrumented groups, there were no significant differences in outcome between the two groups. A trend toward higher patient satisfaction was noted in the instrumented group (82%) versus the uninstrumented group (74%). The addition of pedicle screws significantly increased operative time, blood loss, and early reoperation rate. The two infections in that series occurred in the implant group, and significant symptoms from screw misplacement were seen in 4.8% of the instrumented patients. The authors concluded that these results did not justify the general use of pedicle screw fixation as a routine adjunct to posterolateral lumbar fusion.[140]

A similar prospective, randomized, controlled trial with 5-year follow-up was performed in 129 patients with severe chronic low back pain from either degenerative instability or isthmic spondylolisthesis. In that series, the reoperation rate was significantly higher in the instrumented group (25%) than the uninstrumented group (14%). There was no difference in work capacity between the two groups and no significant difference between the instrumented and uninstrumented groups in regard to functional outcome, as measured by the Dallas Pain Questionnaire and Low Back Pain Rating Scale. When the subgroups of isthmic and degenerative spondylolisthesis were analyzed separately, patients with isthmic spondylolisthesis had a significantly better outcome after posterolateral fusion without supplemental instrumentation compared with instrumented fusion ($P < .03$). Patients with primary degenerative spondylolisthesis had more significant improvement with instrumented posterolateral fusion ($P < .02$).[141]

In a recent American Association of Neurological Surgeons guideline, use of pedicle screws as an adjunct to lumbar fusion in degenerative disease was recommended to be "reserved for those patients in whom there is an increased risk of nonunion when treated with only PLF."[142]

Once a decision has been made to use transpedicular screw fixation, the numbers of levels of fixation should also be considered. Historically, internal spine fixators were applied to the cranial and caudal fusion levels. This approach was associated, in the lumbar spine, with flat back deformity. These systems are also less rigid than segmental fixation, in which one or more bone anchors are placed in every or most intervening levels of long fusions as well.

Classically, additional segmental fixation may benefit patients undergoing deformity correction or trauma stabilization. In a recent finite element analysis of an adolescent idiopathic scoliosis model (with data taken from 20 real patients), fixation was simulated over a mean 8.9 segments with a mean 45-degree Cobb angle correction.[27] Using a simultaneous double-rod rotation technique, a 160-N pullout force was measured at the apical concave screw. Forces on the convex side were lower at about 35 N. Push forces on the lower and upper instrumented vertebrae were 305.1 N on the concave side and 86.4 N on the convex side. The authors concluded that these forces were within safe margins for a segmental construct; however, to protect from implant failure or pedicle fracture, appropriate soft tissue release and facetectomy were required.

Another recent study compared consecutive-level screw fixation with interval fixation and found better corrections in all three planes and better cosmetic results with higher density screw placement.[143] In another study, planned screw dropout at the periapical convexity did not decrease curve correction.[144] One study found that full screw placement did not afford better correction of the rib hump than interval or hybrid constructs.[145]

In posterior-only treatment of Scheuermann kyphosis, the correction and outcomes of a mean of 25 screws placed in 10 patients were compared with 16.8 screws placed in 11 patients.[146] Similar corrections were achieved, but complications and costs were higher in the high screw density group (19% vs. 9% and 32%, respectively) In one recent study, levels fused had a greater impact on outcomes than pedicle screw

density, which was most closely correlated, as expected, with costs.[147]

Posttraumatic spinal instability raises similar questions about the number of levels to incorporate in a surgical construct. One recent biomechanical study found that, with the exception of lateral bending, short-segment fixation with fracture-level screws was equivalent to two-level above and below constructs.[148]

A retrospective review of 32 patients with comminuted burst fractures reported excellent clinical and radiographic outcomes with short-segment fixation incorporating the injured vertebra.[149] In a 70-patient comparative study of short-segment instrumentation for burst fracture with and without fracture-level screw placement, additional screws were associated with better kyphosis and anterior vertebral height correction.[150] The clinical significance of these radiographic findings was not clear. The utility of this six-screw construct has been confirmed in other recent reports.[151]

The ability of posterior implants to function in a bridging mode to stabilize patients with major defects in anterior column stability (such as a burst fracture or tumor) is diminished in osteoporosis. In this setting, formal anterior column support through PMMA augmentation or corpectomy and cage reconstruction may be preferred, even in medically frail patients. One recent study recommended anterior column support through a formal corpectomy approach followed by posterior transpedicular instrumentation over screws and kyphoplasty for anterior column support.[152]

Here, too, it is important to recognize the planes of instability. Although PMMA augmentation may improve axial stiffness, it will do little to compensate for posterior tension band disruption. In a recent biomechanical study, kyphoplasty alone was not effective in stabilizing high-energy burst fractures.[153]

Just as modifications to increase implant hold are needed in patients with poor bone quality, increased rigidity will be needed in patients with additional stress on the construct, such as those of a greater size or with movement disorders.[154]

Certainly, less-robust constructs are required in patients with degenerative spinal conditions. Here, for one-level fusions for degenerative indications, the potential benefits of unilateral instrumentation include decreased surgical time, blood loss, muscle trauma, and cost. In two recent meta-analyses, these conclusions were supported, as were equivalent clinical and radiographic outcomes.[155,156] Other recent studies have supported this conclusion.[157] On the other hand, in one study of 80 patients undergoing single-level lumbar TLIF for degenerative disease, the pseudarthrosis rate was significantly higher in the unilateral fixation group (17.5%) compared with the bilateral fixation group (2.5%).[158] The authors concluded that bilateral fixation was likely biomechanically superior. A 2014 meta-analysis incorporated five prospective studies with 407 patients to compare the outcomes of unilateral and bilateral pedicle screw placement in lumbar degenerative disease.[159] The authors concluded that there were no differences in fusion rates or outcomes, but that operative time and blood loss were lower in the unilateral group.

In a biomechanical study, a translaminar facet screw contralateral to unilateral pedicle screw placement was found to improve stability to the level of bilateral screw-rod placement.[160] A similar group of authors did not find any clinical benefits of adding a contralateral transfacet screw in a comparative study of 58 patients.[161]

Cortical Screws

Laterally directed, cortical screws have been increasingly used in the lumbar spine (Fig. 70.7). Potential advantages of these screws are a near-midline placement, thereby decreasing the muscle dissection required. One biomechanical study argued that a cortical screw trajectory would be more effective in osteoporotic patients, although mixed results with pullout and toggle tests were noted.[162] In one recent biomechanical study, the stabilizing impact of cortical screws as rescue screws after pedicle screw placement was tested in 10 cadaveric spines.[163] L3 pedicle screws were pulled out. Cortical screws were then placed and exhibited 60% of the original pedicle screw pullout strength. The construct's stability in flexion-extension, lateral bending, and axial rotation was similar to the original pedicle screw.

Two small studies reported failure of cortical screws that required revision for pseudarthrosis, pars fracture, and caudal adjacent-segment failure. The authors recommended caution when using this technique clinically, despite the favorable biomechanical studies.[164,165] Other retrospective studies have offered more favorable outcomes.[166]

Pelvic Fixation

Overall, the use of pelvic fixation has increased as authors have recommended greater efforts at correcting or maintaining sagittal balance. In many cases, though, the exact indications for this extension are not always clear. For example, one 2014 study compared the outcomes and complications associated with primary long fusion to the pelvis with revision procedures, including extension to the pelvis.[167] Although the revision procedures offered the "same expectation of radiographic and clinical success," the complication rate was similar to that of the primary procedure, including pelvic fixation. It is not clear how many of those procedures could avoid pelvic fixation.

As with the thoracolumbar spine, the variety of bone anchors used in the pelvis has gradually given way to increased use of screws. For example, the use of intrasacral fixation, such as Jackson intrasacral rods, has continued to decline due to problems with loosening and the improved holding power of segmental fixation to the pelvis.[168]

In addition, when comparing iliac screws to unit rods or the Luque-Galveston technique, screw-based rigid fixation, while costing more at $15,488 versus $3128 for the nonrigid group, offered significantly greater curve and pelvic obliquity correction while decreasing pseudarthrosis and the need for anterior release.[169] A maximal-width sacropelvic fixation technique allows greater correction of pelvic obliquity in neuromuscular scoliosis.[170,171]

A variety of iliac screw placement techniques have been described, but iliac screws placed either under or through the

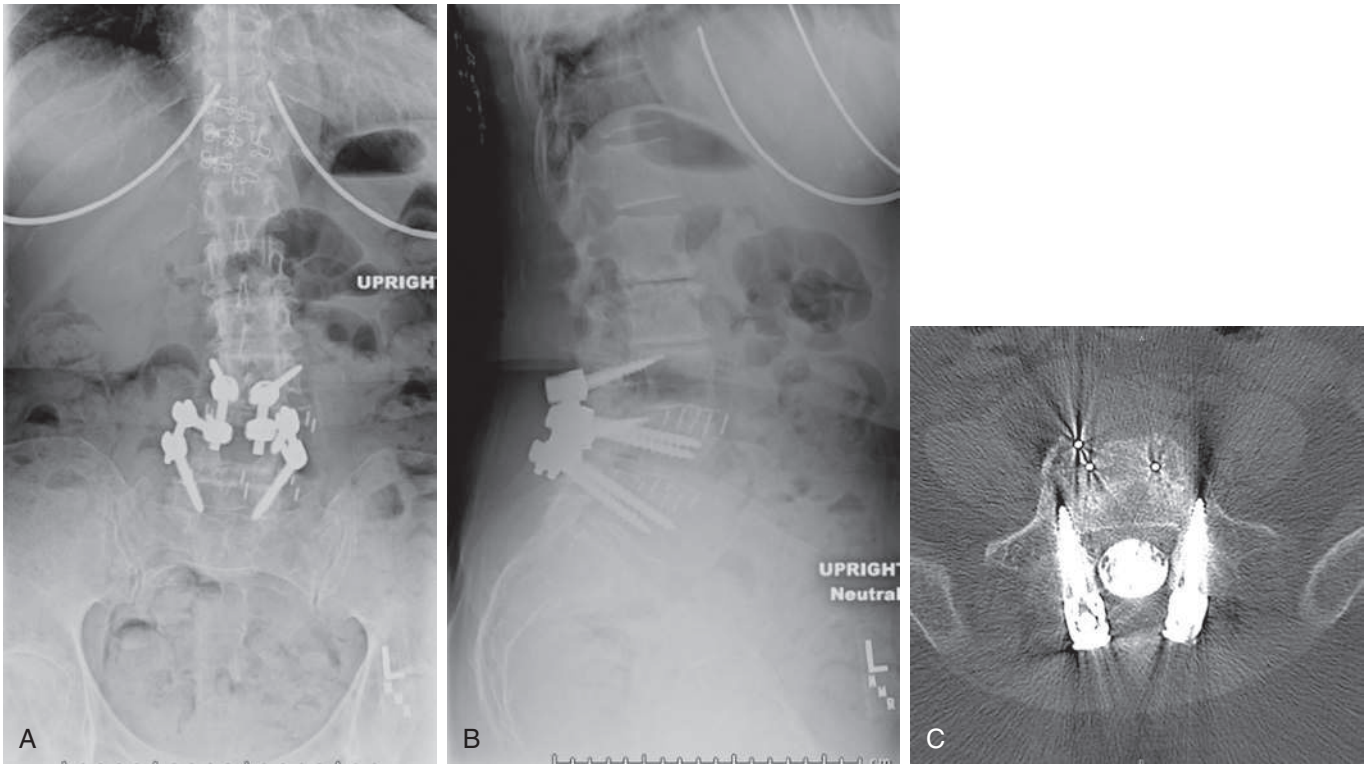

FIG. 70.7 (A) Anteroposterior and (B) lateral views of an initial transpedicular stabilization at L4–L5 was revised and extended to L3–L4 using cortical screws at the more cranial levels. Note the lateral positioning of the interbody cages. (C) Axial computed tomographic view at the L4 pedicle level. These cortical screws were found to be loose and re-re-revision with transpedicular grafting was performed.

posterior sacroiliac spine with transverse connectors to the midline rods and S2 alar iliac fixation are the most common.[172] S2 alar fixation has a number of potential advantages in terms of decreased soft tissue dissection and in-line placement. However, in one recent study, a higher rate of failure was associated with this technique compared with more typical iliac fixation with lateral connectors (25% vs. 12%).[173] The same authors noted a higher rate of failure in patients in whom sagittal balance had not been restored and in patients in whom S2 iliac screws were placed (over more traditional iliac bolts with lateral connectors).[173] In contrast, another study of 60 patients, 23 of whom had received S2 alar-iliac screws, found a lower rate of wound-related complications and instrumentation failures compared with more typical iliac bolts.[174]

Here, too, the number of anchors should match the patient's individual characteristics. In neuromuscular scoliosis, for example, a 30% rate of pelvic screw failure was noted when bilateral L5 and S1 screws were not placed.[175] In other settings, S2 alar or buttress screws may be used in lieu of iliac fixation to neutralize long thoracolumbar fixation to the sacrum.[168] Placement of sacral screws and use of sacroiliac screws reduce the stress on iliac screw fixation.[176]

Access and Guidance

As mentioned in other sections, the degree of soft tissue dissection required to place these implants has been decreasing over time. However, screw placement continues to be challenged by malpositioning, which could result in neurologic injury. A variety of imaging and guidance systems have been developed to decrease this risk.

For example, although intraoperative fluoroscopy remains a standard technique to assess implant trajectories, pelvic fixation may benefit from fluoroscopic views not typically exploited by spine surgeons, such as the pelvic inlet view. One recent series of 14 neuromuscular scoliosis patients had safe placement of iliac screw fixation by identification of the posterior sacroiliac spine and the inlet view.[177] Another study found that anteroposterior images were effective in patients with rotational deformities.[178]

For the last 10 years, cone-beam imaging systems (O-Arm [Medtronic] and Orbic [Siemens]), and now true intraoperative CT scanners, have been available to assess implant placement prior to leaving the operating room or to mate with navigation systems to guide that placement. In one recent study, intraoperative true CT–based navigation guidance with a portable 32-slice scanner was reported in 85 cases.[179] The authors found that the imaging quality allowed a 99.13% accuracy rate in placement of 571 screws regardless of the patient's body habitus or positioning at the time of surgery. Another study reviewed 1148 screws placed in 203 patients utilizing intraoperative CT.[180] Intraoperative CT increased the rate of immediate screw revision but did not affect the rates of reoperation for misplaced screws. The authors concluded that intraoperative CT lowered the threshold for intraoperative screw revision.

Robotic guidance has also become available for thoracolumbar implant placement, although data remain sparse at

this point.[181,182] Custom-printed screw guides and the built-in gyroscopes in modern smart phones can be used to assist screw placement.[183]

Use of percutaneous transpedicular constructs has been increasing. These systems may be used to stabilize an ALIF or lateral lumbar interbody fusion (LLIF) or provide contralateral-side stabilization after a minimally invasive TLIF. Occasionally, a limited facet fusion is included with this less-invasive approach.[184]

Some systems use a rod-insertion device that links to the screw extension sleeves and allows a precut contoured rod to be placed through the screw saddles via a small stab wound and a muscle-splitting technique. A remote engagement of the screw-locking mechanism is then used. Long-term outcomes for these techniques are sparse, but short-term success has been reported in small numbers of patients. Proponents of this technique believe that paraspinous tissue trauma is minimized without compromising the quality of spinal fixation. Techniques reporting safe placement without guidewires have recently been reported.[185]

Because MIS screw placement requires less local soft tissue disruption, the idea that MIS placement of cranial screws in adult deformity surgery would decrease proximal junctional kyphosis was proposed, but it was not supported in a propensity-matched cohort analysis of 136 patients.[186]

Intraoperative monitoring can also be used to assess the safe placement of thoracolumbar implants. One recent study used a unique four-pulse stimulus train within the pedicle screw tract with a ball-tipped probe. Lower extremity electromyography correctly detected 100% of 32 medially breached thoracic screws out of 802 total screws placed.[187,188]

Rods and Cross-Links

In patients with complex deformity, correct rod bending may be quite difficult. The rod should not be contoured in more than one plane at a time. In children and patients with flexible deformities, the rod can be contoured to fit the screws and rotated into proper sagittal balance. Alternatively, a series of force vectors and direct rotational maneuvers may be undertaken. In patients with rigid curves and most adults, accurate rod contouring to fit into the screws can be difficult. It is often helpful to use lateral connectors between the rod and screw instead. Some surgeons, in an effort to maximize correction power, use separate rods in the upper and lower portions of a stiff, dual-curve deformity and connect them with a domino on one side and use a neutralization rod on the opposite side.[189]

When bending rods for hook-based constructs, slight deviation from perfect contour puts a moment on the hook. In the thoracic spine, a kyphotic moment pulls the hook away from the cord. In general, the aim is for a 30-degree thoracic kyphosis with its apex at T7 or T8. The lumbar lordosis should be 45 degrees with an apex at the L2–L3 interspace. The rod should change from kyphosis to lordosis at the T12–L1 interspace. After placement of the hooks, the convex rod is placed first. The more mobile the hooks, the more easily the rod engages. Hook mobility is a function of the amount of bone resection during hook placement. The ease of rod insertion improves with spine mobility, which is a function of facet resection.

Dynamic Rods

Numerous coils, springs, jointed rods, and semielastic cords have been devised to replace rigid rods as pedicle screw connectors. Some of these devices are intended to be used as less-rigid fusion devices. Others are meant to "top off" the most cranial level of a long fusion construct, theoretically to decrease the risk of adjacent-segment degeneration because less-rigid fixation is believed to be associated with reduced adjacent-segment motion compared with rigid fixation.[138] Biomechanical studies continue to assess various dynamic systems. Most show decreased stress on the adjacent segments.[190] In a recent clinical study of 36 patients undergoing the Isobar semirigid dynamic posterior stabilization system, disc degeneration continued despite the dynamic stabilization at 24-month follow-up.[191]

Still other dynamic systems were used without attempt at fusion as motion-preserving spinal stabilization. In this setting, dynamic rod devices were intended to treat mechanical back pain associated with lumbar degenerative disease. These systems varied architecturally and materially. Ideally, each design was logically constructed to "fix" a clearly delineated problem in the painful or degenerated spine. Each system apparently relies on a different theory of pain generation and uses different mechanical means to address the pain. In some cases, a clear hypothesis as to the source of the pain is not evident.

For example, one of the first dynamic posterior instrumentation systems was the Graf ligament, an inelastic cord wrapped around two pedicle screws. The goal was to lock the motion segment into full lordosis, restricting flexion and preventing rotation.[192] There was no experimental basis for this design concept, but clinical results were acceptable. Limitations of the Graf ligament included the increase in posterior anulus load it engendered. This increase led to late failure with back pain or earlier failure resulting from the marked lateral recess and foraminal stenosis the system caused.[193]

The Dynesys implants (Zimmer Biomet) received FDA approval as stabilization devices adjunctive to fusion. As a result, this was the only system available in the United States, but they were typically used in an off-label manner as a fusionless, dynamic construct. As with the Graf system, the Dynesys system connects pedicle screws with a nonelastic ligament. In this case, a plastic cylinder surrounds the ligament and prevents hyperlordosis. At surgery, the ligament is threaded through the cylinder and pulled with a set 300-N force. This force approximates the two screw heads with the interposed cylinder. Active extension opens the anulus anteriorly without compressing it posteriorly. The Dynesys system limits full flexion and extension. The developers of the system claim it decreases pain by eliminating "parasitic" or "abnormal" movement. In addition to restricting the range of movement, it may also unload the disc, however, if the patient achieves a position of lordosis, so that the plastic cylinder becomes weight bearing.[194,195] Limitations of the Dynesys system include the

unpredictable degree to which it unloads the disc and the need for strong extensor musculature to maintain lordosis. Lordosis and load sharing by the plastic cylinder vary markedly with implant placement.[196]

There are common contraindications to use of these nonrigid devices, including significant preoperative instability, osteoporosis, and anterior column insufficiency.

Concerns about the possibility of long-term screw loosening led to modifications with HA-coated or plasma-sprayed screws. Some systems required the screws to be cemented into the pedicle. That said, one recent study compared pedicle screw–based dynamic stabilization systems with more tradition screw-rod fusion constructs in elderly patients with degenerative scoliosis.[197] Although the fusion patient achieved better deformity corrections, operative time, blood loss, and complication rates were lower in the dynamic stabilization group. At a mean follow-up of 64 months, clinical outcomes were similar. Still, among deformity specialists, the current, countervailing trend incorporates larger surgical constructs to effect greater correction of sagittal plane alignment, even in patients undergoing surgery for degenerative disease.[198]

All dynamic systems require perfect screw placement because a pedicle breach risks screw loosening and ultimate dislodgment. A highly medialized trajectory is sought to avoid facet violation and subsequent painful facet degeneration.

Unfortunately, the promise of these systems has not been realized. Screw loosening and other implant failures were common, and use of these systems has markedly declined in North America. In recent reviews, although the idea remains promising, no clear benefits of dynamic systems were uncovered.[199,200] Dynamic systems were associated with a higher rate of loss of lordotic correction.

Variable Stiffness Rods

Several generations of low- or variable-stiffness implants have been developed to improve load sharing with the spine and, perhaps, to decrease stress on the adjacent segments.[201] With partial annealing, a rod's flexural stiffness can be varied.[202] Recently, rods with decreased end stiffness have been assessed biomechanically. In this setting, decreased stress on the anchors and greater load sharing of the instrumentation with the spine were noted.[203] The real mechanical utility of these systems has yet to be conclusively demonstrated.[204]

Larger, stiffer 6.35-mm rods are often recommended for better maintenance of correction in long deformity and trauma surgeries. In one series of 93 patients undergoing surgery for adolescent idiopathic scoliosis, rod size did not affect radiographic outcomes at a minimum of 2 years.[205] Of note, these patients were Taiwanese children; different results could be reported in larger adult patients.

In other cases, a more rigid longitudinal connector is required. For example, in long adult deformity surgery, particularly in the case of pedicle subtraction osteotomy, rod fractures are common. Use of two additional, "outrigger" rods to span the high-risk area (the pedicle subtraction osteotomy level or the thoracolumbar junction) significantly decreased implant failure and symptomatic pseudarthrosis rates.[206,207] In very unstable cases, such as en bloc tumor resections, orthogonal anterior and posterior implants may more effectively restore spinal stability.[208]

Growing Rods

A vertical expandable prosthetic titanium rib (VEPTR; DePuy Synthes) provides an internal, nonrigid brace for spinal or thoracic cage deformity to allow further thoracic cage growth.[209] A recent report described 10 children with arthrogryposis who underwent VEPTR placement at 5 years of age.[210] At a mean 4.2-year follow-up, the scoliosis decreased from 67 to 43 degrees and kyphosis decreased from 65 to 48 degrees. During the treatment period, spinal growth from T1 to S1 increased 4.2 cm. Six complications were reported in four patients: three infections, two rib failures, and one implant failure. Proximal junctional kyphosis greater than 45 degrees was reported in six patients.

More traditionally, "growing rods" have been used to provide temporary, internal bracing of rapidly progressive curves in young children and to allow additional axial growth before a formal fusion is performed. In an effort to prevent long-term pulmonary restriction, these modalities seek to allow maximal chest cavity development.

The first of these techniques, the Shilla growth guidance technique, avoided repeat surgery by performing a short-segment, periapical fusion with sliding pedicle screws cephalad and caudad. In a report of 40 patients with a mean age just below 7 years and 7-year follow-up, a mean 69- to 38.4-degree correction was reported.[211] Although a high 73% complication rate was reported (with 24 of 40 having instrumentation-related complications), it was believed to be acceptable compared with predicate procedures.

A recent porcine study attempted to refute the idea that growing rods were kyphogenic by demonstrating distribution of the distracting force across multiple levels of the spine.[212] Other works have examined use of side-to-side connectors used as gliding connections.[213] As might be expected, dual rods and additional apical and intermediate anchors are likely to improve correction.[214,215]

Two small, early series of magnetically controlled growing rods found that implant-related complications were not uncommon, including rod fracture and apical hook pullout, but "the avoidance of multiple surgeries following implantation is beneficial compared with traditional growing rod systems."[216,217]

Cross-Links

The relative merits of cross-link placement in longer, posterior thoracolumbar constructs continue to be debated. Traditionally, these implants were used to improve torsional stability of anterior and posterior dual-rod constructs.[218,219] Depending on the number of motion segments instrumented, the degree of instability of the spine, and the strength of the bone-implant interface, placement of one to three cross-links has been recommended. Classically, if two cross-links are used, one should be as proximal as possible and the other as distal as possible. If the instrumentation exceeds 30 cm in length, a third

transverse connector should be considered in the middle. The addition of a cross-link may mechanically compensate for a missing pedicle screw in a polysegmental construct.

Various cadaveric biomechanical studies of transpedicular fixation across the thoracolumbar junction found that rotational stiffness increased significantly with the number of cross-links placed; some found improved bending stiffness as well.[220] Another study compared constructs using no, one, or two cross-links. This study found that two cross-links were no more effective than one in significantly increasing axial, flexion, and lateral stiffness, although additional cross-links significantly improved the torsional stiffness of the construct.[219] When comparing different types of cross-links, larger cross-sectional area and diagonal geometries are associated with greater increases in stiffness.[221,222]

Three recent studies concluded that cross-link placement improved construct torsional rigidity and holding power.[223,224] Earlier concerns over cross-link connector bulk affecting the area available for bone grafting and "excessive" stiffness inhibiting fusion through stress shielding have not been borne out. That said, the real utility of cross-links continues to be debated in various clinical contexts. While initially recommended in long deformity and trauma surgery, some surgeons use cross-links in tumor and degenerative cases with spinal rotational stiffness or when a screw site has been compromised.

Anterior Thoracolumbar Instrumentation

Modern forms of anterior thoracolumbar instrumentation were initially developed for deformity surgery separately by Zielke and Dwyer in the late 1960s to mid-1970s.[73] Their techniques of anterior release and fixation allowed better deformity correction, necessitating fewer fused segments. These deformity techniques were adapted to traumatic conditions by Kaneda, Dunn, and others. Use of these early-generation devices began to wane due to reports of catastrophic vascular erosions.

In the 1990s, next-generation, soft tissue–friendly anterior plate-and-rod constructs became more common. As with posterior fixation constructs, anterior systems are used to provide stability, attain or maintain alignment, or improve or accelerate fusion. Over the last 10 years, however, use of anterior surgery has varied. Introduction of lateral lumbar interbody approaches has stimulated interest in less-invasive adult deformity corrections with anterior cages and posterior, often percutaneous, screw-rod constructs. In pediatric deformity, stronger posterior implants and improved correction techniques have decreased the use of anterior release and fusion procedures.[225]

Today, the least controversial indications for anterior thoracolumbar surgery include reconstruction of tumors or vertebral body fractures. These indications include (Fig. 70.8):

- Corpectomy defects (after burst fracture or tumor)
- Marked anterior canal compression
- Marked loss of the spine's ability to support axial loading
- Discectomy defects
- Painful disc in low-grade isthmic spondylolisthesis or degenerative disc disease
- Pseudarthrosis after multilevel fusion
- Anterior support in long fusion constructs (particularly at L5–S1)
- Anterior release procedures (in patients with coronal or sagittal deformity and loss of spinal balance)

The indications for interbody fusion after a posterior decompression and stabilization remain unclear. In many

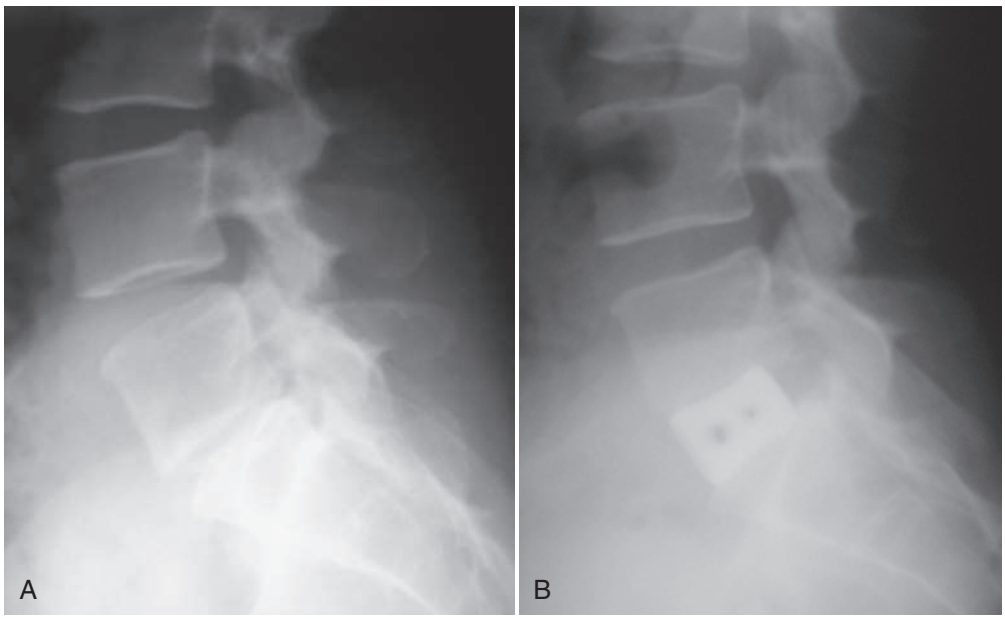

FIG. 70.8 Stand-alone anterior lumbar interbody fusion continues to be performed, albeit with more limited indications, such as patients with markedly collapsed disc spaces. (A) Preoperative and (B) postoperative lateral radiographs in a patient undergoing a tapered cage anterior lumbar interbody fusion with bone morphogenetic protein within the cage.

clinical scenarios such as degenerative or isthmic spondylolisthesis, better radiographic results in terms of slip and, possibly, lordosis correction, are reported but no measurable improvement in clinical outcomes follows.[226] The most controversial indication for anterior surgery is for the treatment of discogenic pain.[227]

In some settings, however, one-stage circumferential approaches from the back have supplanted separate anterior surgery. In tumor and trauma surgery, wide posterior approaches have allowed corpectomy with (often expandable) cage reconstruction without a separate anterior incision.

A number of recent studies have examined the role of multilevel, rigid posterior implants in obviating separate anterior release and instrumentation procedures. For example, in 30 patients with Scheuermann kyphosis, posterior fusion surgery offered similar radiographic and clinical outcomes to an anterior-posterior approach.[228] In right thoracic adolescent idiopathic scoliosis, a recent study compared 18 patients undergoing an anterior and 24 undergoing a posterior approach.[229] Clinical and coronal plane results were similar between the groups. Posterior surgery more effectively addressed sagittal plane deformity.

In most cases, however, the procedural goals remain the same. Anterior surgeries are indicated to release and stabilize thoracolumbar deformity correction (scoliosis, spondylolisthesis, kyphosis), remove anteriorly based tumors and infections, decompress anterior canal compression, and restore the anterior load-bearing column through strut grafting (Fig. 70.9).[230]

Relative contraindications for anterior procedures include osteoporosis. Anterior systems rely on softer cancellous vertebral body bone with thin cortices as opposed to posterior pedicle screw systems that rely on cortical pedicle bone.

On the other hand, osteoporotic patients may be in greater need of anterior column load sharing. Gurwitz and colleagues assessed the stability of several constructs in a burst fracture model.[231] Axial stiffness and torsional rigidity were measured before and after posterior instrumentation alone, posterior instrumentation with anterior strut grafting, and anterior instrumentation with anterior strut grafting. They found that posterior instrumentation alone was associated with 76% less axial stiffness. The addition of an anterior strut rendered the construct as stiff as the intact spine. Anterior struts with anterior instrumentation were as strong as the intact spine in axial loading. All these constructs were 30% less rigid in torsion compared with the intact spine.

The less-expansile nature of anterior approaches decreases their utility in patients with multisegmental pathologic processes (e.g., multiple spine metastases) in which multilevel exposure is required. Contraindications to abdominal or thoracic surgery also limit the utility of these procedures in some patients. Patients with multiple prior abdominal or retroperitoneal surgeries and patients with severe pulmonary dysfunction might be better treated with a posterior reconstruction.

Cages and Struts

Although most anterior column spacers are used to improve the alignment and rate of spinal fusion, some are used without attempted fusion. Traditionally, PMMA was one of the first and simplest constructs for reconstruction of corpectomy defects. It is currently rarely used, but it may be considered in patients with limited life expectancy and is best limited to one-level or two-level corpectomies only. The stability of this construct is improved by the use of Steinmann pins that can be placed through the PMMA construct and embedded into the vertebral endplates above and below the defect.[232] C-clamps and other devices have been used to improve endplate support. In an open total spondylectomy model, PMMA can be packed into the anterior defect from a posterior approach. As with all interbody procedures, endplate coverage is important in avoiding subsequent subsidence. A mechanical assessment of this construct in cadaveric spines found that only combined approaches with posterior screws and anterior PMMA restored the spine to its previous state. With the posterior elements removed, use of PMMA and anterior instrumentation or anterior pins was unable to restore the motion segment stability.[233]

Although morcellized graft material has been used alone, a structural graft or morcellized graft material within an interbody cage is more typically selected. Options for interbody grafts include various types of structural autogenous grafting (e.g., rib or tricortical iliac crest) or allograft struts (e.g., rings or dowels). No mechanical advantage of supplemental screw placement into the graft or cage has been shown.

Regardless of which strut graft, spacer, or cage is placed, a few rules governing endplate and fusion bed preparation must be followed. First, as much disc material as possible should be removed because residual disc material actively discourages fusion. This is more easily and completely attained by a direct anterior approach than a posterior approach via a posterior lumbar interbody fusion or TLIF. Second, the endplate cartilage should be removed down to bleeding bone, but the subchondral bone endplate should be preserved. Some surgeons advocate endplate perforation to facilitate bone ingrowth from the vertebral body into the graft. Because loads and, consequently, the risk of implant subsidence are much higher in the thoracolumbar spine than in the cervical spine, the endplate must be carefully protected, particularly in osteoporotic and obese patients.

In one recent series of 116 patients treated for thoracolumbar trauma, all received posterior instrumentation followed by anterior grafting.[234] When assessed by CT, tricortical iliac crest healed 66% of the time versus 90% of the time for rib grafts and 98% for cages filled with cancellous bone from the fractured vertebra. Another study described successful use of autograft from the adjacent vertebral body to fill ALIF cages in long fusions for adult deformity.[235] The vertebral body was then filled with allograft.

Anterior cages are broadly divided by purpose into interbody and corpectomy devices (Fig. 70.10). There are two main cage varieties: vertical and horizontal. Vertical devices typically fill corpectomy defects, whereas horizontal (cylindric) cages are used in discectomy procedures. For the latter, the mechanical goal is interspace distraction and restoration of annular tension.[236] A wide variety of allografts are available for use in either vertical or horizontal modes. These may be

"off-the-shelf" sections of femur, tibia, humerus, or fibula, which the surgeon cuts into the desired size and shape, or one of myriad machined bone products. Commercial bone implants are typically prefabricated to specific sizes and may have special surface textures to resist extrusion. The rationale behind machined allograft and manufactured cages includes the following:

- Immediate structural support to resist axial compression and maintain distraction
- Adequate contact area with adjacent vertebrae to resist subsidence without stress shielding of bone growing in the cage
- Avoidance of structural autograft harvest

Nonallograft cages have the additional potential advantages of avoidance of structural allograft complications (microfracture, collapse, and potential viral transmission).

The shape of horizontal interbody cage devices has evolved over time to reflect differing methods of insertion and

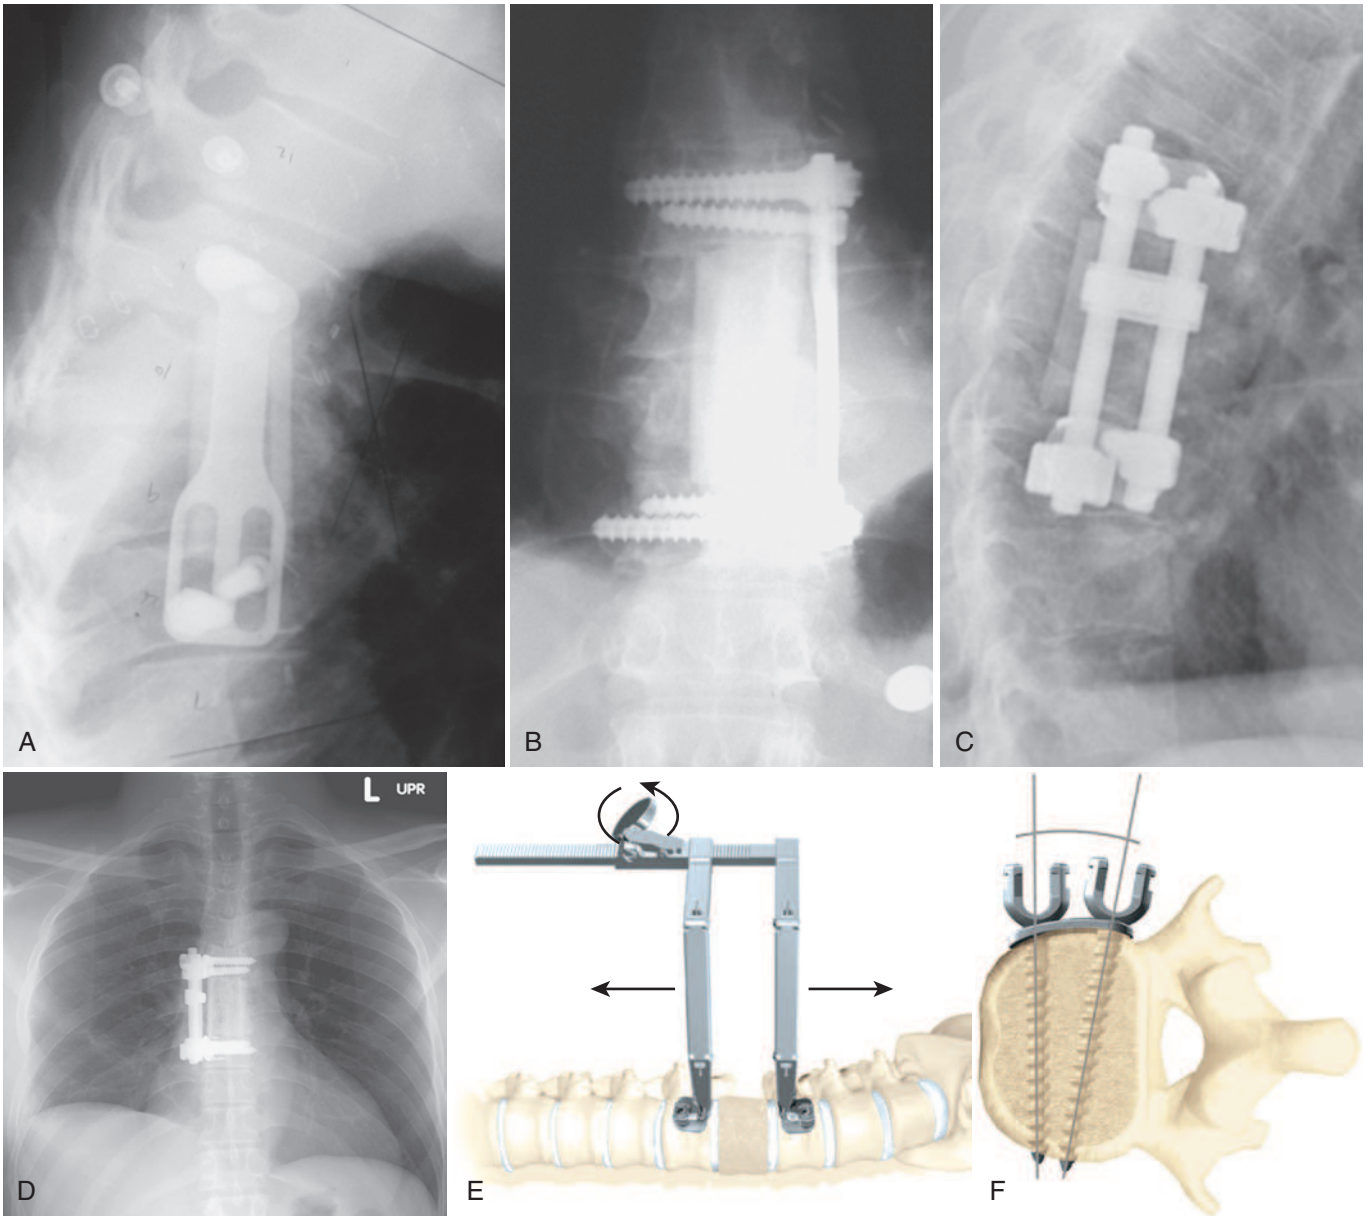

FIG. 70.9 Thoracolumbar corpectomy operations may be performed with or without anterior or posterior instrumentation. When possible, additional posterior procedures should be avoided. In many burst fracture models, anterior column instrumentation may be biomechanically adequate. There are many options, but the most common are plate-and-rod systems. (A–B) Plating systems are said to be easier to implant and have a lower profile. (C–D) Rod-based systems confer greater mechanical strength in that the longitudinal member (in this case the rods) lies farther from the spine's instant axis of rotation. This advantage is also a disadvantage, however, in that it increases implant bulk and profile. (E) Most rigid anterior instrumentation systems allow distraction of the interspace for safe canal decompression and subsequent compression to improve immediate construct stability. (F) For virtually all of these systems, triangulated, bicortical placement of the screws improves holding power in osteoporotic bone.

Continued

FIG. 70.9, cont'd (G) Use of an expandable cage to treat a chronic burst fracture in a patient who had two previous failed posterior fusion attempts. To reduce the focal kyphosis, the anterolateral ligament was resected and bicortical screws were placed in the bone above and below the fracture. The screws and interbody distraction were used sequentially to restore height. The loose posterior instrumentation was revised with larger diameter screws, polymethylmethacrylate augmentation, and short screws in the fractured vertebrae. (E–F, Courtesy Stryker, Kalamazoo, MI.)

different mechanical goals. The earliest cages, applied from an anterior approach, were simple femoral rings. These devices were almost always used in conjunction with posterior rigid instrumentation. Occasionally, "anti-backout" screws with an attached washer were used, though there is little literature support for their effectiveness.

In the 1990s, threaded cylindrical cage designs evolved. Screw-in cages are exemplified by threaded cylinders such as the Bagby and Kuslich device. More recently, threaded designs have given way to all-in-one devices that contain both a ring and a locking screw design. Theoretically, these screws hold the cage to the vertebral body above and below, thereby improving resistance to extension. In the thoracolumbar spine, they are available in several forms, including those optimized for ALIF and lateral placement. Interestingly, the most common horizontal anterior cage has returned to a ring configuration.

Horizontal cages are typically used in anterior lumbar fusion procedures and had been virtually exclusively used in the lumbar spine. More recently, transforaminal approaches to the disc space have been reported even in thoracic level procedures. A recent randomized, controlled study compared transforaminal thoracic interbody fusion with anterior-posterior fusion in 57 patients with thoracolumbar trauma.[237] Similar fusion, loss of correction, and clinical outcomes were reported. Formal posterior-anterior surgery was associated with greater blood loss and perioperative complications.

Transperitoneal approaches enjoyed a short burst of popularity in the mid-1990s when endoscopic techniques were used for threaded cage placement. This attempt at less-invasive fusion surgery has given way to miniopen retroperitoneal approaches, which offer similar recovery and morbidity rates with decreased operative time and retrograde ejaculation.[238]

Currently, the transperitoneal approach is occasionally used in markedly obese patients and when prior retroperitoneal exposure has been performed. In approaching the sacral promontory, some surgeons recommend infiltration of the tissue with a few milliliters of saline to facilitate the dissection and aid in identification of the presacral parasympathetic fibers. More typically, the anterior aspect of the lumbar spine is approached retroperitoneally. This approach improves access to the upper lumbar spine. For limited exposures to the low lumbar spine, a short transverse or paramedian incision is made.

To replace the long flank incision, relatively less-invasive transpsoas lateral approaches evolved in the 2000s and were marketed as extreme lateral interbody fusion and direct lateral fusion by their manufacturers. From the implant standpoint, however, these approaches are similar and will be considered together as lateral lumbar interbody fusion (LLIF). The lateral retroperitoneal, transpsoas approach to the disc space allows sufficient access for a complete discectomy, distraction, and interbody fusion without the need for an approach surgeon (Fig. 70.11).

Complications associated with LLIF surgery include damage to the lumbosacral plexus. The lumbosacral plexus lays within the substance of the psoas muscle between the junction of the transverse process and vertebral body. The nerves exit along the medial edge of the psoas distally. The lumbosacral plexus is most dorsally positioned at the posterior endplate of L1–L2. There is a general trend of progressive ventral migration of the plexus on the disc space from L2–L3 through L4–L5. The safe corridor for performing LLIF procedures narrows when moving caudally from L1–L2 to L4–L5. Average ratios were calculated at each level (distance of the plexus from the dorsal endplate divided by total disc length) and were 0 (L1–L2), 0.11 (L2–L3), 0.18 (L3–L4), and 0.28 (L4–L5).[238a]

This anatomic study suggested that positioning the dilator, retractor, or both too posteriorly at the disc space may result in nerve injury to the lumbosacral plexus, especially at the L4–L5 level. One recent review concluded that there was anatomic justification for lateral cage placement from L1–L2 to L4–L5.[239] Another review confirmed the utility of this approach in improving coronal and sagittal balance in patients with degenerative scoliosis.[240]

These findings have led to newer approaches that access the disc space anterior to the psoas muscle. For example, the oblique lumbar interbody fusion is another variant of LLIF and has been promoted as less likely to irritate the lumbar plexus during cage insertion. A small 12-patient series of kyphoscoliosis patients undergoing anterior-posterior corrections

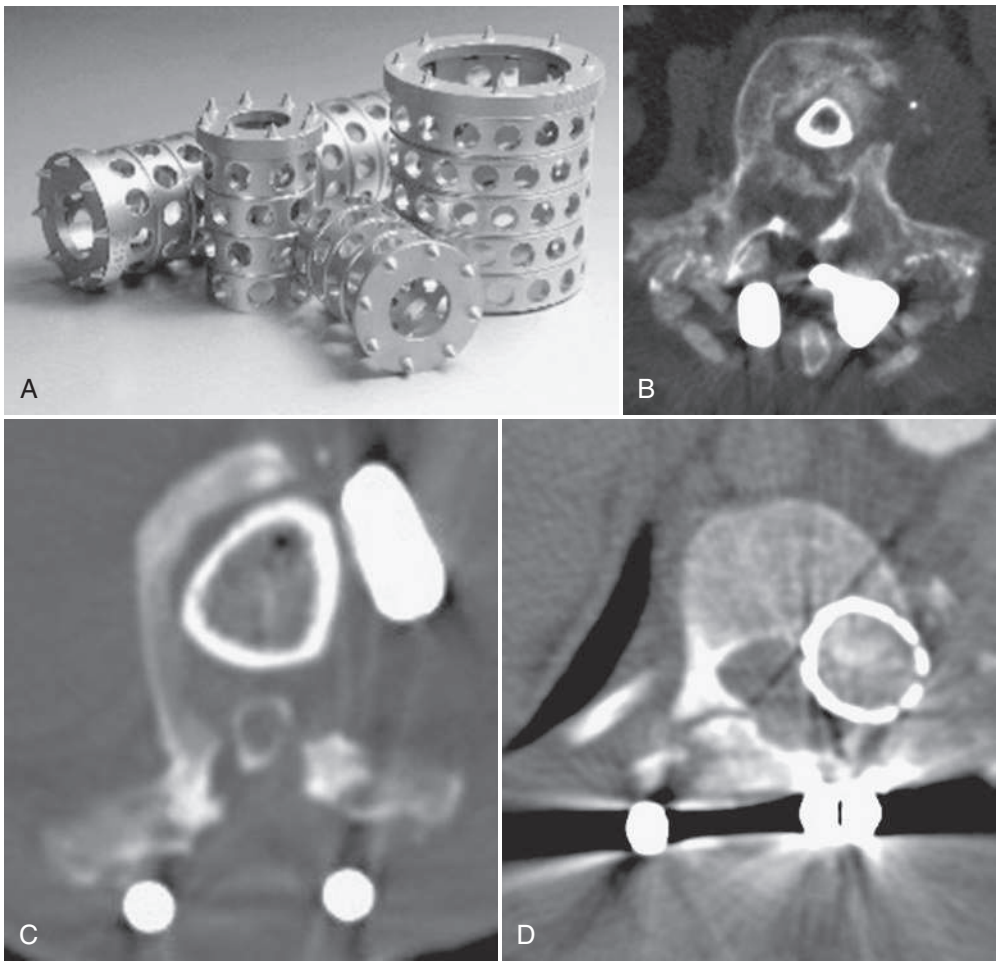

FIG. 70.10 When an anterior corpectomy is performed, various materials are available to reconstruct the defect. (A) Example of vertical mesh cage. These devices offer end caps that engage the host bone, improving rotational stability of the construct. Various allograft materials may be used as well. (B) Use of a single fibular shaft. Graft geometry should match as much as possible that of the host endplate. Particularly in patients with osteoporosis, small corpectomy struts penetrate the endplate, and all axial stability is lost. Disengagement of the hooks posteriorly is noted here. (C) Postoperative axial computed tomographic myelogram in a case in which a tibial shaft has been used. The graft fills most of the corpectomy. As with all other forms of instrumentation, careful attention to positioning of the implant is crucial with corpectomy devices. (D) Grossly malpositioned cage in a patient with postoperative radicular symptoms. (A, Courtesy Stryker, Kalamazoo, MI.)

was reported with a 90% fusion rate and no neurovascular injuries.[241]

However, reasonable results have been reported for LLIF procedures thus far. Stand-alone LLIF outcomes were reported in 59 patients,[242] with a fusion rate of 93%. A recent biomechanical study found that posterior implants improved stability after LLIF.[91] Pedicle screw constructs provided more stability in lateral bending than interspinous process fixation, but the authors concluded that interspinous process devices were likely adequate. Another study found that a lateral plate with an interspinous process device provided similar stiffness to LLIF with pedicle screw-rod constructs.[243]

A recent cohort controlled study concluded that LLIF improved lumbar lordosis more than ALIF.[244] In another recent study of 145 levels in 90 patients, at a mean 12.6-month follow-up 5.3-degree restoration of lordosis was noted but, with subsidence, 2.9 degrees of final correction were noted.[245] A mix of stand-alone cages, lateral plates, and transpedicular instrumentation was used. New postoperative thigh numbness and weakness were noted in 4.4% and 2.2% of the patients, respectively. Good clinical outcomes were also reported. On the other hand, a recent systematic review was unable to establish superiority of LLIF over TLIF in adults with lumbar degenerative conditions.[246]

This MIS lateral transpsoas approach may also be used for corpectomy and anterior release in burst fractures and kyphotic deformity. In a study comparing this approach with an all-posterior approach, similar rates of complications and correction were noted.[247]

By providing disc space distraction, interbody devices and procedures restore foraminal height. Interbody techniques can also provide indirect reduction of central canal compression. One cadaveric CT study found that anteriorly or laterally placed interbody devices can reduce anterior listhesis and increase canal and foraminal volume in a degenerative spondylolisthesis model.[248] One clinical study followed a series of 56 patients with back pain, neuroclaudication, or both from degenerative spondylolisthesis and spinal stenosis

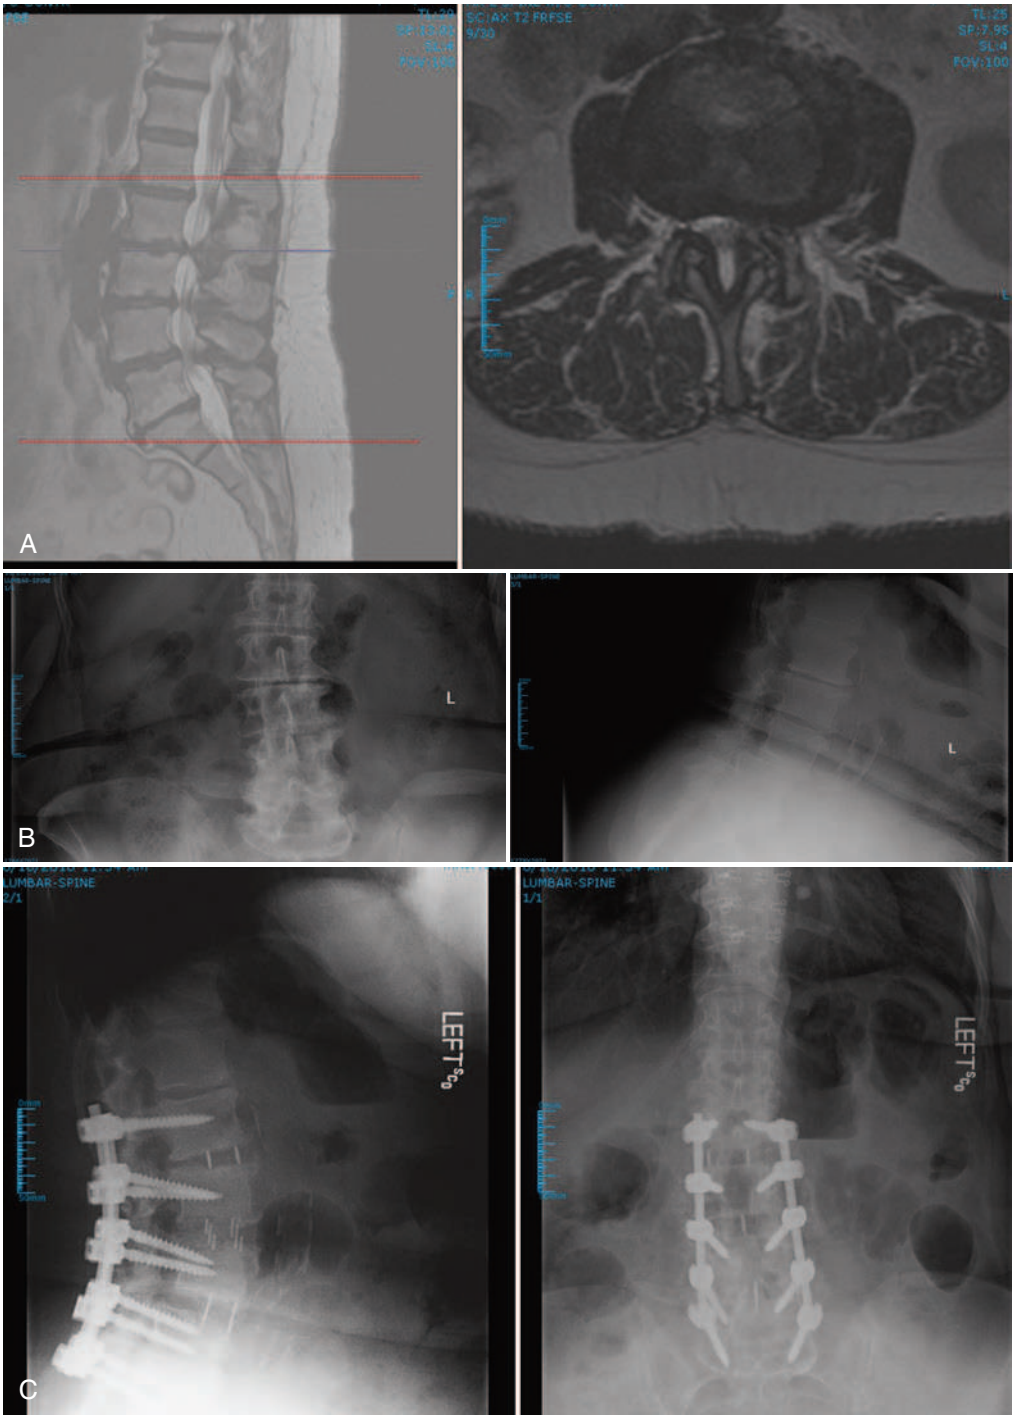

FIG. 70.11 Extreme lateral interbody fusion (XLIF) device minimal access spinal approaches have certain advantages over open procedures, including decreased postoperative pain and narcotic requirements, shorter hospital stay, less blood loss, and smaller incisions. This patient underwent L2–L3, L3–L4, and L4–L5 XLIF instrumentation followed by posterior stabilization. (A) Preoperative magnetic resonance image showing multilevel stenosis and disc degeneration. (B) Preoperative radiographs showing multilevel disc degeneration, spondylolisthesis, and lumbar scoliosis. (C) Postoperative radiographs.

who underwent ALIF for reduction and fusion. Outcomes were comparable to the published outcomes of in situ fusion after formal laminectomy, avoiding the risk of epidural fibrosis and "fusion disease" associated with posterior decompression and fusion.[249]

Vertical cages are most frequently used in the context of thoracolumbar corpectomy procedures. Historically, this procedure was performed in the thoracic spine via a lateral, transthoracic approach and in the lumbar spine via a retroperitoneal approach. The transthoracic approach is a modification of the standard approach to aortic aneurysms and offers excellent exposure to the anterior and lateral aspects of the thoracic and upper lumbar spine. Although double-lumen intubation and postoperative chest tube placement are often

required, this approach provides a safe avenue for decompression of bony stenosis of the thoracic canal. Approaches to the thoracolumbar junction often require partial diaphragmatic takedown. For patients with marked anterior column disruption and axial instability, the anterior approach allows the most stable reconstruction.

The lateral approach used in the thoracolumbar approach limits subsequent instrumentation placement options. A laterally placed plate is less able to prevent segmental spine extension than a plate on the anterior vertebral surface. When approaching the lower lumbar spine anteriorly, the retroperitoneal approach is generally preferred.

In the lumbar spine, oblique flank incision may be used for multilevel and corpectomy procedures. For single-level, low lumbar approaches, a midline or a Pfannenstiel incision may be used.

Numerous miniopen modifications of the standard retroperitoneal exposure have been described and have become commonplace over the last 10 years. These modifications rely chiefly on the experience of the access surgeon and powerful retractor systems to minimize the incision length. In one retrospective 2-year follow-up, 28 patients underwent ALIF via a 6- to 10-cm left lower quadrant transverse skin incision.[250] A paramedian anterior rectus fascial Z-plasty allowed access to the retroperitoneal space for placement of various implants. No vascular, visceral, or urinary tract injuries occurred, but a mild ileus was noted in three cases. Another report described similar use of a 5-cm left flank incision in 25 patients. No injury to the great vessels or neurologic deterioration was noted.[251] This approach is safe, uses a small skin incision, avoids cutting the abdominal wall musculature, allows various interbody fusion techniques, and does not require peritoneal violation or endoscopic instrumentation. Other advantages include fewer radiographs with reduced radiation exposure during surgery and a shortened learning curve because the approach is similar to the anterior open lumbar technique.

As with pedicle screws, vertical cages can be placed through the vertebral body instead of on the endplates. The Bohlman technique used a fibular strut between the sacrum and the L5 vertebral body in high-grade spondylolisthesis. Over time, this approach has been modified to use vertical mesh cages. In high-grade slips, various modifications of the Bohlman technique continue to be reported with high success and low rates of L5 radiculopathy.[252]

The most recent change to these devices, both horizontal and vertical, has been the addition of gears or threads that allow vertical expansion in situ. For corpectomy defects reconstructed with expandable cages, adequate anterior column restoration may be achieved through smaller anterior exposures or through wide posterior approaches. In one recent series, 85 thoracolumbar fracture patients underwent anterior corpectomy with expandable cage and bilateral pedicle screw placement.[253] Impaction into the endplates of the neighboring levels was seen in 35%. The fusion rate was 100%. Reasonable achievement and maintenance of alignment were reported.

Posterior extracavitary resections of tumors using expandable cages in a single-stage posterior approach with adjunctive, rigid, segmental screw-rod stabilization are also being reported. Recent 34- and 46-patient series reported neurologic improvement and excellent early radiographic outcomes with "acceptable" complication rates.[254,255] Use in multilevel corpectomies in metastatic disease has also been reported, albeit with a high complication rate.[256]

In a biomechanical study, expandable cages were superior to femoral strut allografts and more typical cage struts from the ilium to the L5 vertebral body.[257] MIS techniques have increasingly been reported for placement of these cages as well.[258]

In a biomechanical study of expandable cages used in lateral interbody fusions, the stability of the expandable and static changes was similar, but the authors cautioned that "there may be a greater chance of endplate collapse by overdistracting the disc space because of the minimal haptic feedback from the expansion."[259]

In fact, all strut grafts, disc replacements, cages, and other anterior spacers are subject to subsidence and extrusion.[236,260] The rate and degree of this subsidence are related to cage geometry and sizing, endplate coverage, and preparation.

Several studies have shown excellent early interspace distraction but gradual collapse with further follow-up. One clinical study of dual rectangular cages found that 76% of patients developed subsidence, more often into the superior than the inferior endplate, although it did not appear to affect fusion rates or clinical outcomes.[261] A number of studies have shown that increasing cage footprint, either with multiple cages, larger cages, or expandable cages, decreases the risk of subsidence.[240,243,245,246,255]

Faizan et al.[262] describe this subsidence as typically occurring by 4 months postoperatively. In that study, mean preoperative intervertebral disc height was 11.6 ± 3.1 mm, immediate postoperative height was 16.9 ± 2.0 mm, and final follow-up disc height was 13.2 ± 2.4 mm.

The frequency of use of posterior cylindrical implants has decreased due to their higher rates of nerve injury. Anterior use has declined due to greater subsidence than plate-and-graft constructs and rectangular cages.[263-265]

Lateral positioning on the endplate is associated with decreased rates of subsidence. Ultimately, cage size and placement in the disc space are more important than implant design.[266,267] Placement of the cage anteriorly in the disc space gives the construct a better moment arm and therefore better segmental stabilization when compared with more posterior placement.[266] A recent biomechanical study found that cages with rectangular endplates had a lower subsidence rate than those with round endcaps.[268] By their nature, LLIF procedures offer the ability to place very wide cages that cover a large portion of the vertebral endplate. While these cages have a greater surface area than TLIF or PLIF cages, they are still susceptible to subsidence, particularly in osteopenic patients.[46]

For similar reasons, subsidence is a major concern for disc replacement procedures. In contrast to fusion procedures, there is no point at which the construct can be said to be healed in position. Implant sizing is crucial. Because an overly large implant is virtually impossible to insert into a degenerated and collapsed disc space, an undersized implant is more

commonly inserted owing to difficulty in adequately distracting the collapsed disc space. Because small implants cover very little of the vertebral endplate and offer virtually no end bearing, central positioning of the device risks endplate subsidence. Finally, if the patient subsequently develops osteoporosis, endplate support itself may decrease.

Anterior Plates and Screw-Rod Systems

Purported benefits of anterior fixation include decreased rates of pseudarthrosis (particularly in smokers), graft extrusion, postoperative kyphosis, and graft subsidence. Anterior plating reduces the need for postoperative bracing and allows early rehabilitation. Mechanically, anterior devices function in a neutralization mode. The implant partly shields axial stress and minimizes torsional bending and shearing and also provides resistance to vertebral extension.

Anterior thoracolumbar implants are chosen as part of a complete reconstruction strategy. Depending on whether a discectomy or corpectomy is performed, the decision of whether to include anterior or posterior instrumentation is made in conjunction with the decision about the type of interbody device or graft.

Anterior fixation systems can be classified as either unconstrained or constrained. The earliest attempts at anterior fixation used dynamic compression plates, originally designed for the appendicular skeleton, across disc spaces. Most unconstrained constructs are single-rod systems used in the anterior management of scoliosis.[269,270]

The advantage of an unconstrained system is its ease of insertion. The disadvantage is its poor rotational stability.[269] Most unconstrained systems provide no fixed angle between the bone anchor (typically a screw) and the longitudinal member, which increases the risk of screw backout, especially if placed unicortically. Unconstrained anterior systems are often used in deformity surgery and are augmented with bracing. In more unstable settings involving trauma or tumor, their role is best limited to the mid-thoracic spine with an intact rib cage and sternum.[271] The greater stresses associated with the thoracolumbar or lumbar spine limit the usefulness of unconstrained systems there to cases in which supplemental posterior instrumentation would be used.

Constrained systems include rigid fixation between the anchor point and the longitudinal member, be it a plate or a rod. Constrained systems can be divided into plate systems and dual-rod systems. Plating systems are generally considered easier to place and lower profile than dual-rod systems. Anterior plates are not quite as rigid as dual plating systems, particularly with regard to torsional stability.[272]

Advantages of constrained systems include the ability to apply compression across the graft. The fixed angle between the screw and the plate or rod allows maintenance of sagittal balance. A fixed angle can also be a disadvantage because it limits screw placement options, such as in hemicorpectomy, in which screws may need to be placed close together. Other potential disadvantages include implant bulk. Lateral, rather than anterolateral, placement is key in avoiding the great vessels and risk of vascular erosion.

Application of dual-rod systems involves placing screws through spiked plates into the lateral vertebral body. The plates decrease axial load through the screws by distributing axial load across the vertebral body. Distribution of this load is helpful because of the thinness of the lateral vertebral cortices. Without the plates, the screws could tear through the lateral vertebral body wall.[273] In some systems, individual screw plates are available. These single-screw plates spread vertical loads over a smaller area but have increased placement options.

Plates designed to stabilize the lower lumbar spine after ALIFs have been offered by various manufacturers.[274] These devices seek to provide extension stability to the fused segment while obviating the need for a supplementary posterior construct. At this time, biomechanical or clinical support for these devices remains limited, though they may have a role in avoiding posterior surgery in certain degenerative conditions.[275,276] That said, there is renewed interest in anterior plating when combined with LLIF surgery.

Some anterior thoracolumbar implants are placed more to contain graft material than to control segmental motion. Numerous resorbable implants have been developed for this purpose.[277] More common are screw-washer constructs or various small plates that attach to one vertebral body and span the intervertebral disc space. Such "anti-backout" systems have little biomechanical support for their use.

Recently, there has been an increase in the number of all-in-one devices available. These implants integrate the cage with a plate or locking screws. In one recent biomechanical study, integrated lateral cage-plate devices offered similar restriction of motion to a separate plate and cage construct and more restriction than the cage alone.[278] This construct was not as rigid as cage plus posterior pedicle screws or facet screw placement.

In one recent biomechanical study in nine cadaveric spines, an integrated ALIF spacer performed especially well in patients with higher sacral slopes.[279] The authors surmised that this advantage arose from the angulation of the integrated plate screws. They suggested that increasing sacral slope reduced the stiffness of most typical reconstructions and that "more aggressive fixation techniques" be used. Use of an integrated cage-screw construct was reported in 65 patients for degenerative conditions at three spine centers.[280] The fusion rate was 96.3% with a 2.0% subsidence rate.

The drawbacks of anterior thoracolumbar instrumentation include cost, lack of familiarity with the approach, the occasional need for an access surgeon, and space available for the implant. Hardware loosening may be the result of osteoporosis with insufficient bone purchase or inadequate postoperative immobilization. Potential complications, as with all types of spinal fixation, include deep infection, implant failure, and vascular and neurologic injury. Specific risks include parenchymal injuries to the lungs and erosion into the vessels. The exact risk of vascular erosion is unknown. There are no reported cases of late vascular injury reported with contemporary systems, although some earlier anterior fixation systems were discontinued because of this risk. Current recommendations are to keep metal components more than 1 cm away from the great vessels.

Lumbar Disc Arthroplasty, Nuclear Replacement, and Other Motion-Sparing Approaches

Disc-level anterior motion-preserving implants (disc and nuclear replacement systems) are also available, although their use has decreased markedly.

The historical precursor to total disc replacement and nuclear replacement was the stainless steel Fernström ball. This spherical endoprosthesis was developed and implanted in the 1950s and 1960s as a spacer that allowed motion of the adjacent vertebrae.[281] The shape of the device concentrated the loads on a small portion of the implant and vertebral endplate surface. Normal load distribution could not be recovered; because of concerns about device migration and subsidence, the device was subsequently abandoned.[282]

Later efforts at nuclear replacement sought to use less-stiff, preferably viscoelastic materials. These devices included preformed implants and injected polymers that cure in situ. The ideal nuclear replacement restores disc mechanics with much less normal tissue ablation than total disc arthroplasty. These devices sought to offer shock absorption not seen with lumbar disc arthroplasty designs.[283]

These implants were intended for use as a primary treatment of early, painful lumbar disc degeneration or for placement at the time of discectomy in a patient with radicular symptoms. In the latter case, the nuclear replacement was intended to maintain or restore disc height and function. It was hoped that in the short term this restoration of disc mechanics would decrease postoperative back pain. Ideally, nuclear replacement would prevent further motion-segment degeneration, decreasing the likelihood of more invasive and destructive surgeries such as fusion or disc arthroplasty.[283,284]

Contraindications for a nucleus prosthesis include disc height less than 5 mm, anular incompetence (in the form of major tears), grade II or greater spondylolisthesis, and Schmorl nodes.[285]

The most studied device was Ray's prosthetic disc nucleus (PDN), consisting of a hydrogel core encased in a polyethylene jacket and first developed in 1988. The hydrogel absorbs water and expands to fill the nuclear cavity. The jacket prevents the hydrogel from overexpansion. Initially, two devices were implanted at each operated level. After extrusion problems were encountered, a larger, single PDN was designed. Although the device was initially inserted solely through a large posterolateral annulotomy, the consequences of device extrusion into the canal led to anterolateral insertions.[285]

Minimally invasive delivery of injectable materials can be accomplished with small anular windows, decreasing the risk of implant extrusion. Preformed implants may have the advantage of improved mechanical strength and fatigue life, but several designs have been associated with high extrusion rates. In many of these devices, intense, inflammatory endplate reactions were reported as were high rates of explantation and conversion to fusion.[286]

After the Fernström ball, the evolution of total disc and nuclear replacement diverged. Unlike cervical disc arthroplasty, which is typically indicated to restore stable and segmental height after anterior decompression, lumbar disc replacement is indicated for reduction of axial low back pain and to avoid the morbidity associated with fusion. Disc replacement seeks to remove the pain generator while preserving motion. In avoiding fusion, bone graft donor site morbidity is avoided, as is the possibility of pseudarthrosis. Theoretical benefits include decreased rates of adjacent-segment degeneration and improved sagittal balance.

In 1982, in what was then East Germany, Büttner-Janz and Schellnack initiated development of their artificial disc at the Charité Hospital in Berlin.[287] They based their design on the "low-friction" principle used in total knee and total hip arthroplasty. In particular, they placed a polyethylene sliding core between two highly polished metal endplates. This sliding core was to mimic the movement of nucleus within its annular containment. Their initial effort was frustrated by endplate and device fractures as well as insufficient instrumentation for implantation. The large European medical device manufacturer Helmut Link took over production in 1987 and funded an FDA trial in the United States. Eventually, this device was purchased by DePuy Johnson & Johnson (now DePuy Synthes).

The next disc arthroplasty system was the Prodisc, two titanium endplates with a fixed polyethylene core between them. Motion occurs by articulation of only the upper plate on the convex superior surface of the constrained core. This device was designed and implanted into a group of patients, after which the designer, Thierry Marnay, refrained from further implantations for 8 years. Subsequently, Marnay reported 8- to 10-year follow-up results on a group of 44 patients who received this prosthesis. He reported 78% good to excellent results. Synthes brought this device to the North American market and funded an FDA trial. After Depuy and Synthes merged, the Charité was discontinued.[288] Current indications for lumbar disc replacement are as follows:

- One- or two-level (L5–S1 or L4–L5, or both) lumbar disc degeneration (Fig. 70.12)
- Postdiscectomy mechanical back pain
- Degeneration of levels adjacent to a former lumbar fusion

Contraindications for disc arthroplasty are more controversial. Although subtle retrolisthesis related to disc collapse is acceptable, disc replacement with greater degrees of translational instability or spinal deformity should be avoided. Disc arthroplasty should not be performed in patients with marked facet osteoarthritis.[289] The ideal arthroplasty patient presents with a single painful level with more than 4 mm of remaining disc height at that level. This ideal patient has intact posterior elements and no facet or adjacent-level degeneration. Certainly, the percentage of patients who might be candidates for total disc arthroplasty is much smaller than those who could be considered for fusion surgery.

Over the previous decade, many differing lumbar disc arthroplasty designs have been under study. Proponents of constrained versus semiconstrained implants and differing bearing surfaces, such as metal-on-metal versus metal-on-polyethylene, debated at meetings and in the literature.[290-292] Proponents of metal-on-metal designs cite the increased rate at which polyethylene wears. Polyethylene particles could lead to osteolytic reactions and loss of bone stock. Thin polyethylene

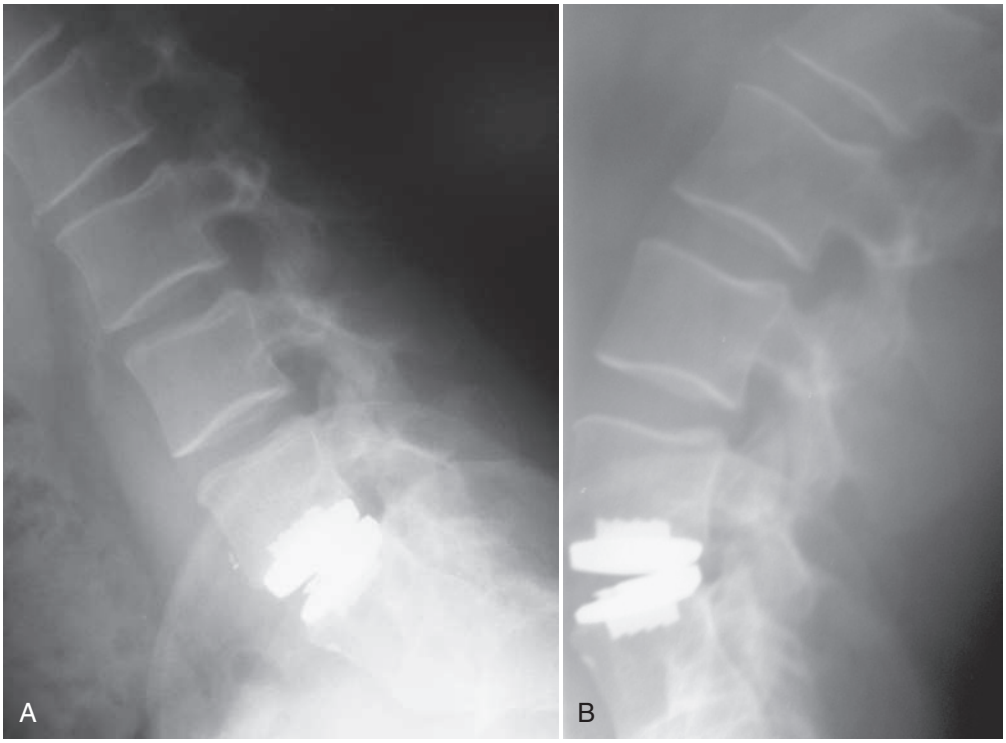

FIG. 70.12 Anterior lumbar disc replacement. All disc replacement systems seek to decrease pain while maintaining motion, eliminating some of the morbidity of fusion such as adjacent-segment disease or graft harvest pain. (A–B) Flexion-extension radiographs obtained 1 year postoperatively in a pain-free patient.

is subject to creep and cracking. However, initial polyethylene wear rate studies suggest excellent prospects for long-term viability.[20]

Metal-on-metal, although more durable, is approached suspiciously by some spine surgeons because of concerns about metal ions leaching into the bloodstream. Currently available data are inadequate to compare these risks. Given the concerns around metal-on-metal hip prostheses, those designs have largely disappeared from the market.[293,294]

The issue of device constraint remains unresolved as well. Proponents of unconstrained devices state that these are most capable of restoring the normal, coupled motion of the lower lumbar spine. Supporters of semiconstrained designs cite occasional polyethylene liner extrusions as evidence that more constraint is needed. The concept of "semiconstrained" is elusive: How much is enough? How much is too much? In particular, do these values hold over various levels of the lumbar spine? The instantaneous axis of rotation of the lumbar spine is not constant, and changes depend on the joint position.[295,296]

If disc replacement systems restore motion, critics worry that improper motion may be worse than no motion. Disc degeneration rarely occurs in isolation. More typically, at least some facet degeneration coexists. One concern is that maintenance of motion would precipitate further facet degeneration. Given that the facets guide segmental motion, further facet degeneration may further disrupt normal kinematics.[297] In a prospective, clinical study of 64 patients, low-grade facet arthrosis did not influence outcomes after implantation of a semiconstrained metal-on-metal total disc replacement.[297a] At 2-year follow-up, the preoperative ODI score of 43.8 had improved to 23.1. Visual analog scale back pain score had decreased from 7.6 to 3.2.

More constrained implants require more elaborate fixation methods to the host vertebral body.[298] Several of the semiconstrained implants in the first generation of devices include keels. Although it is unclear if the keel offers a net advantage to the patient in terms of long-term stability, it would complicate any attempt to remove the implant. Two deep keels at adjacent levels of disc arthroplasty may subject the vertebral body to sagittal split fracture. For all but the tallest degenerated discs, current lumbar disc arthroplasty designs require marked disc space distraction. Too much distraction seems to decrease motion at the adjacent segment. Too little distraction risks implant extravasation.

Finally, critics of the current total disc arthroplasty systems have cited the suboptimal outcomes reported in the published articles. In particular, the actual amount of motion preserved may be very low, and rates of adjacent-segment degeneration have not been definitively affected by arthroplasty over fusion procedures.[299,300]

The final category of anterior implants are staples used for fusion or epiphysiodesis in pediatric scoliosis surgery. Physeal staples, which may be inserted thoracoscopically, are being used to halt growth selectively on the convex side of the deformity.[301] Some seek to cross the disc space, others just cross the epiphysis to compress the growth plate, allowing further growth on the convex side.

A recent computer simulation reported for such a device suggested that properly placed in time (relative to the patient's

growth) and space, the device could control the progression of scoliosis without fusion.[302] Posterior screw placement for posterior convex growth arrest has also been described in congenital scoliosis surgery.[303]

Summary

The use of instrumentation in the thoracolumbar spine greatly increases the surgeon's ability to provide stability to the spine. Enhanced posture and healing of the spine often result. Improved functional outcome for degenerative conditions is more difficult to assess, however. Functional outcome is frequently related more to patient selection, decompression, and patient comorbidities.

At this writing, attempts to restore stability without fusion remain under study, but are limited.

Successful use of thoracolumbar instrumentation requires a detailed knowledge of spinal anatomy and the biomechanics. The intended patient's biologic and pathomechanical factors must also be considered in relationship to the implant's ability to address the identified deficits.

71 CHAPTER Adult Isthmic Spondylolisthesis

Brian Kwon
Neel Shah
David H. Kim

Introduction

Spondylolisthesis is the ventral (or anterior) displacement of one vertebra relative to the subjacent vertebra. Spondylolysis is a defect in the pars interarticularis due to congenital, traumatic, dysplastic, or neoplastic etiologies. It is generally considered to occur prior to appearance of spondylolisthesis, as the anterior column of the vertebra is no longer in continuity with the posterior column. Over time, the vertebral body then displaces ventrally once the disc and supporting soft tissues are no longer able to maintain the structural integrity and anatomic alignment of the vertebrae.

Classification

Spondylolisthesis can be classified by the severity of slippage as described by Meyerding.[1] It is measured as a percentage using the length of slip of the cranial vertebra compared to the length of superior endplate of the caudal vertebra (Fig. 71.1). The classification is based on slip percentage: grade 1, less than 25%; grade 2, 26% to 50%; grade 3, 51% to 75%, grade 4, 76% to 100%, grade 5, greater than 100% or spondyloptosis. An etiologic classification system was described by Wiltse,[2] which includes dysplastic, isthmic, degenerative, traumatic, and neoplastic types. Isthmic spondylolisthesis is the subject of this chapter.

Natural History/Incidence

Fredrickson et al.[3] reported a prospective, population-based study of 500 schoolchildren from northern Pennsylvania in the 1950s. They reported an incidence of lumbar spondylolysis of 4.4% and spondylolisthesis of 2.6% in children younger than 6 years. At adulthood, the incidence of lumbar spondylolysis was found to be 5.4% and spondylolisthesis was 4%. Furthermore, they reported that pars defects did not typically heal, and slippage occurred throughout the follow-up period. Fredrickson also reported that two-thirds of the spondylolysis cases were found in males, and greater than 90% occurred at L5–S1. Spondylolisthesis was found in 74% of patients with bilateral pars defects at L5–S1, but not in patients with unilateral defects or pars defects at other levels. Females had a lower incidence of defects but a higher rate of slip progression.[3]

A more recent study by Urrutia et al.[4] found a similar incidence of isthmic spondylolisthesis in a non-US adult population of 3.8% (range, 1.7–6.8%). The incidence appeared not to change into adulthood, and the authors concluded spondylolysis is more likely an acquired disorder. A 45-year follow-up study on Fredrickson's initial sample population was conducted by Beutler et al.[5] They reported that low back pain (LBP) in patients with pars defects follows a clinical course like that of the general population. Patients with unilateral spondylolysis never experienced slippage throughout the study and half of the patients with bilateral defects did not go on to have any spondylolisthesis. The half who did slip had a mean slippage of 24%.

Kalichman et al.[6] studied spondylolysis on abdominal computed tomography (CT) scans obtained to assess aortic calcification in patients enrolled in the Framingham Heart Study. They reported the incidence of spondylolysis in their sample to be 11.5% and did not find an association with LBP within the previous 12 months of the study. It is notable that this is more than double the incidence reported by radiographically based studies, as CT has been recognized as the most accurate imaging modality for isthmic spondylolisthesis.[7] This suggests that isthmic spondylolisthesis may be more prevalent than initially reported but also that it may be a largely indolent condition with a benign natural history in many, if not most, individuals.

Pathophysiology

The primary pathologic entity in isthmic spondylolisthesis is a defect in the pars interarticularis, a critical structural component of the posterior element of the vertebra. The pars is the intersection of the lamina, inferior and superior articular

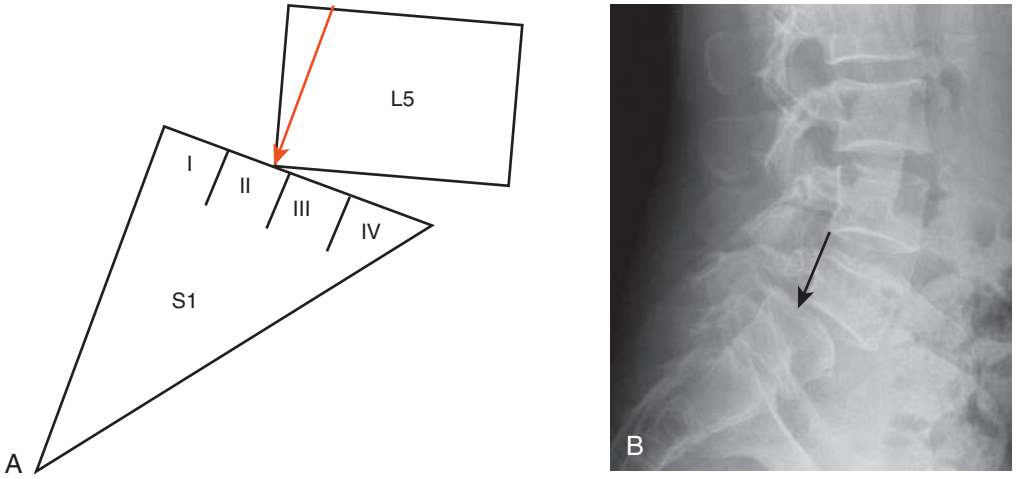

FIG. 71.1 The Meyerding classification measures severity of spondylolisthesis by using a ratio of the amount of anterior listhesis compared to the length of the superior end plate of the S1 vertebra measured in quartiles. Grade 1 = 0–25%; grade 2 = 26–50%; grade 3 = 51–75%; grade 4 = 75–100%; grade 5 = >100% or spondyloptosis. (A) Schematic showing how the measurements for the Meyerding classification are made. This example shows a grade 2 slip, 25–50%. (B) Lateral radiograph showing where the measurement on the S1 end plate is made for Meyerding slip severity.

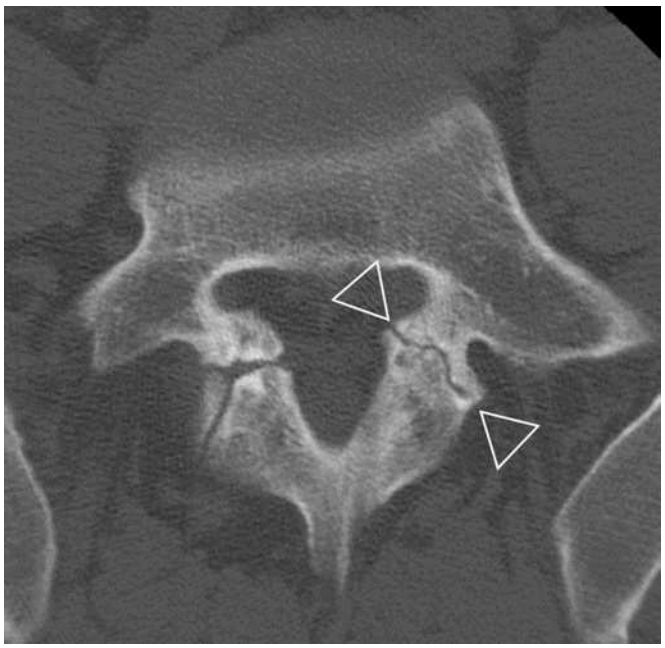

FIG. 71.2 Axial computed tomographic image showing spondylolysis (*open triangles*). Note the undulating course of lucency, making it distinct from a facet joint.

processes, and pedicle. A spondylolysis essentially divides the neural arch (Fig. 71.2). Wiltse divided these defects into three subtypes: A, B, and C. Type A refers to the classic stress fracture of the pars. Type B refers to an intact, but elongated, isthmus due to repeated cycles of trauma and repair. Type C is an acute fracture of the pars interarticularis due to trauma.[8]

Etiologies for spondylolysis are numerous but many believe that the vast majority are due to stress fractures of the pars interarticularis. Biomechanical studies have shown this region is exposed to the highest extension forces in the lumbar spine.[9] It has also been suggested that this region of bone is the weakest structural component of the posterior neural arch.[10] Repetitive lumbar extension loading appears to result in a localized stress reaction in the vulnerable bone of the pars region, and if the stress is sustained or excessive and if the bone is unable to heal, then a spondylolysis develops. Rosenberg et al.[11] support this hypothesis, reporting their observation that spondylolysis does not occur in nonambulatory individuals. Additional support for the relationship between extension stress and spondylolysis is the observation that a high incidence of pars defects are observed in athletes such as wrestlers, football linemen, and gymnasts—who frequently undergo repetitive hyperextension loads.[12–14]

The most common level for spondylolysis is L5, and isthmic spondylolisthesis at L5–S1 accounts for 90% of those who present with the condition.[15,16] Don and Robertson evaluated facet joint orientation in individuals with and without isthmic spondylolisthesis. Due to previous data suggesting that sagittally oriented facet joints predispose individuals to *degenerative* spondylolisthesis, they analyzed facet joint orientation in an *isthmic* spondylolisthesis group. The group with isthmic spondylolisthesis had significantly more coronal orientation of the facets of L3–L4 and L4–L5, that is, above the affected level. They concluded that facet joints with more coronal—less sagittal—orientation allow for less dorsal-ventral translation of cranial motion segments, which leads to greater extension stresses on the L5 pars and results in spondylolysis.[17] Ward and Latimer[18] evaluated the intrafacet distances of lumbar vertebrae in individuals with and without spondylolysis and found an increase in cranial-to-caudal intrafacet distance in nonaffected individuals, which they concluded allowed for overlap of lamina during lordosis. Individuals in whom spondylolysis was found showed relatively lower intrafacet distances, potentially resulting in impingement of the L4 inferior articular process on the pars of L5 (Fig. 71.3).[18]

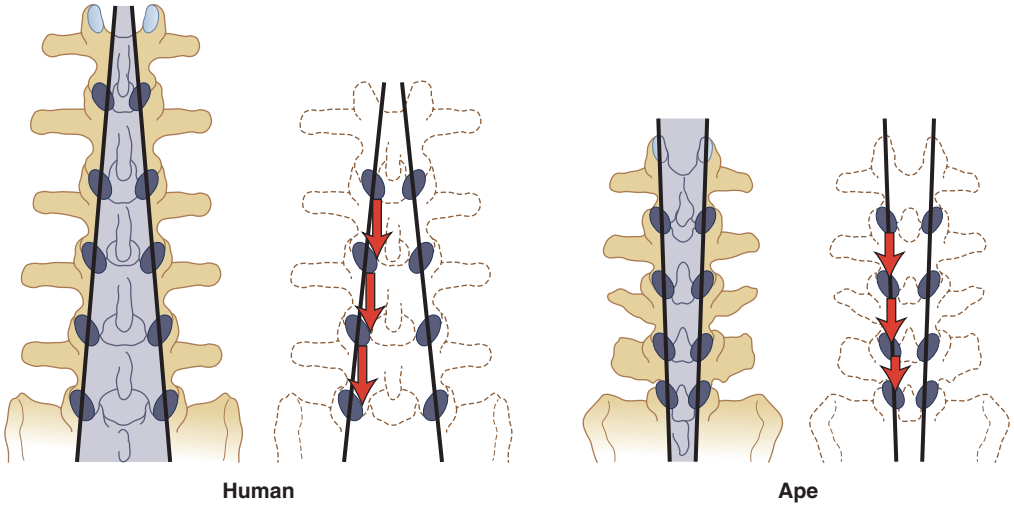

FIG. 71.3 Ward and Latimer's measurement of intrafacet distances. They found that individuals with spondylolysis had a statistically smaller increase in this distance. (From Ward CV, Latimer B. Human evolution and the development of spondylolysis. *Spine*. 2005;30(16):1809.)

Biomechanics

The biomechanical environment at the lumbosacral junction is a complex one that normally functions as a harmonious linkage between the trunk and pelvis. During radiographic assessment of patients, lumbar lordosis (LL), pelvic incidence (PI), sacral slope (SS), and pelvic tilt (PT) are most commonly measured (Fig. 71.4). PI is considered a fixed anatomic measurement and does not change for any given individual through adulthood. LL, SS, and PT are measurements of the relative position of the lumbosacral spine in space. Sagittal spinopelvic parameters have been found to correlate significantly with spondyloptosis[19] as well as the severity of isthmic spondylolisthesis.[20] Labelle et al.[21] show in a sample of 214 young adults (ages 10–40 years) that PI is significantly greater in individuals with isthmic spondylolisthesis and correlates linearly with higher (Meyerding) slip severities. They also showed that PI strongly correlates with the other parameters: LL, SS, and PT. They concluded that individuals with isthmic spondylolisthesis stand with increased SS, PT, and LL. Moreover, these increased values—in particular, LL—are an important factor in the amount of shear stress on the L5 lamina and pars.

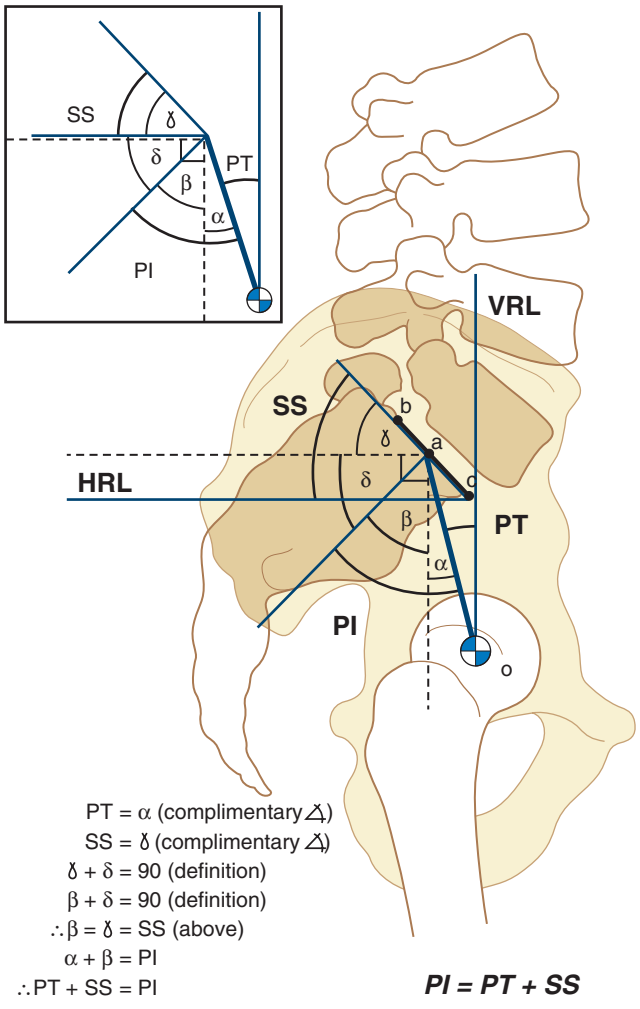

FIG. 71.4 Commonly measured pelvic parameters are altered in individuals with isthmic spondylolisthesis. HRL, horizontal reference line; PI, pelvic incidence; PT, pelvic tilt; SS, sacral slope; VRL, vertical reference line. (From O'Brien MF, Kuklo TR, Blanke KM, et al, eds. *Spinal Deformity Study Group Radiographic Measurement Manual.* Medtronic Sofamor Danek, 2004.)

Diagnosis

History

Most individuals with spondylolysis are asymptomatic. While it is the most common cause of LBP in children, the same does not hold true in the adult population.[22–24] Andrade et al.[25] recently reported a review of observational studies on the association of spondylolysis and isthmic spondylolisthesis with LBP. They reported that only 1 of 15 eligible studies found an association and 11 did not. In fact, they found that LBP was significantly more prevalent in individuals without spondylolysis/isthmic spondylolisthesis.

FIG. 71.5 Lateral radiograph showing step-off of the L4 spinous process from the L5 spinous process (*arrow*). Spondylolysis is outlined by the open triangles.

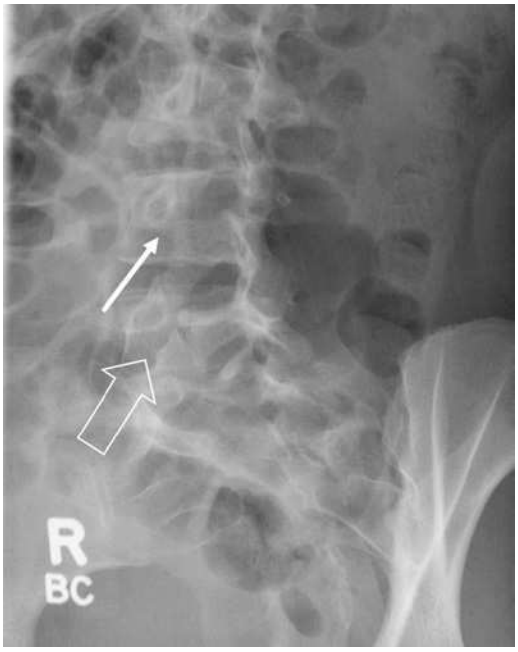

FIG. 71.6 Radiographs of 45-degree oblique image showing the "Scotty dog." Open arrow shows a lucency at pars of L5 commonly referred to as a "break in the neck of the Scotty dog." Solid arrow shows normal pars of L4.

Moller and Hedlund[26] reported on 201 patients with isthmic spondylolysis and found that their patients presented with back pain only in 27%, back pain and sciatica in 65%, and sciatica only in 8% of individuals. Back pain may be positional and may be worsened with standing and/or lumbar extension maneuvers, while it may be relieved with forward flexion or sitting. Lower extremity pain can be radicular in nature, as it is often caused by impingement of the exiting L5 nerve root due to frequent occurrence of associated foraminal stenosis at L5–S1. Pain in lower extremities can often be positional, similar to typical LBP complaints.

Physical Examination

There are no pathognomonic physical examination findings for isthmic spondylolisthesis. Lumbar extension will often elicit LBP, lower extremity radicular complaints, or both. There can be a palpable or visible step-off in cases of high-grade slips. The step-off occurs between the L4 and L5 spinous processes as the posterior elements of L5 remain dorsal and in line with the S1 spinous process (Fig. 71.5). Hamstring tightness is often described but difficult to assess objectively. A positive straight-leg raise test will be present in approximately 50% of patients.[27] Sensory or motor abnormalities can be found due to associated foraminal stenosis and exiting root compression.

Imaging

Routine radiographic images can detect spondylolysis, especially if spondylolisthesis is present, and slip severity can be measured on lateral images. Additionally, standing images that include flexion and extension positioning should be evaluated. If spondylolysis is suspected but not visualized, oblique radiographic images 45 degrees to the sagittal plane can be obtained that can detect up to 96% of pars defects.[28] Abnormalities in the "neck of the Scotty dog" is the hallmark radiographic finding (Fig. 71.6); complete defects are most common, but pars dysplasia and hypoplasia can also be observed.

Computed tomography (CT) scans are the best imaging modality to clearly visualize and define a spondylolysis. On axial images, spondylolysis appears as discontinuity of the posterior neural arch and can be differentiated from the adjacent facet joints. Sagittal reformatted images best show the pars defect as being distinct from facet joints (Fig. 71.7) and are the definitive finding in spondylolysis. One limitation of CT is the lower sensitivity for soft tissue densities, especially the internal anatomy of the neural foramen and the extent of any associated nerve root compression (see Fig. 71.7).

Magnetic resonance imaging (MRI) is increasingly used as the primary imaging modality in patients with LBP with or without radiculopathy. However, compared to CT scans, routine MRI sequences used for lumbar imaging may be less accurate for detecting spondylolysis, especially if no spondylolisthesis is present.[29–31] Sagittal T1-weighted images provide the greatest level of contrast between hyperintense bone marrow and the signal void of bony cortex at the pars defect[32] (Fig. 71.8).

Single-photon emission computed tomography can be used in the evaluation of suspected acute or impending spondylolysis. However, single-photon emission computed tomography has been reported to have notable false-positive and false-negative results in spondylolysis and thus should be used with caution, although it may be of particular value in cases in which MRI is contraindicated.[33]

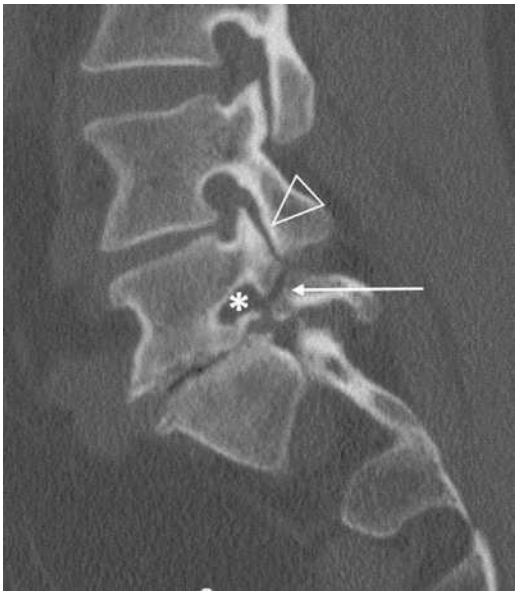

FIG. 71.7 Sagittal reformatted computed tomographic image of L5–S1 foramen. The open triangle shows the L4–L5 facet joint and the arrow highlights the pars defect. Note the difference in orientation. The asterisk shows the usual location of L5 nerve root but no further details of soft tissues within the neuroforamen.

FIG. 71.8 T1-weighted sagittal magnetic resonance image showing subtle sign of pars defect (*open arrow*). Note the difference in orientation from the L4–L5 facet joint just cranial to it.

Differential Diagnosis

The differential diagnoses for isthmic spondylolisthesis are those of its clinical presentations: LBP and sciatica. First, spinal trauma, tumors, and infections should be ruled out. Next, degenerative disc disease, spondylosis, spinal stenosis, or disc herniation should be considered. Other causes include systemic diagnoses, such as rheumatoid arthritis and spondyloarthropathies, and other nonspinal, musculoskeletal etiologies, such as sacroiliac joint arthrosis, hip arthritis, and more. Finally, abdominal/visceral considerations would include renal, gastrointestinal, and vascular disorders.

Treatment

Nonoperative Treatment

Initial treatment for patients presenting with acute LBP should be nonoperative. The mainstays are patient education, activity modification, and medications such as nonsteroidal antiinflammatory drugs. The addition of physical therapy and exercise can be considered when early treatments fail and LBP becomes more long-standing. Other alternative pain management modalities—such as chiropractic care, acupuncture, and massage—have been widely utilized, with reported improvements in pain and function. The short-term use of narcotic analgesics should be considered with caution. A minor neurologic deficit, such as radicular numbness or paresthesias, but excluding severe motor weakness, can also be managed nonoperatively but may benefit from corticosteroid injection via injection therapies, such as fluoroscopically guided selective nerve root blocks.[34]

Operative Treatment

Indications

Severe, persistent back and/or lower extremity pain that is associated with functional limitations or that significantly impacts quality of life—with or without flexion–extension instability on radiographs, progressive motor weakness, or cauda equina syndrome—are all generally accepted indications for operative intervention. Patients should complete a rigorous course of nonoperative treatment prior to considering surgery unless a significant neurologic deficit exists.

Contraindications

Contraindications for surgery outside of absolute surgical ones—such as active infection, life-threatening medical conditions, and a broad range of relative contraindications related to an increased potential for perioperative complications or poor outcomes—include morbid obesity, cigarette smoking, worker's compensation, and active litigation.

Surgery

The goals of operative intervention in isthmic spondylolisthesis are to decompress neural elements and stabilize the affected motion segment. Uncommonly, decompression alone can be performed in certain circumstances when fusion is not necessary. More typically, surgery involves stabilization traditionally performed with posterior in situ fusion techniques with or without pedicle screw instrumentation and sometimes without decompression. Supplemental anterior column support using interbody fusion techniques approached posteriorly (posterior

lumbar interbody fusion [PLIF]) or anteriorly (anterior lumbar interbody fusion) has been recently popularized and may currently represent the most popular form of surgical treatment in the United States.

Decompression

Decompression without fusion can be performed on individuals who have only radicular symptoms and stable spondylolisthesis on dynamic radiographs or a bony fusion seen on CT scans. Low-demand individuals or those with significant medical comorbidities may be reasonable candidates. Gill laminectomy entails removal of the entire posterior arch and the hypertrophied fibrocartilaginous tissue at the pars, as well as partial facetectomies to decompress the nerve root.[35,36] Long-term results of laminectomy alone have not been favorable, leading most experts to believe that addition of fusion is required in most cases to obtain good clinical outcomes.

Direct Pars Repair

Direct pars repair is a potential option in younger patients with no evidence of disc degeneration or spondylolisthesis and in whom pain is believed to arise mainly from the pars defect. Because of the high rate of clinical success with nonoperative treatment in this setting, patients should have failed a rigorous course of nonoperative treatment. The key operative principles are debridement of the defect, bone grafting, and providing adequate compression and stability of the defect for osteosynthesis. In small retrospective studies, this technique has been shown to yield good clinical outcomes in greater than 80% of patients.[37,38] Supplemental fixation is most often used; methods include translaminar screws, translaminar wires, and pedicle screw/sublaminar hook constructs.

Fusion

The primary operative intervention in isthmic spondylolisthesis is segmental fusion. While there are no definitive studies proving superior results of fusion over nonoperative care, spinal fusion at the level of the isthmic spondylolisthesis is a widely accepted treatment option. Several questions remain, however.

Is fusion better than nonoperative treatment? High-level evidence that surgery performs better than nonoperative treatments for isthmic spondylolisthesis has not been established. However, in general practice, most spinal surgeons believe that lumbar fusion is the treatment of choice for an individual with isthmic spondylolisthesis who has severe back or radicular pain, functional disability, and failed nonoperative treatments. Moller and Hedlund[26] evaluated 111 patients randomized to operative versus exercise treatment arms. They found that, at 2 years, patients who underwent posterolateral fusion had significantly better pain and functional outcomes compared to the exercise group. Laminectomy was performed in only those individuals who also complained of sciatica.[26]

Using the same cohort in a long-term study, Ekman et al.[39] reported results after a mean follow-up period of 9 years (range, 5–10 years). They used similar outcome measurements with the addition of the Oswestry Disability Index (ODI) and the Short-Form-36 to capture more disease-specific and quality-of-life data. They found no significant differences in pain and disability scores when comparing operative to nonoperative groups. However, global outcome score was significantly better in the operative group. The authors concluded that posterior lumbar fusion provided superior clinical improvement at 2 years, but at 9 years some of the measured clinical differences were lost. They did make note that no radiographic studies were done and therefore adjacent-level conditions could not be accounted for. Because global patient-reported outcomes were significantly better, spinal fusion appears to have long-lasting, positive effects in a patient with isthmic spondylolisthesis. In 2012, Turunen et al.[40] reported on a long-term, retrospective study of patients who had instrumented spinal fusion performed for degenerative spondylolisthesis, isthmic spondylolisthesis, and failed back surgery. The group with isthmic spondylolisthesis showed statistically significant improvements in pain and ODI scores as well as satisfaction scores of 70% at an average of 11 years after surgery.[40]

Surgical treatment, specifically spinal fusion, for the management of painful isthmic spondylolisthesis provides long-term benefits for pain, disability, and global quality-of-life measures. While this has not been demonstrated using a randomized, controlled clinical trial, the use of fusion has been widely supported in the literature and general practice patterns of spinal surgeons in the United States.

Indeed, fusion without decompression has been reported to yield good if not better outcomes compared to fusion with laminectomy.[41] There are two likely explanations for this finding. First, Gill laminectomy reduces the bone available to participate in the biologic fusion process. The remaining L5 transverse process and sacral ala can be small and act as poor hosts for robust fusion. Additionally, use of instrumentation and an interbody device may further bolster construct rigidity and the fusion process. Second, fusion eliminates repetitive flexion and extension motions at the pars defect and reduces nerve root trauma, which may be sufficient for back and lower extremity pain relief in most patients.

Is there a benefit to use of pedicle screw instrumentation? Several authors have reported on the use of pedicle screw instrumentation supplementing in situ fusion for treatment of isthmic spondylolisthesis and have found no clinical advantages associated with their use.[42,43] Previous papers on the use of pedicle screws in spinal fusions (not necessarily for isthmic spondylolisthesis) have shown no significant clinical advantage with their use.[44,45]

Another claimed benefit of pedicle screw use is lower pseudarthrosis rates, specifically for fusion in isthmic spondylolisthesis. Deguchi et al.[46] reported a retrospective series of 83 consecutive patients with isthmic spondylolisthesis treated with a Gill laminectomy and posterior fusion; 69 received pedicle screw instrumentation. They showed no difference in fusion rates for one-level fusion with or without instrumentation. However, in fusions that were more than one level, rigid posterior instrumentation did lead to higher fusion rates. The series is small and retrospective and likely underpowered to

detect a difference between the two groups. Jacobs et al.[47] in 2006 reported a systematic literature review on best fusion techniques for isthmic spondylolisthesis. Their conclusion, using pooled data analysis, was that any potential advantage of using pedicle screws was not shown and, in two studies, worse fusion rates were reported. While it appears that use of instrumentation in posterior spinal fusion is commonly used in surgical practice, there is little to no definitive evidence that technical or clinical outcomes are necessarily improved with their use.

The use of pedicle screw instrumentation may be relevant due to the demanding fusion environment at L5–S1. Anatomically, the sacral ala is small, as is often the L5 transverse process, and the posterolateral gutter, especially with a spondylolisthesis, is also not a uniform fusion bed. Additionally, following a Gill laminectomy, the vertebral segment is unstable. This can lead to early motion, which challenges the fusion process and can be painful for the patient. Last, rigid internal fixation may lead to better and earlier postoperative pain reduction, resulting in shorter hospital stay and length of disability.

Does the use of interbody fusion result in better outcomes? Anterior column support can be approached posteriorly using transforaminal or posterior lumbar interbody fusion (T/PLIF), lateral lumbar interbody fusion (LLIF), or anterior lumbar interbody fusion techniques. In the review by Jacobs et al.,[47] they found that there was no data to support the superiority of interbody fusion over posterior lumbar fusion (PLF). Although fusion rates were high, 80% to 95% based on their analysis, they could not designate a distinctly superior technique for treatment of isthmic spondylolisthesis. Ye et al.[48] performed a meta-analysis of five studies on the operative treatment of isthmic spondylolisthesis using PLF versus PLIF. There was a total of 389 participants, 188 adults treated with PLF and 201 treated with PLIF. They found that there were no significant differences in pain relief, functional improvement, or infection rate. While fusion rates are significantly higher, it appears that anterior column support using posterior approaches does not yield better clinical outcomes.

Kwon et al.[49] analyzed the literature on surgical approaches for isthmic spondylolisthesis. While the reports and patients reported on varied, the patients were pooled and chi-square analysis was performed to determine the relationship between surgical approach and patient outcome. They found that combined (anteroposterior) approaches versus posterior-only procedures had significantly higher fusion rates and better clinical outcomes. Other notable findings were that use of pedicle screws led to better fusion rates and clinical outcomes, while laminectomy did not influence outcomes. Swan et al.[50] compared clinical outcomes in 92 patients who underwent posterior-alone versus anteroposterior fusion. They measured pain relief, improvement in ODI scores, medication use, and work status. Patients in the combined fusion group had significantly better clinical outcomes at all follow-up intervals except at 2 years, when the difference was not statistically significant. Additionally, fusion rate was higher in the combined group, which had only one nonunion, while the PLF group had three.

There appears to be debate in the literature regarding the ideal operative procedure for the treatment of isthmic spondylolisthesis. A critical goal in treatment of isthmic spondylolisthesis, particularly at L5–S1, is to achieve fusion; the literature supports anteroposterior fusion techniques in the treatment of isthmic spondylolisthesis. The use of an interbody device in the anterior column provides a second, much larger fusion bed compared to posterolateral gutter as well as early postoperative stability, which theoretically should increase short- and long-term segmental rigidity and fusion rates. An interbody device can increase foraminal dimensions and arrest the repeated flexion and extension movements on the nerve root, which should reduce radicular pain. Additionally, because 40% of lumbar lordosis occurs at L5–S1 and 67% occurs at L4–S1, the restoration or maintenance of lumbar lordosis is critical to avoid sagittal plane deformities and the need for future complex surgical reconstruction. This cannot be more emphatically stated, particularly in a group known to have high pelvic incidence and sacral slope.

Reduction of High-Grade Spondylolisthesis

Reduction of high-grade spondylolisthesis has been performed for improved sagittal balance and cosmesis. However, its routine use does not lead to significant improvements in clinical outcomes, may increase the risk of nerve injury, and is not recommended.[51] Clinical outcomes should take priority over radiographic ones and it appears that reduction of high-grade spondylolisthesis compromises clinical outcomes for improved radiographic ones.

PEARLS

1. Isthmic spondylolisthesis is prevalent in approximately 5% to 6% of adults in the United States.
2. Individuals with isthmic spondylolisthesis are rarely symptomatic, but those who do develop severe back pain, radiculopathy, or both can be effectively treated without surgery.
3. Significant evidence exists that isthmic spondylolisthesis develops in adolescence as a result of an extension stress injury. The spondylolisthesis develops as the soft tissues around the vertebral motion segment become incompetent.
4. Isthmic spondylolisthesis in symptomatic individuals who fail nonoperative treatment is commonly treated with a spinal fusion.
5. The ideal treatment technique has not been agreed upon and often involves use of pedicle screw instrumentation and interbody techniques.

PITFALLS

1. Failure to identify spondylolysis on imaging studies is common; if high suspicion exists, further imaging should be considered.
2. Because spinal fusion is the mainstay of treatment, individuals with high risk of nonunion should be approached with caution.
3. Decompression alone should be reserved in individuals who are low demand and poor operative candidates.
4. Nerve root involvement occurs at the level of the foramen and should correlate with clinical symptoms at presentation.
5. Reduction of high-grade slips can increase risk of nerve injuries.

KEY POINTS

1. Spondylolysis is a common radiographic finding that likely arises from a physiologic stress on the pars and occurs sometime during adolescence.
2. When symptomatic, isthmic spondylolisthesis can be managed nonoperatively in many cases, as most cases of low back pain are treated.
3. While spinal fusion is the most common treatment option, the literature is not clear on whether surgery is superior to nonoperative care. Moreover, which surgical techniques lead to the best clinical outcomes are not yet established.

CHAPTER 72

Adult Scoliosis

SECTION X

David Nelles
Kamran Majid

Introduction

It has been estimated that adult scoliosis may be present in anywhere from 1.4% to 68% of adults, based on a variety of studies using various definitions of scoliosis and various methods of studying the population.[1–6] In our aging population, the clinical, financial, and societal impact of this condition cannot be underestimated. Clinically, patients with this condition can range from asymptomatic to severely debilitated. A recent study calculated an average cost of $72,034 for adult scoliosis surgery.[7] In a separate study, patients were found to have improved health-related quality of life (HRQOL) measures with surgery compared with no such improvement in patients treated nonsurgically.[8] These studies highlight the importance of a thorough understanding of this disease state, including the natural history, treatment options, surgical considerations, and potential complications and pitfalls encountered when treating these patients.

Adolescent scoliosis can result in radiographic images not dissimilar to those in adult scoliosis patients, with similar coronal spinal profiles. However, there are many important differences between these two disease processes, and only fairly recently has this understanding begun to be thoroughly addressed in the literature. Differences include symptoms, progression, treatment options, and outcomes. In adolescent scoliosis, patients are typically asymptomatic or have very mild symptoms. Treatment goals emphasize stopping progression of the deformity to prevent further deterioration and symptoms while maintaining as much motion and function as possible. In contradistinction, adult scoliosis patients often present to the physician due to significant spine-related symptoms, including functional deficits, back pain, severe radicular symptoms, and symptoms related to stenosis. Treatment goals emphasize alleviating these symptoms in a manner that is as conservative as possible while still decreasing the likelihood of recurrent or new issues.

Adult scoliosis can be very broadly divided into two groups: adult idiopathic scoliosis, resulting as the natural progression of preexisting adolescent idiopathic scoliosis, and adult degenerative scoliosis, arising de novo from a relatively straight spine as a result of degenerative processes. Degenerative curves tend to be of a lower magnitude than idiopathic ones; lumbar curves predominate in this population.[9]

Terminology

Adult scoliosis can create a deformity that exists in three dimensions, as well as rotational abnormality. Patients with severe deformities can be relatively pain free, and some with comparatively smaller deformities can have debilitating pain and functional limitations. Add to this varying degrees of inflexibility of the deformity and countless other patient factors, and adult scoliosis is by definition a very complex issue. As expected, it comes with a correspondingly large and steadily increasing vocabulary of descriptive terms to help define and quantify it. Table 72.1 provides a cursory glossary of terms used in the treatment of scoliosis.

Current Understanding of Spinal Alignment

The concept of the "cone of economy" was popularized by Jean Dubousset in the 1990s (Fig. 72.1). The cone of economy basically describes the concept of centering our pelvis, torso, and head above our feet and knees. If an individual is able to optimize balance and posture and maintain the majority of the body weight over the feet, or very near to it, the individual is able to maintain this position with minimal effort. However, as deformity causes a person to deviate outside of this energetically economical zone, significantly more energy is required to maintain a standing posture. A supportive device, such as a cane or walker, may be required, and eventually pain and disability may result.[10] This model of alignment emphasizes the underlying importance of the ability to maintain an upright posture and has formed the basis for our current thoughts on spinal alignment.

Scoliosis has classically been defined by deformity in the coronal plane, but it is in reality a three-dimensional deformity that can result in curves in the coronal plane, lordotic or kyphotic (or both) sagittal imbalance, and rotational issues.

TABLE 72.1 Glossary of Descriptive Terms for Adult Spinal Deformity

Term	Definition
Scoliosis	Lateral curvature of the spine on coronal imaging
Kyphosis	Posterior or convex angulation of the spine on lateral view with the patient facing rightward. The terms hyperkyphosis and hypokyphosis refer to conditions in which the kyphosis is greater or less than the normal range, respectively.
Lordosis	Anterior convex angulation of the spine on lateral view with the patient facing rightward. The terms hyperlordosis and hypolordosis refer to conditions in which the lordosis is greater or less than the normal range, respectively.
Kyphoscoliosis	Scoliosis accompanied by a true hyperkyphosis
Lordoscoliosis	Scoliosis accompanied by a true hyperlordosis
Major curve	Curve with the largest Cobb angle measurement on upright long cassette radiograph of the spine
Minor curve	Any curve that does not have the largest Cobb angle measurement on upright long cassette radiograph of the spine
Structural curve	Measured spinal curve in the coronal plane in which the Cobb measurement fails to correct on supine maximal voluntary lateral side-bending radiograph
Compensatory curve	Minor curve above or below a major curve that may or may not be structural
End vertebrae	Vertebrae that define the ends of a curve in a coronal or sagittal projection. The cephalad end vertebra is the first vertebra in the cephalad direction from a curve apex whose superior surface is tilted maximally toward the concavity of the curve. The caudal end vertebra is the first vertebra in the caudal direction from a curve apex whose inferior surface is tilted maximally toward the concavity of the curve.
Neutral vertebra	Vertebra without axial rotation in reference to the most cephalad and caudal vertebrae that are not rotated in a curve
Apical vertebra	In a curve, the vertebra most deviated laterally from the vertical axis that passes through the patient's sacrum (CSVL)
Apical disc	In a curve, the disc most deviated laterally from the vertical axis of the patient that passes through the sacrum (CSVL)
Stable vertebra	Thoracic or lumbar vertebra cephalad to scoliosis that is most closely bisected by a vertically directed CSVL, assuming the pelvis is level. Alternatively, both pedicles of this vertebra should lie between vertical reference lines drawn from the sacroiliac joints.
CSVL	Vertical line in a coronal radiograph that passes through the center of the sacrum.
C7 plumb line	Vertical line drawn starting from the center of the C7 vertebral body and dropped straight downward. If drawn on a coronal view, the horizontal distance from this line to the central sacral line is a measure of the Cobb angle (coronal "balance"), with rightward and leftward deviations designated as positive and negative values, respectively. If drawn on a sagittal view, the horizontal distance from this line to the posterosuperior corner of S1 reflects a measure of the sagittal alignment (SVA), with positive values assigned for C7 plumb lines anterior to the sacrum and negative values assigned for C7 plumb lines that fall behind the sacrum.

CSVL, central sacral vertical line; SVA, sagittal vertical alignment.
From Smith J, Shaffrey C, Kai-Ming G, et al. Clinical and radiographic evaluation of the adult spinal deformity patient. *Neurosurg Clin North Am*. 2013;24:143–156.

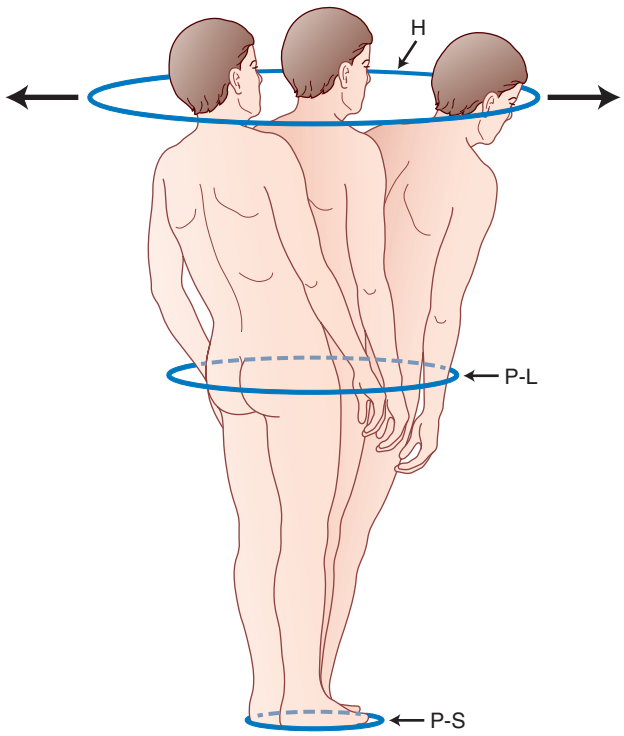

FIG. 72.1 Cone of economy.

Coronal deformities are typically described using the Cobb method. Earlier classification systems (King-Moe) and treatment methods (Harrington-style nonsegmental fixation) focused on the coronal plane, sometimes to the detriment of the other facets of the disorder. However, steady progress has been made in understanding complex deformities and in our ability to simultaneously address deformity in multiple planes using segmental instrumentation.

In recent years, the focus of spinal alignment has shifted toward the pelvis. Thanks in large part to the works of the International Spine Study Group (ISSG), a large multicenter group pooling dedicated resources with the goal of furthering knowledge of adult spinal deformity (ASD), as well as other groups and individuals,[11–19] we are now beginning to understand the complex interaction between sagittal spinal deformity and pelvic morphology/alignment. A brief description follows of each of the various pelvic and spinopelvic parameters that are currently being used or are being studied as useful measurements in ASD. In the following descriptions, assume a lateral radiograph in which the femoral heads are perfectly superimposed (Figs. 72.2 and 72.3 and Table 72.2)

- **Pelvic incidence (PI)[11]:** This parameter describes the angle between a line perpendicular to the sacral endplate and a line from the center of the femoral heads to the center of

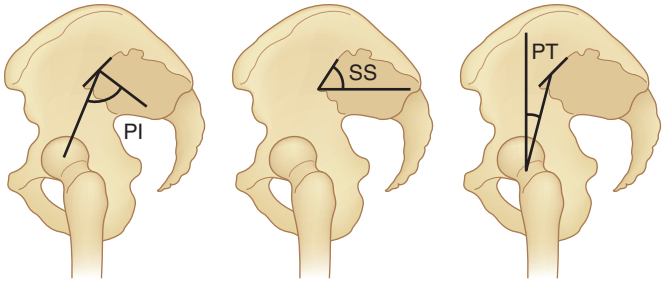

FIG. 72.2 Angles of pelvic incidence (PI), sacral slope (SS), and pelvic tilt (PT).

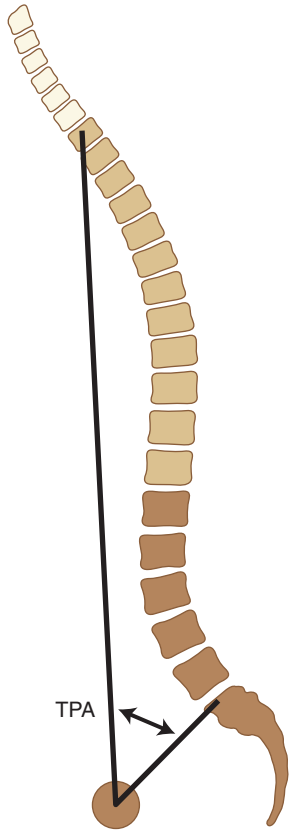

FIG. 72.3 T2 pelvic angle (TPA), a novel radiographic parameter that accounts for both global malalignment and compensation through pelvic retroversion. TPA is defined as the angle between the line from the femoral head axis to the centroid of T1 and the line from the femoral head axis to the middle of the S1 endplate. (From Ryan D, et al. T1 pelvic angle [TPA] effectively evaluates sagittal deformity and assesses radiographical surgical outcomes longitudinally. *Spine*. 2014;39[15]:1203-1210.)

the sacral endplate. This is an individual morphologic characteristic and does not change. It is related intimately with lumbar lordosis, as will be described in the following text. Normal values are considered from 50 to 55, although this can vary substantially.

- **Pelvic tilt (PT)[20]:** This parameter describes the angle between a vertical line through the center of the femoral heads and a line from the center of the femoral heads to the center of the sacral endplate. This angle can be physiologically altered via pelvic retroversion/translation. This can be seen as a compensatory mechanism, as described in the following text.
- **Sacral slope (SS)[20]**: This parameter describes the angle between the horizontal and the sacral endplate. It indicates the sacral inclination. Importantly, these three parameters have a relationship such that **PI = PT + SS.** As PI is a static morphologic parameter, this relationship ensures that changing one SS or PT will affect the other parameter accordingly.
- **Sagittal vertical axis (SVA)**: This parameter is commonly referred to as global sagittal alignment. A line is drawn straight down from the center of the C7 body on a full-length standing lateral radiograph. The SVA is the distance between this line and the posterior superior aspect of the sacral endplate. A positive number indicates that the C7 plumb line is anterior to the sacrum. Normal is considered less than 5 cm.
- **T1/T9 spinopelvic inclination (SPI):** This parameter describes the angle between a line drawn from the center of the femoral heads to the center of the T1/T9 body and a plumb line drawn from the center of the body.
- **T1 pelvic angle (TPA)[21]:** This parameter describes the angle between a line drawn from the center of the T1 body to the center of the femoral heads and the line from the center of the femoral heads and the midpoint of the sacral endplate. Both the TPA and T1 SPI are true spinopelvic parameters that describe the relationship between the spine and the pelvis.

The SVA is the simplest and most primitive means of describing the sagittal alignment. It is referred to as the global sagittal alignment because it gives a broad illustration of the sum of lordosis and kyphosis of the thoracolumbar spine. However, it fails to take into account pelvic parameters and any compensatory mechanisms at work.

Pelvic inclination is a discrete morphologic parameter that changes minimally with aging.[22] Described in Legaye's works, it has formed the basis for other pelvic and spinopelvic measurements. In the work by Boulay,[23] it was linked with the degree of lumbar lordosis, which makes anatomic sense. Assuming minimal to no movement through the SI joints, a large PI indicates a more vertical sacrum, which would require more lumbar lordosis to maintain balance for a given amount of thoracic kyphosis. Conversely, a smaller PI means a horizontal sacrum and a smaller lordosis to balance a given amount of thoracic kyphosis (TK). Schwab et al.[24] investigated this relationship and established the formula for lumbar lordosis (LL) = PI + 9 degrees (±9 degrees) or, put more simply, LL should be within about 10 degrees of PI.

PT is a parameter that changes with time, body position, and shape of the spine.[22] An individual can attempt to alter pelvic tilt by retroverting the pelvis and rotating about the hip joint. This can be done in an attempt to maintain an upright posture in the face of improper spinal balance. This parameter is one of the main reasons that simply looking at SVA to gauge sagittal alignment can be misleading. Depending on the range of motion (ROM) of the hip joints and the flexibility of the soft tissues around the hips, extending through the hips and increasing pelvic tilt can be used to compensate for a net positive balance. This can become important as we get older, and degenerative disc disease leads to a loss of LL.[25] Other factors that occur as

we age, such as hip arthritis and soft tissue contracture, can limit an individual's ability to use PT to compensate.

Sacral slope is a parameter that refers to how horizontal the sacral endplate is. It coexists with the two parameters discussed earlier in a geometric relationship such that PT + SS = PI. Accordingly, when an individual increases pelvic tilt, the sacral slope is decreased, and the sacral endplate gets closer to the horizontal.

TPA is a parameter that was more recently described by LaFage et al.[21] This measurement was developed in an attempt to establish a single parameter that could take into account spinal alignment and pelvic compensatory mechanisms (PT). It describes the angle between a line drawn from the sacral endplate to the femoral head axis and a line from the T1 pelvic body to the femoral head axis. This single measure combines the SVA and PT information. Further advantages include the lack of needing to calibrate imaging due to being an angular measure (and thus standardized across all magnifications) and the ability to be measured intraoperatively using fluoroscopic images. In their study describing this parameter, the ISSG compared using TPA to classify the degree of deformity with the Scoliosis Research Society (SRS)-Schwab Classification system (to be described shortly), and found that TPA was very often similar, and at times better, than the SRS-Schwab system. They proposed a target TPA of 10 degrees, thus allowing for some degree of error or loss of correction before reaching the severe deformity threshold of 20 degrees.

Similarly, T1/T9 SPI includes information from both SVA and PT, thus taking into account pelvic compensatory mechanisms.

Spinopelvic Parameters and Health-Related Quality of Life Measures

When faced with a complex ASD case—in patients with deformity in multiple planes, multiple comorbidities, and multiple complaints—a surgeon is faced with a difficult set of decisions: which areas are the most important and which are the least important? Should all deformity be corrected and how much? Several authors have investigated this area and attempted to correlate the various radiographic parameters with the degree of pain and disability experienced by the patient in an effort to help guide decision making.

Coronal plane deformities are often the most striking and obvious patient deformities on physical examination and on radiographic imaging. Despite this, numerous studies have found no link between the degree of coronal deformity and patient-reported pain or disability.[26–29] Of note, one of the Glassman studies[27] did find that patients who had not been treated surgically with greater than 4 cm of coronal imbalance were at risk for deteriorating pain and function scores, but this correlation was not found in surgically treated patients. They concluded that it was unlikely that improved coronal correction would result in improved clinical outcomes.

Multiple studies have shown the link between SVA and patient-reported pain and disability scales. Lafage et al.[15] quantified pain and disability in 125 adult patients with deformity using the Oswestry Disability Index (ODI), 12-Item Short Form Health Survey (SF-12), and SRS 23 Patient Questionnaire (SRS-23), and then compared their scores over a variety of spinopelvic parameters. They found strong correlations between SVA and SRS-23 scores and the ODI "standing disability" score. Glassman et al.[26] also described a statistical correlation between SVA and pain/disability measures, albeit a weaker correlation. Lafage attributed this difference in strength to the fact that SVA is a measurement requiring calibration of magnification of radiographs, which is difficult to take into account in multicenter studies such as the Glassman one.

In a pilot study,[30] and again in a follow-up study,[31] Schwab et al. established a correlation between self-reported pain and disability and several radiographic measures. Spondylolisthesis, endplate obliquity, and loss of LL were all correlated with worse patient-reported outcomes.

The Lafage study[15] investigated many of the spinopelvic parameters. They found a strong correlation between LL and the walking and standing portions of the ODI, as well as the bodily pain and Physical Composite Scale (PCS) of the SF-12. Other regional sagittal profiles (thoracolumbar, thoracic) were studied, but no such correlation was noted. The strongest correlations between patient-reported disability and radiographic parameters was with the T1-SPI. This measure correlated strongly with SF-12 PCS, SRS total score, SRS activity score, and the ODI standing disability score.

This study also took a rigorous look at PT as it relates to patient-reported outcomes. They reported that this has the second strongest correlation with disability, particularly with walking disability. The investigators concluded that this illustrates the inadequacy of PT as a compensatory mechanism. Patients with a high PT, who were retroverting their pelvis and extending their hips to make up for a positive sagittal balance, were not walking well, including the subgroup that was able to completely compensate (high PT, but normal SVA). At some point, these compensatory mechanisms become a detriment in their own right, and walking with fully extended hips and bent knees may not be efficient or well tolerated. They emphasized the importance of assessing pelvic parameters as well as spinal ones, as this group had significant disability despite an SVA within norms. They also noted a subgroup in this population that had a high SVA but normal PT, thus were not compensating for poor sagittal balance at all. They recommend a careful assessment of hip and knee motion in this subgroup.

In a study of patients treated with lumbosacral fusions, Lazennec et al.[29] also found a correlation between PT and pain postoperatively.

In 2013, the ISSG published a study in which they prospectively enrolled 492 consecutive adult deformity patients.[32] Multiple radiographic parameters were measured, and correlations between these and the ODI, SF-36, and SRS-22 forms were investigated. They determined that the strongest correlations with patient-reported disability were the PT, SVA, and PI-LL mismatch (this parameter having the strongest correlation). They noted a strong correlation between PT and PI-LL mismatch, highlighting the roll that PT plays as a compensatory mechanism for sagittal spinal malalignment, as illustrated by the PI-LL mismatch. They then conducted linear regression analysis for these three parameters to establish equations for predicting ODI scores based on these radiographic measurements. Based on an ODI greater than 40 indicating severe disability, they used these equations to predict severe disability from radiographs. They determined that PT greater than 21, SVA greater than 46 mm, and PI-LL greater than 10 would correlate with severe disability.

Ideal Values for Spinopelvic Parameters

A variety of studies have investigated spinopelvic alignment parameters and anatomic considerations in asymptomatic adults. These investigations have helped us to establish a range of normative values in the "normal" adult population (see Table 72.2). Using these values and an extensive review of the literature to determine the correlations between alignment parameters and HRQOL outcomes, Schwab et al.[32] attempted to establish a set of "target" values for several of these parameters. These are values that a surgeon should hope to obtain postoperatively in order to maximize HRQOL values for the patient.

An SVA less than 50 mm has been identified as a cutoff value for this parameter. Similarly, a T1-SPI of less than 0 degrees is also desirable. Both of these numbers indicate an anatomic position where the patient's C7 plumb line is behind or directly above the femoral heads. This position can help to maximize efficiency of movement for the patient, help to level the gaze, and avoid the common subjective complaint of "falling forward."

PT should be less than 20 degrees. It is important to recognize that this is not an anatomic parameter that can be adjusted surgically. PT represents the individual's response to an existing degree of spinal malalignment. The extent of pelvic retroversion exhibited by the patient should be carefully considered *preoperatively*. A large amount of PT likely indicates an attempt at compensating for a positive sagittal balance, *even in the context of a normal, or near normal, SVA*. If sagittal balance is considered without taking into account PT, this can easily result in surgical undercorrection and continued pain and disability for the patient. PT has been shown to normalize following normalization of the sagittal spinal profile.[33]

Finally, PI-LL should be less than 10. As mentioned earlier, a value greater than 10 can be considered a "spinopelvic mismatch," in which the amount of LL has not been appropriately matched to the individual patient's spinopelvic anatomy.

Classification Systems for Adult Spinal Deformity

As has been stated previously, ASD is a quite complex entity, and our understanding of it is constantly changing and growing. Several attempts have been made at classifying spinal deformity (although most have focused on pediatric deformity, until recently). Classification systems should ideally meet several requirements in order to be clinically useful. They should (1) identify different severities of disease state, (2) facilitate communication between health care providers in order to ensure accuracy and reproducibility in describing the disease state, (3) allow comparison of different treatment methods, and (4) call for creation of accurate treatment recommendations.[34]

The Terminology Committee of the SRS introduced the earliest classification for scoliosis in 1969. It was an entirely nominal classification system, describing the cause of the spinal deformity. Although this was easily reproducible and did give some clinical information regarding the patient's disease state and associated illness, it failed to describe any radiologic parameters or specific symptomatology.

The King-Moe classification was introduced as a guideline for the treatment of thoracic curves in adolescents.[35] It was useful for establishing fusion levels in these patients, but it was not intended for use in patients with complex adult deformities. Similarly, the Lenke Classification system[36] was presented as a means of predicting appropriate arthrodesis levels in

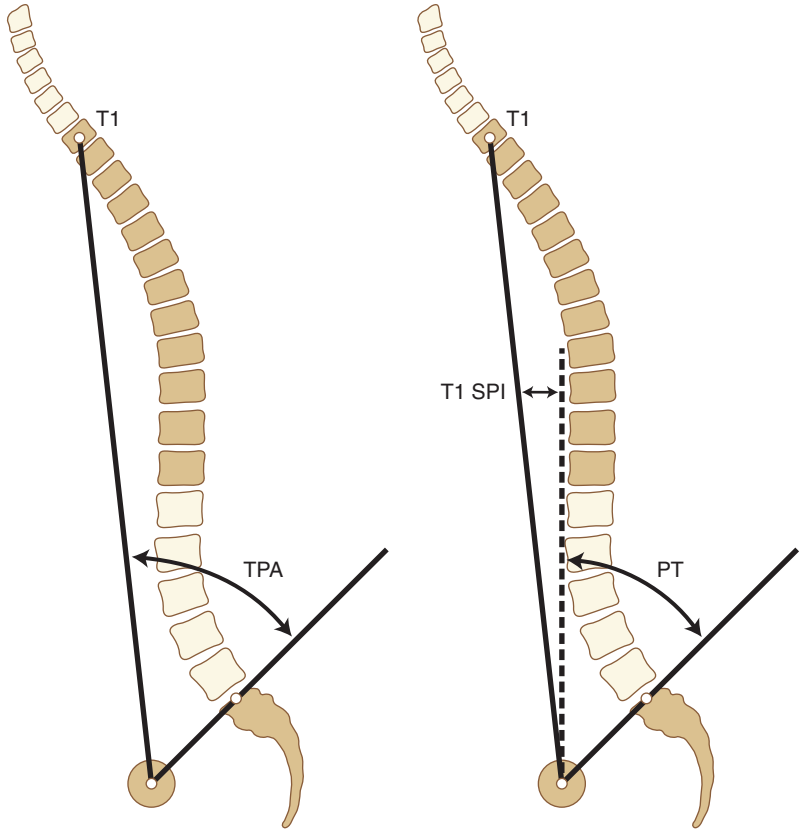

FIG. 72.4 T1 and T9 spinopelvic inclination (SPI). PT, pelvic tilt; TPA, T2 pelvic angle.

patients with adolescent idiopathic scoliosis. This was a far more comprehensive and descriptive system than was previously available and was met with great success in its use in the target population. However, attempts to apply the Lenke system to adult deformity were a mistake in several ways. Most importantly, the fundamental differences in treatment goals between the two disease entities made a combined classification system difficult, if not impossible. Adolescent idiopathic scoliosis is primarily treated to prevent *future* disability, while pain and disability are the primary complaints in adult deformity (with, as has been discussed, sagittal imbalance being the primary driving force of pain).

In 2006, Schwab et al. introduced a clinically oriented classification system based on existing studies linking certain spinal alignment parameters (though not pelvic parameters at this point) with HRQOL data.[28] They described five types of scoliosis based on the apex of the curve in the coronal plane: type I thoracic only, type II upper thoracic major (apex T4–T8), type III lower thoracic major (apex T9–T10), type IV thoracolumbar major (apex T11–L1), and type V lumbar major (apex L2–L4). They then added two modifiers to the classification, LL and intervertebral subluxation. Both of these radiographic findings were linked with poor HRQOLscores. Shortly after its introduction, a third modifier was added, the global balance modifier. This was added in response to new data indicating that SVA was a strong predictor of HRQOL.

This Schwab Clinical Impact Classification system was comprehensive and fairly reproducible. In addition, it was an evidence-based system that focused on parameters shown to correlate with poor patient-reported outcomes. However, in the years following its introduction, multiple studies began to show the importance of pelvic alignment parameters in spinal disorders and linking these parameters with poor HRQOL scores.[11,14–17,19]

In response to the relatively recent findings showing the pivotal role that the pelvis plays in ASD, the Schwab classification was updated and combined with works done through the SRS to become the SRS–Schwab Adult Spinal Deformity Classification[37] (Fig. 72.4 and Box 72.1). This system continues in the path of the Schwab Clinical Impact system in that it focuses on parameters that have been shown in the literature to correlate the most poor patient-reported outcomes and now includes the pelvic parameters that appear to be intimately related with pain and disability related to spinal deformity.

In the SRS–Schwab Adult Spinal Deformity Classification system, coronal deformity is divided into four groups: (1) T, thoracic only (lumbar curve <30 degrees), (2) L, TL/lumbar only (thoracic curve <30 degrees), (3) D, double curve (both curves >30 degrees), and (4) N, no major coronal deformity (all curves <30 degrees). The simplified coronal scheme reflects the mounting evidence that coronal malalignment is not related to pain or disability in ASD.

Similar to the Schwab Clinical Impact system, the sagittal modifiers were based on evidence indicating which parameters had the strongest correlation with poor HRQOL scores. All three of the modifiers are divided into three subgroups such that a score of 0 indicates a normal parameter, + indicates moderate

BOX 72.1 SRS-Schwab Classification System

Coronal Curve Types

Thoracic (T): Lumbar curve <30 degrees
Thoracolumbar/Lumbar (L): Thoracic curve <30 degrees
Double Curve (D): T and TL/L curves >30 degrees
No Major Coronal Deformity (N): All coronal curves <30 degrees

Sagittal Modifiers

PI – LL

0: <10 degrees
+: moderate 10–20 degrees
++: marked >20 degrees

Global Alignment

0: SVA <4 cm
+: SVA 4–9.5 cm
++: SVA >9.5 cm

Pelvic Tilt

0: PT <20 degrees
+: PT 20–30 degrees
++: PT >30 degrees

LL, lumbar lordosis; PI, pelvic incidence; PT, pelvic tilt; SVA, sagittal vertical alignment.

deformity, and ++ indicates a severe deformity likely associated with poor HRQOL scores. The first modifier is PI – LL: 0 is within 10 degrees, + (moderate) is from 10 to 20 degrees, and ++ (marked) is greater than 20 degrees. The second modifier is global alignment: 0 indicates an SVA less than 4 cm, + is an SVA from 4 to 9.5 cm, and ++ is an SVA greater than 9.5 cm. The third modifier is PT: 0 is a PT less than 20 degrees, + is a PT of 20 to 30 degrees, and ++ is a PT greater than 30 degrees.

The investigators' initial validation study indicated good to excellent intrarater and interrater reliability, showing that its use as a classification system is reproducible among and between users and should thus facilitate ease of communication.[37] Another independent group investigated the reliability and ease of use of this system, reporting excellent intraobserver reliability and substantial interobserver reliability, with most disagreements occurring while differentiating between thoracic and thoracolumbar curves in the coronal plane.[38] They concluded that the system was comprehensive, user friendly, and had sufficient reliability. Investigators have since used the system to prospectively analyze a group of ASD patients, who were then treated operatively or nonoperatively at the surgeon's discretion. The operatively treated group had worse HRQOL and worse sagittal modifier scores in all categories than those treated nonoperatively.[39] In addition, it has been shown that, following surgical correction of ASD, changes in SRS-Schwab sagittal modifier scores accurately predicted changes in HRQOL scores.[40]

Clinical Presentation of Adult Spinal Deformity Patients

The first step in evaluating a complex disease process such as ASD in typically complex older patients with significant comorbidities is a thorough history and physical examination. Presenting complaints from ASD patients can range from incidentally noted deformity or mild back pain to severe pain or near-total disability associated with their spinal deformity. It is important to establish early on the reason that the patient has sought medical treatment and the patient's future goals pertaining to health care. Having a clear discussion with the patient regarding these issues can avoid potential miscommunications that could damage the physician–patient relationship.

As has been demonstrated in several studies, pain and disability are both common reasons for a patient with ASD to present to a surgeon.[41–43] Both leg pain and back pain are common in this patient population. Smith et al. looked at a series of patients evaluated at a surgical clinic and found that 99% complained of back pain, 85% complained of some radicular pain, and 10% had complaints that were neurologic in nature. As there is significant overlap, it is important to attempt to quantify the amount that each of these complaints contributes to overall patient disability. Any aggravating or ameliorating factors should be investigated as well, as these could help guide treatment. Any history of subjective weakness, altered sensation, or other neurologic deficits should be carefully explored. Bowel or bladder dysfunction or claudicatory symptoms could indicate lumbar stenosis, and any upper extremity complaints or gait disturbances should elicit an assessment of the neck for cervical stenosis. Other complaints may include cosmetic ones, feeling of "falling over," or difficulty in maintaining eye contact due to an overall kyphotic alignment.

A history of past treatments—including but not limited to prior surgeries, medications, physical therapy, steroid injections, and activity modifications—should be obtained. It is not uncommon for ASD patients to present to a surgeon's office with a prior history of back surgeries, either to address the deformity or for other spine issues.[44] The purpose, extent, and clinical results of these surgeries should be discussed. In addition, an effort should be made to obtain old operative notes and office notes in order to fully understand both technical details of the surgery and the decision-making process involved.

Clinical Evaluation

The clinical evaluation of an ASD patient should begin with careful visual observation.[45] Patients should be observed in the supine, sitting, and standing positions. They should be observed during their normal gait to reveal any gait disturbances. Visual assessment of the patient's back in standing and bending positions may reveal spinal deformity, waist asymmetry, or rib humps, but smaller curves may not be easily appreciable. Clavicle or shoulder asymmetry can help provide clues to the nature of the deformity.

Careful ROM examinations should be done of the knees, hips, and spine. Chronic spine deformity may lead to a crouched knee gait, which can eventually lead to hip or knee flexion contractures. Upon evaluation of the patient in the standing position, the patient should be instructed to fully extend the knees. This can help assess knee ROM and reveal the true extent of the patient's sagittal imbalance, which had been obscured by the crouched posture. The patient should also be assessed for any real or perceived limb-length inequality.

The true incidence and severity of comorbidities in the ASD population is not known. It is likely highly variable, but the older patient population frequently associated with some types of adult deformity (e.g., degenerative deformity) often has a concomitant increase in number of comorbidities. Fu et al.[46] examined a large multicenter database of 22,857 ASD cases and stratified them by American Society of Anesthesiologists (ASA) classification. They found that the rate of perioperative complications increased with ASA grade from 1 to 5. This study highlights the importance of careful perioperative management to understand the risks associated with surgery and minimize them as much as possible.

Some basic preoperative laboratory work should be done to assess for and address any overt metabolic or hematologic abnormalities. Laboratory work should include an assessment of patient nutrition. Adogwa et al.[47] reviewed 136 cases of patients undergoing spine fusion (including deformity and nondeformity, elective and nonelective cases). They found that, in elective cases, preoperative hypoalbuminemia (serum albumin <3.5 g/dL) was a significant risk factor for postoperative complication. Close attention should be paid to the patient's nutritional status perioperatively to maximize outcomes.

Some controversy exists regarding appropriate blood loss management. ASD surgeries are frequently large surgeries with considerable blood loss and often require blood transfusion.[48] A recent study retrospectively reviewed a large multicenter database of patients who had undergone deformity surgery and divided them into two groups based on whether or not they had donated blood preoperatively. They found that preoperative donation was not protective against allogeneic transfusion, was associated with a higher overall transfusion rate, and often went unused. They concluded that, at this time, preoperative donation was not supported in the literature. Red blood cell salvage methods (e.g., Cell Saver) are increasingly popular blood loss management techniques. Similar to preoperative donation, these devices are designed to use the patient's own blood in order to obviate the need for allogeneic transfusion. There are currently conflicting studies in the literature regarding how effective it is for that purpose.

There is a current trend toward using antifibrinolytic therapy in adult deformity spine surgery. Agents such as tranexamic acid and epsilon-aminocaproic acid are lysine analogs that act by inhibiting the formation of plasmin by plasminogen, thereby blocking the fibrinolytic pathway.[49] They have well-accepted use, specifically in the joint replacement literature, indicating a lower blood loss as well as lower transfusion rates when used either intravenously or topically.[50] According to a recent meta-analysis[51] of the current spine literature regarding the topic, as well as a separate review of the literature,[52] the use of tranexamic acid in adult deformity surgery decreases intraoperative, postoperative, and total blood loss, as well as decreasing transfusion rates, while not increasing cardiac or thromboembolic risks. Epsilon-aminocaproic acid has had similar results, and there does not appear to be any consensus on the superiority of one agent over the other.[53]

Imaging Evaluation

The first and essential step in the radiographic evaluation of ASD patients begins with posteroanterior (PA) and lateral 36-inch radiographs. These images should be taken freestanding, with knees fully extended, elbow flexed approximately 45 degrees, with fingers on contralateral clavicles. It is important that these films extend at least as high as C7 and at least as far down as the femoral heads in order to accurately obtain measurements for all of the important parameters that were previously discussed.

The PA image should be viewed with the heart on the left side. Coronal alignment and pelvic obliquity can be measured on this image, as can curve angle. Pelvic obliquity can indicate potential limb-length discrepancy; if it is noted, lower extremity scanograms should be taken to assess for this. Any limb-length discrepancy detected should be corrected with blocks under the shorter leg until pelvic obliquity is normalized in order to get a true sense of the spinal alignment. Scoliosis curve angles should be measured using the standard Cobb method.

Lateral radiographs should be viewed with the patient facing to the right. The full-length lateral is useful for assessing both global and regional alignment parameters.[54] Regional parameters, such as LL and TK, should be documented. Global alignment in the form of the SVA should be measured. This film can also be used to measure spinopelvic parameters, such as TPA, T1-SPI, PT, sacral slope, and PI. As indicated earlier, accurate assessment of these parameters is instrumental in appropriately understanding and treating the patient's spinal deformity.

Flexibility of curves can be measured using a variety of different techniques. Side-bending PA films, traction films, and bolster films can all help improve the understanding of complex deformities. Curves that decrease to less than 25 degrees can be considered compensatory curves, not structural curves that would have to be addressed with any planned surgical procedure. In addition, comparing weight-bearing and supine films can also give information regarding flexibility.[44]

Although a considerable amount of information can be gleaned from the 36-inch PA and lateral films, advanced imaging has become standard in evaluating ASD cases. Considering the large amount of patients presenting with radicular symptoms, magnetic resonance imaging (MRI) is often utilized to evaluate individual nerve roots for compression. MRI is also useful for assessing the degree of disc degeneration and any areas of significant stenosis. Thin-slice computed tomography scans are excellent for assessing bony anatomy, including the location of any significant osteophyte formation, pedicle size, and location. Any patient with a condition precluding MRI (such as some implantable defibrillators) should have a computed tomography myelogram.

Treatment of Adult Scoliosis

When considering various options for scoliosis correction treatment, surgeons need to discuss the various pros and

cons with their patients. The variability of management when considering adult scoliosis depends on the type of pathology and the surgeon's experience and comfort levels. There is also a lack of evidence-based medicine to help decision making. Options include nonoperative management, decompression alone, local decompression and fusion, regional decompression and fusion, and global decompression and fusion. Approach options vary from anterior, anterior/posterior, lateral/posterior, and all posterior.

Nonoperative Management

Nonoperative treatment should be focused on improving quality of life by decreasing the pain and disability in patients with adult scoliosis. This may include physical therapy, epidural steroid injections, acupuncture, massage, aquatics-based programs, and chiropractic manipulation.[55–57] Analgesics, including nonsteroidal antiinflammatory drugs and nerve stabilizers (e.g., gabapentin, pregabalin), may be beneficial; however, these should be used judiciously due to their potential respective side-effect profiles. For acute exacerbations of symptoms, narcotics can be considered, but their long-term use is not routinely recommended due to short- and long-term side effects, including overdose, tolerance, and addiction. There is limited evidence to support nonoperative management with adult scoliosis patients.[58–60]

The cost of nonoperative management has been studied by Glassman et al.[61] They looked at 123 adults with scoliosis who underwent nonoperative management consisting of medications, physical therapy, exercise, injections/blocks, chiropractic care, pain management, bracing, and bed rest. After 2 years, with a mean cost of $10,815, there was no improvement of pain or disability.

Recent studies have focused on identifying the predictors of reaching a minimally clinically important difference in patients who undergo nonoperative treatment.[62] Their retrospective review of a prospective, multicenter database studied 215 nonoperative patients with a minimum of 2-year follow-up. They concluded that nonoperative patients who achieved a minimal clinically important difference in SRS Activity or Pain scores had a lower baseline SRS Pain Score and less coronal deformity in the thoracolumbar region. They proposed that patients with greater baseline pain offered more room for potential improvement. In addition, patients with coronal deformities in the thoracolumbar region with associated vertebral obliquity may not do well with nonoperative management.

Operative Management

With the advancing age of patients with adult scoliosis and our ability to handle more complex deformities, the number of surgeries on adult scoliosis patients is increasing.[63] The goals of surgery on patients with adult scoliosis include nerve decompression, deformity correction (both in the sagittal and coronal planes), and reduction of axial back pain.[64] When discussing the options with patients who present with adult scoliosis, indications for surgery would include pain that has not improved with nonoperative management, inability to do activities of daily living, worsening of their deformity, and/or nerve compression causing radicular or neurogenic symptoms.

Improvements in surgical techniques and perioperative care have expanded our ability to care for adults with significant comorbidities, including pulmonary and cardiac disease, osteoporosis, and nutritional deficiency. The unique aspect of care in adult patients with scoliosis is the frequent presence of associated medical comorbidities. The long duration of surgery, resultant blood loss, and perioperative complications that can arise are factors that need to be considered and discussed in preoperative counseling sessions. The incidence of medical comorbidities in patients with adult scoliosis has been studied. An increasing rate of complications is seen in patients with comorbidities, leading to higher levels of physical status deterioration. Fu et al.[46] reported on a multicenter, multisurgeon Scoliosis Research Society Morbidity and Mortality database of 22,857 cases, stratified by the ASA physical status classification. A progressively increasing rate of complications was found in patients with ASA grade 1 (5.4%) to grade 5 (50%). Medical comorbidities that lead to physical status deterioration have a significant impact on the complications in the perioperative period in this patient population.

Patients with a history of coronary artery disease or other significant cardiac risk factors should undergo preoperative stress testing followed by optimization of cardiac function before scoliosis surgery. Perioperative use of beta blockers in these patients has been shown to cause significant reduction in cardiac events at 30 days after the surgery and decline in the 1- and 2-year mortality rates.[65] In addition, there is a reduction in postoperative pulmonary complication rate following smoking cessation a minimum of 6 to 8 weeks prior to surgery.[66] Diabetes has been implicated in a wide variety of postoperative complications, including reoperation,[67] infection,[68,69] and recurrent disc herniation.[70] Every attempt should be made to control blood sugars preoperatively and perioperatively; consultation with a medical doctor or endocrinologist to aid in the management of this condition may be beneficial. In addition to physical health, the surgeon may consider social, financial, and psychological well-being of the patient because spinal deformity surgery and subsequent recovery will surely affect all of these areas.

Patients with concurrent scoliosis and osteoporosis represent a significant management challenge. Osteoporosis can compromise the interface between bone and instrumentation, which may lead to pedicle screw loosening and graft subsidence.[71] Patients considering surgery should be referred to a bone endocrinologist for evaluation and treatment preoperatively to optimize their bone quality. In general, medical management can include bisphosphonates, nonbisphosphonate antiresorptive agents, and parathyroid hormone analogs. For patients who elect surgery, several important principles should be followed, including the use of multiple sites of fixation; meticulous preparation of endplates for interbody graft placement, making sure not to violate the vertebral endplates; use of bicortical screw fixation where safe; and possibly accepting lesser degrees of deformity correction. Adjuncts to

improve fixation include the use of specialized pedicle screws, cement augmentation of pedicles with polymethylmethacrylate, and the use of anterior column support to reduce the stress on posterior instrumentation.[72]

Perioperative Considerations

The effect of general anesthetic agents and muscle relaxants on intraoperative neuromonitoring potentials warrants consideration. Halogenated inhalational agents and nitrous oxide produce a dose-dependent decrease in amplitude and increase in latency of somatosensory evoked potentials.[73] Benzodiazepines can also cause significant depression of motor potentials. The use of muscle relaxants precludes proper acquisition of motor evoked potentials (MEPs), and their action should be reversed before proceeding with MEP testing again. Ketamine and etomidate, on the other hand, cause increases in cortical amplitudes of somatosensory evoked potentials and MEPs, making them agents of choice when monitoring responses to stimulation are difficult.[74]

Placement of an arterial line facilitates more accurate monitoring of blood pressure throughout the procedure. Monitoring of core body temperature is also essential in addition to blood pressure, pulse oximetry, and urine output monitoring.

The importance of proper intraoperative patient positioning, especially in the backdrop of the long duration of corrective surgeries, cannot be underestimated. Attention should be paid to padding the eyes properly and keeping them free from any source of external compression when placing the patient prone. In patients undergoing surgery in the prone position, abducting the arms greater than 90 degrees or placing them in extension or external rotation should be avoided to prevent excessive stretch on the brachial plexus.[75] Consideration should be given for intraoperative monitoring of upper extremities to help ensure appropriate positioning and brachial plexus function.
