Physical examination reveals decreased spinal flexibility, with inability to touch the toes. On bending toward the floor, the patient often lists to one side. The straight-leg raise test (Lasegue sign) is positive in 85% of children with herniated discs, while objective neurologic findings—such as absent reflexes, motor weakness, and decreased sensation—are less common in pediatric patients than in adults.[36] Hamstring tightness is often present and has been found to persist even after treatment of disc hernation.[37]

Radiographs are generally normal, although if sufficiently symptomatic, films may show an olisthetic scoliosis or trunk lean away from the side of herniation. There is an increased incidence of concomitant spinal abnormalities in patients with herniated discs. In particular, congenital spinal stenosis is frequently seen. Other findings include transitional vertebrae or spondylolisthesis.[38]

Disc herniation is seen best on MRI (Fig. 25.1). The involved disc is readily appreciated, and other processes that might produce sciatica, such as epidural abscess and spinal cord tumor, can be ruled out.[20] Herniation of the disc can be differentiated from an avulsed vertebral apophysis on either MRI or CT scan. Correlation of the MRI findings with the history and clinical examination is necessary, as mild disc bulging can exist as a normal variant.

Treatment is initially conservative, consisting of antiinflammatory medication and bed rest. Prolonged nonoperative management may lead to persistent pain, however; if the patient does not respond to symptomatic treatment, disc excision should be offered.[36] More urgent surgical intervention is indicated when a progressive neurologic deficit develops. Short-term results are very encouraging, with 95% good and excellent results and nearly universal resolution of back and leg pain.[36] Long-term follow-up, however, shows a deterioration in results, with a 24% reoperation rate after 30 years.[39] Outcome studies demonstrate that patients treated with discectomy as adolescents function better than adults following the same surgery.[40] Surgical technique is similar to that in adult patients.

Apophyseal Ring Fracture/Slipped Vertebral Apophysis

The apophyseal ring fracture, also known as a slipped vertebral apophysis, occurs in adolescents and young adults prior to fusion of the vertebral body to the cartilaginous ring apophysis. The etiology is either acute trauma resulting in rapid flexion and axial compression, or cumulative microtrauma. The fracture typically develops at the junction of the posteroinferior vertebral body and the cartilaginous ring apophysis, with posterior displacement of the fragment into the spinal canal.[41] CT can demonstrate the size and location of the bony fragment, with large central fragments being both most common and most likely to result in significant pain if left untreated.[42]

The symptoms are very similar to those of a herniated disc, with the sudden onset of severe back pain radiating into the leg. Physical examination will show a positive straight-leg raise test, but, as is the case with disc herniations, neurologic signs are infrequently present.

The diagnosis is made radiographically. High-quality lateral radiographs may show an arc-shaped rim of cartilage, cartilage with attached underlying bone, or a small triangular bony fragment lying posterior to the vertebral body. The fragment is best visualized on CT scan.[41] The levels most frequently injured are L4 or S1. Treatment is surgical excision of the avulsed fragment.

Vertebral Fractures

Pediatric patients with spine fractures present with back pain. If the energy of injury is sufficient enough that fracture is possible, radiographs should be obtained at once. When compression fractures are seen in children without high-energy trauma, an immediate evaluation should be performed for underlying malignancy. When patients have undergone high-energy trauma and fracture has been ruled out, however, the patient still complains of severe back pain, MRI may be indicated to rule out ligamentous injury, which can lead to instability in one or more of the spinal columns, especially in younger children.[43]

Developmental Disorders

Spondylolysis and Spondylolisthesis

Spondylolysis refers to a stress fracture of the pars interarticularis, occurring predominantly in the lower lumbar spine. The most frequent level is L5, followed by L4. It is extremely rare to have more than one vertebral level involved. Spondylolysis is bilateral in 80% of cases, and unilateral in 20%, although in certain athlete groups unilateral spondylolysis is more prevalent.[44]

Up to 50% of young athletes presenting for evaluation of back pain have injuries to the pars interarticularis.[45] The mechanism of injury is repetitive microtrauma in hyperextension, overloading the pars interarticularis and over time leading to stress fracture. Sports linked to a high incidence of spondylolysis are gymnastics, diving, ballet, and football. Gymnasts and football linemen have a fourfold increase in incidence of spondylolysis compared with the general pediatric population.[46]

Symptoms consist of low back pain, which is exacerbated by athletic activity and at least partly relieved by rest. The pain is present in the lower back, but can radiate into the legs.

Physical examination may reveal hamstring tightness and loss of normal lumbar mobility. The ability to bend forward to the floor may be diminished. In hyperflexible patients (e.g., gymnasts and ballerinas), motion may appear normal. The patient is usually tender to palpation about the lumbar spine. Hyperextension usually reproduces the back pain, and axial rotation in hyperextension exacerbates that pain.

Lateral radiographs may show lysis across the pars interarticularis, and oblique radiographs can be helpful in less obvious cases (Fig. 25.2). The appearance of a collar on the "Scottie dog" suggests stress fracture. Often, plain radiographs are nondiagnostic. In these cases, scintigraphy can reveal increased tracer uptake at the involved level. The use of the SPECT scan is particularly helpful in localizing increased uptake in the pars interarticularis[25,26,47] (Fig. 25.3). A specific scintigraphic pattern, seen as a triangle of increased signal with increased uptake in the pedicles, has been described.[48] Positive bone scans and SPECT imaging are generally seen in the prefracture state and in relatively acute injuries.[49] The bone scan may not be "hot" in chronic spondylolysis.[26]

MRI has also been used to diagnose spondylolysis, but false-positive scans do occur.[50] Better bony definition of the fracture is obtained using CT scans. Additionally, CT is superior to MRI in the assessment of incomplete fractures and in establishing healing in patients with spondylolysis.[51] The pars is best imaged by using a reverse gantry angle and obtaining thin slices on the CT.[52]

Spondylolysis and spondylolisthesis can produce scoliosis. Curves due to these conditions are usually described as olisthetic, are associated with oblique take-off of the spine from the pelvis, are small in degree, and have little rotation. Spondylolysis and spondylolisthesis occur in patients with idiopathic scoliosis more frequently than in the general population but are usually asymptomatic.

FIG. 25.2 Lateral radiograph of the lumbar spine shows spondylolysis of L5 in a 16-year-old volleyball player.

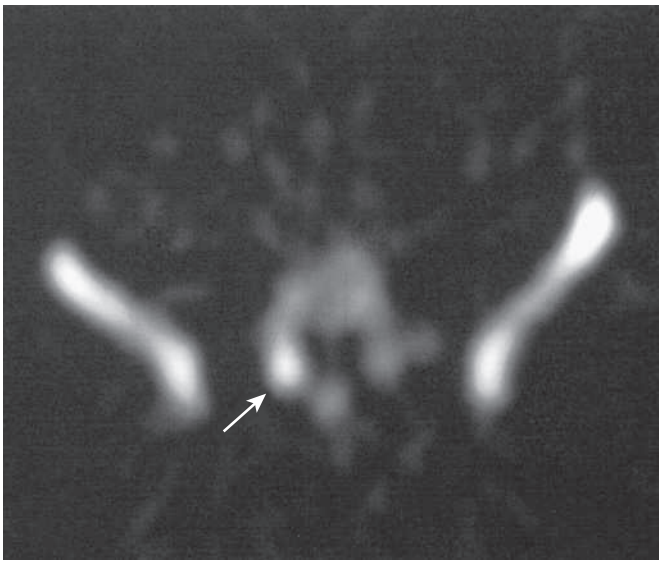

FIG. 25.3 Increased uptake in the pars interarticularis *(arrow)* of an adolescent ballerina with spondylolysis.

Treatment of spondylolysis is initially nonoperative and first involves modifying the patient's level of athletic activity.[53] Cessation of sport until the resolution of symptoms is combined with a concomitant exercise program to stretch the hamstrings and strengthen the paraspinal and abdominal musculature. Resumption of activities is gradual. Modification of the patient's technique or training should be made to minimize recurrent fractures. Use of an antilordotic lumbar orthosis increases the success of nonoperative treatment,

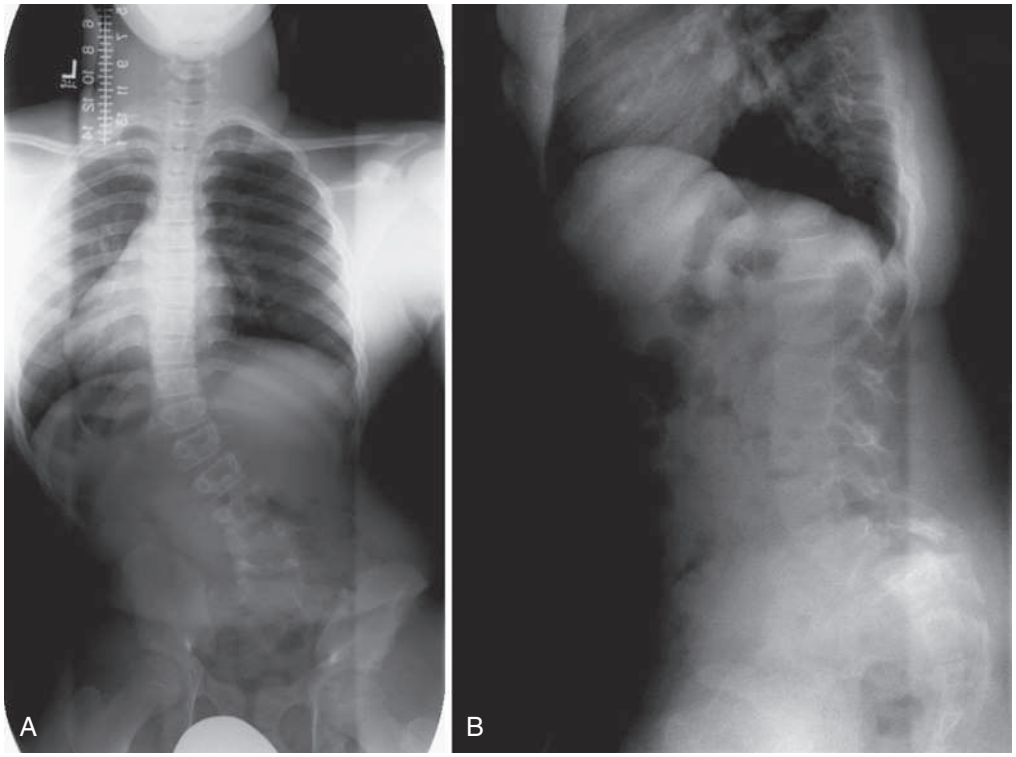

FIG. 25.4 (A) Scoliosis in a 13-year-old male with low back and leg pain of 6 months' duration. (B) Lateral radiograph shows spondylolisthesis at L5–S1.

particularly in patients with acute injuries and "hot" bone scans.[54,55] A recent study found resolution of symptoms following bracing correlated with initial increased activity on SPECT scans and decreased uptake on follow-up scans, while SPECT scans for patients whose pain did not improve showed no significant decrease in activity following bracing.[56] The overall success rate of nonoperative treatment ranges from 73% to 100%.[55] A recent multicenter study of 436 children and adolescents with CT-proven spondylolysis found 95% excellent results and 100% return to sport without surgery following 3 months of cessation of activity with use of a thoracolumbar orthosis.[57] Patients who have normal radiographs but are found to have a stress reaction without fracture on further imaging are highly likely to improve (and not progress to radiographic fracture) with conservative treatment.[58,59] Surgery is typically reserved for the few patients whose symptoms are refractory to 6 months of conservative measures and whose pain recurs with activity following initial nonoperative success.[60]

Spondylolisthesis is a related condition in which anterior slippage of a vertebral body occurs on the more distal vertebra. Most often it is due to bilateral spondylolysis, with the portion of the vertebra anterior to the pars fracture slipping anteriorly. Dysplastic spondylolisthesis occurs in teens who have an elongated but intact pars interarticularis, which allows for the anterior translation without pars fracture.[61]

Patients with spondylolisthesis often present with complaints of low back pain. The pain may radiate into the legs. Physical findings mimic those of spondylolysis, with the addition of a possible palpable step-off at the area of listhesis. In severe spondylolisthesis, the buttocks may appear "heart shaped." If there is significant hamstring tightness, gait alterations are seen where the teen appears to be shuffling with posterior pelvic tilt. Patients may have a painful, or olisthetic, scoliosis (Fig. 25.4).

Plain radiographs establish the diagnosis. The slip is easily seen on a spot lateral radiograph of the lumbosacral junction, and the severity of the spondylolisthesis can be classified as the percentage of forward translation of L5 on the sacrum. Abnormal kyphosis is also seen as the cephalad vertebra tips forward on the caudal segment. A characteristic finding on the AP radiograph, which is the appearance of "Napoleon's hat," can be seen as L5 moves forward on the sacrum and is seen in a nearly axial view.

Treatment is initially conservative in mild spondylolisthesis, and surgical as the magnitude of the slip increases. Surgical treatment of high-grade spondylolisthesis is recommended, but preferred techniques vary among surgeons and reduction remains controversial.[62]

Scheuermann Kyphosis

Scheuermann kyphosis is a developmental condition occurring in adolescence characterized by increased thoracic kyphosis accompanied by lumbar hyperlordosis. Males are affected slightly more frequently than females.

Presenting symptoms are those of back pain, which is usually located at the apex of the thoracic kyphosis, and also may be present in the lower lumbar spine. The pain is usually described as aching in nature, does not wake the patient from

sleep, and does not radiate. It is exacerbated by vigorous activity and prolonged sitting. The severity of the back pain is variable, with some patients denying significant symptoms and instead presenting for evaluation of poor posture. Neurologic symptoms are highly unusual.

Physical examination of the patient with Scheuermann disease shows increased thoracic kyphosis, which is most notable on forward bending, in which the apex appears to protrude posteriorly. The deformity is usually fairly rigid, and does not disappear with hyperextension. There may be concomitant hamstring tightness, with inability to touch the floor with the fingertips.

The diagnosis is made radiographically (Fig. 25.5). Criteria for the diagnosis of Scheuermann disease have been outlined by Sorenson as:

1. three contiguous vertebral bodies with greater than 5 degrees of anterior wedging
2. abnormal disc narrowing
3. endplate irregularities
4. Schmorl nodes, defined as disc herniations into the vertebral bodies

The vast majority of patients with Scheuermann disease can be managed nonoperatively.[63] Physical therapy exercises and nonsteroidal medication can be helpful in relieving symptoms. The role of bracing is controversial. Patients with significant remaining spinal growth may benefit from orthotic treatment because it has been proposed that correction of deformity may be achieved in compliant patients.[64] The Milwaukee brace is the orthosis of choice for the treatment of Scheuermann disease.[65] Surgical correction of deformity and fusion is reserved for patients with severe kyphosis measuring greater than 75 degrees, those whose symptoms are refractory to conservative measures, and those who have significant cosmetic concerns.[66]

FIG. 25.5 Anterior wedging of the thoracic spine in a 15-year-old male with Scheuermann kyphosis.

Lumbar Scheuermann Disease

Lumbar Scheuermann disease is a less common variant in which increased kyphosis and endplate changes are seen in the lumbar spine.[67] It also occurs most frequently in adolescence, with overuse believed to be the cause. Microfractures occur in the vertebral endplates, resulting in low back pain. Radiographs reveal endplate irregularities and disc space narrowing, anterior Schmorl nodes, and possible anterior wedging of the affected vertebrae, leading to loss of lumbar lordosis. Radiographs may also show associated spondylolysis or scoliosis.[27,68] The radiographic appearance of vertebral changes and disc space narrowing may resemble infection or tumor. Scintigraphy may reveal mildly increased uptake at one or two vertebral levels.[27] MRI shows signal change and dehydration in the lumbar discs, with further disc deterioration occurring over time.[69] Treatment is symptomatic, and pain is usually ameliorated with modification of activity or use of an orthosis.

Idiopathic Scoliosis

The majority of patients who have idiopathic scoliosis do not complain of back pain, but symptoms are not as uncommon as previously thought. In a study by Ramirez and coworkers,[23] 32% of 2442 children believed to have idiopathic curves complained of some degree of back pain. The most common factor associated with a positive diagnosis on further evaluation were left-sided thoracic curves, which were associated with spinal cord abnormalities. Plain radiographs were found to be sufficient in the evaluation of typical curves if the neurologic examination was normal. Careful inspection of the apex of the deformity and at the lumbosacral junction (for spondylolysis and spondylolisthesis) will occasionally yield a cause for both the pain and the scoliosis (see Fig. 25.4). In the absence of neurologic findings on physical examination, MRI was not helpful. A recent study did show that MRI was useful in identifying neural axis abnormalities in 6% of 104 patients. Back pain and early age of onset of scoliosis were present in those with MRI abnormalities.[70]

Syringomyelia

Syringomyelia is defined as cystic dilation of the central canal of the spinal cord. The dilation of the cord leads to abnormalities in the neurologic pathways that transmit pain and temperature. While not always symptomatic, patients may complain of pain. There is a predisposition toward left thoracic scoliosis in patients with syringomyelia.[71] Physical findings include scoliosis, foot deformities such as cavus, decreased sensation, and asymmetric abdominal reflexes. The syrinx is clearly imaged on MRI. Treatment is neurosurgical decompression, although controversy exists regarding the size of syrinx that requires surgery.

Tethered Spinal Cord

Low back pain may be the presenting complaint in children with tethered spinal cords. The cord normally terminates at the L1–L2 level. Persistence of the cord more distally implies tethering. Physical findings may include foot deformity, spasticity, or weakness. Often, radiographs will show coexistent congenital vertebral abnormalities. The diagnosis is made on MRI, in which the filum may appear thickened or the conus visualized at L3 or distal. Treatment of the symptomatic tethered cord is surgical release, which is typically performed by a neurosurgeon.

Idiopathic Juvenile Osteoporosis

Idiopathic juvenile osteoporosis is a rare disease that usually affects children in the first 2 decades of life. Presenting symptoms include back and leg pain due to compression fractures and pain during weight bearing.[72,73] Radiographic findings include vertebral wedging due to compression fractures with mildly increased kyphosis. Bone mineral density is decreased, but metabolic laboratory values are normal. The differential diagnosis includes leukemia. Orthotic management of back pain is usually sufficient. Medical management should be under the supervision of a pediatric rheumatologist. The disease is self-limiting, and symptoms resolve during puberty.[74]

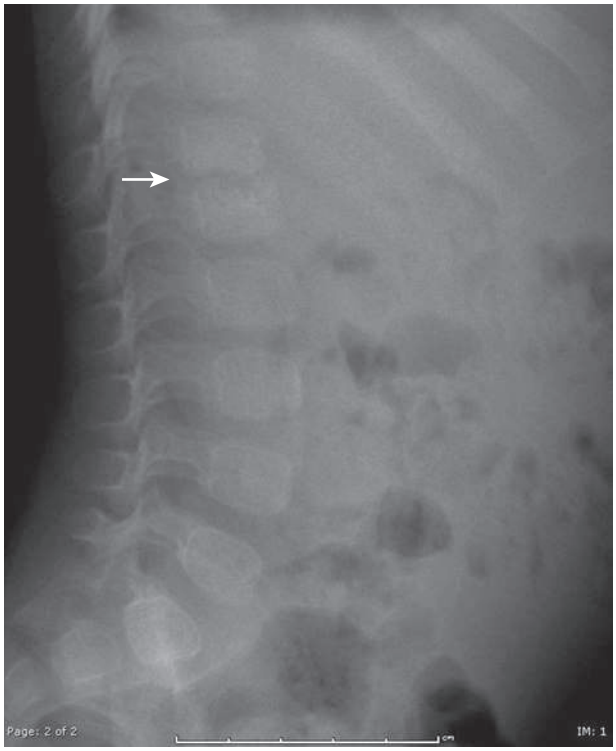

FIG. 25.6 Disc space narrowing *(arrow)* and endplate irregularities in a child with T11–T12 discitis.

Infectious and Inflammatory Etiologies

Discitis

Discitis is defined as a presumed bacterial infection of the intervertebral disc space. It is the most common cause of back pain in the young child. The incidence of discitis is greatest in children aged 5 years and younger, though it can occur in older children.[75] The etiology is believed to be infectious. In the immature child, blood vessels traverse the vertebral endplates and terminate in the nucleus pulposus. Therefore, in young children the disc is vascular, which allows for seeding of bacteria into the disc space.[76–78] Presenting complaints vary, but include back pain, refusal to walk, limping, and abdominal pain. The child usually is systemically ill; therefore, the patient often presents to the emergency department. Approximately half will have fever on presentation.

Physical examination reveals spinal stiffness, and often the spine is held in a flexed position. If asked to retrieve a toy from the floor, the child with discitis will squat by bending the knees rather than bend the spine. Young children may exhibit Gower's sign when rising from the floor, using their upper extremities to push up on the legs as a strategy to minimize lumbar motion. Tenderness in palpation of the affected area can be present.

Radiographic findings are usually minimal at the time of presentation. Subtle disc space narrowing and paraspinal soft tissue swelling on the lateral view are the first radiographic changes (Fig. 25.6). Over time, endplate irregularities are seen. Because plain radiographs are usually normal at the time of presentation, further imaging is required. Technetium bone scans show increased uptake on both sides of the affected disc space (Fig. 25.7A). Bone scans are positive in 74% to 100% of children with discitis[79,80] and can lead to earlier diagnosis and treatment. MRI also localizes the infection and delineates the extent of soft tissue involvement (Fig. 25.7B). In patients who are refractory to treatment, MRI is useful in assessing whether a soft tissue abscess is present.[81] MRI shows decreased signal on T1-weighted images and increased signal on T2 images. If an abscess is present, there is peripheral enhancement with the administration of gadolinium.[82]

The evaluation of the child with possible discitis also includes obtaining laboratory studies. Elevation of the sedimentation rate and C-reactive protein are seen in more than 90% of children with discitis.[20] The white blood cell count may be elevated but is less reliable.[76] Blood cultures should be obtained and are positive in more than 50% of children with discitis.[80]

In the past, the treatment of discitis was controversial, but now there is agreement that discitis represents a bacterial infection and should be treated with antibiotics.[76,81,83] Cultures of the intervertebral disc are positive in 60% of children, with *Staphylococcus aureus* the most common organism. A recent study of disc space cultures showed that *S. aureus* was cultured in 55% and *Kingella kingae* in 27% of children with discitis.[84] Because of the preponderance of *S. aureus*, and the fact that 40% of cultures from the disc space remain negative, routine aspiration of the affected disc is not recommended.[83] If the patient fails to improve quickly with antistaphylococcal antibiotics, then fine-needle aspiration under CT guidance can be useful.[85] Although administration of a second-generation

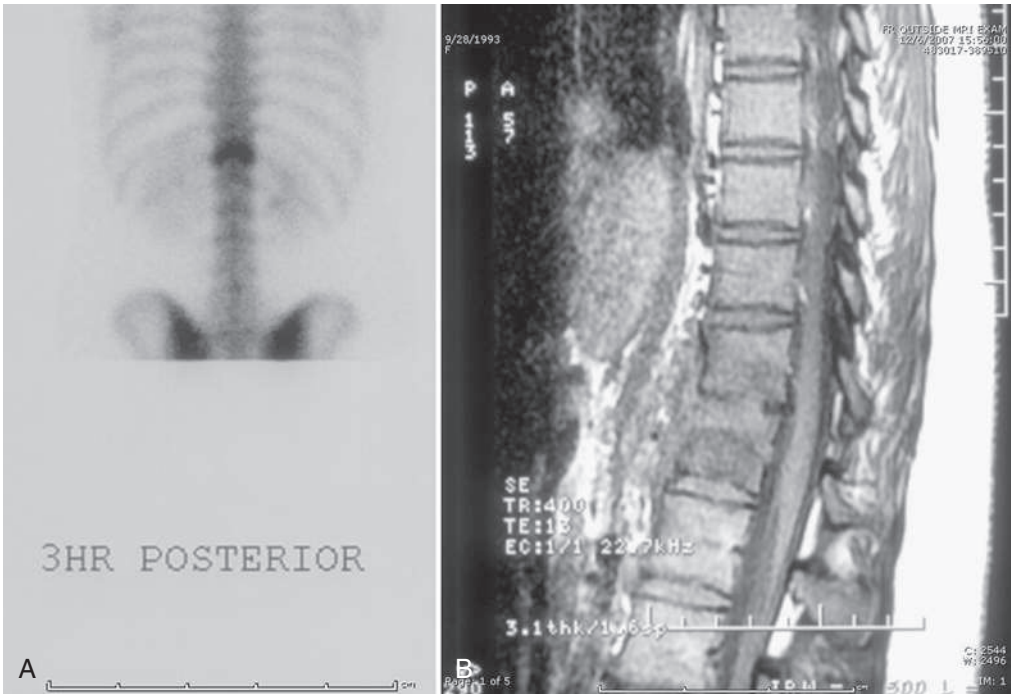

FIG. 25.7 (A) Bone scan in a child with discitis shows increased uptake. (B) Magnetic resonance image reveals destruction of the disc space, erosion of endplates, and vertebral involvement.

cephalosporin for 3 weeks has been recommended,[83] epidemiologic trends in antibiotic resistance may alter which antibiotic should be chosen. Surgical biopsy and debridement are reserved for patients who do not respond to medical management, have a neurologic deficit, have an abscess on MRI, or whose diagnosis is in question.

The outcome of pediatric discitis is favorable. Ten-year radiographic follow-up has shown narrowed disc space (60% of children) or bony ankylosis (40%), but kyphosis is rare and generally mild and patients are pain free.[86]

Disc space infection in children younger than 1 year is usually very aggressive and requires immediate diagnosis and treatment. Infants are often septic at presentation. Residual kyphosis following eradication of the infection has been described.[87]

Vertebral Osteomyelitis

The distinction between discitis and osteomyelitis in children is blurred. It is believed that osteomyelitis is a continuation of discitis,[77] with the two entities representing a condition called *infectious spondylitis*. Osteomyelitis produces more notable vertebral body radiographic changes. Again, *S. aureus* is the most common organism.[78]

Opportunistic infections may also affect the vertebral column, especially in immunocompromised patients such as those with malignancies or who have had organ transplants. Fungal infections such as coccidioidomycosis are rare but must be kept in mind in endemic regions.[88]

Tuberculosis is increasing in frequency and is seen most commonly in children from endemic regions. Symptoms include fever, malaise, weight loss, and night sweats. Neurologic findings occur more frequently in tuberculosis than in discitis.[89] Radiographic changes are more advanced in children with tuberculous spondylitis, and consist of bony destruction of the vertebral body, kyphosis, soft tissue abscesses, and soft tissue calcifications. CT scan findings include erosions with calcification, and intraspinous, paravertebral, and epidural abscesses.[90,91] A chest radiograph shows evidence of tuberculosis in 67% of children with tuberculous infection of the spine.[90] The purified protein derivative test is usually positive, except in the immunologically challenged child, in whom it remains nonreactive. Pathologic examination of tissue from fine-needle aspiration of the affected bone yields a positive diagnosis in 83% of children and teens[92] and shows epithelioid giant cells and caseous necrosis or tubercle bacilli. Polymerase chain reaction has been used for faster identification of the organism.

Ankylosing Spondylitis and Rheumatologic Conditions

Ankylosing spondylitis is a rheumatologic condition characterized by loss of spinal mobility. It may present in adolescence as back pain. It occurs more frequently in males than in females. Physical findings include loss of lumbar flexibility so that lordosis does not reverse on forward flexion, increased kyphosis, and limited chest expansion with inspiration. Plain radiographs may reveal sclerosis, narrowing, or fusion of the SI joints. MRI has been shown to be superior to bone scan in identifying inflammation of the SI joint.[93,94] Laboratory evaluation of patients with ankylosing spondylitis shows a high

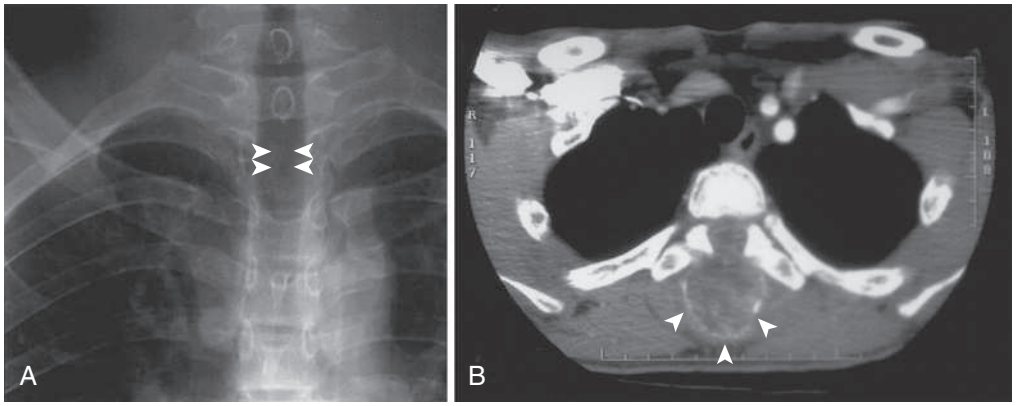

FIG. 25.8 (A) Anteroposterior radiograph of the thoracic spine of a 16-year-old male with lower extremity weakness and loss of bladder function shows absence of the spinous process at T2 *(arrowheads)*. (B) Computed tomographic scan delineates the extent of the aneurysmal bone cyst of the posterior elements of T2 *(arrowheads)*.

incidence of HLA-B27. Onset of ankylosing spondylitis prior to the age of 16 years has been linked to worse functional outcomes than in adult-onset patients.[95] Other rheumatologic conditions linked with back pain include polymyositis, dermatomyositis, and inflammatory bowel disease.

Hematologic Conditions

Sickle Cell Anemia

In a recent study of pediatric patients presenting to a Canadian emergency department for the evaluation of back pain, 13% were found to have sickle cell anemia.[22] The spine has been reported as the second most common site for pain crisis in these patients, second only to the knee. Anemia is present in 86%.[96] Physical examination reveals tenderness to palpation. Treatment is pain management and admission to the hematology service.

β-Thalassemia may also produce pain crises that affect the spine. Up to 25% of patients with thalassemia complained of low back pain in a recent study.[97]

Neoplasms

Aneurysmal Bone Cysts

Aneurysmal bone cysts (ABCs) are nonmalignant expansile lytic lesions of bone characterized by their vascularity. Although not malignant tumors, they can be locally aggressive. Their etiology remains unclear, and a few familial cases have been identified.[98] Approximately 15% of ABCs affect the spinal column, with a predilection for the posterior elements. If of sufficient size, the lesion may extend into the anterior column.[99,100] A large multicenter series of spinal aneurysmal bone cysts documented that 30% were located in the cervical spine, 30% in the thoracic spine, and 40% in the lumbar spine.[101]

Symptoms consist of back pain that can result from the lesion itself, or from an associated pathologic fracture. Neurologic compromise is unusual.

Radiographs show an expansile lytic lesion with a "bubbly" appearance. There is expansion of the cortex. CT scans best define the extent of the lesion, and reveal the thin rim of surrounding bone (Fig. 25.8). On occasion, sacral lesions have been shown to affect more than one vertebral level.[102]

Treatment of ABCs is surgical curettage with bone grafting.[103] Due to the vascularity of the cysts, preoperative embolization is very helpful in reducing intraoperative blood loss and therefore improving visualization.[104–106] Spinal cord monitoring during embolization has been advocated to avoid vascular injury to the spinal cord.[107] Scheduling the surgical resection shortly following embolization is necessary to prevent revascularization of the lesion prior to curettage. When resection of the lesion leads to mechanical instability, simultaneous fusion is recommended.[108] There is a 10% to 14% recurrence rate following curettage and grafting for spinal ABCs. A four-step surgical program—consisting of curettage, use of a high-speed burr, electrocautery, and bone grafting, with stabilization via short posterior fusion with instrumentation as needed—has been recently proposed, with all patients free from disease at follow-up.[109]

Repeat embolizations as well as radionuclide ablation have been used to definitively treat spinal ABCs in limited cases.[106] Repeat embolization has been advocated in patients who do not have neurologic findings or pathologic fracture, for whom the diagnosis is certain, or in patients whose lesions have recurred.[110]

Osteoid Osteoma

Osteoid osteomas are the most common benign spinal tumor occurring in children, with presentation occurring in the second decade of life. They typically are located in the posterior elements of the spine. Osteoid osteomas produce back pain that is worse at night, and ameliorated by aspirin or nonsteroidal medication.

Physical examination reveals decreased spinal flexibility. Often, the patient will stand with a list. The neurologic examination is generally normal.

Plain radiographs are usually insufficient to make the diagnosis, but an olisthetic scoliosis might be apparent. When scoliosis is present, the lesion is usually located in the concavity of the apex of the curve.[111] Bone scan is positive, with distinct increased uptake seen (Fig. 25.9). CT scans provide the best imaging of osteoid osteomas, with a small radiolucent nidus and surrounding sclerosis and new bone apparent (Fig. 25.10). MRI shows increased signal intensity in the muscles and surrounding bone.[112] The MRI appearance, as well as the tendency for enhancement in the soft tissues near the lesion, may lead the physician to suspect a malignant tumor.[113]

FIG. 25.9 Bone scan of a 15-year-old male with a 2-year history of back pain shows increased uptake at T10 *(arrow)*.

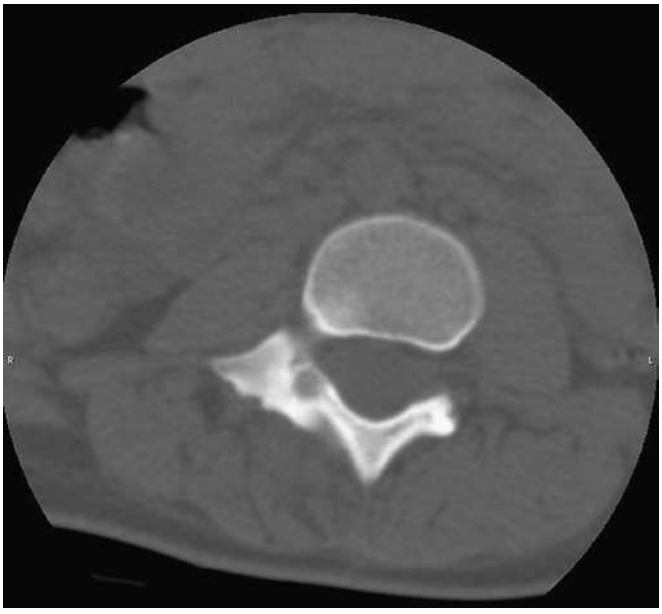

FIG. 25.10 Computed tomographic scan shows a radiolucent nidus with surrounding bony sclerosis in an 11-year-old with back pain due to an osteoid osteoma.

Long-term administration of NSAIDs can provide pain relief in a small group of patients with spinal osteoid osteomas; thus, a trial of nonsurgical treatment is warranted. Usually, symptoms are sufficient to merit surgical removal of the nidus, which typically results in immediate relief of pain. Intraoperative CT imaging has been used to better target the nidus and therefore minimize bony resection.[114] Newer treatments are under investigation, including percutaneous CT-guided burring of the nidus and thermocoagulation.[115,116] When scoliosis has been long-standing, persistence of the deformity is possible following successful removal of the osteoid osteoma.

Osteoblastoma

Although osteoblastoma is a less common benign lesion of the spine, 40% of osteoblastomas are located in the vertebrae. They also are located in the posterior elements of the spine, but because they are by definition larger than osteoid osteomas, they often extend anteriorly into the vertebral bodies.[117] The primary symptom of osteoblastoma is back pain, which is usually less severe than in osteoid osteoma. Neurologic abnormalities may result based simply on the size of the lesion and its encroachment on the spinal canal or neural foramina.[112]

The lesion can be usually seen on plain radiographs, but CT scans are invaluable in assessing the size and extent of the osteoblastoma. As in osteoid osteoma, the MRI in osteoblastoma can overestimate the extent and aggressiveness of the lesion.[118] Plain radiographs also reveal scoliosis in approximately 40% of affected patients.[111]

Treatment is surgical removal of the lesion, with fusion as needed to address instability based on the size of resection. Recurrence occurs in 10% of osteoblastomas.

Eosinophilic Granuloma/Langerhans Cell Histiocytosis

Eosinophilic granuloma, also known as Langerhans cell histiocytosis (LCH) or histiocytosis X, is a peculiar condition of childhood typified by the development of lytic lesions of bone. The lesions may occur singly or affect multiple areas of the skeleton, including the spine. When the condition is associated with systemic involvement, it is known as Hand-Schuller-Christian disease or the more severe Letterer-Siwe disease. LCH has a higher incidence in males. The average age at diagnosis is 6 years, with the majority of patients in their first decade of life.[119]

Vertebral lesions in LCH occur in 10% to 17% of affected children. The patients may present with back pain or a limp. On occasion, neurologic signs can be present.

Radiographs show lytic lesions within the vertebral body or, more rarely, the posterior elements. Larger lesions lead to collapse of the vertebral body, which can be either symmetric or asymmetric (Fig. 25.11). Although vertebra plana (also known as coin-on-end appearance) is the classically described spinal lesion in LCH, it has been reported that only 40% of

children with LCH and vertebral lesions have vertebra plana.[120] Skeletal surveys often result in the identification of other sites of involvement, which supports the diagnosis. Typical sites of involvement include the skull, the pelvis, and the diaphysis of the long bones. Bone scan is positive in 90% of children with LCH.[121]

The differential diagnosis includes leukemia, infection, and other malignant tumors, such as Ewing sarcoma.[122] If the radiographic appearance is atypical and other peripheral skeletal lesions are not identified, a surgical biopsy of the spinal lesion is warranted. Pathologic specimens show clonal proliferation of Langerhans-type histiocytes, eosinophils, and giant cells.[123]

Most patients with LCH experience spontaneous resolution of their disease. Because the condition appears to be self-limiting, the indications for treatment are few. Back pain due to a unifocal spinal lesion can usually be relieved by rest and the use of orthoses.[119,123] Patients with neurologic compromise may be treated with low-dose radiation therapy or surgical debridement of the lesion and stabilization.[121,124] Radiation therapy has fallen out of favor as treatment for LCH of the spine due to the potential for secondary malignancies. Multifocal disease, particularly when associated with systemic involvement, is treated with chemotherapy.[125]

The long-term outcome of LCH in the absence of systemic disease is very good. Recurrence of disease is not seen in children.[125,126] Over time, improvement in vertebral body height is seen, although complete restoration to normal is unusual.[127,128]

Malignant Tumors

Leukemia

Leukemia is the most common pediatric malignancy that produces back pain. Many children first present to the orthopaedic surgeon; reports indicate that 6% to 25% of children with acute leukemia present initially with back pain.[129,130] Many of these children are initially misdiagnosed; thus, the orthopaedic surgeon must have a high level of suspicion to properly evaluate this population.[131] The history may reveal symptoms of pallor, fatigue, loss of appetite, or fever. The parent should be questioned about a history of bruising or abnormal bleeding.

Radiographic findings are not always initially present but include generalized osteopenia, vertebral compression fractures, and metaphyseal leukemic lines. Of children with acute lymphoblastic leukemia, 7% have vertebral compression fractures[130,132] (Fig. 25.12).

The diagnosis can usually be made on laboratory examination, with abnormalities seen in any or all of the three cell lines, that is, anemia, thrombocytopenia, and leukopenia. The sedimentation rate is usually elevated. Of children with leukemia, 10% or more will initially have normal automated counts.[132,133] Inspection of the peripheral smear will reveal the diagnosis in some of these children.

Chemotherapy under the direction of pediatric oncology is the treatment of choice. Spinal bracing can be prescribed to relieve back pain and prevent further compression fractures.

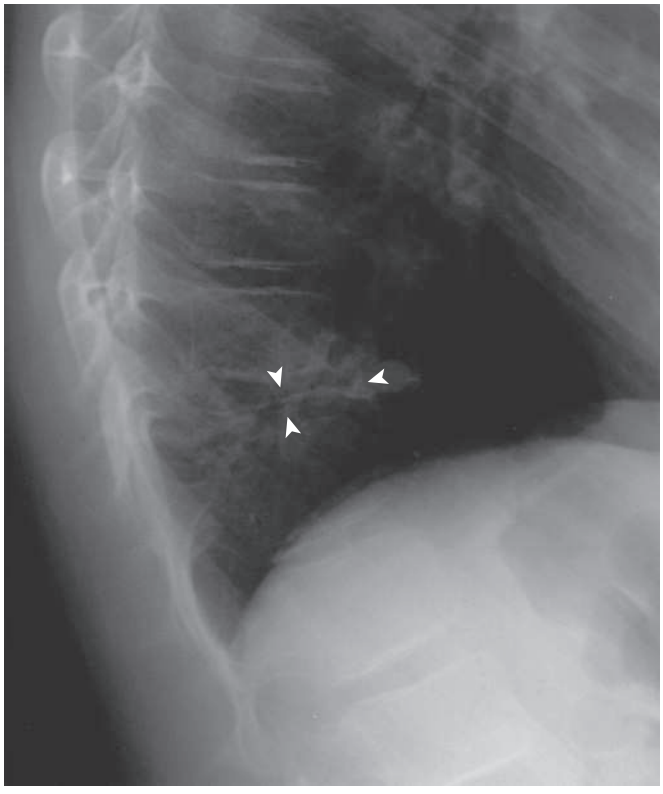

FIG. 25.11 Lateral radiograph of a 12-year-old male with vertebra plana of T11 consistent with eosinophilic granuloma *(arrowheads)*. Back pain resolved with conservative treatment.

FIG. 25.12 Osteopenia and multiple compression fractures in a child presenting with back pain due to leukemia.

Vertebral Malignant Tumors

Malignant tumors of the spine cause significant back pain in over 50% of children at the time of diagnosis.[134] Although rare, they must remain in the differential diagnosis of pediatric back pain. Pain may radiate into the legs, resembling the symptoms of a herniated disc. While patients with disc herniation are in their second decade of life, children with spinal or spinal cord tumors may be younger. Neurologic deficits and reflex changes are uncommon in disc herniation but frequent in tumors.[135]

Vertebral tumors include Ewing sarcoma and osteosarcoma.[136] Osteosarcoma rarely affects the spine.[137] Radiographs are variable, with osteolytic, osteoblastic, and mixed appearances possible. CT and MRI are used to stage the tumor. Treatment is difficult.

Up to 10% of Ewing sarcomas occur in the spine, with the sacrum the most frequent site.[138] The average age at presentation is 13.3 years.[139] Symptoms consist of relentless back pain. Neurologic deficits are present in 58% of patients with spinal Ewing tumors.[140] Radiographs may show an expansile lytic lesion with variable vertebral collapse. Cases of Ewing sarcoma that radiographically resemble vertebra plana have been reported, leading to the misdiagnosis of eosinophilic granuloma.[140] MRI delineates the extent of the lesion and its accompanying soft tissue mass.

Spinal Metastasis

Neuroblastoma is the most frequent tumor to metastasize to the spine in children.[141] In a recent study of 29 malignant spine tumors, neuroblastoma represented one-third of all cases.[134] Radiographs usually show diffuse vertebral involvement. The thoracic spine is most frequently involved. An elevation of urinary normetanephrine may help diagnosis.[138] Other tumors that involve the spine include rhabdomyosarcoma, Wilms tumor, and primary neuroectodermal tumors.[142]

Spinal Cord Tumors

Common spinal cord tumors in children are astrocytomas and ependymomas. The onset of symptoms is indolent. Neurologic signs such as deterioration of gait, delay in motor skills, and loss of bladder control raise suspicion.[143–145] Back pain is usually present, leading to initial referral to the orthopaedic surgeon in 31% to 58% of patients who are eventually diagnosed with spinal cord tumors.[143,144] Physical examination reveals motor deficits, clonus, and possibly scoliosis. There may be limitation of spinal flexibility. Radiographs can show changes due to pressure or expansion of the tumor, including absence or thinning of the pedicle or widening of the intervertebral foramina. Spinal cord tumors are best seen on MRI.

Although uncommon, neurofibromas in children and adolescents with neurofibromatosis can undergo malignant degeneration into neurofibrosarcoma. Back pain in a patient with neurofibromatosis should be evaluated.

Nonorthopaedic Causes of Pain

Intraabdominal processes such as inflammatory bowel disease, hydronephrosis, ovarian cysts, endometriosis, and urinary tract infections can produce back pain. Pain due to these conditions is not exacerbated by activity and tends to be more intense at night. Pediatric referral should be made when nonmusculoskeletal causes are suspected.

Psychosomatic Pain (Conversion Reaction)

As discussed in the beginning of this chapter, there are children in whom an organic etiology for back pain cannot be found despite thorough evaluation. Back pain can be influenced by psychosocial factors that alter the patient's perception of pain and the effect of pain on everyday life. Psychosomatic pain remains a diagnosis of exclusion. It is more prevalent in adolescence, particularly in those teens whose family members have a history of similar back pain. A detailed social history often reveals problems at home or school, often resulting in anxiety and depression. Treatment is difficult but includes intervention by a psychologist and physical therapy. Recent studies show that up to 71% of children and adolescents who have negative diagnostic evaluations for back pain continue to have pain at an average of 4.4 years of follow-up.[19] Even 8 years after initial evaluation, 62% of 58 patients were still symptomatic.[146]

KEY POINTS

Use of Diagnostic Tests

Radiograph: History of significant trauma; night pain, fever or inability to walk; age 8 years or younger; duration of pain greater than 2 months

Bone scan: Negative plain radiograph with normal neurologic examination, persistent pain, history of athletic overuse

CT scan: Positive plain radiograph or bone scan

MRI: Abnormal neurologic examination, painful scoliosis in patient younger than 8 years, painful left thoracic scoliosis

Laboratory tests: Night pain, fever, age younger than 8 years, constant pain

Likely Diagnoses Based on Age

Younger than 5 years: Tumor, discitis

Age 5 to 10 years: LCH, discitis, tumor/leukemia

Age 10 to 18 years: Musculoskeletal back pain, lumbar Scheuermann disease, herniated disc or apophysis, spondylolysis, osteoid osteoma, tumor/leukemia

26 CHAPTER Congenital Scoliosis

Alexandra Miller Dunham
Paul D. Sponseller

Congenital scoliosis is a three-dimensional deformity of the spine that is directly due to congenitally anomalous vertebral development. This results in an imbalance of the longitudinal growth of the spine, which is most typically progressive in nature. By definition, this is different from neuromuscular scoliosis, in which deformity is secondary to myoneural causes, and idiopathic scoliosis, the cause of which is unknown.

Some cases of congenital scoliosis cause such minor deformity that they remain undetected; thus, the true incidence in the general population remains difficult to determine. However, current estimates suggest that approximately one in 1000 persons is affected.[1,2]

The familial incidence in the congenital scoliosis population is estimated between 1% and 5%, suggesting that most cases appear to be sporadic.[3–6] The male/female ratio for congenital scoliosis is 1 : 1.4.[7–9]

To fully understand the management of congenital scoliosis, one must first appreciate the foundation of how the deformity develops in utero. This discussion encompasses embryology as it relates to the bony etiology of deformity and associated differences, a classification system that aids in understanding growth potential, the natural history of curve progression, assessment of the patient, various imaging modalities and their unique utility, and, finally, treatment modalities.

Embryology

Congenital scoliosis is accurately described as altered embryologic development of the spine. Depending on which step of development is altered, spine morphology will be differently impacted. The bony malformations that cause congenital scoliosis typically occur during the fourth through sixth weeks of gestation. This timing is of particular importance, as it explains why patients with congenital scoliosis often have additional associated anomalies, which likely develop during the same intrauterine time period as other organ systems are similarly developing.

Normal Development

In the process of somitogenesis, paired paraxial mesoderms on either side of the notochord condense to form somites. Each somite further differentiates into a ventral sclerotome and a dorsolateral dermomyotome. During the fourth week of gestation, cells from each sclerotome migrate ventrally to fully engulf the notochord. The cranial half of one sclerotome and the caudal half of the adjacent sclerotome fuse, each contributing a portion of cells to the development of a single vertebra. Thus, a single vertebra results from the proper formation and migration of cells from two somite levels (Fig. 26.1). The ventrally migrated cells of the sclerotome will go on to form the vertebral body, and the dorsal portion of the sclerotome will form the vertebral arch as well as costal processes.[10]

Ossification begins during the sixth week of gestation from three primary ossification centers: one in the body (or centrum, formed by early fusion of two centers) and one in each half of the vertebral arch. During the sixth week of development, mesenchymal cells between cranial and caudal parts of the original sclerotome fill the space between two vertebral bodies to contribute to formation of the intervertebral structures.[11]

Somitogenesis relies on the oscillatory expression of several genes and gene products, some of which have been elucidated. Principal gene networks influence *Notch, Wnt,* and *FGF* pathway targets.[12–15] The networks responsible for putative segmentation appear to be regulated by cell-autonomous oscillations between permissive and nonpermissive states in a consistently timed manner, so much so that somitogenesis is said to be coordinated by a "clock-and-wave" mechanism[16,17] (Fig. 26.2). One of the many key outputs of the clock mechanism is the interval production of *MESP2* transcription factor, which has been implicated in the formation of somite boundaries and the rostrocaudal development of the sclerotome.[18,19]

Associated Anomalies

Because the development of the spine coincides with the development of many other organ systems, associated anomalies occur in 30% to 60% of children with congenital spine malformations. Many associated anomalies are part of the VATER association. The acronym includes various deficiencies: vertebral defects (V), anal atresia (A), tracheoesophageal fistula (TE), radial limb reduction, and renal defects (R). The acronym VATER was modified in 1975 to VACTERLS by

adding cardiac defect (C) and limb defect (L)[20–22] and single umbilical artery (S; Fig. 26.3). The most common anomalies involve the spinal cord, the genitourinary tract, and the cardiac system. Intraspinal anomalies include problems such as tethered cord, diastematomyelia, syringomyelia/Chiari malformations, and intradural lipomas (present in up to 35% of patients with congenital scoliosis). The most common genitourinary defects are horseshoe kidney, renal aplasia, ectopic kidney, duplication, reflux, and hypospadias (present in up to 20% of patients with congenital scoliosis). Congenital heart defects range from the more common atrial and ventricular septal defects to the more complex tetralogy of Fallot, transposition of the great vessels (present in up to 25% of patients with congenital scoliosis).[23,24]

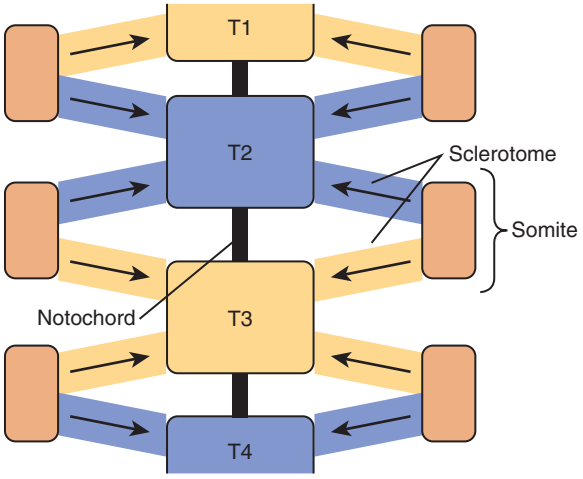

FIG. 26.1 Each vertebra is formed by a part of four somites.

Genetic Etiology

Mutations in downstream components and targets of the Notch signaling pathway contribute to observed congenital vertebral malformation phenotypes in humans,[25] which are mirrored in mouse models. Specifically, genetic mapping has enabled the identification of three forms of spondylocostal dysostosis (SCD): mutations of *DLL3*[26–29] to *SCD1, MESP2* to *SCD2,*[30–32] and *LFNG* to *SCD3.*

Alagille syndrome is an autosomal dominant condition characterized by bile duct, heart, eye, kidney, pancreas, and facial anomalies, as well as butterfly vertebral anomalies.[33,34] Vertebral anomalies are observed in 22% to 87% of patients with Alagille syndrome. Mutations in *JAG1* have been identified in approximately 70% of patients with Alagille syndrome.[35] Additionally, mutations in Notch2 have been observed, especially in those with severe renal anomalies.[36]

Congenital vertebral anomalies are also found with a high incidence in Klippel-Feil syndrome, which is characterized by the combination of cervical fusion, limited neck range of motion, short neck, and low hairline.[37] Various genetic anomalies have been reported to occur in association with Klippel-Feil syndrome including *SLIT3, FBXW11, DUSP1, FGF18, DC-UbP,* and *CDCA2.*[25,38]

Additionally, congenital scoliosis has been associated with Sprengel deformity, Mayer-Rokitansky-Küster-Hauser syndrome, Jarcho-Levin syndrome, Goldenhar syndrome, Genoa syndrome,[39–42] and many others.

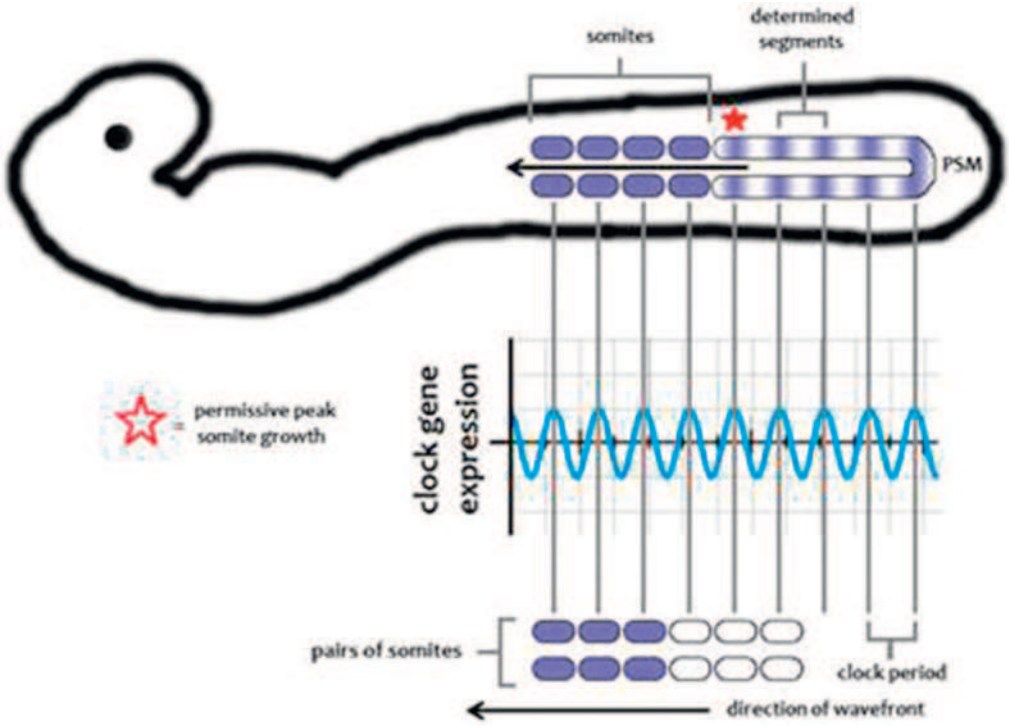

FIG. 26.2 Illustration of "clock-and-wave" mechanism of somitogenesis segmentation. Oscillatory gene expressions allow the development of "permissive peaks," leading to somite formation. Shorter clock periods lead to shorter somites and shorter intersomite spacing. PSM, presomitic mesoderm.

FIG. 26.3 Computed tomographic image of a 6-year-old child with congenital scoliosis who also has epidural lipoma and neurenteric cyst at T12.

Environmental Etiology

Growing evidence continues to suggest that congenital scoliosis is not strictly a genetically caused anomaly. Studies in mice suggest that maternal exposure to medications or toxins, such as carbon monoxide, alcohol, boric acid, and/or valproic acid, may cause congenital scoliosis.[43–48] Aberrations in the developmental milieu have also been associated with vertebral malformations consistent with congenital scoliosis such as hyperglycemia, hypoxia, and hyperthermia.[45,49–51] The causative mechanism underlying the carbon monoxide effect on vertebral anomalies remains vague. However, maternal acute exposure to carbon monoxide during embryo somitogenesis may act via gene mutation from the resulting hypoxia or directly by disruption of the cartilaginous spine.

The interplay between genetics and environmental factors is complex. Epigenetic factors in the development of congenital vertebral malformations are a possible pursuit.[52] The observation that increased DNA methylation can alter the phenotypic expression of tail kinks in the axin-fused mouse (AxinFu) supports an epigenetic contribution to congenital scoliosis.[43,53] The literature continues to grow in elucidating the multiple factors of pathogenesis of congenital vertebral malformations.

Classification

Two basic types of vertebral anomalies occur: failures of formation and failures of segmentation.[54-57] These anomalies can occur as a solitary malformation or in conjunction with additional vertebral malformations, adding complexity to the resulting deformity with each additional malformation.

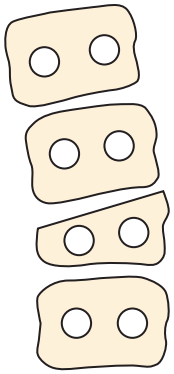

FIG. 26.4 Wedge vertebrae due to a mild form of unilateral vertebral failure of formation. Vertebral height is asymmetrical on the right and left sides.

As in other types of scoliosis, compensatory curves also develop.

Failures of Formation

Failures of formation (type I deformity) exist along a broad spectrum and have multiple subtypes characterized by longitudinal growth potential. Formation deformity can be partial, which causes wedged vertebrae with intact pedicles, or complete, which causes hemivertebrae with a unilateral pedicle (Fig. 26.4). Vertebral growth typically is provided by apophyses on both the superior and inferior endplate of each vertebra. In vertebrae affected by failure of formation, the apophyses may be disrupted, thus affecting growth and lending a natural method to the subtyping of type I deformity.

- *Fully segmented*: Both the superior and inferior endplates of the affected vertebrae have growth potential, with disc space both above and below. Adjacent vertebrae are normal.
- *Semisegmented*: Either the superior or inferior endplate of the affected vertebrae has growth potential, with normal disc space with the adjacent vertebrae; the other end is fused to the adjacent vertebrae with an intervening thin, fibrous lamellar tissue (Fig. 26.5).
- *Nonsegmented*: Neither the superior nor inferior endplate of the affected vertebrae has growth potential. Both endplates are fused to the adjacent vertebrae and the interval disc space is replaced by fibrous lamellar tissue (see Fig. 26.5).
- *Incarcerated*: Both the superior and inferior endplates of the affected vertebrae have growth potential; however, the affected vertebra is bound within the lateral margins of the adjacent vertebrae, and the adjacent vertebrae compensate for the deformity by expanding their growth potential. This results in the affected vertebrae appearing "carved into" the adjacent levels (see Fig. 26.5).

Failures of Segmentation

Failure of segmentation (type II deformity) is associated with derangements of the segmentation phase of somitogenesis. Improper segmentation occurs along a spectrum from a partial failure resulting in a partially segmented vertebra,

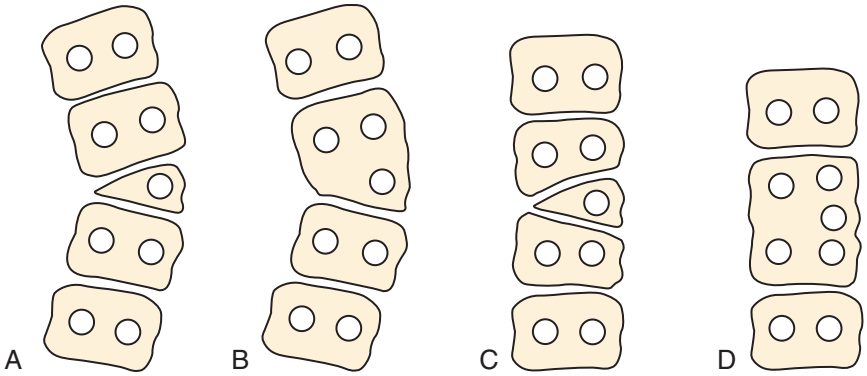

FIG. 26.5 Hemivertebrae, classified according to growth potential. (A) Segmented hemivertebra. (B) Semisegmented hemivertebra. (C) Incarcerated hemivertebra. (D) Nonsegmented hemivertebra.

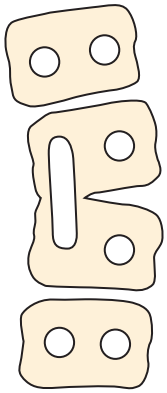

FIG. 26.6 Congenital unilateral bar. Partial fusion between two vertebrae prevents longitudinal growth on its side.

causing a bar, or complete failure resulting in a complete absence of intervening space between vertebrae, causing a block vertebra. A congenital bar can be anterior, posterior, lateral, or mixed. Depending on the position of the bar, a different deformity may develop as the patient grows (Fig. 26.6). As with other bar malformations in the body, the bony vertebral bar resulting from a partial failure in segmentation will restrict growth in the same plane of direction as the bar.

Mixed Deformity

Vertebral anomalies often exist in conjunction—failures of formation and failures of segmentation frequently coexist as mixed deformity (type III deformity). Occasionally, anomalies are found on several levels. For example, unilateral bar with contralateral fully segmented hemivertebra is a type III deformity and has the most rapid progression of curvature among the deformities (Fig. 26.7).

FIG. 26.7 Radiograph of 9-year-old child with congenital scoliosis of mixed pattern, including multiple hemivertebrae, both incarcerated and nonincarcerated, and fused pedicles and ribs on the left at T9–T10.

Natural History

Congenital scoliosis, as with other types of scoliosis, progresses in the majority of patients during periods of rapid growth. Given that deformities of congenital scoliosis are by definition present at birth, they are subject to the intense growth of early childhood—progression is most rapid in the first 3 years of life. Multiple reviews have shown that, statistically, 25% of curves do not progress, 25% progress minimally, while 50% progress significantly and require treatment[58–61] (Fig. 26.8). Without any treatment, 85% of patients with congenital scoliosis will have a curve greater than 45 degrees by maturity.[56] The potential for the increase in curvature is dependent on the imbalances of growth potential (Fig. 26.9). The natural history of congenital scoliosis relates to the type of deformity, location, number and span of deformities, initial severity of the scoliosis, and the global growth potential balance between each side of the spine. Analysis of these factors will allow the

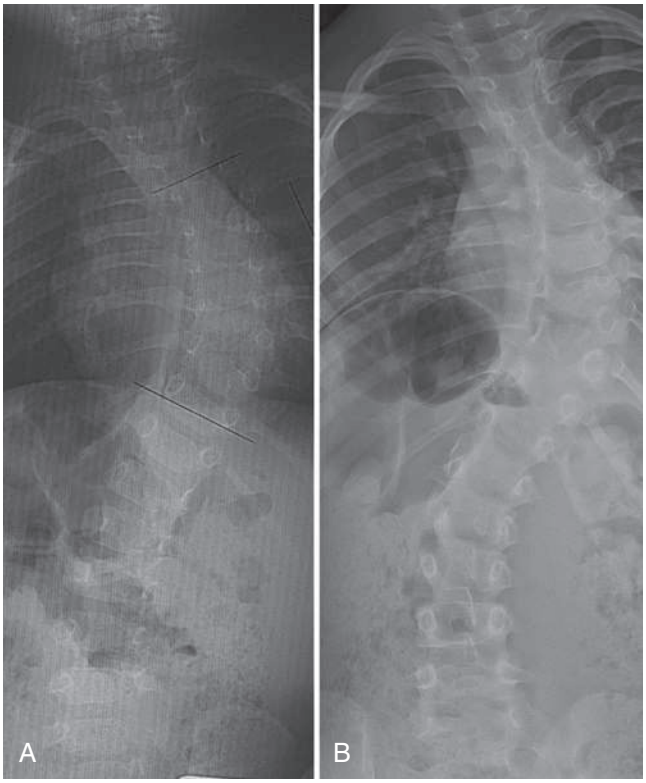

FIG. 26.8 Radiographs of congenital scoliosis with VACTERLS association (vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities) managed by observation since birth. Right thoracic curve and compensatory lumbar curve remain relatively unchanged from birth at (A) age 1 year and (B) age 8 years.

surgeon to determine the most appropriate treatment at the proper time.

Location

The most deforming anomalies tend to be those at the cervicothoracic or lumbosacral junction. Both types of deformity (formation and segmentation) may be lateral, causing scoliosis; dorsal, causing lordosis; ventral, causing kyphosis[62]; or a combination of these positions. Posterolateral positioning of a hemivertebra may cause kyphoscoliosis; anterolateral may cause kyphoscoliosis.[62] Furthermore, if the anterior part of the vertebra is deficient while the dorsal part is not malformed, kyphoscoliosis, especially in the lumbar spine, is common.[58,62]

Progression of Curvature by Deformity Type and Location

The spectrum of vertebral deformities associated with congenital scoliosis is associated with different growth potentials. In general, curves with fully segmented hemivertebrae have a greater capacity for continued growth potential and therefore greater risk for progression of curvature, whereas vertebrae whose apophysis is blocked are at minimal risk. Complex combinations of deformity contribute to a more pronounced spine imbalance and are associated with the greatest risk for curve progression.

For example, complete block vertebrae (complete type II deformity) or nonsegmented hemivertebrae are blocked

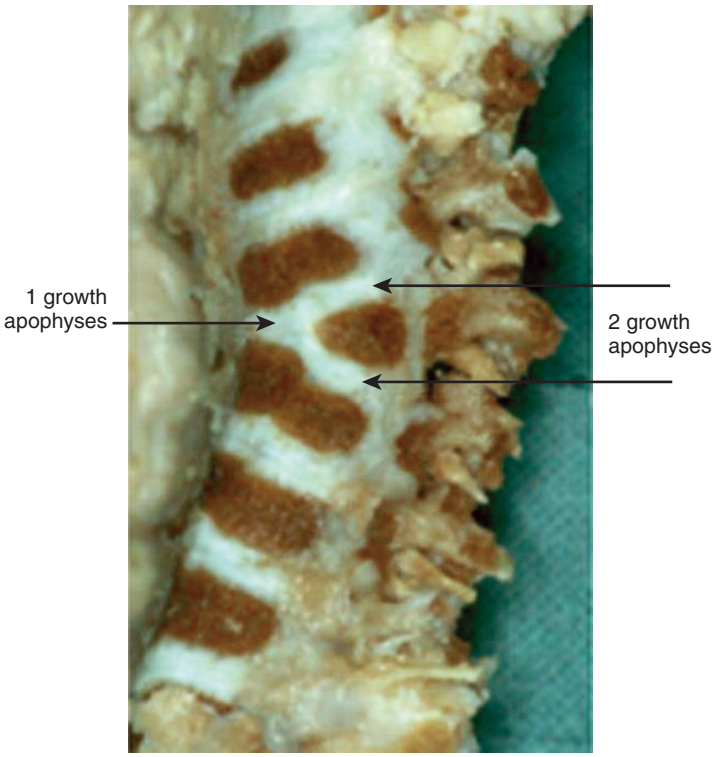

FIG. 26.9 Hemivertebra forcing spine into a curve. There are two growth apophyses on the hemivertebra side and only one on the other side, leading toward worsening during growth.

on both the superior and inferior apophysis. Therefore, the longitudinal growth potential is very small, and tends not to cause progressive scoliosis. Block vertebrae usually occur in multiple sites along the spine and are associated with a small potential for growth and a slow rate of progression (<1 degree per year[56,58,63]). Nonsegmented hemivertebrae demonstrate a similar rate of progression since they are also limited in their growth potential by being fused to the adjacent vertebrae. Incarcerated hemivertebrae also do not cause progressive scoliosis. When wedge vertebrae are located in the lower thoracic or thoracolumbar regions, the deformity demonstrates a relatively low rate of progression of 1 to 2 degrees per year.[56,58,63]

The location and number of hemivertebrae deformities along the spine affect the rate of curve progression. Specifically, the upper thoracic hemivertebrae tend to progress on average 1 to 2 degrees per year before puberty, then 2 to 2.5 degrees during the pubertal growth spurt. However, when the deformity is present in the lower thoracic spine, curves demonstrate a more rapid progression of 2 degrees per year before puberty and 2.5 to 3 degrees per year during the pubertal growth spurt. Furthermore, when located in the thoracolumbar spine, the rate of progression is again much more rapid—2 to 2.5 degrees per year before puberty and about 3.5 degrees per year during puberty. The more rapid progression and caudal location result in substantial trunk imbalance compared to other locations of curvature.[56,58,63]

Similarly, the span and location along the spine of a unilateral unsegmented bar greatly affect the natural development of the resultant curve. When located in the upper thoracic spine, the rate of progression averages 2 degrees per year before puberty and 4 degrees afterward. For deformity located within the lower thoracic area, curvature progression is 5 degrees per year before puberty and 6.5 degrees per year during puberty. Again, deformities with an apex located in the thoracolumbar area demonstrate the highest rate of deterioration—curves typically increase 6 degrees per year prior to puberty and 9 degrees per year after. Curves in the lumbar area progress about 5 degrees per year both before and after puberty.[56,58,63]

The most progressive anomaly is a convex, fully segmented hemivertebra associated with a concave unilateral bar. There is no growth potential on the side of the bar, but the side of the spine with the segmented hemivertebra continues to grow. Therefore, the spine is imbalanced, resulting in highly progressive curves. These types of disorders occur more frequently in the thoracic spine and are the most severe of all scoliosis disorders. They demonstrate rapid deterioration of up to 14 degrees per year prior to puberty, resulting in trunk shortening, limb-length discrepancy, and frank cosmetic deformity.[56,58,63]

Effects on Thoracic Contents

Congenital defects in the ribs and vertebrae often occur in conjunction. Rib fusion in the setting of scoliosis may constrict the thoracic contents during a crucial developmental period, and ultimately compromise pulmonary development. This occurs because alveolar development mostly takes place before 5 years of age and early restriction of the respiratory physiology effectively causes restrictive lung disease.[64–66] As the patient grows, the patient's thorax becomes unable to support normal respiration, a condition termed thoracic insufficiency syndrome (TIS). TIS can be assessed both clinically by respiratory rate and the thumb excursion test, by specific tests such as pulmonary function tests, and radiographically by plain radiographs and computed tomography (CT) volumetric studies.[67] Early fusion of scoliotic deformity before age 9 years, especially in patients requiring more than four levels of fusion and those with proximal fusions, also puts patients at risk for the development of restrictive pulmonary disease.[68,69] Additionally, compared with healthy peers, congenital scoliosis patients who were treated with extensive early spinal fusion demonstrate decreased pulmonary function test values in forced vital capacity, forced expiratory volume, vital capacity, and total lung capacity, and lower quality-of-life scores at 6.9 years' follow-up. Compared to congenital scoliosis patients who were fused in nonthoracic areas, patients treated with thoracic spinal fusion have reported shorter spinal height, more pain, and lower pulmonary functioning.[70] The increased appreciation of the need to preserve pulmonary function and to allow maximum spinal height has spurred the development of growth-preserving surgical alternatives to spinal fusion, including growing rods, guided growth, epiphysiodesis, and distraction thoracoplasty.

Assessment of Patient

Physical Examination

The physical examination of a patient with congenital scoliosis is guided by the knowledge of a high frequency of other structural and neural anomalies. Maternal, perinatal history, and developmental milestones must be fully explored. Presence of a dimple, nevi, hemangiomas, or hairy patches and/or any other cutaneous mark on the back should be noted. The sagittal plane balance and coronal balance, shoulder malalignment, as well as any deviation of head and trunk from the center of the pelvis should be checked. Due to the connection of scoliosis with Klippel-Feil syndrome, the cervical spine should be especially examined, including range of neck motion. In addition, it is critical to assess and document the neurologic status, including strength, reflexes, presence of atrophy, and the existence of latent ataxia or myelopathy. Flexibility of the deformity, gait, trunk shortening, and limb-length inequality should be checked. Pain, if present, should be localized and quantified. The examiner should search for other anomalies of the extremities (particularly radial malformation).

Associated Anomalies

Patients with congenital scoliosis have an increased incidence of other systemic differences including but not limited to respiratory, cardiac, renal, gastrointestinal, and neurologic systems. Pulmonary function tests, echocardiogram, and renal duplex may add to the overall case preparation. Often, the renal system is visualized on spinal magnetic resonance imaging (MRI), obviating the need for an additional study.[71] Collaboration with other specialties and with the patient's

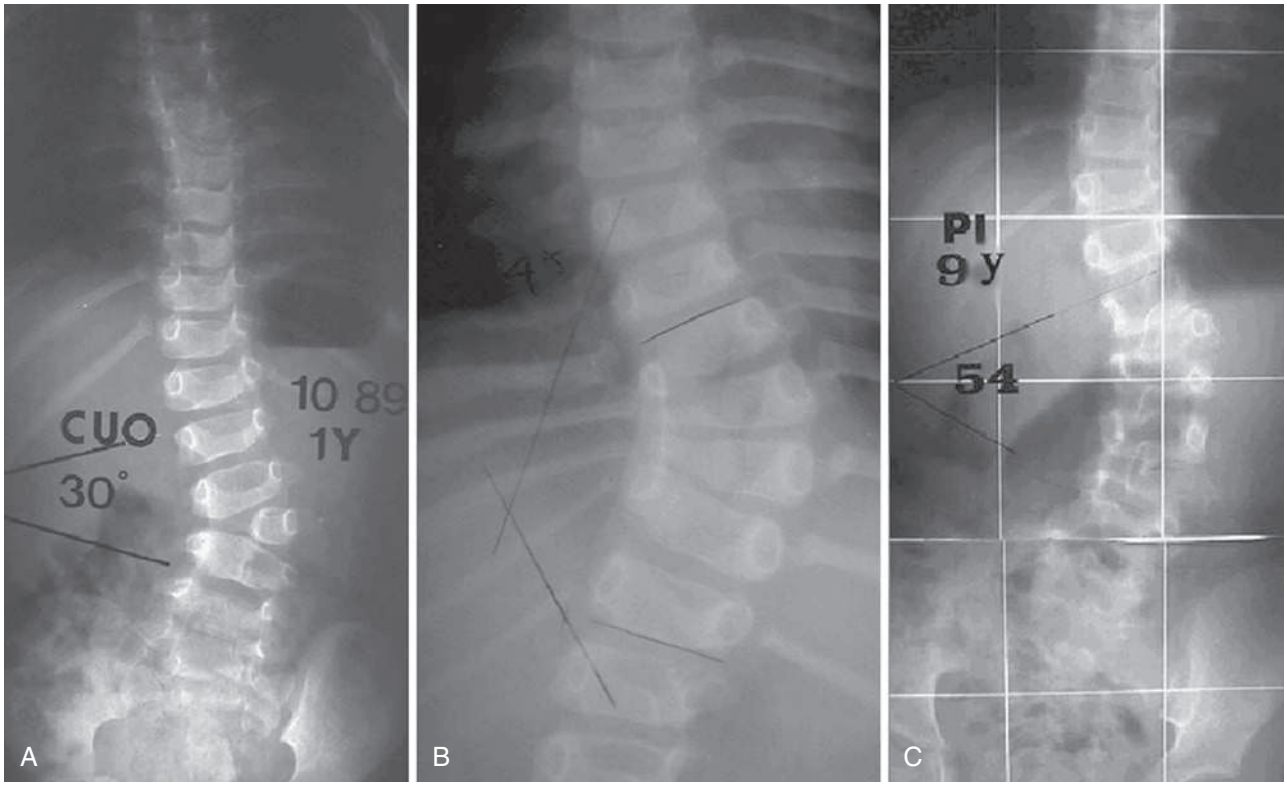

FIG. 26.10 It is easier to analyze a (A) segmented hemivertebra or a (B) unilateral bar when radiographs are taken prior to 4 years of age. (C) Lumbar segmented hemivertebra in a 9-year-old child.

primary care provider will serve to prepare the surgical team and optimize the patient for surgery.

Imaging

Preoperative CT scans define the anatomy and posterior element deficiencies. MRIs can exclude associated conditions of the spine, craniocervical junction, and viscera.

Radiographs

Plain radiographs remain the standard for the diagnosis and classification of congenital scoliosis and measuring curve magnitude and progression. Ideally, radiographs are obtained prior to 4 years of age (Fig. 26.10). After this time period, it may be difficult to fully appreciate the deformity because vertebrae are more ossified, especially in the areas of fusion or bars. Radiographs that were taken earlier—such as chest, abdominal, or renal radiographs—can provide valuable information to the orthopaedic surgeon about early development. Subtle findings—such as the presence and spacing of pedicles as well as fused, atretic, or absent ribs—provide clues about underlying deformity.

Standard anteroposterior and lateral films allow one to check the type and the location of deficiency, to measure the spine curvature, and to assess the pedicle width. However, studies have shown that, even in the hands of an expert, congenital scoliosis curves measured by the Cobb angle on traditional radiographs are difficult to reliably measure. Irregular landmarks and irregular numbering/positioning of vertebrae increase intraobserver and interobserver measurement error up to 10 degrees. Comparing current radiographs with prior radiographs reduces this error.[72–74] Since compensatory curves involve normally formed vertebrae, they are more reproducibly measured and can serve as a marker for progression of the congenital curvature. If a compensatory curve has not progressed, it is less likely that significant progression has occurred in a congenital curve.

Computed Tomography

Intraobserver reliability of measuring Cobb angles from plain radiographs is low in congenital scoliosis, with up to 10 degrees of measurement error; interobserver reliability demonstrates a greater measurement error.[74] Accurate and reliable reporting of curves as the patient matures through time is especially difficult. Furthermore, plain radiographs cannot demonstrate the spatial relationship of each structure of the vertebrae and the three-dimensional component of congenital scoliosis is difficult to appreciate. CT with three-dimensional reconstruction can be used to more completely and more consistently identify spinal abnormalities, especially posterior element deficiencies, in complex cases (Fig. 26.11). Spatial disposition of the affected vertebrae and the balance of deformity can be better classified. CT and three-dimensional reconstruction aid in the evaluation of the thorax and the lung and highlight thoracic wall deformities, including: rib synostoses, rib hypoplasia or agenesis, intracanal protrusions through the radicular foramina, and evaluation of TIS.[75,76]

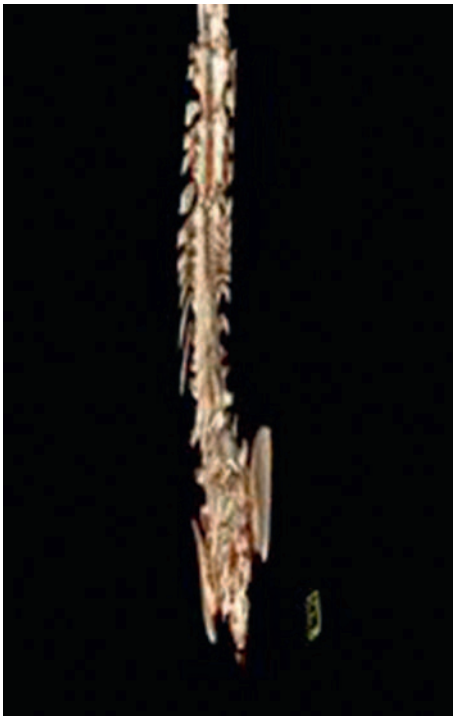

FIG. 26.11 Computed tomographic image with three-dimensional reconstruction allows the surgeon to more fully appreciate complex spine abnormalities.

Magnetic Resonance Imaging

Intraspinal anomalies are often associated with congenital scoliosis. Careful physical examination can suggest underlying spinal dysraphism.[38,77] MRI demonstrates intraspinal anomalies in 30% to 41% of cases.[78–80] Congenital scoliosis patients with cervical and thoracic hemivertebrae tend to have more intraspinal abnormalities than those with lumbar hemivertebrae.[81] The most common anomalies reported are tethered cord, syringomyelia, and diastematomyelia. MRI is indicated to assess congenital scoliosis because of three factors:

1. Intraspinal anomalies are encountered in about one-third of cases of congenital scoliosis.[81] Some may require neurosurgical treatment for their own sake (e.g., a large syrinx), whereas others may require neurosurgical collaboration if corrective orthopaedic surgery is planned (e.g., diastematomyelia).
2. Normal neurologic exam does not rule out malformations of the neuraxis.[79,80]
3. MRI of the spine will also typically demonstrate the presence or absence of renal anomalies, which may or may not capture evaluation of genitourinary anomalies.[71]

In practice, given the need for general anesthesia to obtain MRI in young children, it should be ordered when there is a concerning examination finding and/or prior to surgical procedure.

Treatment

Those malformations that present a very low progression rate should be periodically evaluated for possible progression. However, about 50% of congenital scoliosis cases require surgical treatment.[58–61] Correction of deformity should occur early in congenital scoliosis, which allows the correction of the fewest vertebrae possible and protection against continued, severe structural spine decompensation.[82–84]

Congenital vertebral anomalies require close clinical monitoring at periodic intervals during growth. Consistent observation allows for assessment of the evolution of spinal curves. In complex malformations, early treatment is often more straightforward and safer.

Nonoperative

Contrary to idiopathic scoliosis, nonoperative treatment has little value in congenital scoliosis. Only a small number of cases, characterized by long and flexible curves, may be temporized by bracing to slow the progression of the curvatures.[58,85,86] However, these curves will eventually decompensate to the degree requiring surgical management. In general, carefully monitoring every 4 to 6 months with regular examination and radiographic evaluation is prudent in curves measuring up to 40 degrees.[87] However, other factors—including deformity personality, pulmonary, cardiac, or neurologic function—may require earlier surgical intervention. For example, spines with successive, fully segmented hemivertebrae concomitant with additional severe deformities of the rib cage, therefore causing TIS, may undergo surgical intervention earlier regardless of the Cobb's angle.[87]

Operative

Without any treatment, 85% of patients with congenital scoliosis will have a curve greater than 45 degrees by maturity.[56] Congenital scoliosis progresses because the growth potential of the spine is imbalanced. Early recognition of curves with a poor prognosis is crucial to prevent severe curve progression and possible neurologic complications. The advent of pediatric-specific implants has minimized the problem of implant prominence in young children and has been shown to be safe from a neurologic standpoint.[83] Motor- and sensory-evoked potential monitoring is recommended whenever possible. There is an increased risk of a perioperative neurologic injury when baseline monitoring cannot be established.[88] Furthermore, postoperative monitoring and thorough documentation of neurologic functioning is important because paraplegia after deformity surgery may present in a delayed fashion, especially in the first 72 hours.[89,90]

Indications for surgery depend on many factors, including the nature of the vertebral anomaly as well as its location and span, the curve magnitude and its flexibility, the patient's age, and the presence of other deformities. The aim of surgery is fourfold: (1) achieve a straight spine, with or without deformity reduction; (2) restore a physiologic sagittal profile while maintaining flexibility; (3) limit curve progression; and (4) preserve normal spinal growth as much as possible by fusing only a short segment. Seven major operations have been described: posterior spine fusion, combined anterior and posterior spine fusion, convex hemiepiphyseodesis, hemivertebra excision,

vertebral column resection, osteotomies, and guided growth progression.

Posterior Spine Fusion

Posterior fusion is among the "simplest" and "safest" techniques, but is not without its limitations or complications.[91] Ideal candidates for posterior fusion are those with small, relatively short curves who otherwise have limited growth potential in the anterior spine. In general, curves no greater than 25 degrees that are limited to no greater than five vertebrae may be considered.[87]

Selection of these curves minimizes the risk of the crankshaft phenomenon[92] that can be seen if the anterior spinal growth is still active. The crankshaft phenomenon occurs when growth remaining increases the curve. Additionally, lordosis in the proposed region of fusion is a contraindication to posterior fusion because anterior growth will worsen lordosis. A review of 54 congenital scoliosis patients reported a 15% crankshaft incidence in patients undergoing posterior fusion before the age of 10 years, especially those with surgery at an early age and greater than 50-degree curves.[92]

Posterior spinal fusion may cause significant issues as the child continues to age. In a large meta-analysis review of patients with early-onset scoliosis, congenital scoliosis, and infantile scoliosis who underwent posterior spinal fusion for presumed definitive fusion in early childhood, revision surgery has been required in 24% to 39% of cases.[93] Additionally, restrictive pulmonary disease occurs in many of these patients,[93] although it should be noted that nonoperative management and continued curve progression are also likely to have negative effects on pulmonary function.[94] Patients 1 to 4 years old are best suited for this procedure. Posterior fusion can be considered a prophylactic procedure.

Imaging the spine prior to exposure is useful because the area of deformity is often difficult to localize by inspection and palpation alone. During exposure, failure to recognize the potentially complex posterior laminar defects can lead to neurologic injury. After exposure of the posterior elements, the spine should again be imaged to confirm that the targeted deformity, which may have anterior components, aligns with posterior elements. Some deformities, particularly anterior bars or malaligned hemivertebrae, have anterior elements that do not correspond to the logical posterior elements. Due to difficult localization of the deformity, there is a risk of extending the fusion past the originally planned surgery. Fusion must include all vertebrae involved in the congenital curve and should extend laterally to the transverse processes. Successful fusion is achieved by thorough facet resection, decortication, and placement of abundant bone graft. Posterior instrumentation can be used safely in the pediatric patient to decrease the risk of pseudarthrosis. Of course, posterior elements may be deformed, with fused or missing laminae, or thin pedicles that do not lend themselves well to instrumentation. With advancing age, typically by the age of 2 years, instrumentation becomes feasible. A postoperative cast or a rigid brace is then required for 2 to 3 months to achieve fusion and curve correction.

Combined Anterior and Posterior Spine Fusion

While the posterior-only approach has shortcomings due to the risk of anterior growth, the combined anterior and posterior fusion can more effectively prevent progression.[84] The main indications for a combined anterior and posterior fusion are a deformity with significant anterior and posterior growth potential. For example, a unilateral bar with a contralateral hemivertebra would be appropriate for a combined anterior and posterior spine fusion.

Performing an anterior approach allows for discectomy and removal of the vertebral endplates, which augments spine flexibility and the potential for deformity correction. Unlike the posterior-only fusion, the combined approach, or even anterior only, is appropriate for lordotic curves. The combined fusion may decrease the rate of pseudarthrosis, decrease the crankshaft phenomenon, and can also be augmented by instrumentation. Anterior bone graft is typically placed for fusion. Depending on surgeon preference and the location of the deformity, the anterior procedure may be performed either through an anterior, open technique, thoracoscopically,[95] or through a posterior approach. Accessing the anterior vertebrae via a posterior approach is most feasible at the thoracolumbar junction via retropleural dissection, especially if the surgeon is able to take advantage of a kyphotic element.

Convex Hemiepiphysiodesis

The concept of convex hemiepiphysiodesis is the same as that commonly employed for deformity of growing long bones. The surgeon is able to take advantage of this and spare the patient intraoperative destabilization or growth arrest of the whole fused spine segment, with convex growth arrest. Convex hemiepiphysiodesis slows convex-side growth while the concave curve still grows, allowing for safe and relatively controlled progressive deformity correction.[96] Thus, failures of segmentation with little or no growth potential cannot be successfully treated this way. Ideal candidates for convex hemiepiphysiodesis are young enough that growth will allow for significant correction, a curve less than 70 degrees, have six or fewer involved vertebrae, and demonstrate significant concave growth potential.[97] Patients should be 6 years old or younger because spinal growth is two-thirds complete by this age.[98] Traditionally, pathologic congenital kyphosis or lordosis has been a contraindication for this procedure.[99] For example, an appropriate deformity for this treatment may be a single or multiple hemivertebrae in a patient 6 years old or younger.

Convex hemiepiphysiodesis typically requires an anterior and posterior exposure; however, posterior-only methods are feasible. The traditional combined anteroposterior approach allows for the removal of the convex portion of discs and vertebral endplates and fusion of this convex portion with bone graft via the anterior approach; removal of the unilateral facet joints and fusion is completed via the posterior exposure. Traditional convex hemiepiphysiodesis without instrumentation typically yields modest curve correction, on the order of 0 to 15 degrees by maturity; some patients achieve only an arrest of progression.[100] Much of the correction with convex

growth arrest seems to be achieved acutely at the time of the initial procedure, which is then attempted to be maintained with postoperative immobilization.

As with the other treatments, instrumentation can be used to achieve better intraoperative correction—convex posterior compression is typically utilized with good results in convex growth arrest.[101,102] Early follow-up analysis of 11 patients with long, sweeping congenital curves (involving multiple anomalous vertebrae) who underwent this method of concave posterior distraction in convex instrumented hemiepiphysiodesis yields encouraging results. A posterior-only instrumented convex growth arrest with pedicle screws at each segment on the convex side may obviate the need for anterior surgery. A collection of 13 patients treated with the posterior-only convex growth arrest procedure described earlier demonstrated that the procedure is safe and that curves improved by 5 degrees or greater in nine patients, while two patients' curves remained the same.[103]

Hemivertebra Excision

Hemivertebra excision is preferred in cases in which a hemivertebra causes progressive curve and deformity with truncal imbalance. In contrast to fusion and convex epiphysiodesis, hemivertebra excision acutely corrects the curve and corrects for truncal imbalance. Excision of the hemivertebra is recommended if the curve progresses significantly. Instrumented hemivertebra excision provides the highest degree of correction, particularly if carried out before 3 years of age.[104] Hemivertebra excision is ideal for a fully segmented hemivertebra at the apex of the curve in the thoracolumbar junction, lumbar spine, or lumbar sacral spine, and with a fixed lateral translation of the trunk. Cervicothoracic or cervical hemivertebra excision has been reported but is a more complex procedure due to the vertebral artery.[105] Hemivertebrae may be resected by an anteroposterior or posterior procedure only.

The combined anterior and posterior excision of the hemivertebra allows for the circumferential exposure of the spine and complete excision of the adjacent discs. Anterior and posterior exposure can be achieved either by sequential procedures under a single anesthetic or when performed simultaneously.[106,107] After excision, the unstable spine is then stabilized with anterior and/or posterior instrumentation typically by utilizing an anterior structural graft, which is useful on the concave side to maintain a normal sagittal contour. Instrumentation may then be used both anteriorly and posteriorly to apply compression and to further stabilize the spine. The need for postoperative immobilization is determined by the surgeon's impression of spinal stability (Fig. 26.12).

Similar to convex hemiepiphysiodesis, hemivertebra excision can also be accomplished via a single posterior approach due to advances in imaging and monitoring.[108–111] The ideal indication for a posterior-only approach is a hemivertebra located at the thoracolumbar junction or in the lumbar spine, with some associated kyphosis.[62] The posterior-only approach is stabilized with segmental transpedicular instrumentation after excision.[111,112] Clinical experience has shown that pedicle screws even in young children do not cause spinal stenosis. If needed, hooks can augment the screws.

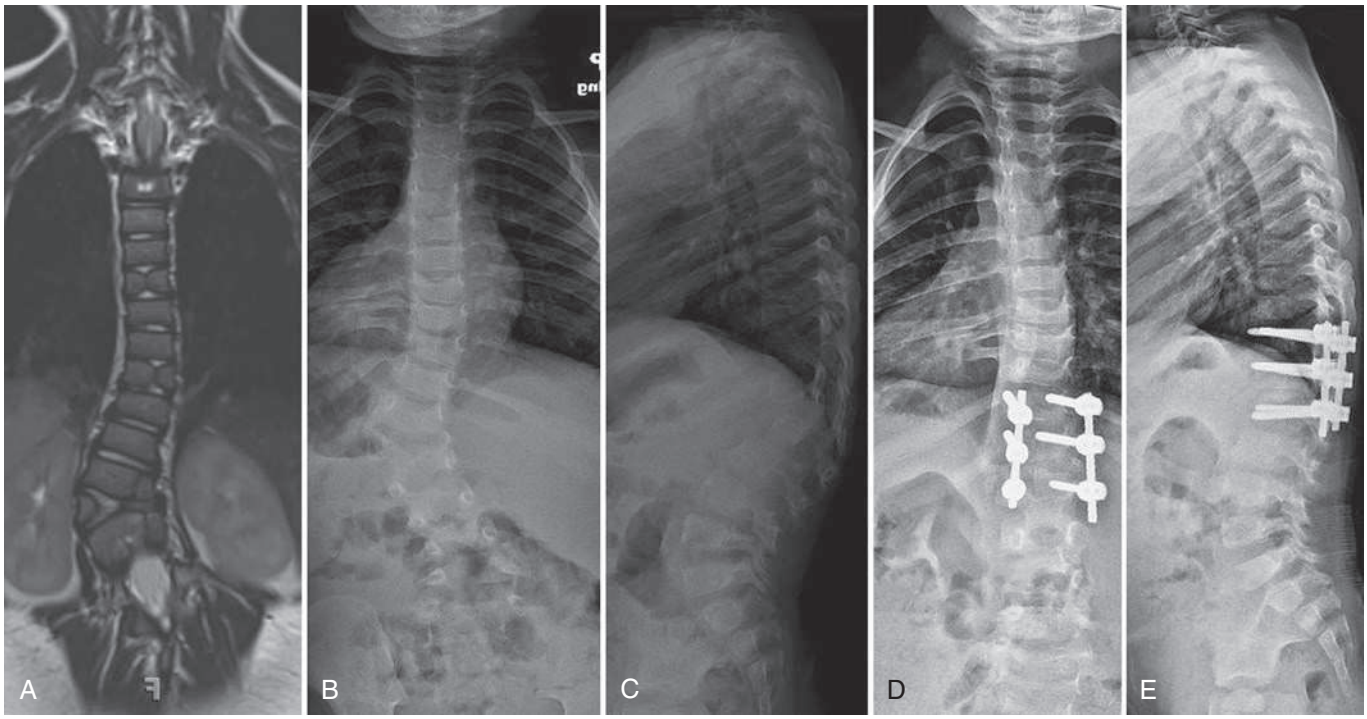

FIG. 26.12 (A–C) Radiographs of a 2-year-old boy with progressive kyphoscoliosis at the level of the L1 hemivertebra. (D–E) The patient underwent hemivertebra resection and anterior and posterior spinal fusion with posterior spinal instrumentation. He was placed in a cast and maintained good correction postoperatively.

Osteotomies

Complex curves with multiple fusions, prior instrumentation, and significant trunk imbalance may justify multiple anterior and posterior osteotomies to allow for spinal mobilization. Patients undergoing osteotomies should have preoperative imaging of the entire spine to rule out intraspinal anomalies in the canal. After osteotomies are created, correction of the curve may be achieved at the same stage. Complex deformity correction may incorporate osteotomies with other types of procedures. Multiple concave rib osteotomies add flexibility. It can be considered as an alternative in the treatment of rigid congenital curves involving more than three levels or multiple curves separated by at least two segments that would otherwise require multiple vertebral resections.

Vertebral Column Resection

Vertebral column resection (VCR) describes the complete resection of vertebral segments using either combined anterior and posterior approaches or a posterior-only approach, which enables significant three-dimensional deformity correction.[113,114] This technique may be applied to correct moderate to severe spinal deformities, including those with large rigid curves, fixed trunk translation, or asymmetry between the length of the convex and concave column of the deformity. VCR carries significant risk of neurologic injury[114–116] (Fig. 26.13). This high risk is partially secondary to the severe nature of the deformity eligible for VCR and partially due to the resulting instability from segmental resection and instrumentation.

Rigid instrumentation that controls the spinal column above and below the resection area must be performed in VCR procedures. Instrumentation is imperative for preventing and treating the very real risk of spinal subluxation. Anterior structural graft can be used on the concave side of the construct to maintain a normal sagittal contour. Similarly, a posterior structural graft, preferably from the patient's rib, can be used to cover a laminectomy defect.[115,116] Releases are also typically performed at the apex of scoliosis or kyphoscoliosis deformities to facilitate pedicle screw placement.

Guided Growth Procedures

In a young patient with progressive deformity, growing rods provide progressive correction of the curve and the expansion of the thorax. This is especially of value for congenital spine deformities with concomitant rib fusions, which lead to restrictive pulmonary disease and/or TIS. In general, guided growth procedures should be considered as an alternative to long spinal fusion. An important consideration to discuss with the patient and family is the commitment to undergoing multiple surgical spinal procedures, typically every 6 months. Among the potential complications are drift of the spinal anchors, infection, postoperative pain, device fracture due to stress fatigue, brachial plexus palsy, and neurologic injury.[117,118]

Dual growing rods lengthened at 6-month intervals were shown to achieve greater curve correction and allow for greater spinal growth when compared to single growing rods.[119] In patients with spondylocostal dysostosis, vertical expandable prosthetic titanium rib guided growth has more marked impact on curve progression and chest wall development:

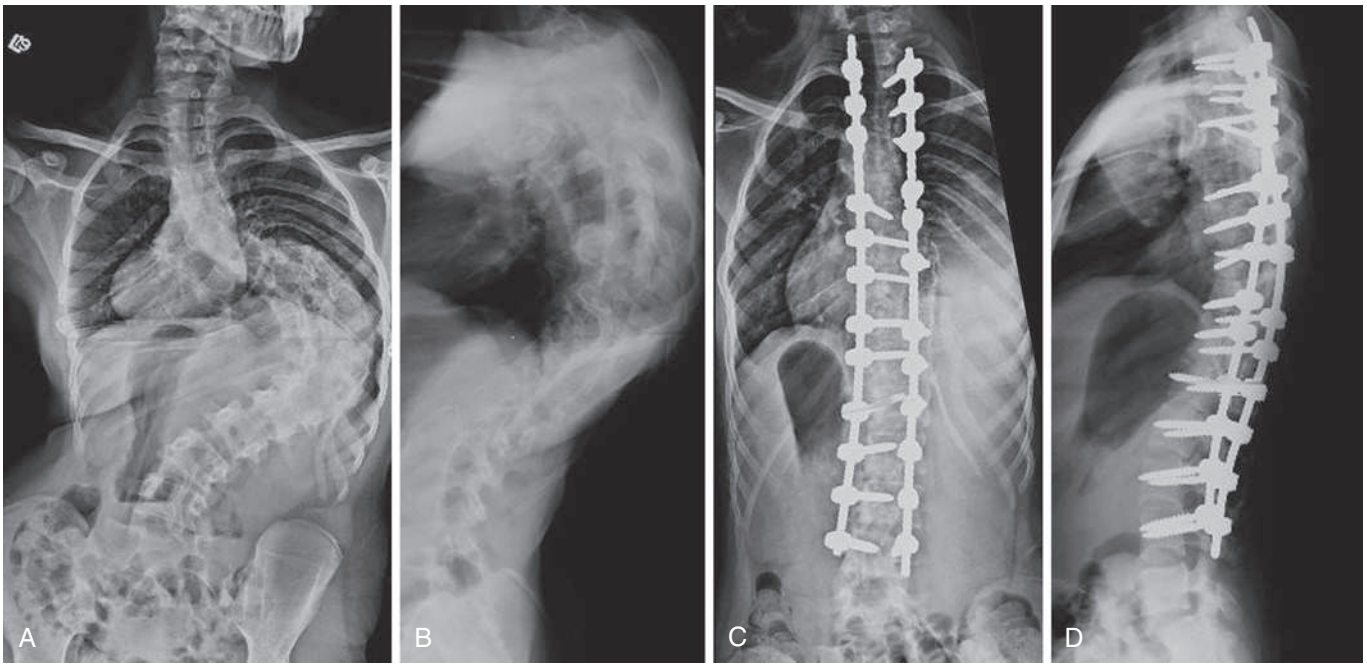

FIG. 26.13 (A–B) Radiographs of severe congenital scoliosis measuring 120 degrees in a 15-year-old girl. (C–D) The patient underwent posterior spinal fusion instrumentation, right vertebral column resection, and multiple discectomies.

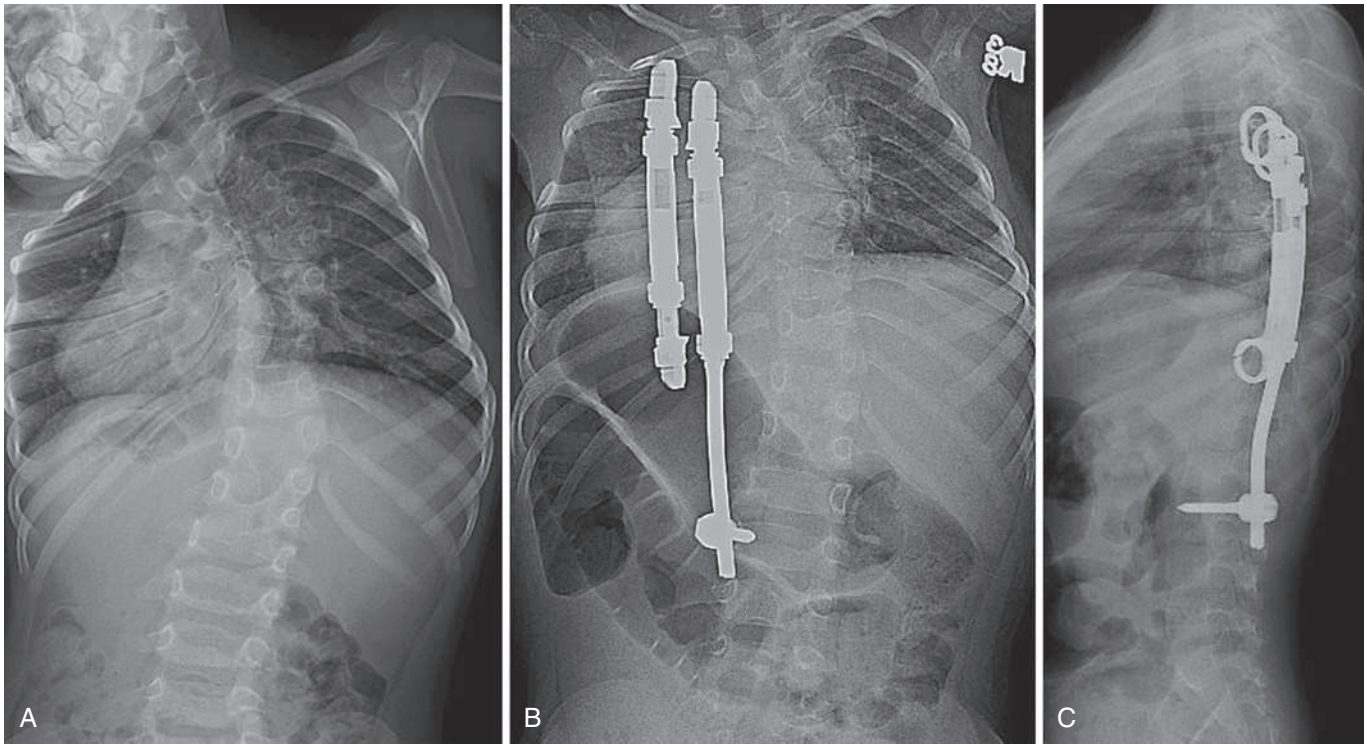

FIG. 26.14 (A) Radiograph of severe chest deformity associated with congenital scoliosis and multiple rib fusions in a symptomatic 4-year-old child. (B–C) The patient underwent multiple rib osteotomies with the use of vertical expandable prosthetic titanium rib anchored from rib to rib and from rib to spine.

increases in thoracic height and width and improvement in the Cobb angle (Fig. 26.14).

Magnetic controlled growing rods (MCGRs) continue to expand the possibilities for guided growth procedures. Rather than continued reoperation with exchange of implants, as is needed with conventional growing rods, MCGRs can facilitate curve control, maintain growth along the spine, and spare the patient multiple reoperations by using nonsurgical distraction methods. Preliminary data on MCGRs are promising both from a safety and efficacy standpoint.[120,121] Long-term outcome studies are needed to better inform surgical decision making regarding the use of guided growth procedures.

Conclusion

Congenital scoliosis presents immense variation in deformity, impact, and treatment options. Not all cases benefit from surgery. Regular examination will make clear which patterns require intervention. Advances in growth-friendly surgery have provided many other options for treatment. Advances in imaging, monitoring, and operative techniques will make the treatment as safe as possible.

KEY POINTS

1. Assessment of vertebral anomalies is best in early childhood.
2. Progressive deformation is due to imbalance in spine growth. Some vertebral anomalies do not lead to imbalance and are not likely to produce deformity.
3. Bracing has almost no effect on congenital spine curves.
4. Surgery should be performed as early as is practical to prevent secondary structural changes.
5. All patients with congenital scoliosis should be evaluated for genitourinary anomalies. They should also undergo panspinal MRI if significant progression occurs or if surgery is indicated.
6. The first available film should be analyzed and used for subsequent comparisons.
7. The measurement error for congenital scoliosis is greater than idiopathic (approximately 10 degrees).
8. Neurologic risk of spine surgery is higher for congenital scoliosis than other types.
9. Congenital anomalies of the posterior elements do not often correlate with anomalies of the bodies and may require three-dimensional CT to previsualize.
10. The surgeon should be aware of midline laminar defects when using a posterior exposure.

CHAPTER 27

Idiopathic Scoliosis

SECTION IV

Lawrence G. Lenke
Fernando E. Silva
Ronald A. Lehman Jr

Idiopathic scoliosis is the most common cause of spinal deformity in pediatric patients, encompassing 80% of all scoliosis. Because its etiology is not known, it is a diagnosis of exclusion—other causes such as congenital, syndromic, neuromuscular, and positional (leg-length discrepancy) must be ruled out. The radiographic diagnosis requires a coronal plane angle, measured by the Cobb method, of 10 degrees or greater. Patients with curves less than 10 degrees are considered to have spinal asymmetry.[1,2] Ponseti and Friedman[3] first described early-onset scoliosis in 1950. Later, Dickson[4] expanded further on that concept and proposed that idiopathic scoliosis be divided into early (0–5 years old) and late onset (>5 years old), based on spinal growth velocity noted in these two age groups. Currently, idiopathic scoliosis is divided into four categories based on the age of onset: infantile (birth to 2 years + 11 months), juvenile (3–9 years + 11 months), adolescent (10–17 years + 11 months), and adult (18 years and older).[5] Treatments include close observation, bracing, and surgical intervention. Patient safety is imperative and is achieved by appropriate training, careful patient selection, and adherence to the principles of deformity surgery. Advanced technology and procedures have improved surgical treatment, with the ultimate goals being patient safety, satisfaction, motion preservation, and choosing the optimal fusion levels to prevent the need for further surgical intervention.

Epidemiology

Infantile and juvenile scoliosis are less prevalent than adolescent idiopathic scoliosis. Infantile idiopathic scoliosis is more common in Europe, constituting less than 1% of idiopathic scoliosis cases in the United States. Typically, these are left-sided thoracic curves, often occurring among boys. Recent reviews suggest that there might be a decline in its incidence.[6] In contrast, juvenile cases are typically diagnosed at age 5 years in boys and 7 years in girls, accounting for about 10% to 20% of idiopathic scoliosis cases.[3] Additionally, juvenile cases occur predominantly in girls; however, between 3 and 6 years of age, there seems to be a similar distribution between boys and girls, only to become predominant again in girls after age 6 years. The curve patterns closely resemble those of adolescents. Adolescent idiopathic scoliosis (AIS) is the most prevalent type. Among adolescents, the prevalence of 10-degree curves is less than 3%, with about 5% of curves showing a progression of greater than 30 degrees.[4] This prevalence decreases as a function of curve magnitude, however, to about 0.3% to 0.5% and 0.1% in curves measuring 20 degrees and 40 degrees, respectively.[7] The prevalence of curves greater than 10 degrees is higher among girls, with a 4:1 ratio of girls to boys, increasing to 9:1 when curves reach an operative range of about 40 to 50 degrees.[8]

Etiology

Despite decades of research, the specific cause of idiopathic scoliosis remains elusive and likely multifactorial. Possible causes of infantile idiopathic scoliosis include intrauterine molding or postnatal pressure on the spinal column from supine positioning during sleep. Other etiologies that have been considered in idiopathic scoliosis include dysfunction in proprioception to maldevelopment in central pattern generators in the spinal cord, connective tissue disorders, hormonal issues, and muscle/structural changes.[9-12] The literature suggests, however, that in the observed deformation of the spine, the unique mechanics of the fully erect posture, which is exclusive to humans, as well as genetics, both play important roles in its development and progression. Kouwenhoven and Castelein[13] concluded that many factors may play a role in the initiation and progression of AIS at a certain age. The growth spurt noted among adolescents seems to play a role in progression because, as the spine grows, there seems to be a mechanical influence as a critical buckling load is reached. Reports in the literature continue to strongly suggest a genetic link.[14]

Genetics

It is widely accepted that genetics plays a major role in idiopathic scoliosis. In 2008, Kulkarni and colleagues[15] mapped a developmentally critical *CHD* gene to 15q26.1 and, together

with *CHD7,* suggested a possible role of *CHD2* in the embryonic development of the spine. In efforts to map out the gene(s) responsible for idiopathic scoliosis, Gao and colleagues[16] reported the first gene (*CHD7*) in the 8q12 locus to be associated with a familial idiopathic scoliosis. However, Tilley and colleagues failed to replicate Gao's findings.[17] In contrast, Takahashi et al. detected a strong association between AIS and rs11190870 near LBX1, noting that this was associated with both susceptibility and curve progression of AIS.[18] Hua et al. corroborated the latter findings as they reported on the strong association between AIS and rs11190870 near LBX1 in a Japanese group with AIS.[19] In terms of inheritance, the prevalence is 11% among first-degree relatives, 2.4% among second-degree relatives, and 1.4% among third-degree relatives.[20] Concordance among monozygotic and dizygotic twins has been reported to range from 73% to 92% and 36% to 63%, respectively.[21,22] Anderson and colleagues[23] published a population-based study taken from the Danish Twin Registry in which 46,418 twins were registered. From the 34,944 respondents, the concordance rate for monozygotic twins was 13% versus 0% for dizygotic twins. Gurnett and colleagues[24] published a report of a single multigenerational family in which AIS and pectus excavatum segregated as an autosomal dominant condition. Through linkage analysis, the investigators identified a genetic locus for the two conditions on chromosome 18q. Hence, even though the exact genetic and hereditary basis of scoliosis remains elusive, several chromosomes appear to play a role. Furthermore, its mode of inheritance remains unclear as both autosomal recessive, autosomal dominant with variable penetrance, and X-linked dominant modes of inheritance have been reported.

Natural History

About 90% of infantile curves show spontaneous resolution, especially among infants who are younger than 1 year at diagnosis.[6,25] Curves that typically progress are double curves with a thoracic component. Insight into curve progression can be obtained from the rib-vertebral angle difference (RVAD) and "phase of the rib head."[26] To calculate the RVAD, a line is drawn perpendicular to the *apical* vertebral endplate, another line is drawn from the mid-neck to the mid-head of the corresponding rib; the angle formed by the intersection of these lines is the rib vertebral angle or RVA. For calculating the RVAD, the angle on the other side of the same vertebra is calculated as well. The difference between the values of the RVAs on the concave and convex sides of the curve is the RVAD. In terms of phase of the rib head, if the head and neck of the *convex* rib of the vertebral body at the apex of the curve does not overlap the vertebral body, it is termed *phase I*; if it does overlap, it is termed *phase II*. It is unnecessary to calculate the RVAD when a curve is noted to be a phase II type, as those are almost certain to progress. Curves with RVAD greater than 20 degrees or phase II angles are very likely to progress.

Although juvenile scoliosis curves less than 25 degrees can also spontaneously resolve, about 70% of juvenile curve types tend to progress, with 50% requiring bracing and 50% surgical treatment. These curves tend to progress if idiopathic scoliosis is diagnosed before age 6 years and/or if they have a Cobb angle of greater than 30 degrees. Here, the RVAD has not proven to be a useful predictor of curve progression.

Many factors influence the natural history of AIS. Growth potential, skeletal maturity, curve magnitude, and location are important considerations when assessing progression of AIS. Family history, gender, and rotation do not seem to influence progression. Peak height growth seems to correlate best with, and is a better predictor of, progression than skeletal maturity. In terms of biomechanical influences, this likely is secondary to attaining a critical vertebral column height, which leads to a critical buckling load and greater bending moments with eventual curve progression. In girls, peak height growth seems to occur 6 to 12 months before the onset of menarche. In boys, peak height growth seems to correlate with the closure of the triradiate cartilage. Larger or double curves tend to progress more than smaller or single curves. Additionally, curves can progress *after* skeletal maturity; thoracic curves greater than 50 degrees and thoracolumbar/lumbar (TL/L) curves greater than 40 degrees can progress on average 1 degree per year.[27,28]

Evaluation

History and Physical Examination

A complete history, including any family history of scoliosis, is obtained and a physical examination is performed. With infantile and juvenile cases, in particular, a thorough prenatal, birth, and developmental history is obtained. In the adolescent, the growth spurt history is noted. Length of time postmenarche is an indication of potential growth remaining. A girl grows fastest one year *before* onset of menarche and usually finishes growing 2 years *after* its onset. Voice changes in boys are noted as well, because when such change has begun, the growth spurt is in its most intense phase. When the voice has acquired adult characteristics, the growth rate has started to decelerate. The duration of voice change varies between less than 1 year to more than 3 years. This information is imperative in determining peak growth velocity and as predictors of growth potential and its implications on possible curve progression.[29] Symptoms of pain and/or weakness and how the patient perceives her or his appearance relative to the deformity are especially important with AIS.[30] During the examination, height, weight, and age (years plus months since last birthday) are recorded. The head is examined with special attention to torticollis and plagiocephaly, given its higher incidence with infantile scoliosis. Possible conditions and anomalies that might be present include buccal and palatal anomalies, café-au-lait spots, and midline dimples or hair patches, or both, over the lumbodorsal spine, which can be important clinical clues to the presence of intraspinal pathology. Limb laxity is also checked and, when present, genetic counseling is requested. Trunk shift, a clinical correlate of curve rotation, is evaluated as the patient stands with the hips and knees fully extended. The relationship of the patient's head to the pelvis is also noted in evaluating the overall coronal and sagittal balance. Any shoulder, breast, or pelvic asymmetry is

noted.[31] Curve rotation is assessed by performing an Adams forward-bend test and is quantified with a scoliometer. This is of critical importance when considering a selective thoracic fusion. This assessment is modified in infants by laying the patient on the examiner's knee, which also helps in assessing the rigidity of the curve, an important factor in terms of prognostication. Alternatively, a sitting forward-bend test can be performed. The latter maneuver can also help assess for plagiocephaly and developmental hip dysplasia, especially in infants. Leg-length discrepancy and pelvic obliquity are also evaluated.[32] When leg-length discrepancy is the likely cause of the deformity, a shoe lift is used to reevaluate the patient to determine if the curve corrects. A thorough neurologic examination includes all cranial nerves, motor strength, reflexes (including abdominal reflexes, often associated with Chiari malformations), sensory modalities, and gait.[33] Finally, other possible causes of scoliosis—such as congenital, syndromic, and neuromuscular types, as well as infection, neoplasms, and spondylolisthesis—must also be ruled out.

Radiographic Evaluation

Initial posteroanterior and lateral 36- × 14-inch standing long cassette views are obtained. Coronal and sagittal Cobb angles are measured.[2] Curves greater than 20 degrees in infants and children; any neurologic symptoms present in patients with idiopathic scoliosis; and left-sided, sharp angular, or irregular curve patterns require further investigation, including screening with total spine magnetic resonance imaging.[34,35] When anomalies of the nervous system are present on magnetic resonance imaging, a pediatric neurosurgical consultation is indicated.[36,37] In advanced curves when surgery is planned, supine, side-bending, and push-prone films are obtained for curve classification and to assess curve flexibility.

Classification Systems

Currently, there are no accepted formal curve classification systems for infantile or juvenile scoliosis. However, utilizing formal consensus-building methods, surgeons experienced in treating early-onset scoliosis (EOS) have developed a novel classification system for EOS, with all core components demonstrating substantial to excellent interobserver reliability. This classification system will likely serve as a foundation to guide ongoing research efforts and standardize communication in the clinical setting.[38] Similarly, in their effort to develop a classification system for juvenile scoliosis, Lenke et al. have modified the initial Lenke classification for AIS. This basically follows all the tenets of the AIS classification, but uses the C7 plumb line and the central sacral vertical line (CSVL) to decide on whether the minor thoracic or thoracolumbar curves are structural or not, respectively. The proximal thoracic curve's structural character is assessed by the relationship of the first rib to the main thoracic curve. Although such classification has not gained wide use, it attests to the authors' desire to continue to contribute to the treatment of deformity patients.[39]

The first treatment-based AIS classification was developed in 1983 by King and colleagues.[40] Based on a series of 405 patients with AIS, their uniplanar system analyzed thoracic curves only in the coronal plane. This system allowed for surgical planning and helped in assessing whether or not a King II curve could be selectively fused.[41] Interobserver and intraobserver reliability of this traditional thoracic classification system has proven to be fair at best.[42,43] Additionally, coronal decompensation has been reported after King II selective fusions, leading Lenke et al. to develop stricter criteria for selective thoracic fusions.

Lenke and colleagues[44] developed a comprehensive, practical classification system in 2001 that analyzes the coronal and sagittal planes (Fig. 27.1). It includes not only thoracic curves, but also TL/L curve patterns. Its interobserver and intraobserver reliability has been demonstrated.[42,43] Its definition of the structural characteristics of the proximal thoracic curve has been deemed reliable, leading to shorter proximal fusions when that curve is nonstructural.[45] It also allows a stricter evaluation of a curve's structural nature, permitting a more objective analysis of when a given curve can tolerate a selective fusion leading to a balanced outcome.[46,47] The latter is clinically significant, as one of the most important principles in preventing postoperative decompensation is proper identification of curve patterns, including which curves can tolerate a selective fusion.[41,48] This three-tiered classification combines a curve type (1 through 6) with coronal lumbar (A, B, or C) and sagittal thoracic (–, N, or +) modifiers to produce a triad comprehensive curve classification (e.g., 1A–).

Recent advances based on the Lenke classification system have led to the tentative inclusion of a third modifier: the last touched vertebra (TV). The TV is the most cephalad TL/L vertebra, T12–L5, of the lowest *structural* curve that is touched by the CSVL. In curve types 3 to 6, the TV is the most cephalad vertebra (T12–L5) touched by the CSVL *below the apex* of the structural TL/L curve, whether that curve is included in the fusion or not. Such a modifier aids in a more thorough evaluation of the Lenke curve classification (e.g., 5CN–L3, where L3 is the TV of the lowest *structural* curve), and serves as a landmark for the objective selection of the lowest instrumented vertebra (LIV) in Lenke 1A curves as well as selective thoracic fusions. Identification of the TV and comparison with the selected LIV also helps in postoperative curve analysis, assessment of distal fusion length, and overall evaluation of the surgical treatment of AIS.[49,50] If the LIV is the preoperative TV, then the TV to LIV relationship is (0); if the LIV is one level cephalad to the TV, then it is (–1); and (+1) when the LIV is one level caudal to the preoperative TV.

Three-Dimensional Classification

Scoliosis is a known three-dimensional deformity, and although the Lenke classification system takes into account the coronal and sagittal planes, it does not account for the axial or transverse planes of the deformity. A task force of the Scoliosis Research Society continues to work on developing a clinically useful three-dimensional analysis to aid in further defining the classification of scoliosis. The key factor in a

THE LENKE CLASSIFICATION SYSTEM FOR AIS

Curve type	Proximal thoracic	Main thoracic	Thoracolumbar/lumbar	Description
1	Nonstructural	Structural*	Nonstructural	Main thoracic (MT)
2	Structural†	Structural*	Nonstructural	Double thoracic (DT)

Modifier	Cobb angle
– (Hypo)	<10°
N (Normal)	10°–40°
+ (Hyper)	>40°

Curve type (1–6) + Lumbar coronal modifier (A. B, C) + Thoracic sagittal modifier (–, N, +) =
Curve classification (e.g. 1B+): _____

FIG. 27.1 Lenke adolescent idiopathic scoliosis (AIS) classification system schematic.

three-dimensional assessment is the plane of maximum curvature, which is the three-dimensional deformity that occurs as the spine translates and rotates out of the normal sagittal profile in scoliotic deformities. This work is expected to provide further understanding so that three-dimensional analysis and classification will become a standard for all scoliosis surgeons.[1,51]

Treatment Options

Three fundamental treatment options exist for idiopathic scoliosis: observation, casting/bracing, and surgery. These treatment modalities are based on the natural history of idiopathic scoliosis or the potential or probability of curve progression.[1,52] However, other modalities have been proposed to slow or halt curve progression, such as electrical stimulation and physical therapy. Yet, none of these modalities has been scientifically proven to be a viable alternative in the treatment of scoliosis.[53] Romano et al. noted that there is a lack of high-quality evidence to recommend the use of scoliosis-specific exercises for AIS, although a very low-quality study suggested that these exercises may be more effective than electrostimulation, traction, and postural training to avoid scoliosis progression.[54] Better-quality research needs to be conducted before the use of scoliosis-specific exercises can be recommended in clinical practice. Similarly, Mordecai et al. concluded from their extensive literature search that there is poor-quality evidence supporting the use of exercise therapy in the treatment of AIS.[55]

Observation

Up to 90% of infantile curves have been known to resolve spontaneously, but they can progress.[56] Deciphering which infantile curves will progress can be guided by the RVAD and the relationship of the apical rib head to the vertebral body, as previously noted.[27] Infants with curves less than 30 degrees and RVAD less than 20 degrees and juveniles with curves less than 20 degrees should be followed clinically and radiographically every 3 to 6 months. Adolescent idiopathic patients with curves less than 25 degrees are also followed clinically and radiographically every 3 to 6 months. Brace treatment is started for curve progression.

Bracing and Casting

Bracing[57] is the nonoperative treatment of choice in *small but progressive* scoliosis in growing children and adolescents. In about 75% of cases, bracing can control the curve and avoid progression, rendering the curve small enough so that the risk of progression after growth is unlikely.[53] In a younger child whose growth potential remains a significant issue, bracing allows curve control and continued growth until the patient requires eventual operative treatment should curve progression ensue.

With infantile cases, serial Mehta casting (derotational type) or a thoracolumbar orthosis are appropriate treatments in flexible curves, Cobb angles greater than 30 degrees, RVAD greater than 20 degrees, and curves with a phase II vertebral-rib relationship. Bracing alone can be employed where there is incomplete correction with Mehta casting. Bracing and casting of these patients comes with potential consequences, however, that include pulmonary restriction, which can have future ramifications.[58,59] Yet, Sanders and colleagues[60] found serial casting to be beneficial in the treatment of infantile scoliosis. They reported that curves less than 60 degrees often fully corrected in infants if casting was started before age 20 months.

Juveniles with curves 20 to 50 degrees are candidates for bracing. Here, the intent is *to prevent curve progression* and not so much attain correction. These patients are essentially braced 16 to 23 hours a day until the completion of skeletal growth or until they become surgical candidates. Patients with thoracic hypokyphosis should not be braced.

In adolescents with curves between 20 and 30 degrees, bracing is started if a curve progresses greater than or equal to 5 degrees or more in two consecutive visits or greater than or equal to 10 degrees in one visit. Bracing is usually started after the first office visit if the patient is skeletally immature (Risser ≤2) and presents with a 25- to 40-degree curve. This treatment modality is effective only for flexible curves and, as with the juvenile type, the goal is *to stop progression* versus curve correction. Male, obese, and noncompliant patients, as well as those with poor in-brace correction and hypokyphotic curves, are less likely to benefit from bracing. Patients must wear their brace 16 to 23 hours a day until the completion of skeletal growth or until they become surgical candidates. Bracing is deemed successful if there is less than 5 degrees progression at brace discontinuation (skeletal maturity). Conversely, if the curve progresses to greater than 60 degrees after brace discontinuation and/or if there is absolute progression to greater than 45 degrees at or prior to discontinuation, the patient is considered to have failed bracing treatment.

Several brace options exist. Deciding which brace to use depends on the apex of the curve and physician preference. Curves with an apex above T6 would likely require the use of a Milwaukee (cervicothoracolumbosacral orthosis).[61] Conversely, curves with apices at T7 or below and above L2 do well in a Boston underarm thoracolumbosacral orthosis. These braces are more socially acceptable due to lack of a cervical extension. The Charleston bending brace is an option if the child is noncompliant to wearing the brace during the day. Although the efficacy of a brace seems to depend on the length of time the brace is worn,[62] this brace is typically worn at night, and some studies have shown its efficacy.[63,64] Modifications to the standard thoracolumbosacral orthosis include variations of the Chêneau brace (Jacques Chêneau) and the SpineCor dynamic brace (SpineCorporation). The Chêneau 2000 orthosis allows for a greater amount of initial correction by using a hypercorrected mold and pads, which provide derotational forces.[65] This brace is the first that uses the theory of expansion to allow for active correction by respiratory movements.[66] The SpineCor[67] and TrIAC (Boston Brace International) are nonrigid braces. They work by using straps, which correspond to a specific correcting movement depending on the curve pattern, producing a progressive positional change, dynamic curve correction, and appropriate muscle balance. When bracing is initiated and pad placement is deemed appropriate, patient follow-up occurs every 4 to 6 months, with in-brace radiographic evaluation and appropriate fitting adjustments made when necessary.

Operative Intervention

Operative intervention is usually recommended for patients whose curves progress despite nonoperative management.[67] In infants, operative intervention is controversial. It is occasionally performed in infants with thoracic curves greater than 45 degrees, TL/L curves greater than 40 degrees, or those who fail Mehta casting or bracing. Juveniles are typically more prone to curve progression and are more likely to require operative intervention, particularly with curves greater than 50 degrees. Other patients who are likely to benefit from operative intervention are skeletally immature patients with AIS with a greater than 40- to 45-degree curve and mature patients with curves greater than 50 degrees.[27]

Surgical Techniques

Anterior-only, posterior-only, and circumferential procedures remain the mainstay of surgical treatment options.[68] However, the prevalence of anterior-only and circumferential procedures has declined with a concomitant development of surgical technologies permitting successful posterior-only procedures. Surgeons are now aware that early intervention with a definitive anteroposterior fusion for progressive infantile and juvenile curves leads to loss of trunk height development, which can lead to chest wall and lung underdevelopment.[69,70] This problem has promoted innovative techniques to try to control progressive curves surgically without definitive fusion, including epiphysiodesis,[71,72] dual growing rod placement (Fig. 27.2),[73] intervertebral stapling (Fig. 27.3),[74,75] spinal tethering (Fig. 27.4),[76,77] and the vertical expandable prosthetic titanium rib (VEPTR),[78] with the last used more in progressive EOS, in which rib and chest wall deformities can be quite severe. In those cases, Cobb angles greater than 45 degrees and failed Mehta casting or bracing are operative indications, with fusion as close to skeletal maturity as possible. Among juveniles, fusionless techniques are also indicated in small children with

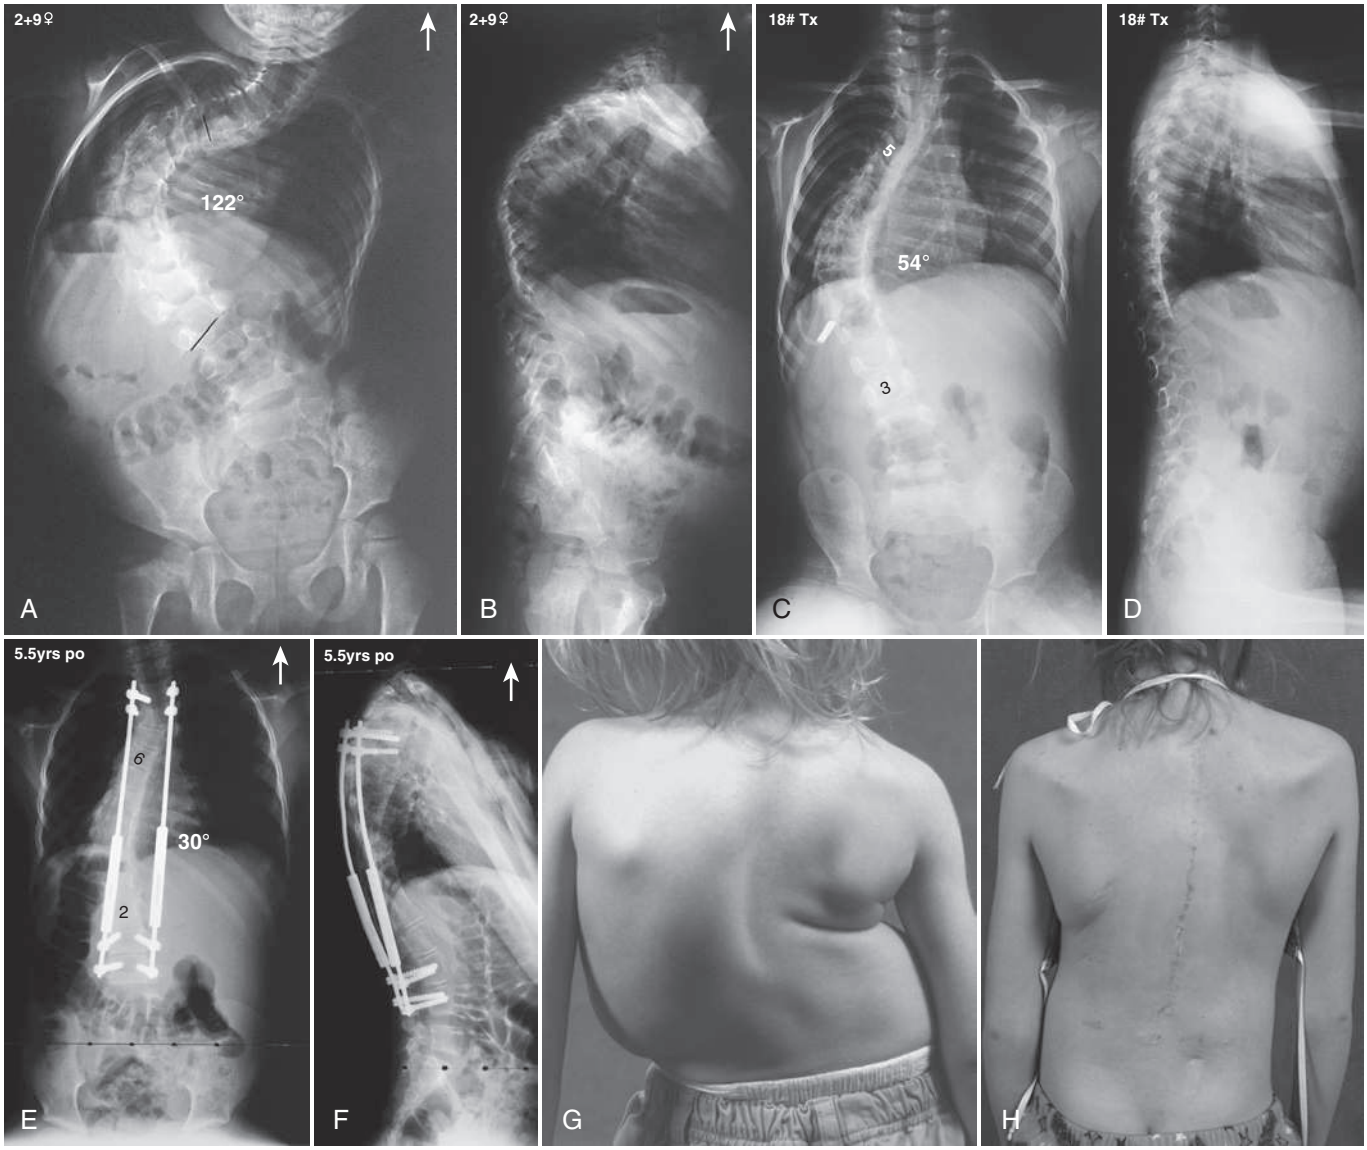

FIG. 27.2 (A–B) Radiographs of a girl, age 2 years + 9 months, who presented with severe infantile-onset idiopathic scoliosis. Her left thoracic curve measured 122 degrees. (C–D) She was placed in halo-gravity traction and underwent a short apical anterior release and fusion, and was prepared for a growing rod construct. (E–F) She had a dual-rod, pedicle screw growing rod construct placed. At 5 years + 6 months after initiation of growing rod treatment, she continues to be lengthened with overall good coronal and sagittal balance and acceptable lung fields. (G–H) Preoperative and latest postoperative clinical images show maintenance of trunk alignment and growth.

curves greater than 40 to 50 degrees with significant growth potential, allowing continued spinal growth over unfused segments, until a definitive fusion can be performed *close to or at* skeletal maturity. Anteroposterior fusions are reserved for younger patients with curves greater than 50 degrees with a potential to crankshaft or for very severe curves. Anterior-only instrumentation and fusions are indicated for TL/L curves greater than 40 to 50 degrees with a normal sagittal profile. Posterior-only fusions are performed for curves greater than 50 degrees as well as double major curves, when the child has grown closer to skeletal maturity, or even in those who are skeletally immature with the use of segmental pedicle screws and adequate fusion levels that will prevent the adding on phenomenon.

Many surgeons today still prefer to perform an anterior approach in younger patients when there is risk of crankshaft development and especially for thoracolumbar and lumbar major curves. However, with the introduction of pedicle screws, a posterior approach has shown numerous benefits over an anterior procedure, such as better maintenance of the obtained correction, more powerful corrective forces, three-column control, and often obviating the need for anterior releases and thoracoplasties.[79–85] In addition, a posterior approach avoids the negative consequences of chest cage disruption and pulmonary compromise that can result from an open anterior approach[86,87] (Fig. 27.5). Yet, according to a 2010 study by Tis and colleagues,[88] with the advances in anterior instrumentation, surgeons theoretically should see

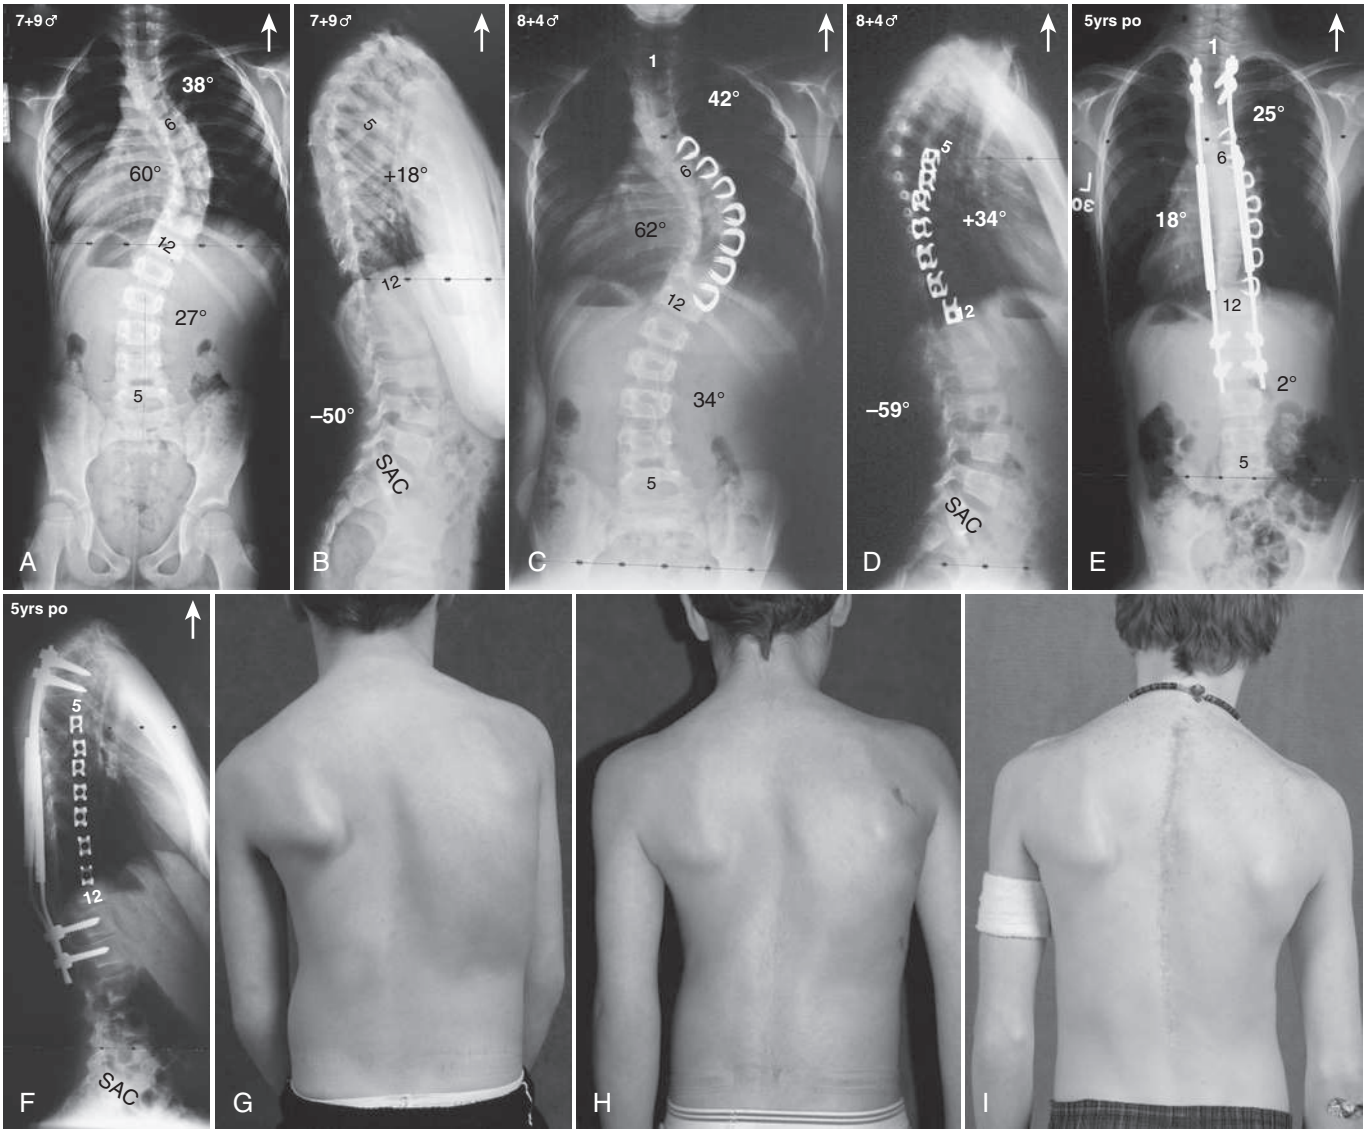

FIG. 27.3 (A–B) Radiographs of a boy, age 7 years + 9 months, who presented with progressive juvenile-onset right thoracic idiopathic scoliosis. His main thoracic curve measured 60 degrees and was progressive despite bracing. (C–D) He had anterior thoracic stapling performed but had slow progression of his deformity with growth. (E–F) A posterior dual screw-rod growing construct was placed. Five years after insertion, his deformity correction has been maintained to 18 degrees in the main thoracic curve with a good sagittal profile. (G–I) Clinical images before surgery, status post-stapling, and 5 years status post–growing rod construct show improvement of truncal deformation.

a reduction in the rate of rod breakage, pseudarthrosis, and sagittal decompensation, and obtain improved correction rates. These authors concluded that open anterior spinal fusion surgery is a safe method for the treatment of thoracic AIS. At 5-year follow-up, they reported good coronal and sagittal correction of the main thoracic and compensatory TL/L curves, but they also reported that pulmonary function was mildly decreased as with any procedure in which a thoracotomy is performed. Tis and colleagues also concluded that in skeletally immature patients, an open anterior spinal fusion can increase kyphosis; however, newer techniques used in their series seemed to limit progressive kyphosis, which has been noted in previously published reports.[89]

Adolescent curves can typically be surgically treated via an anterior or posterior approach (or both) with instrumentation and fusion.[88] Thoracoscopic procedures have shown advantages over open anterior thoracotomy procedures. Kishan and colleagues[90] showed that anterior thoracoscopy had fewer adverse effects on pulmonary function. Sucato and colleagues[91] found that adding a thoracoscopic release performed in the prone position to a posterior instrumentation and fusion offered the advantages of minimally invasive surgery and did not require repositioning to perform the posterior procedure. In addition, when double-lung ventilation is used, acute pulmonary complications are significantly reduced. A significant learning curve is required, however, and these techniques have diminished in popularity owing to the proliferation of pedicle screw constructs.

During surgical planning, determination of proximal and distal fusion levels is paramount because choosing incorrect

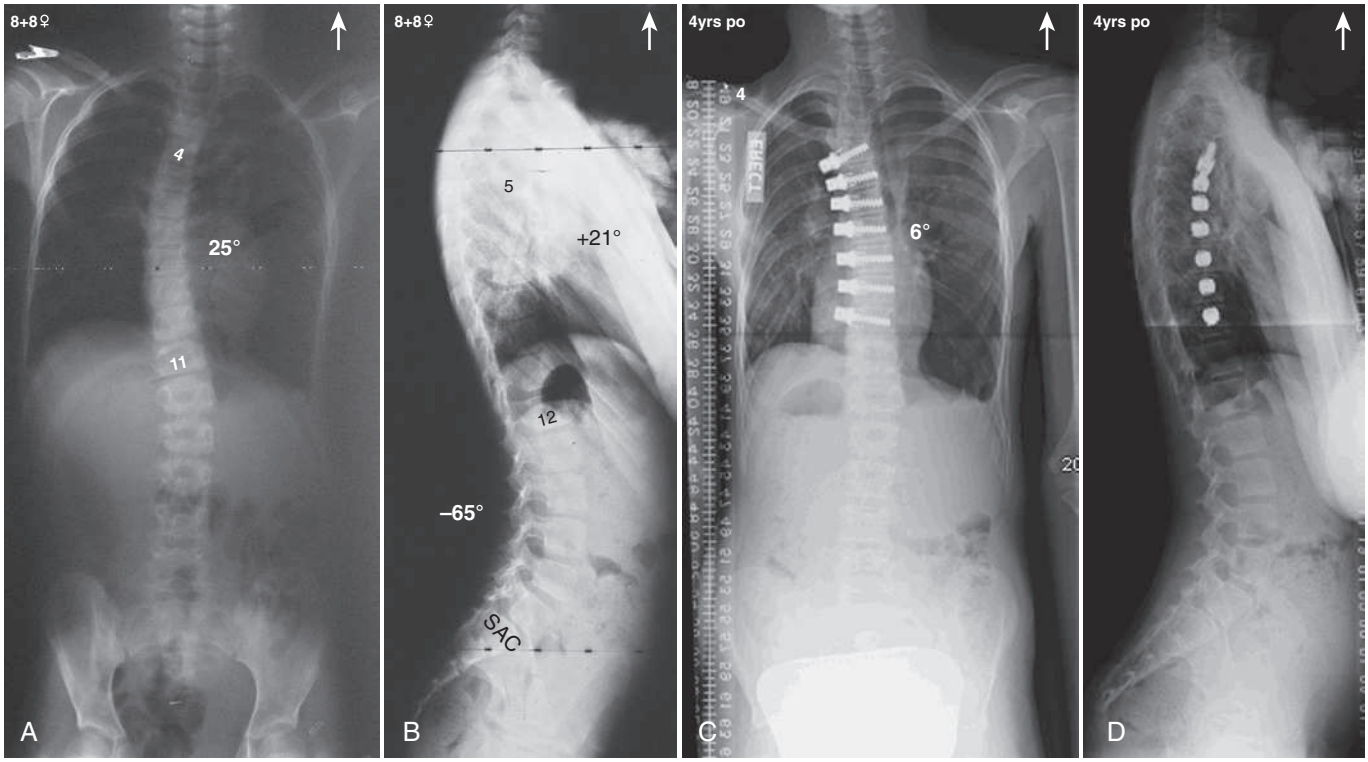

FIG. 27.4 (A–B) Radiographs of a girl age 8 years + 8 months who presented with progressive left thoracic scoliosis. She had a positive family history of scoliosis, with her mother requiring scoliosis fusion as a child. Her left thoracic curve progressed to 25 degrees with a normal sagittal profile. (C–D) She was treated with a single left thoracic mobile tether, with slow progressive correction of her deformity to 6 degrees with a normal sagittal profile 4 years after treatment. She had only one surgery and did not wear a brace postoperatively.

levels is the main reason for postoperative decompensation.[31,92] *Adding on* is another phenomenon that can result if a fusion is stopped "short." Suk and colleagues[93] reported 5-year results of 203 patients in which they found that adding on occurred in 17 patients who were fused, on average, two levels short of the neutral vertebra.

Upper and Lower Instrumented Vertebra Selection

With anterior-only approaches, fusion levels typically extend from end-to-end vertebrae, as measured with the Cobb technique. Short fusions above and below the apex, depending on whether the apex is a disc or a vertebra, have been advocated for flexible thoracolumbar curves.[9] In this technique, if the apex is a vertebral body, the discs above and below the apex are included in the fusion. If the apex is a disc, the two discs above and below the apex are included in the fusion. Brodner et al.[94] predicted fusion levels based on the supine-pull ("stretch") films, ensuring that a thorough release is performed to obtain a bone-on-bone fusion. Anterior structural grafts have been used to counter the kyphogenesis associated with anterior instrumentation.[88]

With posterior approaches, the selection of the upper instrumented vertebra is based on clinical and radiographic shoulder height, size, and stiffness of the proximal thoracic (PT) curve, hyperkyphosis of the upper thoracic region and amount of main thoracic curve correction planned (dynamic criteria). In general, when the left shoulder is elevated, the PT curve is structural and/or kyphotic (T2–T5 >20 degrees) and marked correction is planned (apical translation), T2 is a wise choice for the upper instrumented vertebra in this scenario. When the shoulders are level and the PT curve is close to being structural and/or mildly kyphotic (T2–T5 >10 degrees and <20 degrees), with marked correction planned, T3 is an appropriate choice. Finally, T4 or T5 is a wise choice when the right shoulder is elevated and the PT curve is nonstructural and not kyphotic.

Selection of the lower instrumented vertebra (LIV) requires identification of the end, neutral, and stable vertebra (SV) of the distal structural curve to be included in the fusion.[95] A safe place to end the fusion is the SV; however, the Lenke classification and current correction techniques employing pedicle fixation and derotation maneuvers allow for shorter distal fusion levels (Fig. 27.6). As noted earlier, in addition to all Lenke 1A curves, in selective thoracic fusions of Lenke 1C and 2C curves, the TV can be the LIV if it is proximal to the stable vertebra. With possible selective thoracic fusion of Lenke 3C and 4C curves, the TV is still going to be below the apex of the structural TL/L curve even when that curve is not included in the fusion. Similarly, with nonselective thoracic fusions, as well as Lenke 5C and 6C curves, the LIV can be cephalad to the SV provided that the intended LIV touches the CSVL, does not have significant rotation (Nash-Moe grade ≤1.5), and the disc below is parallel or closed on the convexity and the apex of the TL/L curve is L1 or the L1–L2 disc, *not* L2.

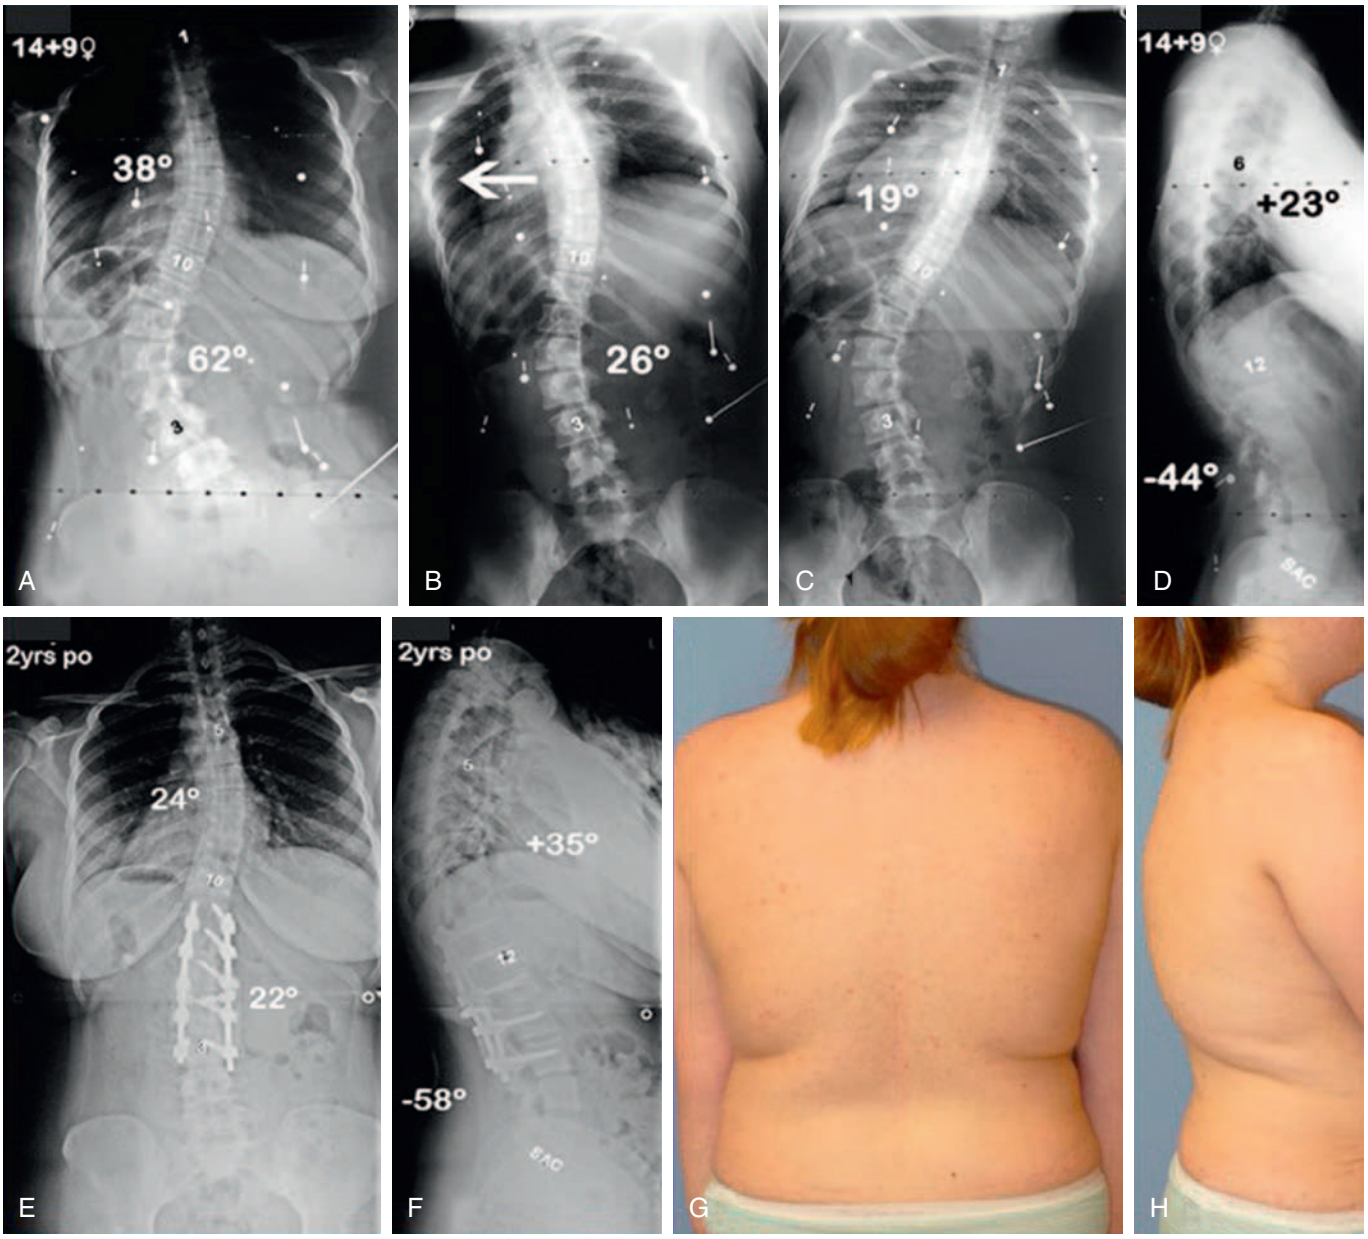

FIG. 27.5 (A–D) Radiographs of a female, age 14 years + 9 months, with a Lenke 5CN curve. She was treated with a posterior-only approach. (E–H) Note postoperative balanced spine and excellent clinical results.

In placing thoracic screws, it is essential to follow sequential steps at every screw placement.[79,80] With small pedicles, time should be taken to expand the pedicle to accommodate a screw.[96] Alternatively, parapedicular screw placement is a safe possibility.[97] Although we advocate the use of pedicle screws whenever possible, when employing hook-and-rod segmental instrumentation, it is imperative to reverse hook orientation where the discs are reversed in orientation to maintain coronal and sagittal balance.[98] We also advocate selective thoracic fusions whenever feasible.

Selective Fusions

The term *selective fusion* refers to minor structural thoracic or lumbar curves that cross the midline, but are not included in the fusion. That is, they are left untreated. Similarly, rare situations arise when one considers fusing nonstructural, secondary curves for the sake of cosmesis, spinal balance, or both.

The Lenke classification system provides an objective way to decide when to perform selective fusions in patients with AIS, especially with type C curve patterns, including Lenke 1 and 2C, and possibly Lenke 3C and 4C types.[47,92] Selective fusions of the latter types are achieved by having stricter criteria that define the *structural characteristics* of individual curves, leading to an objective analysis that helps in choosing which curves can be selectively fused without ensuing clinical imbalance.[43,44,99,100] Clinical assessment of the deformity cannot be overemphasized because it plays as important a role as the radiographic assessment when deciding whether to perform a selective fusion. Hence, the analysis of whether or not to proceed with a selective thoracic fusion (STF) begins

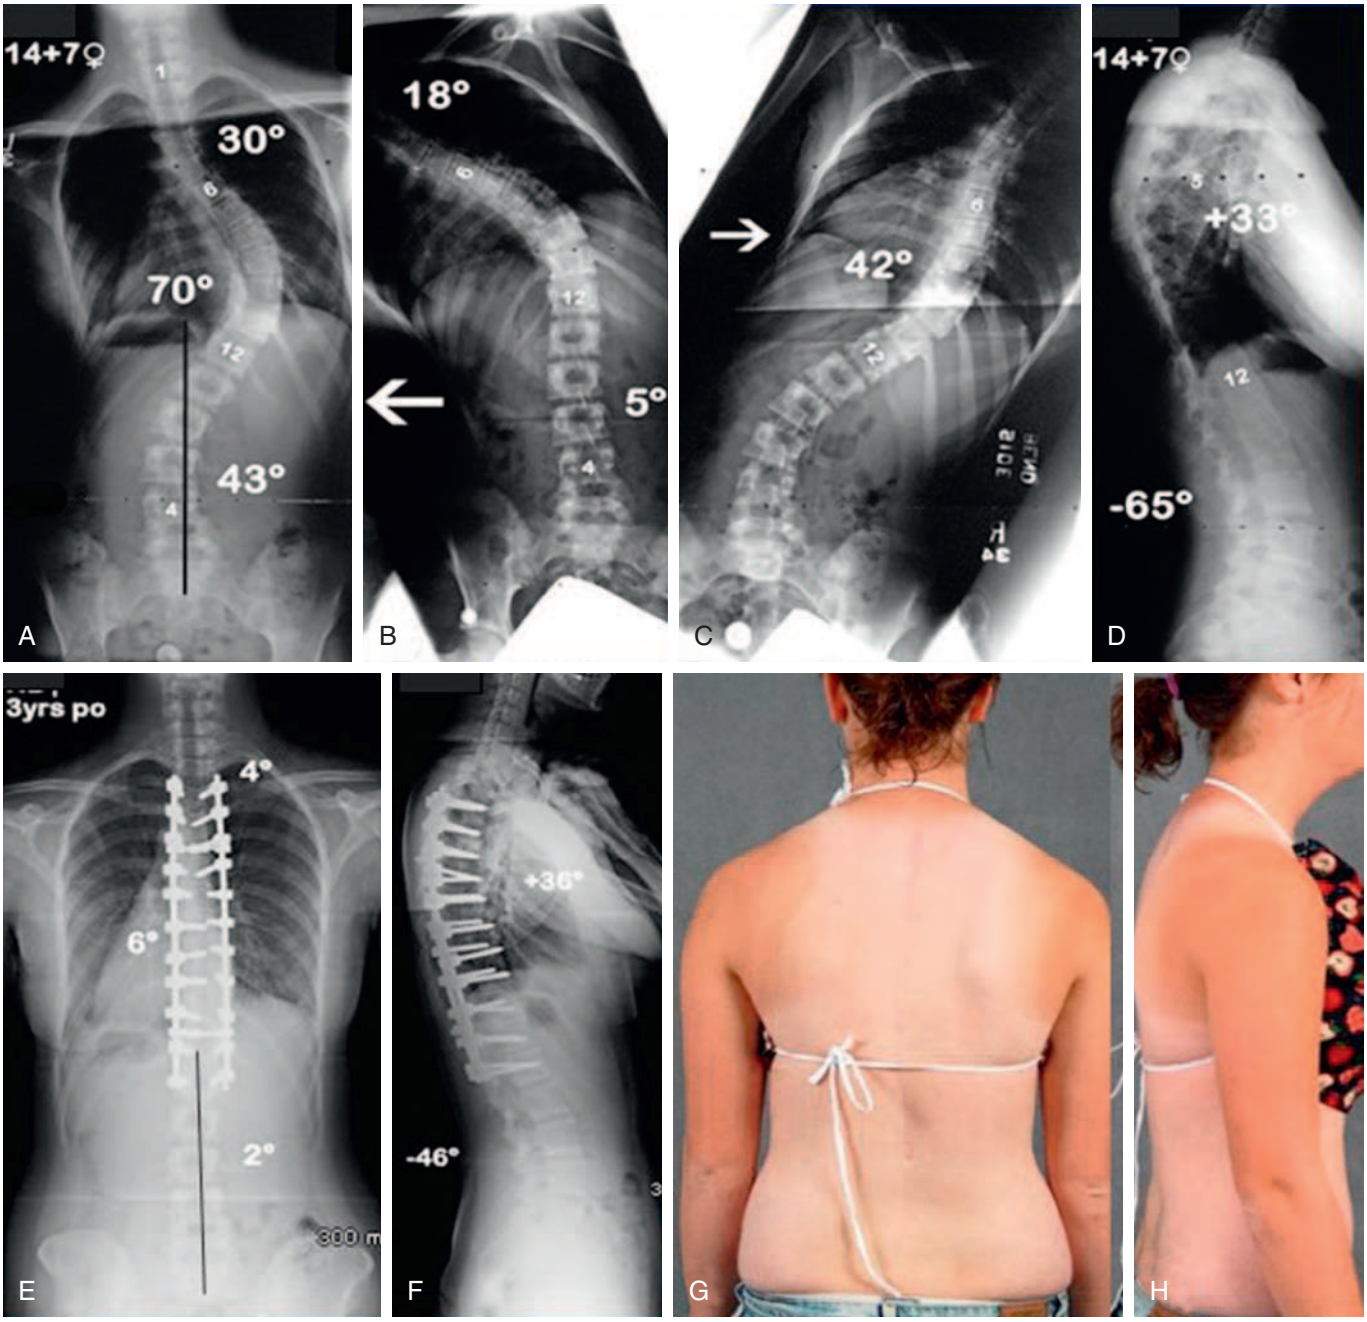

FIG. 27.6 (A–D) Radiographs of a female, age 14 years + 7 months, with a Lenke 1BN/L1 curve. She was treated by posterior-only approach, T3–L1 (0). (E–H) Note postoperative balanced spine with spontaneous lumbar correction from B to A modifier and excellent clinical results.

with the clinical assessment of the patient's deformity as well as skeletal maturity.[41,43,92] The magnitude of the thoracic and lumbar prominences are evaluated in order to decide if the patient is willing to accept a moderate lumbar hump when contemplating an STF. Next, the radiographic analysis entails comparing the relative Cobb angle measurements and apical vertebral rotation and translation ratios of the thoracic and TL/L curves.[48,49] Also, *one cannot overlook the thoracolumbar sagittal profile* because this can lead to curve misclassification and incorrect operative management; that is, proceeding with an STF in a curve pattern when selective fusion might not be recommended. In terms of operative management, attention must be paid to the degree of tilt left on the LIV when carrying out an STF; this is guided by the lumbar modifier to allow for harmonious balance of the unfused structural lumbar curve.

A rough estimate of the degree of tilt to be left on the LIV is equal to the remaining tilt on a preoperative supine film. This tilt is further assessed with intraoperative full-spine radiographs.[99] Again, this is imperative in allowing for accommodation of the structural component of the lumbar curve, especially with selective fusions.[47] The lower endplate of the

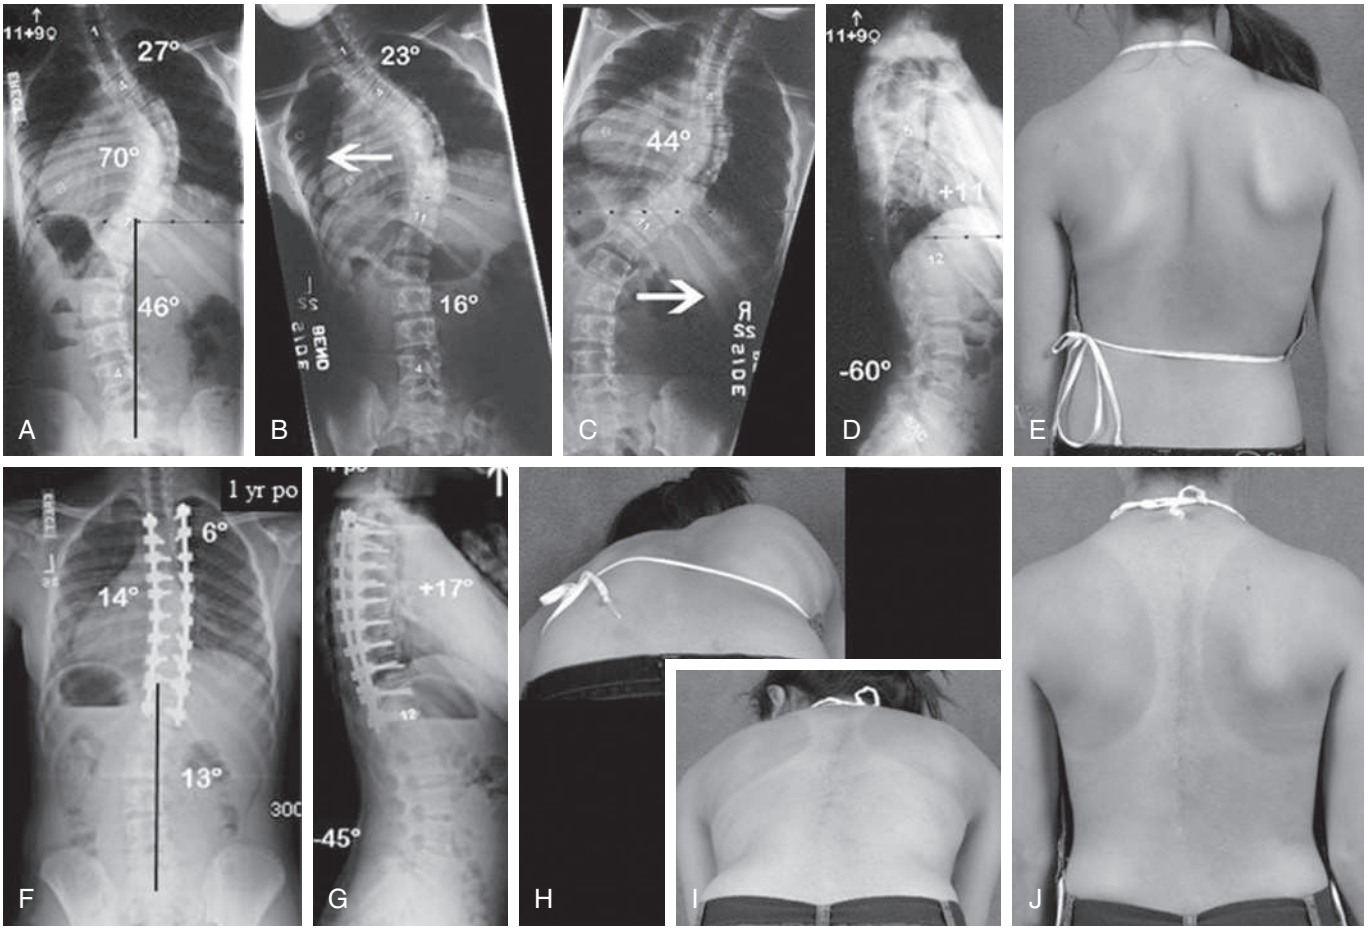

FIG. 27.7 (A–D) Radiographs of a girl, age 11 years + 9 months, with progressive right thoracic compensatory left lumbar scoliosis. Her main thoracic curve progressed to 70 degrees, and her compensatory 46-degree curve decreased on side bending to 16—a 1CN/T12 classification. (F–G) She underwent a selective thoracic fusion, T3–T12 (0) with a pedicle screw construct, with nicely matched 14-degree thoracic and 13-degree lumbar scoliotic curves 1 year postoperatively with spontaneous lumbar correction from modifier C to B and adequate sagittal balance. Preoperative and postoperative clinical images show improved truncal correction on upright (E, J) and forward bend (H, I) views.

LIV should be horizontal for type A lumbar modifier curves, a mild tilt should be left on type B curves, and an appropriate degree of tilt should be left on the LIV for type C curves (Fig. 27.7).

Selective anterior fusions of major TL/L curves associated with minor and partially structural thoracic curves in Lenke 5C and 6C curves can also be considered.[92] The analysis here parallels that of a thoracic STF. Additionally, the thoracic curve should be less than 50 degrees, bend out to 20 degrees or less, the TL/L-to-thoracic Cobb ratio should be 1.25 or greater, and the triradiate cartilages should be closed.[46] However, such selective fusions should *not* be undertaken when shoulder depression ipsilateral to the TL/L curve exists, the patient is highly skeletally immature, or a clinically unacceptable thoracic hump is present. To prevent decompensation, if the lumbar curve bends out more than the thoracic curve does, the lumbar curve should not be overcorrected because the thoracic curve likely would not compensate to achieve postoperative balance.[91] One study showed an average spontaneous correction of 14 degrees or 36% improvement of the thoracic curve when a selective TL/L fusion was performed.[47]

Adjuncts to Correction

Direct Vertebral Rotation

In the past, curves greater than 75 degrees, curves that do not correct below 50 degrees, and curves needing a thoracoplasty have required anterior releases. With the use of modern techniques of multisegmental pedicle screw fixation and the addition of direct vertebral rotation (DVR) techniques, safe and effective procedures demonstrating greater coronal and sagittal realignment along with acceptable cosmesis without the need for an anterior procedure have been reported.[101-103] Additionally, in the thoracic region, DVR helps derotate the spine and significantly decreases the rib prominence. Care must be taken to use stiffer rods, prebent in the sagittal profile, to prevent inducing hypokyphosis in the thoracic spine. DVR also helps to obtain better three-dimensional correction in the

TL/L component of Lenke double major curves and to minimize the LIV tilt angle.[101]

A DVR is performed only if screw placement is adequate, if the thoracic spine is not overly lordotic or kyphotic, and when there is a clinically significant thoracic or lumbar prominence. The DVR technique necessitates accurate placement of pedicle screws at the apex of the deformity and the three levels at the proximal and distal ends of the fusion. When the thoracic spine has a (+) sagittal modifier, per the Lenke classification, a DVR maneuver is not performed because increased kyphosis places considerable strain on the proximal screws unless appropriate releases via posterior column osteotomies are performed. Otherwise, the coronal and sagittal deformities are addressed simultaneously by convex rod instrumentation first.

Osteotomies

Several osteotomy choices are available to correct sagittal, coronal, and multiplanar deformities associated with previously fused or more severe idiopathic scoliosis curves, including posterior column osteotomies (Ponté, Smith-Petersen), pedicle subtraction osteotomy, and vertebral column resection (VCR). A Smith-Petersen osteotomy classically refers to an osteotomy performed through a previous lumbar fusion mass, whereas a Ponté osteotomy refers to a posteriorly based thoracic osteotomy through a previously unfused spine. We prefer the term posterior column osteotomy, as it avoids this prevalent confusion. Like sagittal imbalance, coronal imbalance can be classified as type A or B. In type A, the shoulders and pelvis are tilted in the opposite direction, whereas in type B, they tilt in the same direction.[104,105] Typically, single-plane type A deformities can be addressed with one pedicle subtraction osteotomy (PSO); multiple or asymmetrical pedicle subtraction osteotomies can be used when dealing with stiff or kyphoscoliotic cases. Simple trigonometric calculations at the vertebral body where the osteotomy is going to be performed permit precise determination of the angle of bony resection required for global balance.[106] Type B deformities likely require a VCR.

VCRs can be performed via a combined anterior and posterior approach (i.e., circumferentially) or from a posterior-only approach (Fig. 27.8).[107] Compromised pulmonary function lends consideration, however, to performing a posterior-only approach. The surgeon must balance the potential pulmonary compromise of the patient with the understanding that the extracavitary approach (i.e., posterior only) requires a higher level of surgical expertise and is technically more demanding.[108,109] As with all surgical procedures, adherence to safety is the most important principle, and if the surgeon is uncomfortable with a particular approach or technique, a referral should be made.[110] Nevertheless, this correction modality is appropriate in the setting of congenital cases, multiplanar or stiff kyphoscoliotic curves, curves previously fused circumferentially, and cases of global imbalance. In the last-mentioned situation, attention must be paid to the direction of the shoulder and pelvic tilt imbalance (see Fig. 27.8).

Minimally Invasive Techniques

Minimally invasive spine surgery is a popular concept that uses imaging, retraction, and implant technologies to help surgeons locate the exact area on which they are to operate. This type of procedure is done through incisions less than 1 inch long, minimizing damage to surrounding muscles and other tissues, which rapidly increases the healing and reduces recovery time. It also uses technology to perform the surgery more efficiently. One example is a video-assisted thoracoscopic procedure. According to Newton and colleagues,[111] this procedure can be used for an anterior thoracic release or to achieve deformity correction via rod-screw constructs. Given the small incisions and the muscle-splitting technique used, a reduction in chest wall disruption and subsequent lung volume decrease, as is the case with an open thoracotomy approach, was noted. This procedure offers comparable curve correction and a faster return to presurgical function.[90,91] However, with advances in instrumentation as mentioned previously and the enhanced ability to perform a direct vertebral derotation with posterior pedicle screw constructs, the use of video-assisted thoracoscopic instrumentation procedures has declined substantially. The decision between an anterior and a posterior approach is based purely on surgeon preference at this point.

Postoperative Care

Patients are usually observed in the intensive care unit overnight. Sitting and standing with assistance is permitted, and physical therapy is usually started on the first postoperative day. When stable, patients are transferred to the regular floor. As bowel function returns and patients are able to tolerate clear fluids, routine intravenous narcotics are replaced with oral narcotics as needed. Typically, no postoperative bracing is used. When patients are ambulatory, the urinary catheter is removed. On postoperative day 3, the drains are discontinued along with prophylactic antibiotics. After discharge, usually on postoperative day 4 or 5, patients may start to slowly resume activities.

Complications

Complications can occur during any of the treatment stages—preoperative, intraoperative, or postoperative.[112,113] At the preoperative stage, inappropriate curve classification and inadequate surgical planning can lead to inappropriate surgical decisions. Thus, it is essential to ensure that when performing a selective fusion, the clinical exam is considered and appropriate structural curve criteria are met.[92] Choosing inappropriate fusion levels can also be included in the category of preoperative complications.[114]

Intraoperative complications most commonly result from technical errors, including instrumentation misplacement. Hooks that do not hug the lamina or misplaced pedicle screws can lead to devastating complications, including spinal cord insults. Overcorrection of curves and, conversely, inadequate

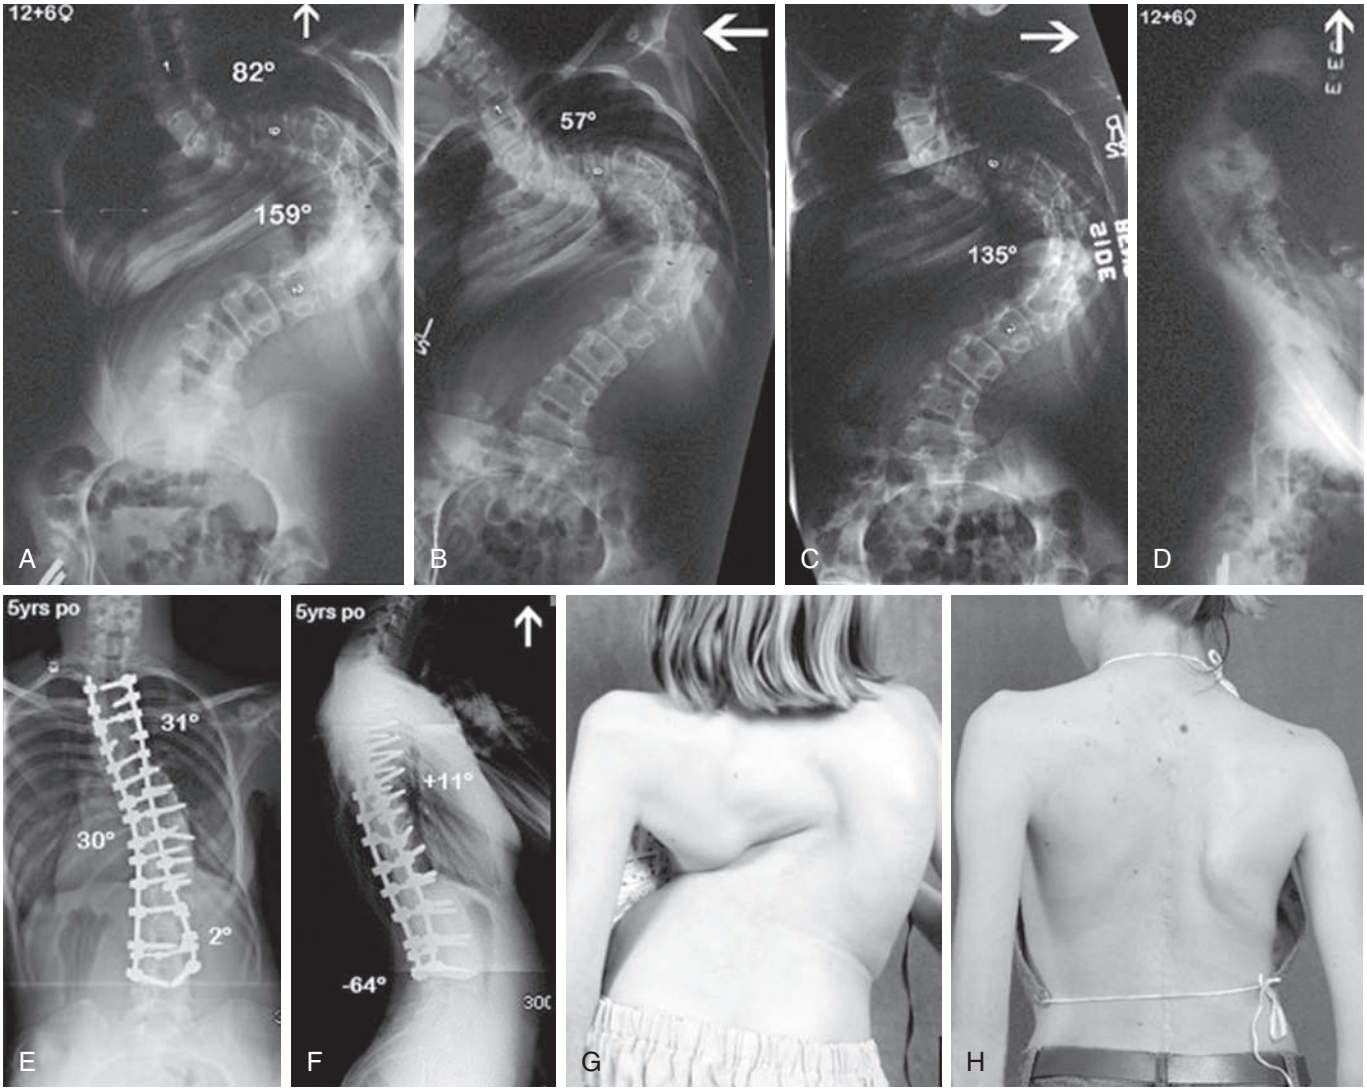

FIG. 27.8 (A–D) Radiographs of a girl, age 12 years + 6 months, with a severe progressive right thoracic scoliosis. Her curve progressed to 159 degrees bending to only 135 degrees. (E–F) She underwent a posterior single-level vertebrectomy and T2–L4 fusion with pedicle screw construct with marked correction of her coronal plane deformity at 5 years postoperatively. (G–H) Preoperative and postoperative clinical photographs show her much improved clinical appearance.

releases, leading to an unbalanced spine, account for other types of intraoperative complications. Inappropriate decortication, inadequate bone graft material, and the use of bulky crosslinks can result in a higher rate of pseudarthrosis.

Intraoperative neurophysiologic monitoring with somatosensory evoked potentials, motor evoked potentials, and/or descending neurogenic evoked potentials help alert the surgeon to any impending intraoperative spinal cord neurologic deficit.[115,116] These deficits typically occur from spinal cord distraction, overcorrection, vascular compromise, or, rarely, directly from instrumentation. If intraoperative neurophysiologic monitoring declines past warning criteria, the surgeon should implement a course of action that includes ensuring that the irrigation being used is of adequate temperature, keeping mean arterial blood pressure elevated at a minimum greater than 80 to 90 mm Hg, and reversing instrumentation or spinal correction to the prewarning criteria state. If intraoperative neurophysiologic monitoring data do not return to baseline within a reasonable time, a wake-up test should also be performed to assess true neurologic function. In addition to adhering to the proven sequential technique of freehand screw placement, pedicle screw stimulation provides an added safety measure.[79,80] Judicious use of intraoperative imaging can also be employed, especially with significant deformities.

Postoperative complications can arise from delayed consequences of technical errors, neurovascular compromise, medical comorbidities, and wound infections. Although perioperative antibiotics are commonly used, when wound infections do occur, they generally are treated aggressively with wound irrigation and debridement. Instrumentation well seated on the spine is always left in place; however, the decision to remove or maintain the bone graft is defined by the individual case and surgeon preference. Removal of the

instrumentation can lead to loss of curve correction and decompensation.[117] Additionally, at final closure, powder antibiotics can be placed inside the wound (deep and superficial to the fascia), and long-term parenteral antibiotics are provided based on the results of intraoperative wound cultures and sensitivities. With delayed or late infections, the instrumentation is initially removed and later usually replaced because the deformity can progress as the fusion mass is subject to repeated bending forces.[117,118] Also, the fusion mass is inspected further, and any pseudarthrosis noted is repaired at the reinstrumentation stage.

Summary

Understanding and treatment of spinal deformities has broadened; however, idiopathic scoliosis remains a diagnosis of exclusion. With advances in genetic mapping of idiopathic scoliosis, better understanding of the etiology and incidence of the disease is promising. It is hoped that better understanding will bring earlier identification, more insight into curve progression risk, and treatments of the condition without the need for major surgery of severe curves. Technological advances—including the advent of pedicle screw instrumentation, better derotation equipment, and osteotomy techniques—have significantly improved spinal surgeons' ability to treat more rigid curves while obtaining better correction and maintaining safety.

Possible treatment modalities include close observation, bracing, and surgical intervention. The Lenke classification of AIS allows for the identification of appropriate fusion levels and choice of selective fusions, which are imperative for optimal surgical management. Although all curves can be approached posteriorly, one can employ an anterior approach in selected Lenke 1 curve patterns, Lenke 6CN curves, and many Lenke 5CN curves. Selective fusions should be performed whenever possible, and critical curve analysis should be performed preoperatively with all available objective modalities. Direct vertebral rotation offers improved thoracic correction and a decreased need for thoracoplasty. Complex, decompensated, large, rigid curves and curves previously fused may require osteotomies to achieve the desired correction. Some pitfalls of scoliosis surgery, such as decompensation and adding on of a fused curve, can be avoided when these principles are applied.

One must be mindful of the lessons of the past in understanding the assessment and management of spinal deformity. Spinal surgeons constantly must strive for improvements in surgical technique that lead to shorter, selective fusions and a balanced spine with maximum possible correction. These improvements can include less invasive approaches while not forgetting the basic principles of curve identification and fusion techniques. The ultimate goal should be correction of the curve without fusion of unnecessary vertebrae, allowing for continued spinal motion. Safety for patients is of the utmost importance and is achieved by appropriate training, careful patient selection, and adherence to the principles of deformity surgery.

PEARLS AND PITFALLS

1. Bracing of the juvenile idiopathic or skeletally immature adolescent idiopathic patient is still a viable option for those with curves between 25 degrees and 45 degrees. Brace compliance, the fit of the orthosis, and the number of hours of brace wear per day are critical components to success, along with the genetic predisposition toward curve progression.
2. It is important to determine the flexibility of the spinal deformity. Therefore, preoperative radiographic assessment should include not only upright radiographs, but also side-bending, supine, push-prone, traction (if applicable), and hyperextension (for hyperkyphosis) radiographs, alone or in combination.
3. Proper classification of AIS curves preoperatively will aid in the regions of the spine to be fused. One must remember to include the thoracolumbar sagittal profile in preoperative planning to prevent misclassification and incorrect surgical management.
4. It is critical to examine shoulder symmetry clinically and radiographically, the PT curve (stiffness and sagittal profile), and degree of MT curve correction when selecting proximal fusion levels in idiopathic scoliosis patients to obtain optimal shoulder balance after surgery.
5. Distal fusion levels are determined by the relationship among the end, neutral, and stable vertebrae of the distal structural curve to be fused, along with the TV in relation to the position of those vertebrae to the CSVL. Most commonly, the distal fusion level will be one level above stable if that level is fairly neutral and the vertebra is at least "touched" by the CSVL on the upright coronal film (the TV rule), does not have much rotation, and the disc below is parallel or closed on the convexity.
6. Satisfactory clinical and radiographic results can be achieved with selective thoracic fusions of properly selected lumbar C modifier curves.
7. The use of anterior procedures and circumferential surgery for AIS has markedly decreased since 2000, with the predominant use of posterior-only surgery with spinal osteotomies as needed for adequate three-dimensional correction. Disadvantages such as chest cage disruption (including suboptimal pulmonary function), risk of implants abutting the major vessels, and the ability to treat only a single curve at a time have limited these approaches over time.
8. The use of posterior instrumentation and fusion with or without various forms of spinal osteotomies has become the mainstay for the surgical management of pediatric and adult idiopathic scoliosis deformities. All curve patterns can be managed by surgeons familiar with the classic midline posterior approach.
9. Surgical outcomes are based on radiographic parameters and clinical assessments, such as scoliometer measurements and shoulder height, as well as patient-reported outcome questionnaires.
10. The use of segmental pedicle screw fixation for the posterior treatment of pediatric and adult idiopathic scoliosis curves has become the primary instrumentation construct. In addition, thorough bone grafting with a combination of autogenous bone, allograft bone, and/or the use of osteobiologics, especially in the adult population, has become routine at many centers throughout North America.
11. Optimal surgical outcomes in the treatment of idiopathic scoliosis deformities include proper patient selection, exacting surgical technique, and a well-balanced spinal alignment with minimal to no complications.

KEY POINTS

1. Patient evaluation skills and highly specialized technical skills are essential for the scoliosis surgeon.
2. Anterior approaches are possible, but all curves can be addressed posteriorly.
3. Selective fusions should always be considered when appropriate.
4. Adjuncts to posterior correction possibly can help obviate more extensive approaches.
5. Be careful in choosing appropriate fusion levels and leaving an appropriate tilt on the LIV when performing a selective fusion.
6. Avoidance and treatment of complications in the preoperative, intraoperative, and postoperative periods is important.
7. Some form of spinal cord monitoring is mandatory for all scoliosis corrective procedures.

28 CHAPTER Neuromuscular Scoliosis

Peter O. Newton
Pawel P. Jankowski
Burt Yaszay
Dennis R. Wenger
Scott J. Mubarak

General Principles

Neuromuscular disorders commonly lead to spinal deformities that are some of the most challenging treatment dilemmas addressed by spine surgeons. Despite the various conditions that fall in this category, neuromuscular disorders involve neurologic or muscular deficiencies that produce progressive multiplanar skeletal deformities. Common features of neuromuscular scoliosis include the following:

Large curves early in life: Early neuromuscular insult predisposes patients to rapidly progressive scoliosis.

Stiff curves: These patients are more likely to develop stiff curves because of the early onset of neuromuscular deficiency, resulting in limited mobility and secondary contractures.

Progressive curves: As in idiopathic scoliosis, the potential for curve progression is greatest during rapid growth and with loss of ambulation. Increasing weakness or persistent muscle imbalance around the spine in patients with neuromuscular disorders can cause progression of scoliosis independent of growth, however.

Long curves: Less severely affected individuals may have an S-shaped curve with well-balanced double curves. Long C-shaped curves are more likely in severely affected patients with resultant sitting imbalance.

Pelvic obliquity: Lower extremity contractures and imbalanced spinal deformity cause pelvic obliquity, which may impair comfortable sitting for these patients.

Sagittal plane deformity: Gravity and muscular deficiency can also lead to sagittal plane deformity, including thoracic or lumbar hyperkyphosis or lumbar hyperlordosis.

Patients with neuromuscular disorders are challenging because of the complexity of their deformity and fragility of their overall health; they are best treated by an experienced surgeon with support from a multidisciplinary team.

Classification

The classification of neuromuscular scoliosis can be based on the underlying disorder: neurologic (e.g., cerebral palsy) or muscular (e.g., muscular dystrophy). Neurologic deficiencies can be broken down further into upper motor neuron dysfunction, as seen in myelomeningocele, or lower motor neuron dysfunction, as seen in spinal muscular atrophy (SMA).

Natural History and Associated Complications

Neuromuscular scoliosis generally begins early in life, is often rapidly progressive, and causes significant morbidity. Some patients are capable of ambulation, although many lose their ability to walk early in life or never achieve ambulatory status at all. The use of a wheelchair affords these patients educational and social opportunities that enrich their lives. Spinal deformity can impair comfortable sitting and dramatically reduce the individual's quality of life. Unbalanced curves and significant pelvic obliquity make wheelchair positioning difficult and may cause uneven distribution of weight that may lead to pressure sores (Fig. 28.1). Prominences created by the convexity of a curve may result in skin breakdown; creases within the concavity of the trunk deformity are susceptible to skin maceration and infection (Fig. 28.2). Majd and colleagues[1] showed a correlation between deformity size, functional decline, and decubitus. Large rigid curves restrict lung volume and impair respiration in patients who often already have limited pulmonary capacity. Treatment of neuromuscular scoliosis can also help the caretakers of these patients, improving the ease of transfers, positioning, feeding, and hygiene. The ultimate goal of treatment of patients with neuromuscular scoliosis is the maintenance of as much independence and function as possible. When patients with neuromuscular scoliosis lose the ability to sit comfortably, their quality of life is dramatically decreased. The natural history for a given patient is largely determined by the specific underlying neuromuscular condition and the degree of involvement.

Treatment Principles

The basic principles of observing or bracing smaller, flexible curves and surgically fusing larger, more rigid curves

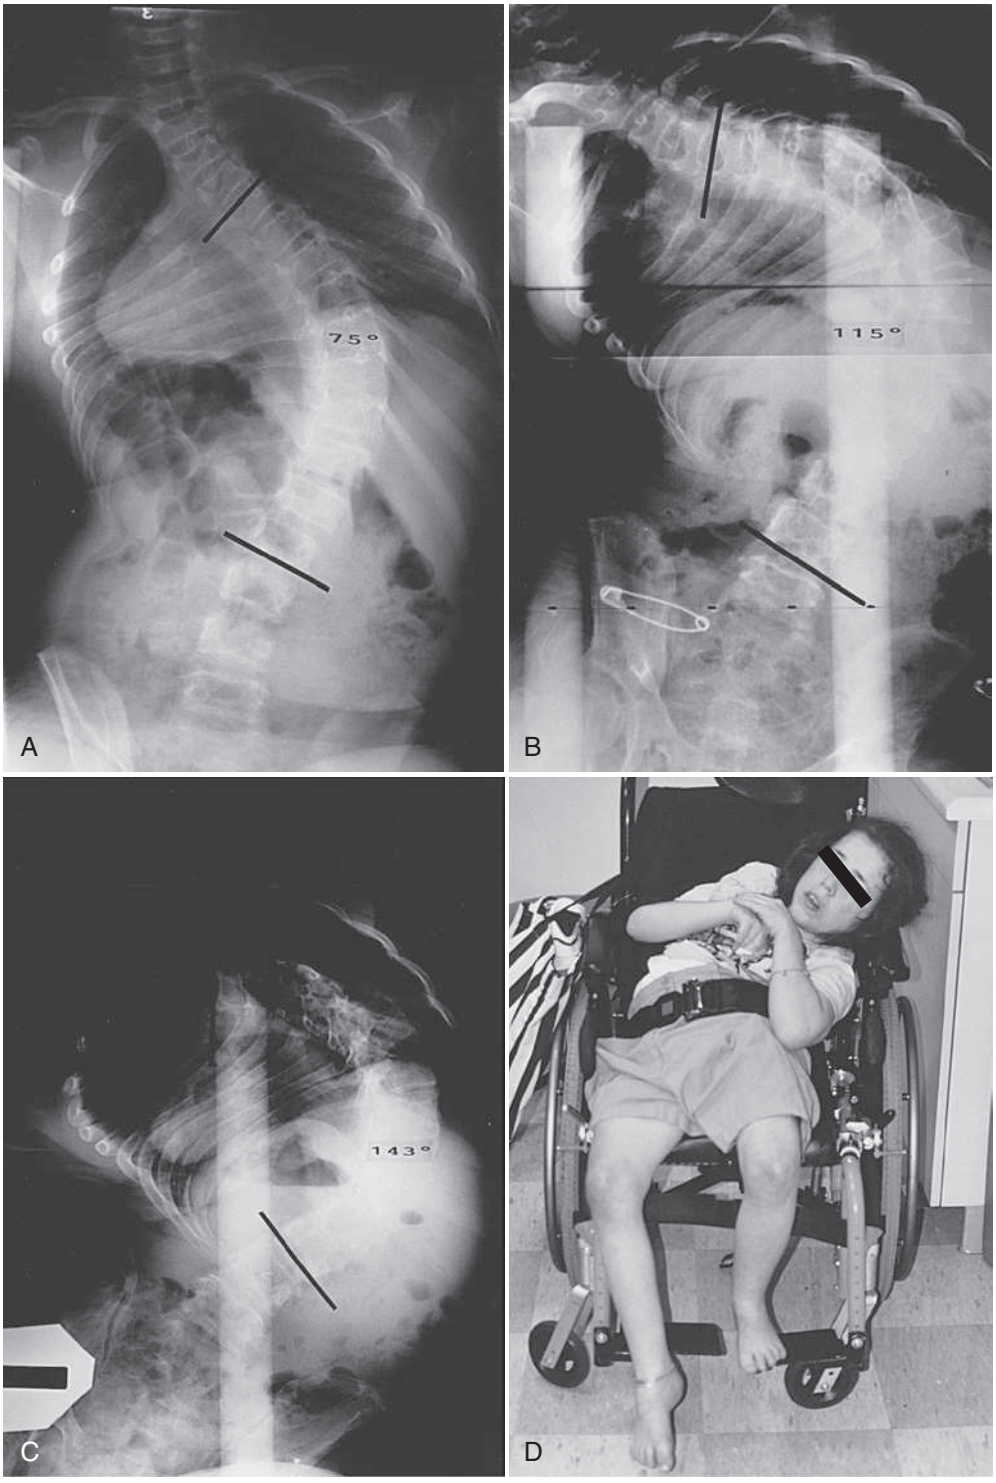

FIG. 28.1 Progression of scoliosis after skeletal maturity in a patient with cerebral palsy. (A) At age 15, curve measures 75 degrees. (B) At age 18, curve measures 115 degrees. (C) At age 23, curve measures 143 degrees. (D) The patient is unable to be comfortably positioned in her wheelchair.

in adolescent idiopathic scoliosis apply to the treatment of neuromuscular scoliosis, although with less aggressive parameters. Observation alone is employed until curves begin to cause functional impairment. Bracing can be a temporizing measure, used primarily to provide sitting support while the patient grows. Eventually, many of these patients require surgical stabilization with a spinal instrumentation and fusion procedure.

Nonoperative Treatment

Medical Treatment

Spinal Muscular Atrophy

Before the 1990s, there was no clear molecular target for SMA diseases. As a result, various medications were tried in an

FIG. 28.2 Severe spinal deformity can lead to skin maceration on concave side of curvature and pressure sores on convex side.

off-label fashion that found different degrees of success in other diseases causing muscle weakness, such as amyotrophic lateral sclerosis. Randomized placebo-controlled trials have been conducted to investigate the efficacy of several medical treatments for SMA, including creatine, phenylbutyrate, gabapentin, and thyrotropin-releasing hormone.[2–5] None of these compounds has proven to be an efficacious drug treatment for SMA.[2] The discovery of the survival of motor neuron (SMN) gene has resulted in the development of animal models to test new therapies. The main objective of these therapies is to increase the expression of the SMN protein. These RNA-based molecule therapies along with gene therapy have shown promise in animal models and are currently in the preclinical testing phase.[6] However, as of yet these therapies have not been effective in human trials.

Cerebral Palsy

Several medical therapies have been investigated for the treatment of spasticity in patients with cerebral palsy (CP). Botulinum toxin has gained a growing acceptance as a treatment of upper and lower limb spasticity. Initial reviews of the literature by the Cochrane Collaboration and others yielded inconclusive evidence that could neither confirm nor deny the efficacy of botulinum toxin in the treatment of spasticity.[7] Inclusion of more recent randomized controlled trials (RCTs) into the analysis has provided evidence that supports the use of botulinum toxin to provide a time-limited benefit to decrease muscle tone in children with upper and lower limb spasticity associated with CP.[8] In a study of 16 children with CP, botulinum toxin A injections into the gastrocnemius muscle decreased spasticity and improved ankle range of motion (ROM), pattern of walking, and reduced energy consumption, providing improvement in function. The evidence trend is in favor of using this therapy to reduce spasticity early in the management of CP, although there is little evidence that this has a role in preventing or treating scoliosis.

Intrathecal baclofen is a well-established treatment that has been shown to provide significant benefits in controlling spasticity in patients with CP. Intrathecal baclofen has been shown to reduce the need for orthopaedic lower extremity procedures and the rate of postoperative complications associated with these procedures.[9] Concerns have been raised, however, regarding its impact on the progression of scoliosis in patients with spastic quadriplegia. In a retrospective review, Ginsburg and Lauder[10] found a six-fold increase in the rate of scoliosis curve progression at 2-year follow-up in a group of 19 quadriplegic CP patients with spasticity. Caird and colleagues[11] showed a significantly higher rate of complications associated with posterior spinal fusion and instrumentation in a group of 20 CP patients with spasticity with intrathecal baclofen pumps compared with a matched control group. This study was limited by its relatively small sample size and lack of a control group. Shilt and colleagues[12] found no difference in curve progression at 3-year follow-up between 50 CP patients treated with intrathecal baclofen and 50 matched control CP patients. In a review of the literature, Scannell and Yaszay suggested that no conclusive evidence exists to support the hypothesis that intrathecal baclofen pumps lead to worsening of the scoliosis in CP patients.[13] Therefore, based on the current evidence, no significant conclusions can be drawn about the impact of intrathecal baclofen pumps on the progression or treatment of spinal deformity in patients with CP. Baclofen can provide significant relief of spasticity, and this evidence must be considered in the context of any potential side effects.

Duchenne Muscular Dystrophy

Advances in general care, glucocorticoid treatment, noninvasive ventilatory support, cardiomyopathy management, and scoliosis management have significantly changed the course of Duchenne muscular dystrophy (DMD). Survival into adulthood is now a realistic expectation for many patients who receive optimal treatment.[13] Although gene-based and cellular-based therapies are currently under development for the treatment of DMD, the efficacy of glucocorticoid steroids has been evaluated by several randomized controlled trials. In their Cochrane review and meta-analysis, Manzur and colleagues[14,15] concluded that there is evidence that muscle function and strength are improved in the short term (6 months to 2 years) with corticosteroid therapy. The authors based their conclusion on six RCTs and observed that the most effective prednisolone dose seemed to be 0.75 mg/kg per day, given daily.[14] Markham and colleagues[16] showed that glucocorticoid therapy provides the added benefit of retarding the anticipated development of ventricular dysfunction if begun before ventricular dysfunction in their series of 14 DMD patients treated with steroids compared with 23 DMD

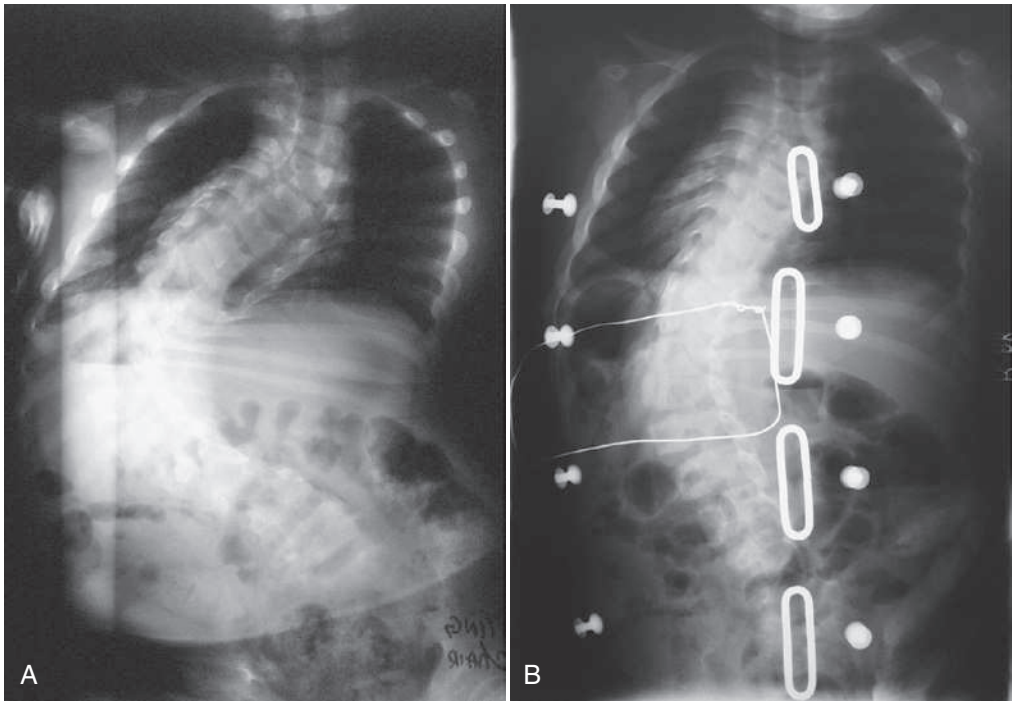

FIG. 28.3 Bracing in neuromuscular scoliosis is often poorly tolerated. Although it provides modest correction, as shown in these radiographs, rigid bracing may lead to excessive skin pressure in patients who cannot actively pull away from the brace.

patients treated without steroids. Shapiro and colleagues[17] evaluated 85 DMD patients who were not receiving steroids, finding that 97% had progression of their scoliosis of more than 10 degrees after becoming wheelchair dependent, regardless of age. Based on their findings, Shapiro et al.[17] advocated for spinal fusion in the majority of patients after the curve had progressed beyond 20 degrees and who were not on steroid therapy to avoid future cardiac and pulmonary complications. Conversely, Lebel et al.[18] found a reduced incidence of scoliosis development and need for spinal fusion in patients treated with long-term glucocorticoids.

Genetic and Family Counseling

Because of the complexity of the medical and psychosocial issues associated with neuromuscular disorders and spinal deformity, care needs to be coordinated with a multidisciplinary team. The primary care physician should be well informed of all orthopaedic issues and play a central role in managing care. Psychosocial support for patients and parents is also vital. Patient advocacy groups have proven to be very useful in helping families cope with the illness and associated surgical care. Physicians may wish to provide information regarding clinical trials or refer families to clinical trial websites (www.clinicaltrials.gov provides a current listing of open clinical trials). Patients and parents may need to be referred for genetic counseling to confirm the patient's diagnosis and aid in family planning.

Bracing

Bracing is a controversial treatment method in idiopathic and neuromuscular scoliosis. Bracing in neuromuscular scoliosis may be used for postural support, although there is limited evidence of its efficacy in limiting curve progression (Fig. 28.3). The etiology of the patient's scoliosis and the patient's muscle tone have an impact on the practicality of brace treatment. Patients with spastic disorders generally do not tolerate rigid brace treatment, whereas patients with flaccid paresis are more apt to be compliant with brace treatment. The type of orthoses may play a role in the outcome of the treatment.

Kotwicki and colleagues[19] followed 45 nonambulatory patients with neuromuscular scoliosis treated with a suspension trunk orthosis (STO) and found that the STO slowed curve progression in 23 patients. The STO construction functions contrary to the classic thoracolumbosacral orthosis (TLSO), with the STO not resting against the patient's pelvis but rather directly against the seat. The evidence supporting STO use to prevent curve progression is limited, however, and skin intolerance found in 36 patients complicates its clinical practicality. Although there is limited research on the results of the STO brace, there are numerous studies investigating the TLSO brace. In a study of 15 patients, Shoham and colleagues[20] found that a TLSO reduced scoliotic deformity and pelvic obliquity leading to reduced sitting pressure. These results are contrary to other studies reported in the literature. In a study of 23 patients, Miller and colleagues[21] followed 23 patients with CP who wore a rigid Wilmington TLSO for an average of 67 months and concluded that the bracing did not slow progression of their deformity. Olafsson and colleagues[22] followed 90 patients with various neuromuscular conditions treated with a soft Boston orthosis for an average of 3 years after brace treatment. They concluded that brace wear was indicated only in a limited subset of patients—ambulatory patients with hypotonia and short thoracolumbar curves (<40

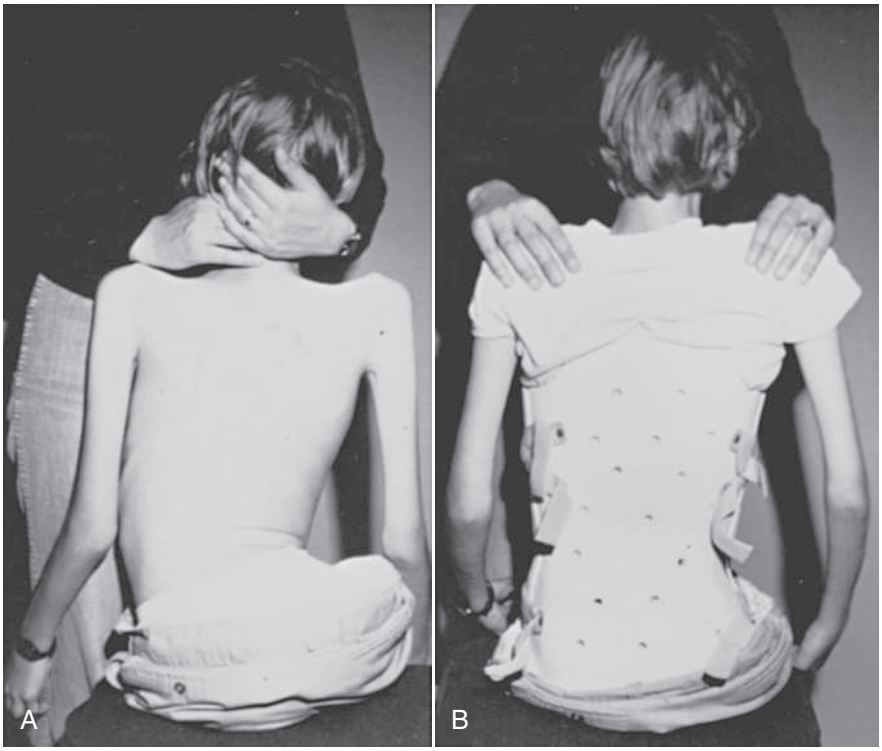

FIG. 28.4 Soft total-contact thoracolumbosacral orthosis in an older child. Less rigid forms of bracing are better tolerated but do not seem to alter the natural history of curve progression.

degrees). In all other patients, brace wear was ineffectual in altering progression but did provide assistance in sitting.

Patients with neuromuscular scoliosis may lack sensate skin to feel pressure from the brace or the muscular control to pull away from the sides of the brace. These patients rarely tolerate the rigid braces often used in idiopathic scoliosis. Patients tend to tolerate soft TLSOs designed to provide improved sitting stability and head and trunk control, while limiting discomfort and skin breakdown (Fig. 28.4).[23]

The impact of the orthosis on pulmonary function is another important factor to consider when contemplating a TLSO for patients with neuromuscular scoliosis. The effect of bracing on pulmonary dysfunction seems to depend on the level of muscle spasticity. Flaccid patients are more amenable to rigid bracing, although this bracing may significantly decrease chest expansion, leading to compromised pulmonary function.[24] Patients with spasticity seem to be more amenable to soft bracing, which does not seem to compromise pulmonary function,[24] although this bracing has been shown only to enhance seating comfort.[21] Olafsson and colleagues[22] and Bunnell and MacEwen[25] suggested that a subset of patients with minimum deformity and muscle hypotonia or mild spasticity may experience slowing of curve progression by bracing without a negative impact on pulmonary function.

Other factors to evaluate when choosing orthotic treatment for neuromuscular scoliosis include ease of application and obstructions. A bivalved brace may be easier for a caregiver to place, although it cannot provide as much corrective strength as a single-opening brace. Winter and Carlson[26] found the two-piece bivalved brace to be a useful support in children with myelomeningocele and SMA. Patients with a stoma or gastrostomy tube require modification of the brace to accommodate these features. Nakamura et al[27] described their preliminary results on 52 patients with neuromuscular scoliosis who were treated with a dynamic spinal brace (DSB), which is a novel three-point support brace. Many of the patients in the study were not surgical candidates due to significant surgical risk factors. Although the authors found that the brace could not prevent the progression of scoliosis, it was effective in maintaining sitting stability and function in neuromuscular patients. Furthermore, no patients needed to discontinue the brace during the study period due to complications. In summary, the study showed that the DSB could be a useful tool in patients who are poor surgical candidates with long C-shaped curves in the early stages of their scoliosis.

Wheelchair modifications can aid in providing a more comfortable seating position for patients with spinal deformity. Modular seating systems can be configured for optimal support of an individual patient (Fig. 28.5). A biomechanical evaluation of seating insert configurations by Holmes and colleagues[28] concluded that three-point force application provides significant sitting support and static correction of scoliosis. Patients with more severe deformity may benefit from custom-molded seatbacks, although these items are expensive, and younger patients may outgrow them quickly.

Operative Treatment

The timing for operative treatment is influenced by curve severity, underlying neuromuscular pathology, and other

FIG. 28.5 Wheelchair systems can provide sitting support for patients who are not good candidates for bracing. Custom-molded seatbacks can be made to accommodate substantial spinal deformities.

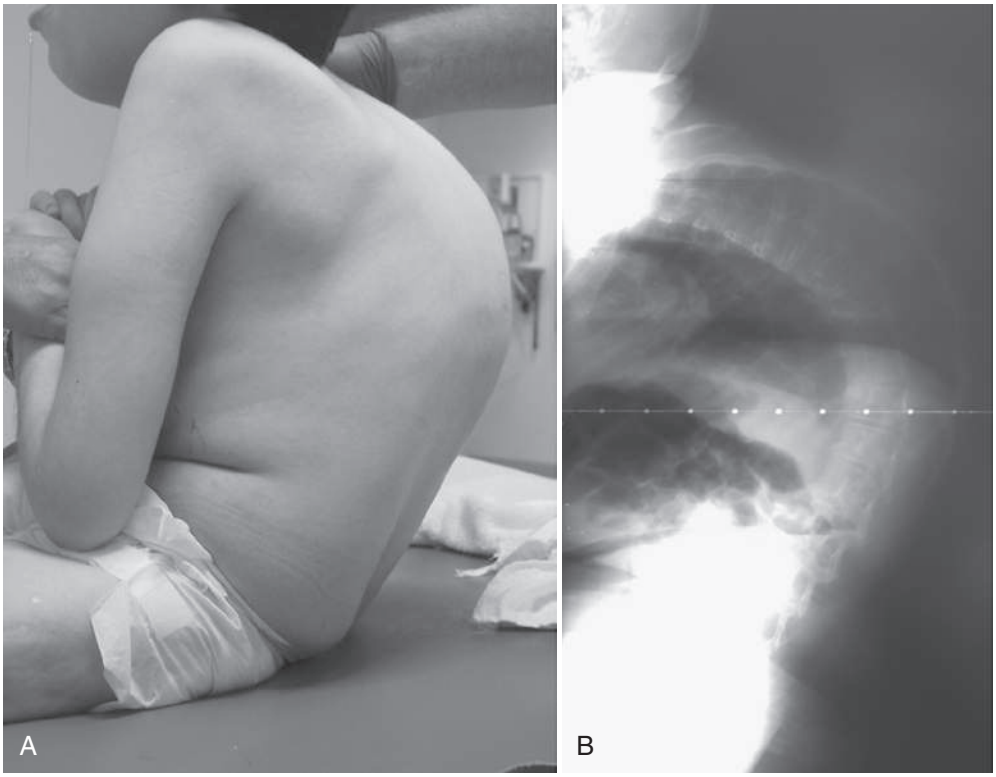

FIG. 28.6 (A) Clinical photograph and (B) lateral radiograph of a child with severe kyphosis that impedes balanced sitting.

factors. The curve severity guidelines are loosely based on, but less aggressive than, the guidelines used in idiopathic scoliosis. Fusion should be considered as coronal deformity approaches 40 to 60 degrees. DMD may be an important exception to this concept: surgery has been advocated when the deformity reaches 20 to 40 degrees because of pulmonary considerations.[29] Patients with severely limited respiratory function have been shown to have good outcomes in spinal surgery, however. The sagittal profile is another important consideration because lordotic and kyphotic deformities can also impair sitting balance and pulmonary capacity (Fig. 28.6). Other factors that play a role in the decision to operate

include patient age, nutritional status, cardiac function, curve progression, patient comorbidities, and family and caretaker support.

The benefit of scoliosis surgery in this population is a topic of much debate. Many of these patients are poor operative candidates and risk much undergoing involved corrective surgery. Preoperatively, patients may have compromised pulmonary function, limited cardiac capacity, poor bone stock, and high risk for aspiration, which put them in danger of intraoperative or postoperative complications. Correction of large deformities requires extensive exposures and long procedures that can lead to blood loss greater than one to two patient blood volumes. Although many patients already have neurologic compromise, they are still at risk for further compromise because of intraoperative spinal column manipulation. More powerful instrumentation systems have led to less postoperative decompensation and pseudarthrosis; however, there remains a considerable risk of curve progression, sometimes necessitating revision surgery.[30-32]

Despite the risk of surgery, the benefits of corrective scoliosis surgery for many of these patients are substantial. Halting or slowing curve progression has a positive impact on the functional ability, comfort, and overall quality of life of these patients. Lonstein and Akbarnia[33] reported that more than 50% of patients treated had functional improvement after surgery. In a study of 79 patients with total body spastic CP, Comstock and colleagues[31] found that 85% of caretakers surveyed were satisfied with the surgery, reporting improved comfort, sitting ability, and cosmesis for the patients. Bridwell and colleagues[30] found similar trends in a study of 54 patients with neuromuscular disorders with all caretakers reporting benefit from the surgery, specifically in the areas of ease of patient care, skin breakdown, patient comfort, pulmonary complications, and quality of life. Askin and colleagues[34] evaluated 20 patients with neuromuscular scoliosis preoperatively and 6, 12, and 24 months after corrective spinal surgery. The authors noted decreased physical ability at the 6-month time point followed by a return to preoperative function by 12 months, and concluded that scoliosis surgery in these patients can stabilize, but not improve, function. However, 75% of patients or caregivers were extremely pleased with the cosmetic results of the surgery. Although most of these patients have deteriorating courses, the correction of spinal deformity seems to improve their function and quality of life.

Although these positive results make a strong case for spine surgery in patients with neuromuscular scoliosis, several review studies have been unable to show a clear benefit of surgical intervention for the patient. Mercado and colleagues[35] evaluated 198 publications and graded their results on the concept of Grades of Recommendation introduced in the *Journal of Bone and Joint Surgery*.[36] These authors concluded that the current literature shows that there is poor-quality evidence that spinal fusion improves the quality of life in patients with CP or DMD.[35] In a 2015 updated Cochrane Collaboration review by Cheuk and colleagues[37] that reviewed 49 relevant studies, they found that no relevant randomized controlled clinical trials were available to sufficiently evaluate the effectiveness of scoliosis surgery in DMD patients. Therefore, no evidence-based recommendations could be made. Although the practicality of conducting an RCT of this nature is questionable, the literature does not provide sufficient evidence to support the role of spinal surgical treatment in patients with neuromuscular scoliosis. It is recommended that the decision for surgical intervention be made based on the needs of the individual patient in consultation with the multidisciplinary neuromuscular care team.

The goal of treatment is preservation of function, which may entail maintaining ambulatory status, maintaining sitting without upper extremity support, or simply allowing assisted comfortable sitting. The decision to operate on a patient with neuromuscular scoliosis is a highly individualized process that should involve a frank and open discussion with the family and patient about the risks and expectations of such a procedure.

Preoperative Considerations

Neurologic

Many patients with neuromuscular scoliosis are on long-term antiseizure therapy, which has some important operative ramifications. Antiepileptic medications such as phenytoin and valproate have been linked to decreased bone turnover and decreased intestinal absorption of calcium, resulting in osteopenia, which may affect implant fixation and should be considered in the selection of construct components.[38,39] A study by Kumandas and colleagues[40] that analyzed 88 prepubertal ambulatory epileptic patients divided into two treatment groups over the course of 2 years on carbamazepine or valproic acid found bone mineral density (BMD) to be adversely affected. The BMD in the lumbar spine was significantly reduced in patients taking carbamezapine or valproic acid compared to the age- and sex-matched control group. According to the authors, carbamazepine and valproic acid therapy results in a hyperparathyroid state and altered vitamin D metabolism associated with reduced BMD. It is well known that antiepileptic drugs (AEDs) adversely affect the coagulation system. Drugs such as carbamazepine, phenytoin, and valproic acid can result in thrombocytopenia.[41] Valproic acid and gabapentin in previous studies have shown to cause acquired von Willebrand disease type 1, hypofibrinogenemia, decreased factor XIII, and abnormal platelet function.[42] Koenig and colleagues[43] showed that 47% of patients receiving valproic acid had abnormal thromboelastographs (TEGs). However, other studies have shown that patients on valproic acid are not at increased risk of bleeding complications at surgery. Manohar and colleagues[44] showed in a study of 84 children undergoing craniotomy for resection of seizure focus or hemispherectomy that none of the cohort showed significantly abnormal prothrombin time, activated partial thromboplastin time, or platelet count preoperatively. A total of 38% of the study patients received allogenic blood transfusions; 4.7% showed clinically significant coagulopathy intraoperatively and postoperatively. However, prospective clinical studies are needed that evaluate platelet function and coagulation problems to confirm if indeed AEDs pose little or significant intraoperative bleeding risks.

Pulmonary

Patients with neuromuscular disorders are prone to pulmonary complications, necessitating a thorough preoperative pulmonary assessment. Poor upper airway tone and anatomic deviations can lead to increased risk of airway obstruction during and after surgery. These patients are at high risk for aspiration because of poor oropharyngeal tone and coordination; not only can chronic aspiration lead to pulmonary fibrosis, but acute aspiration can result in perioperative aspiration pneumonia. Patients may require a dietary change, placement of a gastrostomy tube, or a Nissen fundoplication with gastrostomy tube placement to control this aspiration tendency before undergoing spinal surgery. Reactive airway disease is common in these patients and may necessitate the use of preoperative bronchodilators and inhaled steroids. In addition, these patients may have chronic hypoventilation with carbon dioxide retention and poor oxygenation.

Full pulmonary assessment should be conducted by a pulmonologist and include a chest radiograph, arterial blood gases, and pulmonary function tests if the patient's developmental age is at least 4 years old. Vital capacity that exceeds 500 mL and peak expiratory flow greater than 180 mL/min are associated with decreased perioperative pulmonary complications. Although surgery may be considered in appropriately selected patients with preexisting respiratory failure, Chambers et al.[45] and Gill and colleagues[46] showed that patients with a forced vital capacity (FVC) of 20% of predicted value can safely be operated on for deformity correction. This prospective observational study followed eight patients on noninvasive night ventilation for respiratory failure 48 months after surgery and found that all patients recovered well with no major complications.

As a follow-up study to that of Gill et al., Chong and colleagues[47] evaluated the prognostic value of preoperative pulmonary function tests (PFTs) for postoperative pulmonary complications and the operability despite significantly decreased FVC (<30%) in flaccid neuromuscular scoliosis. A total of 74 patients stratified into three groups (<30% FVC, 30–50% FVC, and >50% FVC) were evaluated. They found no statistical difference between groups in the number of complications. If a patient cannot be assessed with formal pulmonary function tests, other signs of ventilatory capacity must be used, including crying, laughing, and other vocalizations.[48-50]

Proper nutritional balance is crucial for successful surgical outcomes in patients with neuromuscular scoliosis. Many patients are malnourished secondary to a combination of reflux, low calorie intake, and high metabolic demand from frequent illness. Malnourished patients are more prone to perioperative complications such as wound dehiscence, wound infection, and pulmonary complications. Conversely, older patients may be obese, presenting further operative complications associated with their body habitus. Nutritional status should be assessed preoperatively with albumin and total blood lymphocyte levels. Albumin should be greater than 3.5 g/L, and total lymphocyte count should be greater than 1.5 g/L.[50] In a study of 44 patients, Jevsevar and Karlin[51] found that patients had a lower incidence of postoperative infections if they met these criteria.

A prospective randomized control study of total parenteral nutrition (TPN) for long spinal deformity, performed by Lapp and colleagues[52] on 46 patients who underwent same-day or staged procedures to evaluate the effect on complications and recovery from postoperative malnutrition, showed TPN to be safe. There was a trend toward faster recovery to nutritional baseline in patients receiving TPN versus those who did not.

Gastrointestinal

Because patients with neuromuscular scoliosis are prone to gastrointestinal dysmotility, they are at risk for a postoperative ileus, requiring aggressive hydration, maximized nutritional status, and a rigid daily toilet regimen. In addition, some patients are very thin, and supine positioning and the acute straightening of their deformity put them at risk for superior mesenteric artery syndrome with obstruction of the duodenum. Although less common since the advent of segmental instrumentation and decreased use of casting, this prolonged obstruction carries significant morbidity; identifying at-risk patients and maintaining a high index of suspicion when encountering protracted vomiting is essential.

Cardiovascular

Patients may have cardiac problems secondary to their deformity and other cardiac issues that are comorbidities of the primary disorder. Thoracic cage deformity resulting from scoliosis can cause hypoventilation and subsequent increased pulmonary vascular resistance; this increased vascular resistance can cause right ventricular hypertrophy and eventually cor pulmonale. Patients with DMD may have cardiomyopathy and arrhythmias. The complications associated with arrhythmias may be alleviated with glucocorticoid steroid treatment.[14] Patients with myotonic dystrophy may also have cardiac arrhythmias. Left ventricular hypertrophy can be associated with Friedreich ataxia.

Hematologic

Studies have shown that patients with neuromuscular scoliosis have greater blood loss than patients with idiopathic scoliosis undergoing similar procedures. In this neuromuscular group, the underlying disorder plays a major role in determining the extent of blood loss. In a review article, Shapiro and Sethna[53] found that patients with DMD had the greatest mean levels of blood loss. Much of this difference is due to the requirement for larger fusions in patients with neuromuscular scoliosis, although osteopenia in these patients may also play a role.[54,55] Preparation for major blood loss, sometimes exceeding 200% of a patient's blood volume, is essential.[48] Often, these patients have already had major surgery, and previous blood loss experience can be used as a guideline for preoperative preparation. Patients should have partial thromboplastin time, prothrombin time, and platelet function evaluated as a part of their preoperative blood work. A more aggressive coagulopathy workup should be conducted if the patient has previously shown a tendency toward excessive blood loss.

For a posterior procedure, 2 to 4 units of packed red blood cells is generally sufficient; however, the addition of a kyphectomy or an anterior procedure may increase this requirement. Intraoperative blood work may confirm a dilutional coagulopathy, necessitating the use of fresh frozen plasma, platelets, or cryoprecipitate to correct this imbalance.

Several pharmacologic agents have been under investigation for their efficacy in reducing blood loss during surgery. Aprotinin, tranexamic acid (TXA), and aminocaproic acid have also been investigated to determine their effect on blood loss in spinal surgery. Aprotinin, a serine protease inhibitor, was shown to reduce blood loss in adults, but its production was halted in 2007 by the US Food and Drug Administration (FDA) because of concerns of higher mortality rates after its use in cardiac surgery.

A prospective, double-blinded, placebo control study of 40 pediatric patients[56] found that TXA administration significantly reduced perioperative blood transfusions. These results have been supported by a meta-analysis by Gill and colleagues,[57] which found that TXA and aminocaproic acid are effective in minimizing blood loss and transfusion in patients undergoing spine surgery. A multicenter retrospective review of a prospectively collected database of 84 consecutive enrolled patients with CP who underwent posterior spinal fusion and instrumentation showed that the use of antifibrinolytic agents (AFs) significantly reduced the estimated blood loss (EBL) intraoperatively without adverse effects.[58] However, the investigators could not demonstrate a significant difference between total transfusion requirements between patients who received AF agents and those who did not except for cell salvage transfusion. The study showed that patients who received TXA had significantly less EBL compared with patients who did not.[58]

A prospective, randomized, double-blind comparative study performed on 125 patients with adolescent idiopathic scoliosis by Verma and colleagues showed that TXA and epsilon-aminocaproic acid (EACA) reduced operative blood loss but not transfusion rate compared to control subjects.[59] As in the study by Dhawale et al,[58] the investigators showed that TXA was more effective in reducing total blood loss and postoperative drainage compared to EACA. Furthermore, the authors recommended maintaining the mean arterial pressure (MAP) greater than 75 during the exposure to utilize the maximize benefit.[59] The side effects for TXA and aminocaproic acid are minor but should be discussed with the patient before using these agents. The surgeon and the anesthesiologist should familiarize themselves with these agents and make a collaborative decision on their use based on the needs and concerns of the individual patient.

Radiographic Assessment

Patients should have preoperative anteroposterior and lateral films taken of the entire spine, preferably in an upright (sitting or standing) position. For assessment of skeletal maturity, a separate anteroposterior radiograph of the pelvis should be considered because scoliosis films often truncate the anatomy necessary to determine skeletal maturity. To assess spinal flexibility, supine bending films or traction films are used. Accurate measurements of the coronal Cobb angle, sagittal Cobb angle, and pelvic obliquity are crucial for complete preoperative planning and postoperative evaluations. In a more recent analysis of the interobserver and intraobserver variability of radiographic measurements of patients with neuromuscular scoliosis, Gupta and colleagues[60] found that neuromuscular radiographs can be reliably analyzed with the use of the coronal Cobb angle. Patients who may have congenital spinal anomalies or spinal tethering, such as patients with myelomeningocele, should undergo MRI to evaluate the neural elements fully before surgery. CT may also be useful in some patients with severe deformity or in patients with a congenital malformation of the vertebrae.

History of Instrumentation in Neuromuscular Scoliosis

In 1942, Haas[61] published one of the first references to surgical intervention in neuromuscular scoliosis: a case report describing muscle and fascial transfers to obtain complete and permanent correction in one patient. With the introduction of the Harrington rod in 1962, use of this instrumentation with fusion of the spine in patients with neuromuscular scoliosis became the standard. Series using only Harrington rods and posterior spinal fusion have been associated with high incidences of pseudarthrosis (19–40%), moderate initial correction (20–57%), and loss of correction ranging from 14% to 28%.[33,62] After Harrington rod instrumentation, most patients required bed rest and bracing or casting for up to 1 year.

The introduction of segmental spinal instrumentation by Luque[63] in 1976 led to major advances in the biomechanical stability and correction of these very deformed spines (Fig. 28.7). Several studies revealed that Luque segmental sublaminar wire fixation had fewer complications than Harrington instrumentation and was stable enough so that most patients required no brace or cast postoperatively.[62,64,65] Using the Luque method, the only patients with CP requiring postoperative bracing may be patients with athetosis or poor fixation because of severe osteopenia. This is a tremendous advantage because postoperative casting carries the potential for skin and pulmonary complications. Because of these attributes, the Luque technique became the standard method for posterior spinal instrumentation in patients with neuromuscular spinal deformities.

Contouring Luque spinal rods after the technique introduced by Allen and Ferguson[66] (Galveston technique) allowed the rods to be fixed to the pelvis, providing surgeons with a more effective method of controlling pelvic obliquity. Bell, Moseley, and Koreska developed the unit rod, a precontoured U-shaped rod that includes the Galveston portion for pelvic fixation (Fig. 28.8). Studies of patient outcomes with unit rod fixation have revealed excellent correction and maintenance of correction.[66-69] Bulman and colleagues[70] compared the unit rod with double Luque rods and reported superior correction of sagittal and coronal alignment and pelvic obliquity with the unit rod constructs. Tsirikos and colleagues[71] evaluated 287 children treated with unit rod instrumentation to the pelvis

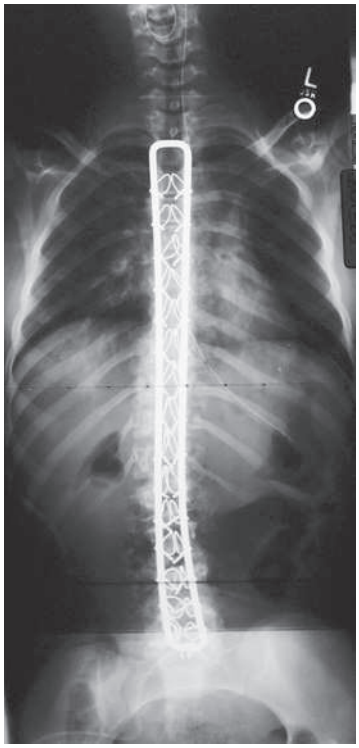

FIG. 28.7 The one-piece Luque "box" modification of the original double Luque rod technique is a more rigid construct.

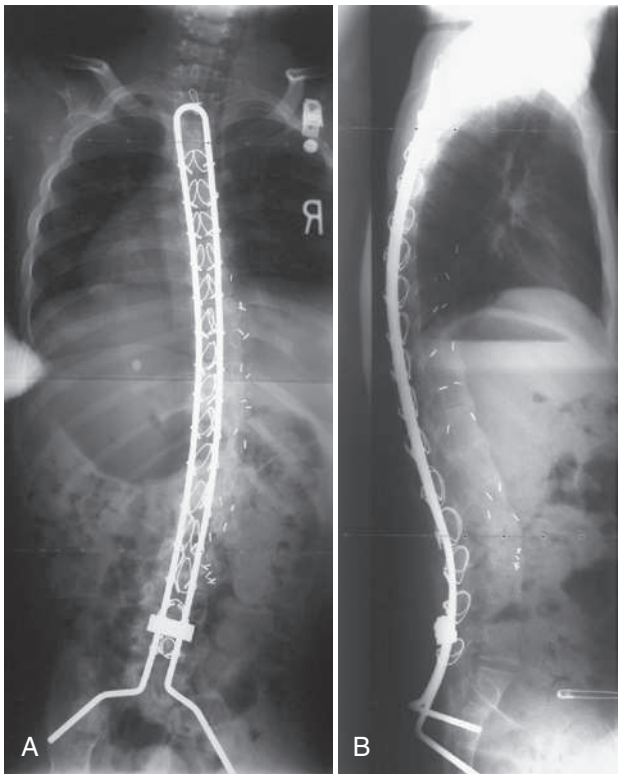

FIG. 28.8 Unit rod, as shown in a patient with cerebral palsy, provides a method for obtaining fixation to the pelvis and correction of pelvic obliquity.

with 2-year follow-up and concluded that it offers the advantages of good correction of deformity and pelvic obliquity, a low complication rate, and a 96% caretakers' survey satisfaction rate. Unit rod instrumentation has also been shown to have good results in ambulatory patients, with excellent deformity correction and preservation of ambulatory function at 2.9-year follow-up in 24 patients.[72] Additionally, biomechanical studies have shown that the addition of an L5 pedicle screw increases the construct stiffness and the strength-reducing complications associated with the loss of fixation.[73]

Through a desire to achieve similar correction as the unit rod construct, without the need for pelvic fixation, the U-rod was investigated by McCall and Hayes.[74] This rod is an outgrowth of the unit rod concept except that the rod terminates in pedicle screws at the L5 level, relying on the iliolumbar ligaments to achieve correction of the pelvic obliquity. In their comparison study of 30 patients with unit rod instrumentation and sacral fusion and 25 patients with U-rod instrumentation and L5 fusion, McCall and Hayes[74] found that the U-rod provided comparable correction of scoliosis and pelvic obliquity in curves with less than 15 degrees L5 tilt at 4 years of follow-up. Regardless of whether the precontoured unit rod or double Luque rods are used, segmental sublaminar wire instrumentation provides simple, inexpensive, and fairly powerful correction of coronal plane deformity. Segmental sublaminar wire instrumentation has limitations in the maintenance of sagittal plane alignment, however, because the sublaminar wiring fails to fix spinal length and the vertebrae can slide along the smooth rod construct, particularly during trunk flexion (Fig. 28.9A).

Multihook segmental systems, such as Cotrel-Dubousset (CD) and Isola, have also been shown to be efficacious in patients with neuromuscular scoliosis.[75-77] The comparative efficacy of these two different constructs is inconclusive. In a study of 47 patients with neuromuscular scoliosis, Yazici and colleagues[78] concluded that the Isola instrumentation combined with Galveston pelvic fixation provided correction and maintenance of pelvic obliquity superior to Luque-Galveston, unit rod, or CD instrumentation. The results of this study are in contrast to the work of Wimmer and colleagues,[77] who found that there was no difference between Luque-Galveston and Isola instrumentation in radiographic outcomes, patient satisfaction, or complication rate.

In some circumstances, a hybrid system with a combination of hooks, pedicle screws, and sublaminar wires may provide optimal fixation with maximal correction. A biomechanical study conducted at the authors' institution showed that the addition of bilateral L1 pedicle screws to a Luque-Galveston construct on a cadaveric axial skeleton increased construct stiffness by greater than 60%. The addition of selective hooks or screws or both to an otherwise sublaminar wire construct allows use of compressive and distractive force to address the coronal and the sagittal deformities. Additionally, proximal fixation with sublaminar wires compromises the ligaments above, making junctional kyphosis more likely. Hooks (transverse process) or pedicle screws or both may limit this complication in kyphotic patients at greatest risk. Pedicle screw fixation has become the standard at many

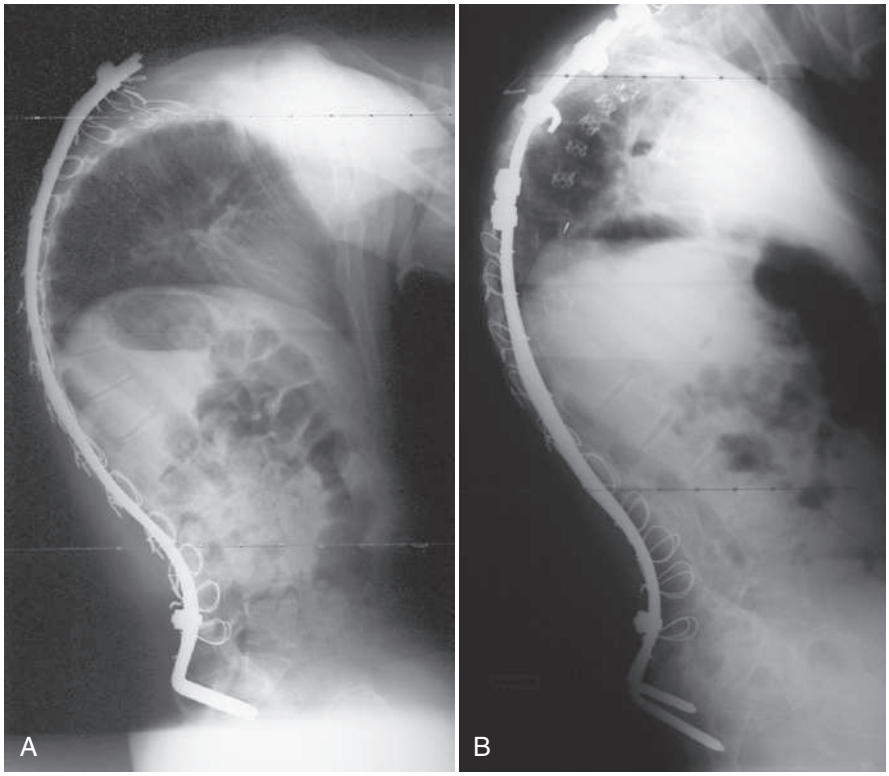

FIG. 28.9 (A) Failure of proximal sublaminar wiring in this construct resulted in increased kyphosis and prominent hardware, necessitating revision surgery 3 years after primary procedure. (B) After proximal revision, the patient developed pullout of the Galveston portion of his construct. This clinical course emphasizes that fixation challenges are present in patients with neuromuscular deformity, particular hyperkyphosis.

centers for nearly all forms of spinal deformity, although there are synthetic bands now available that can be utilized in a sublaminar fashion similar to Luque wires.

Pelvic and Sacral Fixation

Severe pelvic obliquity secondary to unbalanced scoliotic curves and lower extremity contractures is common and progressive in patients with neuromuscular scoliosis. A solid spinal fusion to the pelvis aids in sitting comfort and balance[79]; however, achieving this goal can be troublesome (see Fig. 28.9B). Controlling the motion across the lumbosacral joint requires secure fixation to the pelvis to prevent a pseudarthrosis.

Various systems have been proposed to provide fixation to the pelvis. The Galveston technique was the first advancement to improve fusion rates and clinical success in long fusions to the sacrum.[60,66] When paired with either contoured Luque rods or unit rods, it provides powerful coronal correction of pelvic obliquity. This technique places greater forces, however, on the lumbrosacral junction, and proper contouring of the rods may be difficult. The initial concern regarding the association between radiolucency around the screw tips ("windshield wiper" sign) and an increased incidence of complications is of little clinical significance (Fig. 28.10).[79-81] Although a biomechanical evaluation of the Galveston technique by Sink and colleagues[32] showed that this construct creates a long lever

FIG. 28.10 Radiolucency around rod tip in ilium ("windshield wiper" effect) suggests lumbosacral pseudarthrosis, which may remain asymptomatic and resolve spontaneously.

arm that places considerable cantilever forces at the lumbrosacral junction, these forces lead to a high incidence of proximal fixation pullout and distal migration of Galveston rods. The rods also require three-dimensional bending, which makes it difficult to contour the rod properly.[82]

Other systems of sacropelvic fixation use an "S" bend,[83] which hooks distally over the sacral alae, while the more proximal portion is secured to the lumbar spine at L4 or above with a pedicle screw or infralaminar hook. Reviewing the results of 67 patients, McCarthy and colleagues[83] found that this technique had decreased operative time compared with Galveston fixation and achieved excellent clinical results, although in 2 of the 67 constructs, there was migration of the rods into the pelvis. Other techniques of rod contouring to fix to the pelvis include the Warner-Fackler and McCall techniques, both commonly used in the treatment of myelomeningocele-associated kyphosis, in which posterior elements of the lumbar or sacral spine may be absent. In the Warner-Fackler technique,[84] Luque rods are bent to 90 degrees in two places at the distal end, allowing the rods to pass through the S1 foramina and lever against the front of the sacrum to provide sagittal correction (Fig. 28.11). In a slight variation of this technique, McCall[85] described bending Luque rods to 20 to 40 degrees, passing them through the S1 foramina and bending the protruding portion according to the contour of the anterior sacrum. In 16 myelomeningocele patients with hyperkyphosis, McCall[85] found satisfactory correction and maintenance of correction after 5 years of follow-up.

Improvement on the Galveston concept has been the focus of many clinical studies.[83,86-88] The use of S1 screws alone was investigated, but bone quality is generally not substantial enough for successful use in patients with neuromuscular scoliosis. Early and colleagues[86] compared the biomechanical properties of Galveston sacropelvic fixation versus Colorado II sacropelvic plates using S1 screws, S2 alar screws, and iliac screws, and found that both methods provided similar construct stiffness with the Colorado II plate limiting L5–S1 motion in flexion-extension. These authors found that addition of a pair of L1 screws increased the construct stiffness by approximately 50% in both fixation techniques.

The use of iliac screw fixation has become a subject of several more recent articles because of its ease of implantation, avoiding the complex lumbosacral three-dimensional Galveston rod contouring. Clinical and biomechanical studies have shown an improved fusion rate and high pullout strengths after the use of iliac screws for caudad lumbosacral fixation.[87,88] In a review of 50 patients treated with one or two bilateral iliac screws, Phillips and colleagues[89] concluded that iliac screws provide a safe and effective means to treat neuromuscular scoliosis at 21 months of follow-up. These authors also noted that two screws in each iliac wing provided a more stable fixation with fewer implant-related complications than using a single screw. In a direct comparison of 20 patients with Galveston rod fixation versus 20 patients with iliac screw fixation, Peelle and colleagues[90] found that both techniques offer similar pelvic fixation with the iliac screw construct, allowing additional screw fixation points to the sacrum and lower lumbar vertebrae. The long-term impact of these screws on the sacroiliac joint was investigated in 67 adult patients by

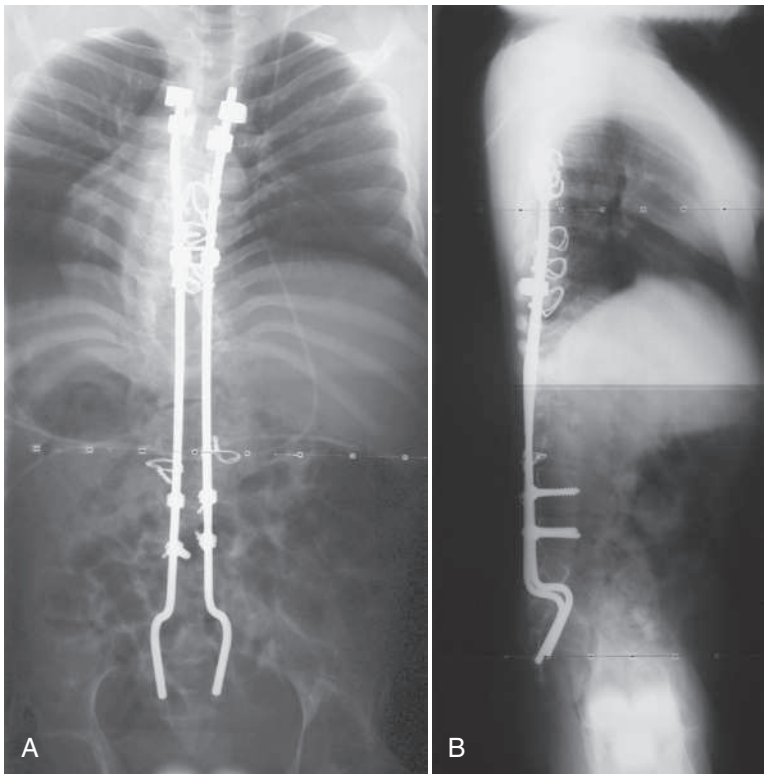

FIG. 28.11 Warner-Fackler method of pelvic fixation used after kyphectomy in a patient with myelodysplasia.

Tsuchiya and colleagues[88]; no evidence of degeneration was observed at 5- to 10-year follow-up.

Although iliac screws provide a promising alternative to Galveston fixation, several studies have shown difficulty with implant prominence causing skin irritation.[91] Peelle and colleagues[90] did not observe this complication in their patient series, however, because they countersunk the screws below the superficial portion of the posterior iliac crest. The patient's body habitus must be considered when selecting the means of sacropelvic fixation.

A lower profile method of iliac fixation has been developed by Kebaish[92] and Whitaker and colleagues[93] that starts in the sacral ala lateral to the S1 foramen and traverses the sacroiliac joint before entering the iliac wing. This has proven a useful method for limiting implant prominence (Fig. 28.12).

A retrospective study by Funk et al.[94] looking at patients treated with posterior spinal fusion to the pelvis for neuromuscular scoliosis with minimum 1-year follow-up in 80 patients showed advantages in favor of rigid spinopelvic instrumentation. In this study, the authors defined rigid instrumentation as consisting of at least 50% pedicle screw fixation with iliac or sacral alar iliac screw pelvic fixation. The correction of deformity at final follow-up was significantly greater when measuring Cobb angle and pelvic obliquity in the group of patients treated with rigid instrumentation. The pseudarthrosis rate was 5% in the rigid group and 22% in the nonrigid treated group.[94]

When patients with neuromuscular scoliosis are instrumented because of the severe obliquity of the pelvis, intraoperative halofemoral traction may also be beneficial. Previous studies on this traction technique have been described for patients with idiopathic and congenital scoliosis. In nonambulatory patients with neuromuscular scoliosis, surgeons have relied on rods or screws inserted into the iliac wings by a cantilever method to level the pelvis. This method has the potential to weaken the bone-construct connection in patients with poor bone stock. In a study of 20 nonambulatory patients with neuromuscular scoliosis with halofemoral traction and 20 matched patients without halofemoral traction, Takeshita and colleagues[95] found that halofemoral traction provided significantly improved lumbar curve and pelvic obliquity correction at 2-year follow-up. These authors had no associated perioperative complications with this technique, and found that unilateral femoral traction with corresponding halo traction was able to level the pelvis to an acceptable position before the surgery was begun. However, when a significant hip flexion contracture exists, traction results in an increase in lumbar lordosis that may be undesirable.

Some authors have argued that the pelvis can be left unfused in patients with slight pelvic obliquity, mild contractures, and little pelvic deformity in the sagittal plane, whereas others have argued that an ambulatory patient should never be fused to the pelvis.[92-94] McCall and colleagues[74] advocated that patients with less than 15 degrees of L5 tilt should be considered for a fusion to L5. These authors believed that this fusion allows greater mobility and improves the patients' ability to carry out activities of daily living (ADLs). Other studies promote fusion to the pelvis in all patients regardless of ambulatory status. A study by Tsirikos and colleagues[71] of

FIG. 28.12 A 12-yea-old with neuromuscular scoliosis status post T2 to pelvis with sacral-alar-iliac screw technique.

ambulatory CP patients with severe pelvic obliquity who were treated with fusion to the pelvis by Luque-Galveston instrumentation found that 23 of 24 patients maintained their ambulatory status. Given the progressive nature of this deformity and the fragility of these patients as operative candidates, the authors generally recommend including the pelvis in the fusion mass for most neuromuscular deformities.

Growing rod (GR) constructs connected to the pelvis in the neuromuscular population have become more common over the past decade. Sponseller and colleagues[96] analyzed the outcomes and complications unique to GR systems with the pelvis as the distal anchor point. The records of 36 patients from the Growing Spine database were analyzed with diagnoses including SMA, CP, multifocal motor neuropathy (MMN), congenital, arthrogryposis, and syndromic deformity with follow-up greater than 2 years. They found that GRs anchored to the pelvis can be used to safely and effectively correct pelvic obliquity, with dual iliac fixation providing the best correction. Iliac screws performed significantly better at correcting Cobb angle and pelvic obliquity when compared to sacral fixation.[97]

Anterior Spinal Release and Fusion

Indications

The addition of an anterior procedure can assist in the correction of neuromuscular spinal deformity and may be justified in several situations (Fig. 28.13). Anterior release and fusion has generally been indicated in patients with rigid scoliosis, patients with rigid kyphosis, immature patients at risk for the development of crankshaft growth, and patients at risk for pseudarthrosis owing to incompetent posterior elements (myelomeningocele or severe osteopenia).[93] In assessing the rigidity of the deformity, traction and supine bending films are useful but may underrepresent the available flexibility. An anterior release of a large rigid curve increases the overall spine mobility and makes the posterior correction easier with a relatively high fusion rate. In a study by Newton and colleagues,[98] the fusion rate achieved with anterior release combined with posterior corrective instrumentation and fusion was found to be comparable between adolescent patients with neuromuscular scoliosis and idiopathic scoliosis at 3-year follow-up. Keeler and colleagues[99] performed a comparative study in 52 patients who underwent intraoperative halofemoral traction. Twenty six patients underwent posterior spinal fusion (PSF) only for spastic neurmuscular scoliosis and were matched against an equal numbered cohort that underwent an anteroposterior spinal fusion (A/PSF) with no demographic or preoperative radiographic differences between the two groups. The study revealed that PSF-only surgery provides excellent curve correction and spinal balance with no statistical differences in terms of the final thoracolumbar/lumbar curve Cobb angle, percentage of correction of the thoracolumbar/lumbar Cobb angle, pelvic obliquity, C7 plumb line, and the center sacral vertical line at 2-year follow-up compared to A/PSF.[96] The patients who underwent PSF only had significantly reduced operative time, lower EBL, and lower frequency of postoperative pulmonary complications.[99] On the other hand, Auerback and colleagues[100] determined that CP patients with rigid and large major curves benefited more from an anterior release combined with a posterior fusion versus a posterior fusion alone. They compared 19 patients who had larger major curves, greater pelvic obliquity, and more rigid curves preoperatively who underwent anterior release against 42 patients with more flexible curves who underwent posterior fusion only. Correction of pelvic obliquity was similar in both groups.

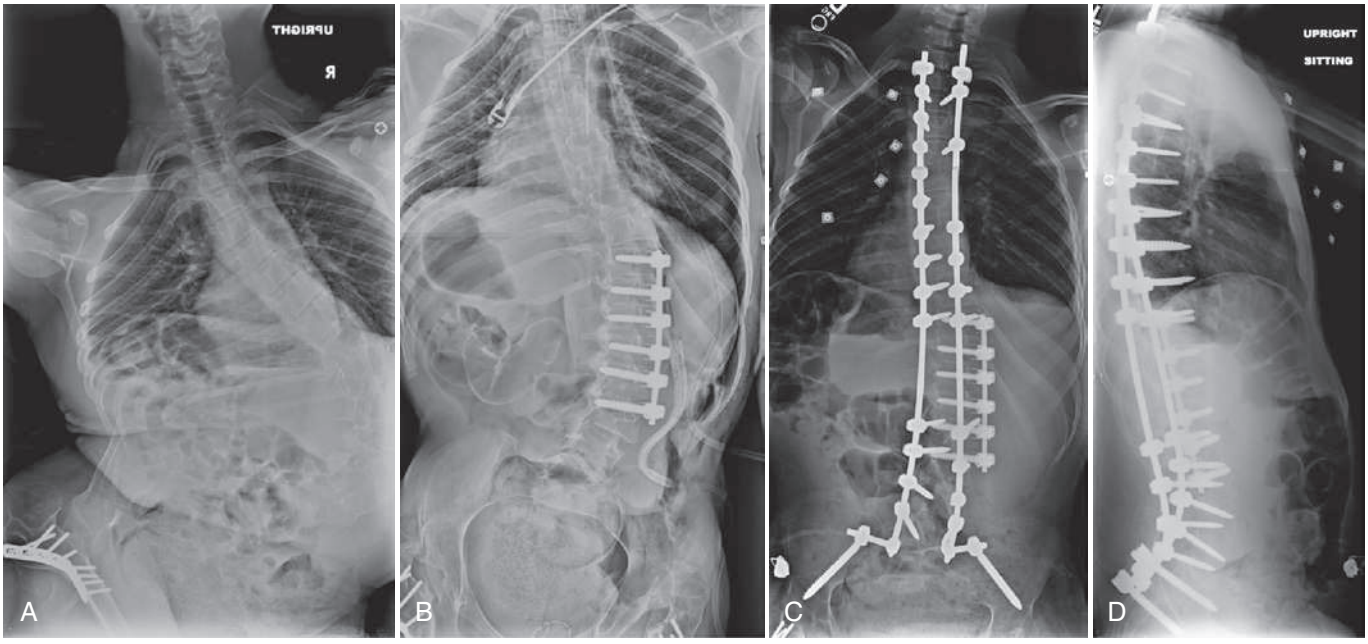

FIG. 28.13 (A) This severe thoracolumbar curve has a preoperative Cobb angle of 136 degrees. (B) Because of inflexibility, anterior disc excision and anterior instrumentation were used as the first stage of this procedure. (C–D) Posterior instrumentation T2 to pelvis was used in this quadriplegic patient with spasticity.

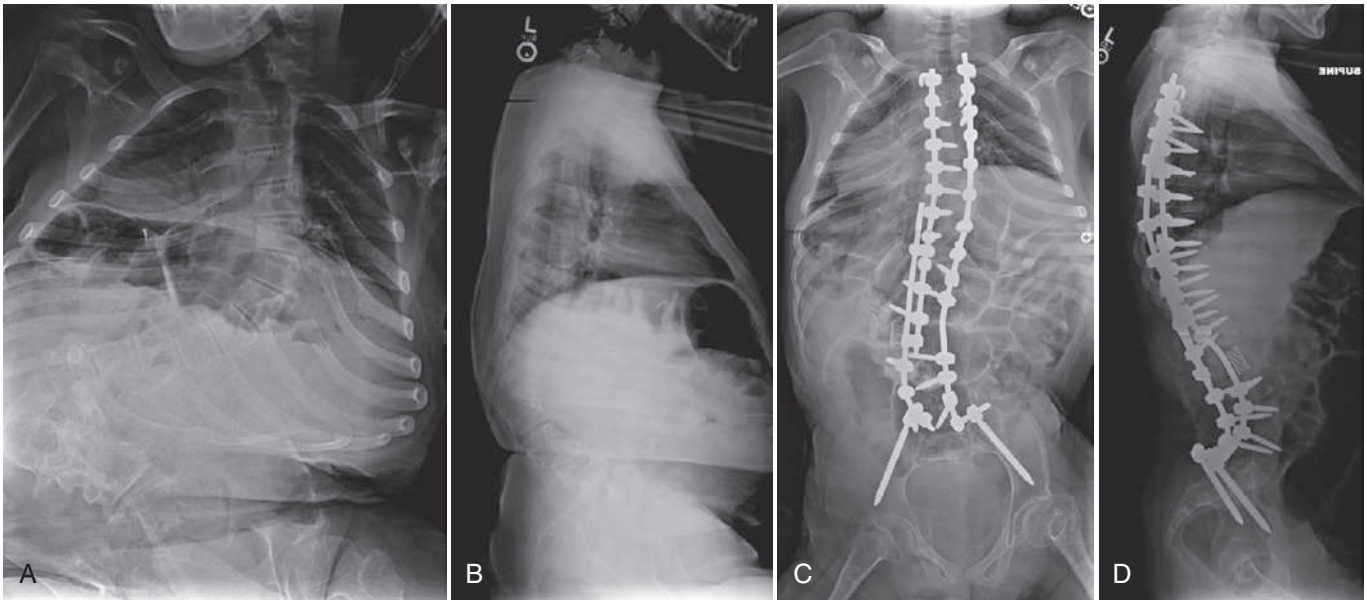

FIG. 28.14 (A–B) A severe 140-degree lumbar curve was upsetting wheelchair sitting balance in a quadriplegic patient with spasticity. (C–D) This curve was treated with a staged procedure. Anterior release did not provide sufficient flexibility, and anterior L1 and L2 corpectomy was performed. This procedure was followed by T2 to pelvis posterior instrumentation with completion of L1 and L2 corpectomy posteriorly.

While no significant difference was noted in the percentage of correction in the coronal and sagittal plane in the group, those with more rigid curves who underwent anterior release tended to have a greater percentage of correction compared to their preoperative bending films.[100]

Anterior instrumentation and spinal fusion alone and in combination with posterior instrumentation have also been shown to be successful techniques in a subset of patients with neuromuscular scoliosis. Our current algorithm indicates an anterior procedure for "severe" curves (most often thoracolumbar). If a near-complete correction of the major curve can be predicted with anterior instrumentation after an aggressive multilevel discectomy, a single-rod anterior system is included. If the curve remains rigid after an anterior release, the anterior instrumentation is skipped, and either an apical vertebrectomy is performed or the correction is achieved after posterior osteotomies (Fig. 28.14). It is important to avoid "locking in" a poor correction with anterior instrumentation in rigid curves. The goals of achieving a level pelvis and balanced spine must be weighed against the added morbidity of an anterior release or instrumentation procedures, or both.

In skeletally immature patients with idiopathic scoliosis, anterior release and fusion reduces anterior overgrowth that results in crankshaft deformity; however, whether this principle can be applied in neuromuscular scoliosis is controversial. In a study of 50 skeletally immature patients with neuromuscular scoliosis treated with posterior instrumentation only, Smucker and Miller[101] noted no significant curve progression at an average of 4 years of follow-up. In contrast, Comstock and colleagues,[31] after review of 60 skeletally immature patients with CP who underwent surgical scoliosis correction, concluded that skeletally immature patients have the best correction and long-term outcomes when treated with anterior and posterior procedures.

Instrumentation

The indications for anterior instrumentation have been a subject of investigation more recently. Several studies have shown that anterior instrumentation alone provides acceptable correction without the need for posterior instrumentation in selected short flexible curves that do not include the pelvis or have less than 15 degrees of pelvic obliquity.[102,103] Some studies advocate anterior release followed by posterior instrumentation, whereas others find indications for anterior disc excision and anterior instrumentation before proceeding posteriorly. Anterior instrumentation provides a very powerful means of addressing coronal plane deformities, and in many cases simplifies the posterior instrumentation across the levels instrumented anteriorly.

The present options for maximal deformity correction include anterior instrumentation followed by relatively simple posterior fixation versus anterior release and posterior fixation with greater use of posterior osteotomies. The first option also has the advantage of allowing an indefinite time between stages if required. Ultimately, the decision to include an anterior procedure (release or instrumentation) is multifactorial and depends on the experience of the surgeon, the overall health of the patient, and the characteristics of the deformity.

Intraoperative Considerations

Patient Positioning

The patient is positioned for anterior surgery with the apex of the deformity centered over the table break in a nearly lateral position. Flexing the table improves exposure, as does leaning the patient back toward the surgeon. If anterior instrumentation is planned, a direct lateral position is preferred. Posterior surgery is generally performed on a spinal frame; this allows

the abdomen to hang free, decreasing the pressure on the vena cava and epidural venous system. This position limits problematic epidural blood loss, particularly when a laminotomy for posterior release and sublaminar wire passage are required at several levels. In a smaller patient, chest rolls may suffice for prone positioning.

Spinal Cord Monitoring

Multimodality monitoring is a useful tool in children with neuromuscular scoliosis. Although patients with true paralysis and myelomeningocele do not benefit from this observation, the use of spinal cord monitoring is helpful for other patients to protect existing extremity function. Current evidence supports the use of transcranial motor evoked potentials (TcMEPs), somatosensory spinal evoked potentials, and H-reflex potentials in spinal cord monitoring.[97,98] TcMEPs provide useful data on the motor function and vascular status of the spinal cord, whereas somatosensory spinal evoked potentials provide information on the integrity of the sensory pathways of the dorsal columns. TcMEP monitoring has become a vital component of spinal cord monitoring. In a study of 1121 consecutive patients with adolescent idiopathic scoliosis undergoing spine surgery, Schwartz and colleagues[105] concluded that TcMEP monitoring is the most effective means to detect evolving spinal cord injury. TcMEPs monitor the anterior horn motor neurons, whose high metabolic rate is especially vulnerable to ischemic injury.[106]

Salem and colleagues[106] determined that TcMEPs do not increase the likelihood of triggering intraoperative or postoperative seizures and are not associated with deterioration in the seizure control of patients afflicted with epilepsy prior to scoliosis surgery. Because of the complexity and associated hematologic issues of patients with neuromuscular scoliosis, multimodal spinal cord monitoring is highly recommended.

Surgical correction of scoliosis in patients with CP has a higher morbidity associated with it compared to adolescent scoliosis.[107,108] Reames et al.[107] showed that surgical correction of neuromuscular scoliosis had the highest rate of complications (17.9%) when compared with correction of congenital scoliosis (10.6%) and adolescent idiopathic scoliosis (AIS) (6.3%). The complication rate with surgical correction of neuromuscular scoliosis is 1.1% compared to 0.8% for AIS. Difficulties with obtaining baseline intraoperative neuromonitoring (IONM) signals with neurologic deficits such as CP is well documented. Mo and colleagues[108] analyzed the IONM data of 206 children with neuroanatomic malformations such as hydrocephalus, encephalomalacia, and periventricular leukomalacia. From their analysis, they found that patients with these neuroanatomic malformations are significantly at risk of having unobtainable IONM signals, in particular TcMEPs. They recommend, if possible, to review all cranial imaging studies prior to scoliosis correction to help with predicting IONM outcomes.[108]

Blood Conservation

Antifibrinolytic agents, hypotensive anesthesia, Cell Saver, subperiosteal dissection, and electrocautery all can reduce blood loss. If an anterior approach is selected, unilateral ligation of the segmental vessels can be performed without significant risk of ischemia of the neural elements. Several studies have concluded that unilateral ligation carries no risk of causing neurologic compromise. Some authors recommend spinal cord monitoring during temporary (10–15 minutes) clamping of the segmental vessels before division.[109-111] Periodic intraoperative coagulation panels should also be used to detect a dilutional coagulopathy, which ideally can be treated with early use of fresh frozen plasma, cryoprecipitate, and platelets before disseminated intravascular coagulopathy (DIC) develops. The hematologic status of CP patients should be monitored very closely because they typically have increased bleeding that starts earlier in a procedure despite a normal coagulation profile.[112]

Bone Graft

In patients with neuromuscular scoliosis, the autologous iliac crest bone graft is often of poor quality and limited quantity. Also, harvesting may interfere with the placement of pelvic instrumentation. Because these patients need a significant volume of graft given the extent of fusion, supplemental graft in the form of freeze-dried or frozen cancellous allogeneic bone is almost always necessary to supplement local bone graft (facets, spinous process). Although allograft is generally regarded as safe and reliable for fusion augmentation in these patients,[78] evaluation by Sponseller and colleagues[113] of 210 patients with neuromuscular scoliosis revealed an increased risk of infection with the use of allograft. Glotzbecker and colleagues[114] performed a systematic literature review to analyze the risk factors and preventive strategies for surgical site infection (SSI) following spine surgery in the pediatric population, finding good evidence from their review to indicate that ceramic bone substitute did not increase the risk of SSI when compared with autograft. However, there is poor-quality evidence to determine whether allograft increases SSI risk following scoliosis surgery in the pediatric age group.[114] In a study by Yazici and Asher,[115] the rate of pseudarthrosis in patients with neuromuscular scoliosis undergoing surgery with allograft was 2.5%.

Timing of Combined Procedures

The evidence for performing staged versus same-day anterior and posterior procedures is unclear. In a study of 45 patients who underwent combined anterior and posterior surgery, Tsirikos and colleagues[116] found that same-day procedures were associated with longer operative time, greater blood loss, and a higher incidence of medical and technical complications. These results were in contrast to a study by Mohamad and colleagues,[117] who found no difference between single-stage and staged surgical procedures in their review of 175 patients with neuromuscular scoliosis. Further studies on staging combined procedures have focused on the use of traction and defining the curve characteristics that would be most appropriate for a staged procedure. For large, rigid curves, the use of staged surgery with anterior release and halopelvic traction as the first stage and posterior instrumentation and fusion as the second stage was investigated by Yamin and colleagues.[118] These authors concluded that patients whose Cobb angle was greater than 80 degrees and flexibility was less

than 20% should be treated with this method. Yamin and colleagues[118] also recommended that patients whose spine flexibility was less than 10% with a Cobb angle that remained greater than 70 degrees after the first-stage anterior release and halopelvic traction should undergo pedicle subtraction osteotomies in the second-stage surgery.

It is important to anticipate the need for a staged procedure because unplanned staged procedures have a higher complication rate than planned staged procedures.[117] Given the evidence, the authors recommend planning a staged procedure in larger patients with severe deformity or a history of large-volume blood loss in previous surgeries or both. Despite careful planning, hemodynamic instability may force unplanned staging. Blood loss in the posterior procedure tends to be two to three times the blood loss during the anterior procedure; if the surgeon encounters anterior blood loss greater than half the patient's blood volume, a staged procedure should be considered.

Anterior Surgical Approaches

Transthoracic Approach

The standard approach to the thoracic spine is via an open thoracotomy performed on the convexity of the scoliosis. The rib one to two levels above the most cephalad vertebral body to be approached should be removed. The spine can be exposed over approximately six levels between T4 and L1 with this approach. The superficial dissection is in line with the rib, dividing the serratus anterior and latissimus dorsi muscles. The rib is stripped subperiosteally and removed as far posteriorly as possible. With a rib-spreading retractor in place, the parietal pleura is opened longitudinally along the spine. The segmental vessels may be clamped and ligated or maintained, based on the required exposure.

Thoracoscopic Approach

In the thoracic spine, thoracoscopy is an option instead of open thoracotomy. Video-assisted thoracic surgery allows exposure of the entire thoracic spine through three to five intercostal portals. The thoracoscopic approach is less invasive, sparing the chest wall musculature. Investigation has shown that there is less perioperative pulmonary dysfunction associated with this approach in adolescent patients with idiopathic scoliosis. This assertion is supported by Newton and colleagues,[119] who found that comparable correction rates and pulmonary function are present at 5-year follow-up in adolescent patients with idiopathic scoliosis. Although the benefits in adolescent patients with idiopathic scoliosis have been well described, the potential benefits in respiratory function remain unclear in patients with neuromuscular scoliosis.

In a study of perioperative complications after surgical correction in 175 patients with neuromuscular scoliosis, Mohamad and colleagues[117] discussed no positive or negative correlations associated with video-assisted thoracic surgery and pulmonary function. Given this lack of evidence and the technical demands of this technique, the benefits of this procedure must be weighed in the context of the experience of the surgeon and possible complications. Mastery of this less invasive approach may prove to be a valuable tool in treating these fragile patients, however.

Thoracoabdominal Approach

When exposure of the thoracolumbar junction is required, the thoracoabdominal approach extends a thoracotomy incision distally. This extended incision allows exposure from the lower thoracic spine to the sacrum. The diaphragm is detached from the chest wall, which may have pulmonary consequences in patients with limited pulmonary reserve. The thoracotomy approach is combined with a retroperitoneal exposure of the lumbar spine. The diaphragm is divided near the chest wall circumferentially to its origin on the spine at L1.

Retroperitoneal Lumbar Approach

The retroperitoneal approach to the lumbar spine provides exposure from L1 to the sacrum, but placement of instrumentation above L2 often requires a thoracoabdominal exposure. The incision is in line with the 12th rib, curving to parallel the rectus abdominis inferiorly. The three abdominal muscle layers are divided, taking care to identify the translucent layer of peritoneum. The plane between the transversus abdominis and the peritoneum is developed posteriorly. The psoas muscle is reflected posteriorly, exposing the spine. Inferiorly, the iliac vessels and commonly a large iliolumbar vein require careful dissection. The L5–S1 disc can be exposed either by elevating the iliac vessels or by working between the bifurcation anteriorly.

Vertical Expandable Prosthetic Titanium Rib

The vertical expandable prosthetic titanium rib (VEPTR) has gained attention more recently for its role in the correction of early-onset scoliosis (EOS) and congenital spinal deformities.[120] Hell and colleagues[121] investigated the efficacy of VEPTR in 15 children, 6 of whom were diagnosed with neuromuscular scoliosis. These authors concluded that this technique was safe, effective, and improved sitting ability and cosmesis. These results were supported by a preliminary investigation by Latalski and colleagues, who found that VEPTR considerably improved respiratory capacity in two patients with congenital spinal deformity and one patient with neuromuscular scoliosis.[122]

Neuromuscular patients with pelvic obliquity can be treated with GR constructs anchored to the pelvis to help correct the obliquity. Sponseller and colleagues[96] analyzed the records of 36 patients from the Growing Spine Study Group database with neuromuscular disorders and found that GRs anchored to the pelvis with dual iliac fixation provided the best correction of the patient's pelvic obliquity.

Akabarnia and Emans[123] described that the best indication for VEPTR in EOS is thoracogenic scoliosis or multiple fused ribs in association with congenital scoliosis. This is compared to GRs, which are indicated in the setting of a progressive deformity in a normally segmented deformity such as infantile idiopathic scoliosis not controlled by bracing or casting. They also describe various complications associated with GR and VEPTR devices. Among the possible complications of VEPTR devices is proximal fixation failure. Neuromuscular scoliosis curves exert a high stress on VEPTR devices due to their

rigidity. The high-tensile stress forces on the VEPTR devices caused by the coronal and sagittal demands of the curves can lead to proximal fixation failure. Park and colleagues[124] showed that neuromuscular patients with increased major curve angle and normokyphosis or hyperkyphosis had a high correlation with rapid VEPTR anchor failure. Neuromuscular scoliosis curves exhibit high stress on VEPTR devices due to the rigidness of the curves. Furthermore, the increased coronal and sagittal curves result in a high-tensile stress level on VEPTR devices, which leads to complications associated with growing spine surgery. Although initial results show promise, the clinical application of the VEPTR in neuromuscular scoliosis remains a subject that requires further study. The Shilla method[119] and others designed to guide growth posteriorly have also been utilized by some in the very young neuromuscular patients. Hybrid methods of limited fusion and some form of growth guidance/maintenance remain an option in these most challenging cases (Fig. 28.15).

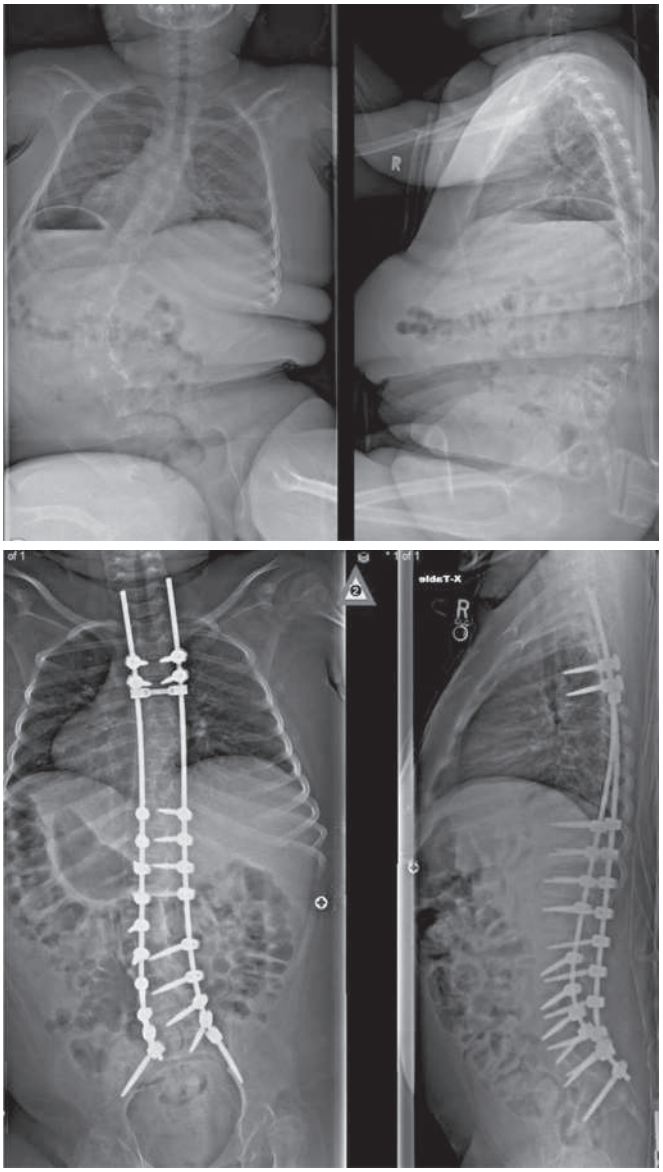

FIG. 28.15 An 8-year-old with spinal muscle atrophy status post T2 to T3 Shilla procedure and T10 to pelvis posterior spinal fusion.

Postoperative Care

Intensive Care Unit

Patients with neuromuscular scoliosis who have undergone extensive spinal surgery are best managed immediately postoperatively in an intensive care unit (ICU) setting. Ventilatory support is often needed for 24 to 48 hours or more. An intensivist accustomed to caring for these children is invaluable in the early postoperative course.

Bracing

Postoperative bracing is usually not required if the bone quality is sufficient to provide secure implant fixation. In difficult cases, a molded orthosis may be needed; it should be molded after the surgery if significant deformity correction is anticipated. After kyphosis correction, an orthosis may be helpful for reducing the stress on the proximal posterior fixation points.

Complications

The surgical treatment of neuromuscular scoliosis has been shown to have a higher complication rate compared with surgical treatment of idiopathic scoliosis. In the largest study to date of perioperative complications associated with neuromuscular scoliosis surgery, Mohamad and colleagues[117] reported their complication rate to be 33% in 175 patients. These results are consistent with previous studies that found the complication rate to range from 24% to 75%.[80,81,126,127] The factors that are associated with perioperative complications include a history of seizures, unplanned staged surgical procedures, and increased blood loss.[128] Pulmonary issues have been found to be the most prevalent complication of spinal surgery in these patients, thus should be closely monitored by the multidisciplinary care team.

Wound Infections

The rate of wound infections in this type of surgery is higher than in surgery for adolescent idiopathic scoliosis, ranging from 8% to 15% in the literature. Superficial wound infections are more common than deep wound infections, and require close monitoring because they can quickly progress in patients with neuromuscular disorders. Wound infection is also more common in nonambulatory patients with severe involvement, and tends to involve multiple gram-negative organisms. A higher rate of wound infection has also been found in patients with sacropelvic fixation with a trend toward a higher rate of deep wound infection.[117]

Croft et al. found in their analysis of 598 patients, 22 of which had SSIs, that patients with neuromuscular scoliosis and a weight-for-age at the 95th percentile or higher were at significantly higher risk for SSI.[129] Their results supported the findings of earlier studies by Allesia et al.[129a] and Mackenzie et al.[129b] The authors also found that use of allograft alone (or in combination with autografts or synthetic grafts) and

increased blood loss were significantly correlated with SSI. Prevention of SSIs in this patient population is the goal, with one study showing that the incidence of deep wound infection may be reduced in patients with neuromuscular disease undergoing spine surgery by using an antibiotic-loaded bone graft. In a study of 220 children with CP treated with unit rod instrumentation, Borkhuu and colleagues[130] found that the use of gentamicin-impregnated bone graft decreased the incidence of deep wound infection by 11% compared with patients who received bone graft without antibiotics. However, when Mikhael et al.[131] analyzed the effects of gamma irradiation, they found that irradiated bone allograft did not decrease the rate of culture-positive infection following spinal fusion compared to nonirradiated allograft and autograft at 1 year.

In patients with neuromuscular disease, a high index of suspicion must still be maintained, and any suspected infection must be aspirated from deep and superficial layers. A wound infection requires débridement and closure over drains with broad-spectrum antibiotics. Vacuum-assisted closure for deep infections has shown good results, with an ease of use and a marked reduction in the need for hardware removal.[132] When a wound has been infected, the risk for pseudarthrosis increases.[115,126]

Respiratory Complications

Given the baseline susceptibility of patients with neuromuscular disorders to respiratory complications and the chest wall insult and immobilization associated with scoliosis correction, respiratory complications are common in the postoperative period; the reported incidence ranges from 9% to 22%. These complications include pneumonia, pleural effusion, and atelectasis that may require prolonged intubation.[80,81,127] A preoperative consultation with a pulmonologist to maximize the patient's pulmonary health and aggressive care in the ICU help to reduce the incidence of problems; however, caregivers and patients should be warned that permanent ventilator dependence is a possible sequela of surgery for some patients.

Urinary Tract Infections

The incidence reported in the literature of urinary tract infections (UTIs) in patients with neuromuscular scoliosis is 9% to 22%. Expeditious removal of a urinary catheter inserted for the procedure and adequate hydration may reduce the risk of UTI. Patients with myelomeningocele often have chronic colonization of bacteria in their bladder. Perioperative prophylactic antibiotics should address these organisms.[8,81,126,127]

Cerebral Palsy

An estimated 25,000 children are diagnosed with CP each year. With this huge volume of patients, CP has replaced polio as the prototypic neuromuscular disorder. CP is caused by a static upper motor neuron lesion that interferes with the developing motor system. This lesion is usually caused by an anoxic insult in the perinatal period; however, child abuse in young infants is another common cause of brain injury that can lead to CP.

Scoliosis in Cerebral Palsy

Scoliosis is common in CP, with a 25% incidence of spinal deformity in all CP patients. The incidence and degree of deformity correlate with the amount of neurologic deficit and ambulatory status. In a study of 272 institutionalized patients, the highest prevalence of scoliosis was found in the most severely affected patients with 75% of spastic quadriplegic and 68% of spastic diplegic patients having at least 10 degrees of spinal deformity. In this study, 44% of patients who could ambulate independently, 54% of patients who could ambulate with assistance, 61% of patients who could sit independently, 75% of patients who could sit with assistance, and 76% of bedridden patients had significant deformity. Although these numbers may be inflated by the fact that the study population was composed entirely of institutionalized patients, they still reveal a trend of increased deformity with increased spasticity and decreased independent mobility.[135,136]

The development of scoliosis in CP patients is thought to result partly from persistent primitive reflex patterns and asymmetrical tone in the paraspinous and intercostal muscles. Pelvic obliquity from contractures around the hip plays a role in scoliosis development; however, it is often difficult to isolate this as a contributing factor because pelvic obliquity, hip contractures, and scoliosis often develop simultaneously. Placing patients with a weak trunk and total body involvement into artificial upright sitting positions without appropriate spinal support may encourage gravity-related kyphosis and scoliosis. This suspicion was raised by Madigan and Wallace[136] when they found a 75% incidence of scoliosis in a predominantly institutionalized population comprising "prop sitters" but only a 25% incidence in a population of quadriplegics with spasticity in which prop sitting was not pursued.

Scoliosis in CP has been classified into four categories based on curve pattern (single vs double) and the presence or absence of pelvic obliquity. Long C curves with pelvic obliquity generally occur in more severely involved nonambulatory patients with spasticity. S curves occur more frequently in sitting or walking patients with little spasticity. S curves seem to be more idiopathic in nature, often without associated pelvic obliquity.[33] Patients with severe involvement and a developmental level less than 6 months seldom attain independent sitting balance. Lack of neuromuscular control prevents proper alignment of the head; these patients do not develop compensatory curves to bring the shoulders and head over the pelvis.

Curve progression is related to these risk factors and quadriplegia, poor functional status, and a single thoracolumbar curve.[1,137,138] As in idiopathic scoliosis, risk of progression is also related to curve magnitude and to the amount of remaining spinal growth. Because progression of spinal deformity begins at the onset of the neuromuscular condition, patients with CP have a much longer time to progress and have the potential for developing larger curves than patients with adolescent idiopathic scoliosis. This period of potential curve progression is prolonged further because these patients often maintain open growth plates into their late teens or early 20s. In adults, Thometz and Simon[138] found that larger curves

progress faster than smaller curves; they noted curve progression of 0.8 degree per year in curves less than 50 degrees and 1.4 degrees per year in curves greater than 50 degrees. Even patients who have completed growth are at risk for scoliosis progression.

Treatment Options

Bracing

The natural history of scoliosis in children with CP is early onset with a flexible spine deformity between 3 and 10 years of age with a relatively fast progression to a rigid structural curve.[137] Most of the articles in the literature do not support the use of bracing. Bracing can function as a temporizing measure, however, in patients with early-onset, flexible scoliosis or in patients with contraindications for surgery.[19] CP patients with spasticity have poor tolerance for bracing because of the spasticity of their limbs inhibiting brace application, the incidence of skin pressure irritation, and sometimes increasing respiratory problems.[19,21] A soft brace may be used owing to the lack of practicality of dynamic bracing, although it becomes mainly a sitting support rather than a treatment modality. For patients who cannot tolerate bracing, wheelchair seating systems can facilitate upright posture and allow patients to participate in more activities with greater social interaction.

Surgical Management

Various techniques and instrumentation exist for surgical scoliosis correction in CP patients. In patients with hypotonia, a thoracolumbar or lumbar curve that does not extend to the pelvis, and a pelvic obliquity less than 15 degrees, fusion to L5 without sacropelvic fixation may occasionally be appropriate.[71] For most CP patients with spinal deformity, an extensive posterior fusion with instrumentation from the upper thoracic level (T1 or T2) to the pelvis is indicated. The most common instrumentation systems used have been the combination of Luque wires and a unit rod or two Galveston rods. Luque-Galveston constructs may be modified with iliac screw fixation to aid in the ease of insertion and to provide safe, reliable correction.[88,89] Several studies have shown the efficacy of these methods in CP patients. Boachie-Adjei and colleagues[127] retrospectively reviewed 45 patients treated with Luque-Galveston constructs and found 53% correction of scoliosis and 50% correction of pelvic obliquity. The correction was maintained at an average of 3 years of follow-up despite a 6.5% pseudarthrosis rate. Benson and colleagues[126] reported on a cohort of 50 patients also treated with Luque-Galveston instrumentation who showed a 65% scoliosis correction rate with maintenance of correction at 40 months of follow-up. Only one patient in this series had a pseudarthrosis (2%).

Other studies have reported successful correction using the unit rod system in CP patients. Bulman and colleagues[70] compared 15 patients instrumented with Luque-Galveston constructs to 15 patients with unit rod instrumentation and concluded that the unit rod provided significantly improved correction and maintenance of correction of both scoliosis and pelvic obliquity at 2 years after surgery. Although the power of this study is limited by its small size and short follow-up, the findings are echoed in the results of other studies. Westerlund and colleagues[139] reported 66% scoliosis correction and 75% pelvic obliquity correction that was maintained at an average of 5 years' follow-up. Tsirikos and colleagues[116] retrospectively reviewed 287 CP patients treated with unit rod instrumentation and found a 68% correction of scoliosis and 71% correction in pelvic obliquity at 2-year follow-up.

More recently, there has been a trend toward using more hooks and screws in neuromuscular constructs. Segmental screw fixation common in idiopathic scoliosis may result in improved fixation with a reduced complication rate.[140]

Teli et al.[141] analyzed 60 patients with CP with a minimum 2-year follow-up who were treated with segmental third-generation CD instrumentation and showed an average correction of coronal deformity of 60% and pelvic obliquity of 40%. In their study, 26 patients received anteroposterior surgeries and 34 had posterior-only procedures, noting that correction of the scoliosis was similar in both groups. However, correction of pelvic obliquity was improved in patients who underwent an anterior release. Significant complications affected 13.5% of patients and included loosening of implants, deep tissue infection, and pseudarthrosis.[141]

Despite the recent trend away from anterior approaches, in patients with very rigid curves, an anterior release is a powerful technique that can help correction of these challenging curves. Auerbach and colleagues[100] assessed whether posterior-only fusion would be sufficient for correcting large curves in CP patients. They compared 19 patients who underwent anterior release with larger major curves, greater pelvic obliquity, and more rigid curves preoperatively against 42 patients with more flexible curves who had posterioe-only fusion. Correction of pelvic obliquity was similar in both groups.[100]

Surgical correction of scoliosis and pelvic obliquity may also be improved with the use of intraoperative traction. In a comparison study of patients with and without asymmetrical intraoperative halopelvic traction, Vialle and colleagues[142] concluded that intraoperative traction resulted in reduced anesthetic duration and improved correction of scoliosis and pelvic obliquity. These results are supported by Takeshita and colleagues,[95] who found that halofemoral traction improved scoliosis and pelvic obliquity surgical correction in nonambulatory patients with neuromuscular disorders.

Keeler and colleagues[99] found that PSF-only surgery provides excellent curve correction and spinal balance with no statistical differences in terms of the final thoracolumbar/lumbar curve Cobb angle, percentage of correction of the thoracolumbar/lumbar Cobb angle, pelvic obliquity, C7 plumb line, and the center sacral vertical line at 2-year follow-up compared to A/PSF in patients with spastic neuromuscular scoliosis. The patients who underwent PSF only had significantly reduced operating room time, lower EBL, and lower frequency of postoperative pulmonary complications.

Sagittal plane deformities are also common problems in CP patients with scoliosis and require a different approach than that required for coronal plane deformities. Lumbar

hyperlordosis and thoracic hyperkyphosis can impair sitting balance and comfort. Hyperkyphosis can be exacerbated by pelvic obliquity and gravity in a patient who sits propped up unsupported and is associated with an increased incidence of instrumentation pullout and failure.[32] Sagittal plane kyphotic deformities require treatment similar to treatment of the deformity in Scheuermann disease with or without an anterior release and a hybrid system of hooks and pedicle screws to apply segmental compression across the kyphotic segments.

Authors' Recommendations

For gravity-dependent mild scoliosis or hypotonic kyphosis in children younger than 10 years, the authors recommend a Plastizote body jacket. This body jacket supports the spine, assists head control, and is well tolerated by the patient. The orthosis usually lasts more than 2 years before it is outgrown. For more rigid curves, between 30 degrees and 50 degrees, or in less rapidly growing patients older than 12 years, a rigid total-contact orthosis may be tried. Although less well tolerated, a total-contact orthosis provides better correction and may delay the need for surgery by providing greater sitting support.

As discussed earlier, defining the precise indications for surgical intervention in patients with scoliosis and CP is difficult. The authors recommend that surgery be considered when scoliosis greater than 50 to 70 degrees exists, taking into consideration the patient's functional, mental, and general health status. The decision to proceed with surgery of this magnitude requires a thoughtful analysis and discussion with the family and caregivers. If Luque instrumentation is used posteriorly, when possible, 5.5- to 6.35-mm rods and a combination of infralaminar hooks, pedicle screws, and double 16- to 18-gauge wires should be used to maximize correction and rigidity. Smaller diameter rods (4.5–4.75 mm) should be used only in very small patients for fear of rod breakage. Anterior fusion should be considered in patients with rigid curves greater than 60 to 80 degrees, in skeletally immature patients, or in patients with fixed pelvic obliquity. In severe curves with marked pelvic obliquity, the correction of the pelvic obliquity and the certainty of permanent correction are often enhanced by the addition of anterior lumbar instrumentation.

The use of pedicle screws and aggressive posterior osteotomies has reduced the use of anterior surgery for some patients. For the most flexible cases, an all-posterior hybrid construct is appropriated; we prefer pelvic fixation with iliac bolts over Galveston rods. If the curve is more rigid, Ponte-type osteotomies are added, and the density of pedicle screws is increased. Patients with curves that do not correct to less than 70 degrees on side bending are considered for an anterior procedure, most often at the thoracolumbar junction. If, after complete disc excision (including the posterior longitudinal ligament), the spine is now flexible enough for near-complete correction, the correction is achieved with an anterior rod system. If the spine remains rigid after discectomy, performing an apical vertebral excision is considered. In either case, an anterior rod is avoided when residual rigidity remains, and the correction is achieved with posterior instrumentation.

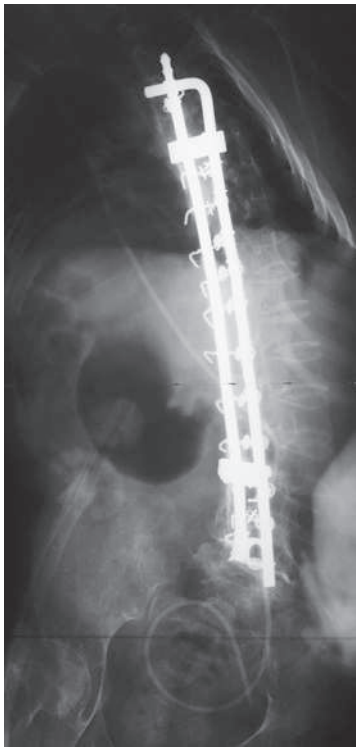

FIG. 28.16 This patient with cerebral palsy presented at age 17 years with Harrington-Luque instrumentation from T4 to L4 done 5 years previously. At presentation, the patient had 85-degree, C-shaped scoliosis with marked pelvic obliquity, rotational deformity, and resultant sitting difficulties. In most nonambulatory patients who have adequate spinal length, fusion to pelvis is recommended to avoid this dilemma.

All CP patients with limited ambulatory capacity should be fused inferiorly to include the pelvis, even if their pelvic obliquity is correctable, because of the potential for increased obliquity owing to persistent muscle imbalances (Fig. 28.16). Most patients do not require postoperative immobilization. In patients with poor bone stock or a motion disorder undergoing fusion to the pelvis, a brace is considered for 3 to 6 months after surgery.

Myelodysplasia

Myelodysplasia is characterized by a persistent open neural arch owing to failed proliferation of neuroectodermal cells in early embryonic development and has been associated with maternal hyperthermia and folate deficiency. The spinal deformity comes from a congenital malformation of levels at the defect, often resulting in a regional hyperkyphosis, and from the muscle imbalance around the spine distal to the lesion (Fig. 28.17).

Scoliosis in Myelodysplasia

The incidence of scoliosis in patients with myelodysplasia (spina bifida) varies in the literature from 52% to 90%.[143,144] In

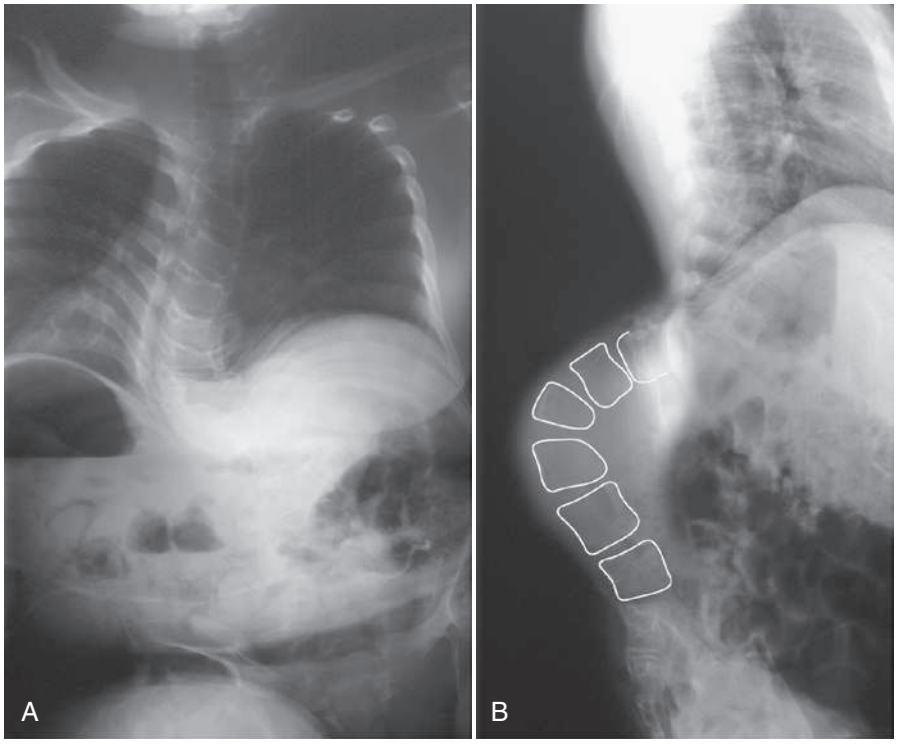

FIG. 28.17 Severe progressive kyphosis in a patient with thoracic-level myelomeningocele caused skin breakdown problems and difficulty with self-catheterization before she underwent kyphectomy and instrumentation (see Fig. 28.11).

a more recent study of 141 patients by Trivedi and colleagues,[144] the authors defined scoliosis in myelodysplasia as curvature greater than 20 degrees and concluded that new curvature could develop as late as 15 years of age. In this cohort of patients, 89% of patients with the last intact laminar arch located in the thoracic region had scoliosis, whereas 44% and 12% had scoliosis if their last intact laminar arch was in the upper and lower lumbar regions. From this trend, Trivedi and colleagues[144] concluded that the last intact laminar arch was the most useful early predictor of scoliosis risk, although ambulatory status and clinical motor levels were also useful predictors.

Myelodysplastic spine is one of the most difficult treatment dilemmas in scoliosis management. These patients present with congenital malformations (Fig. 28.18), often in the form of severe kyphosis preventing comfortable sitting and causing skin breakdown that may necessitate separate and early intervention. The risk of deformity from weak, spastic paraspinal musculature and asymmetrical hip contractures remains, often requiring more definitive surgical correction in the preteen or teen years. Surgical correction for myelodysplasia presents unique problems because of the absent posterior elements, increasing the dependence on anterior fusion and fixation. In addition, the posterior approach for surgical correction traverses the poor-quality skin and scar tissue that results from the defect and the early neurosurgical repair (Fig. 28.19).

There may be an association between myelodysplasia patients with a tethered spinal cord and rapidly progressive scoliosis.[145] Most of these patients have some variation of cord tethering as a residuum of the defect and its neurosurgical closure. The neural tube closure defect needs to be neurosurgically repaired between 24 and 72 hours after birth to avoid risk of infection.[146] The surgical repair, however, frequently later leads to tethering of the spinal cord at the repair site in as many as 70% of patients with myelomeningocele.[147] In patients with unexpected rapid curve progression or increased trunk spasticity (hypertonicity), a tethered cord with or without syringomyelia should be considered. Studies such as MRI or myelography may help define the anatomy; however, the literature does not support a causal relationship between scoliosis and Chiari malformation or syringomyelia.[145] Thoughtful teamwork with a neuroradiologist, neurologist, and neurosurgeon helps clarify these issues.

Jankowski and colleagues[148] in a single institution analysis over a 10-year period identified 15 pediatric patients with intraspinal pathology who had scoliosis and received neurosurgical intervention. Diseases of the neural axis in the studied population consisted of Chiari I malformation (CM I), Chiari II malformation (CM II), tethered cord syndrome (TCS), and syringomyelia. The authors found that for patients with preoperative Cobb angles less than 30 degrees and without CM II, neurosurgical intervention may prevent scoliosis curve progression irrespective of the intraspinal pathology. Patients with CM II are at a higher risk of curve progression and undergoing fusion compared to patients with CM I, TCS, or syringomyelia. The authors recommended, in patients with a preoperative Cobb angle less than 30 degrees and without CM II, neurosurgical intervention followed by a period of monitoring of the scoliosis for progression. For patients with CM II, the authors recommended close radiographic monitoring

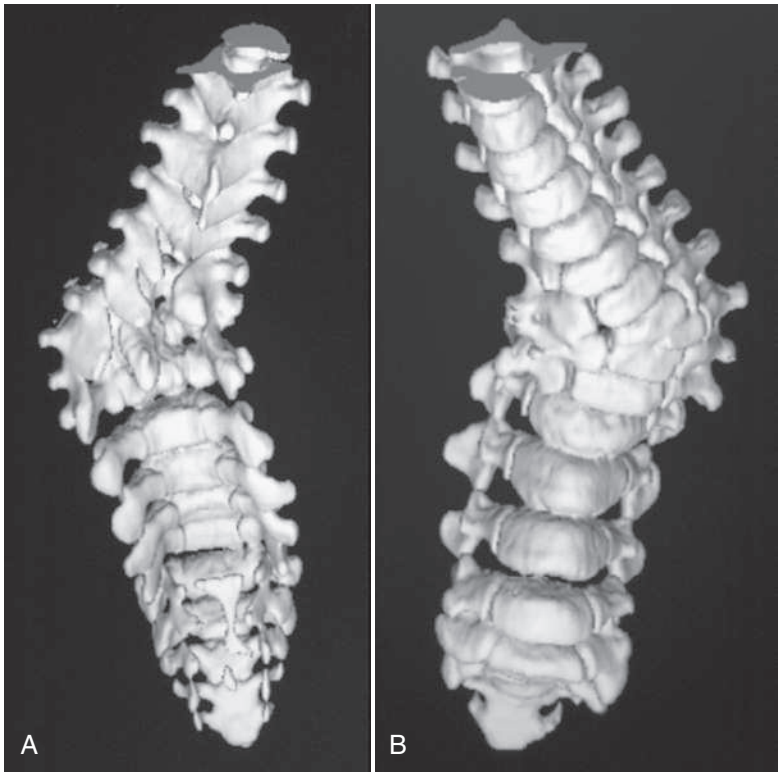

FIG. 28.18 Three-dimensional computed tomographic scan shows absence of posterior elements and congenital vertebral anomalies that make myelomeningocele spinal deformities challenging treatment dilemmas.

FIG. 28.19 An infant with severe scarring from original neurosurgical closure of spinal defect.

for curve progression with awareness of the high rate of scoliosis progression and eventual need for spinal fusion.

Surgical release of a tethered cord may help in scoliosis stabilization, maintenance of motor function, and decreased back pain.[149] Pierz and colleagues[150] evaluated 21 cases of detethering, however, and concluded that improvement or stabilization of scoliosis after detethering is less likely in patients with curves greater than 40 degrees or thoracic level defects, or both.

Chern and colleagues[151] analyzed 45 consecutive patients with tight film terminale who underwent tethered cord release. Of the 14 patients who presented with scoliosis prior to surgery, 7 had worsening of their curve deformity, in 5 the curve stabilized, and 2 had improvement after tethered cord surgery. The authors were able to conclude that patients who presented with a Cobb angle greater than 35 degrees were most likely to observe progression of their coronal deformity following tethered cord release.[148,151]

There has been an attempt to establish which curve characteristics might serve as predictive factors to aid in determining whether a curve's coronal deformity will progress or stabilize, albeit with inconclusive results.

Given the high incidence of scoliosis and the tendency for rapid progression in these patients, annual follow-up evaluations with posteroanterior and lateral radiographs should closely track coronal and sagittal spinal deformity, hip contractures, and trunk spasticity.

Treatment Options

Bracing

Bracing in myelodysplasia is even more difficult and less successful than in other neuromuscular disorders. Studies show that braces offered as a temporizing measure rarely yield effective curve control. Although Muller and Nordwall,[152] after evaluating 21 myelodysplasia patients treated with bracing, concluded that deformity progression can be halted in patients with curves less than 45 degrees, a more recent study by Olafsson and colleagues[22] reviewed outcomes in 20 patients and reported a successful outcome in only 20%

of patients. Bracing is difficult in these patients because of pressure sores, especially prevalent over kyphotic deformities at the level of the neurologic defect. Obesity, poor-quality and insensate skin, decreased vital capacity, and obstructing stomal bags also contribute to the difficulty of brace wear in these patients. In the study by Olafsson and colleagues,[22] half of the patients stopped wearing their braces because of discomfort. Custom-molded or modular wheelchair inserts offer another temporizing measure for comfortable upright posture until surgery is conducted.

Surgical Management

Definitive surgical management need only be delayed until patients reach 10 to 12 years of age because growth hormone deficiency limits their growth, and truncal height has reached its maximum around this time. Indications for operative management are similar to the indications for other neuromuscular disorders, although a curve that is rapidly progressive in a patient with myelodysplasia may be treated earlier at 40 to 50 degrees. Because a significant hip flexion–abduction contracture can produce lumbar lordosis and scoliosis, the hip contracture should be surgically released before any attempt at surgical correction of the spine.

Anterior Fusion

As previously discussed, anterior fusion is very important in myelodysplasia because the anterior spine provides a large surface for bony fusion in the lumbar spine, in contrast to the deficient posterior elements at these levels. A thoracoabdominal retroperitoneal approach from the convex side of the curve and division of the diaphragm allows anterior disc excision and bone grafting; this may be combined with posterior instrumentation to provide curve correction in select patients (Fig. 28.20). Use of anterior instrumentation alone has a specific role in the treatment of myelodysplasia scoliosis. In a study of 14 myelodysplasia patients treated with a Texas Scottish Rite Hospital anterior construct alone, Sponseller and colleagues[153] concluded that anterior instrumentation was successful in a select group of patients with thoracolumbar curves less than 75 degrees, compensatory curves less than 40 degrees, no hyperkyphosis, and no syrinx in the spinal cord. Basobas and colleagues[154] found excellent surgical correction and maintenance with an anterior instrumentation and fusion procedure in their study of 11 myelodysplasia patients at 5-year follow-up. In patients with a lumbar curve and fixed pelvic obliquity, anterior instrumentation provides a powerful means of correcting the deformity (Fig. 28.21).

Posterior Fusion

Although essential to a solid fusion in most myelodysplasia patients, the posterior procedure is difficult because of the poor quality of overlying tissue, decreased paraspinal muscle vascularity, and missing posterior elements. Posterior fusion in combination with anterior fusion is recommended by several authors. In a study of 50 patients, Banit and colleagues[155] concluded that posterior fusion alone yielded a much higher pseudarthrosis rate of 16% than rates reported for anterior and posterior fusion combined. Parsch and colleagues[156] reviewed results of 54 myelomeningocele patients treated surgically and also concluded that anterior and posterior instrumented fusion resulted in the best correction and lowest complication rate.

Luque or unit rods with sublaminar wiring can be used in segments of the spine in which the posterior elements are intact, although supplementation with screws and hooks

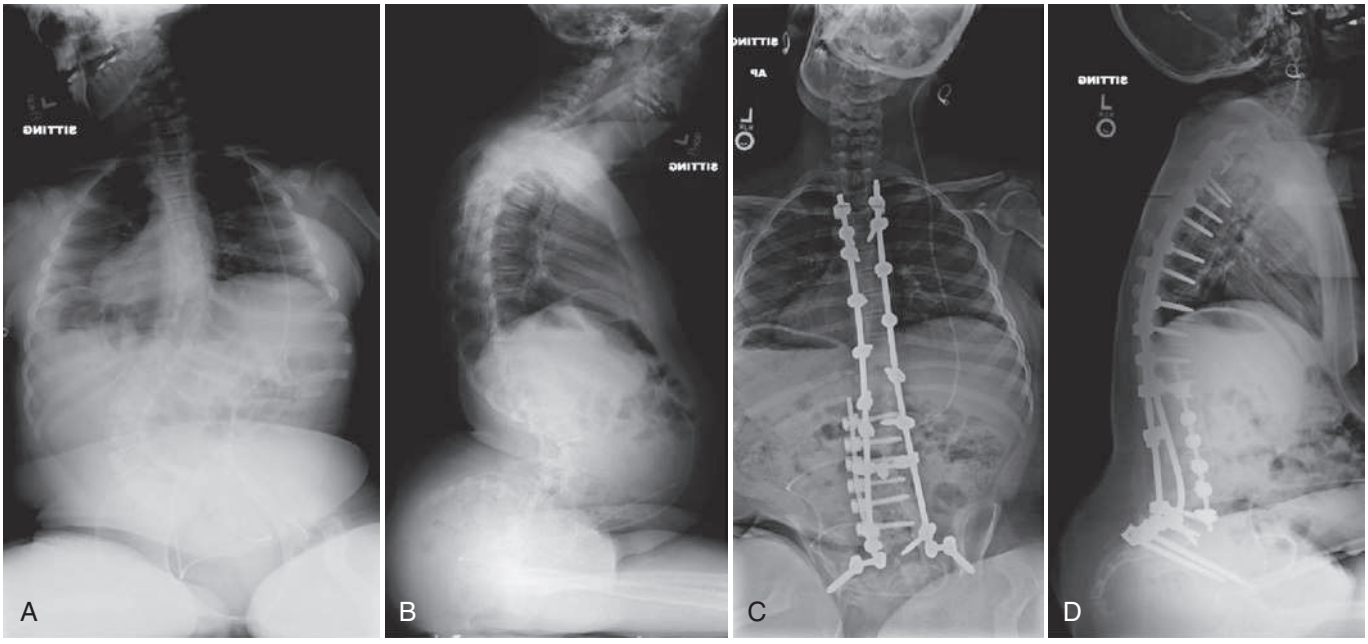

FIG. 28.20 (A–B) This young patient with myelodysplasia presented with 80 degrees of scoliosis and severe lordosis. (C–D) Severe lordosis was treated with anterior instrumentation from T12 to L5, followed by posterior instrumentation from T3 to the pelvis.

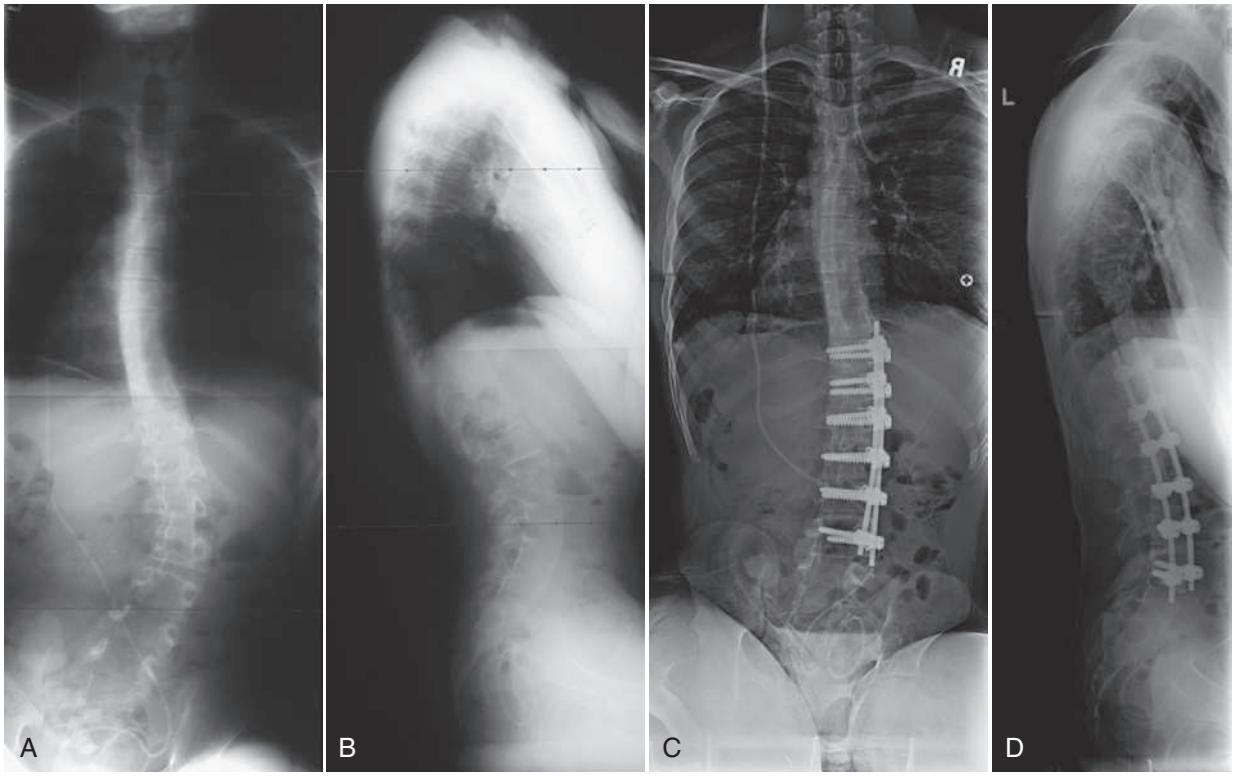

FIG. 28.21 Idiopathic-like lumbar or thoracolumbar curves in patients with myelomeningocele may be successfully treated with anterior instrumentation only.

increases construct stability. In regions in which the posterior elements are missing, pedicle screws are stronger, although the atypical anatomy makes accurate screw placement difficult. In addition, pedicle screws may be prominent, particularly in a kyphotic region because the lateral bony columns are often subcutaneous.

Fusion to the Pelvis

There is considerable controversy over whether the pelvis should be included in the fusion mass. Lindseth and colleagues[157] contended that this is necessary only if there is a component of kyphosis in the lumbar spine or if pelvic obliquity is greater than 15 degrees. They noted an increased incidence of ischial ulcers in patients left with residual pelvic obliquity and fusion to the pelvis probably because the rigid, long, curved segment prevents easy shifting of weight between ischial tuberosities. A prospective evaluation of 11 myelomeningocele patients treated with anterior and posterior instrumented fusion to the lumbar spine revealed good correction of coronal and sagittal plane deformities with fair maintenance of correction. From this experience, the authors of the study concluded that, with the advent of more stable segmental instrumentation, the pelvis could be spared to allow more lumbosacral mobility and to avoid the morbidities associated with pelvic fusion.[158] Similar results have been found in a select group of myelodysplasia patients with anterior-only instrumentation and fusion where pelvic obliquity can be corrected without pelvic fixation.[154]

The most predictable approach from the standpoint of the spinal deformity is fusion to the pelvis. In patients with limited activity, the authors recommend fusion to the pelvis to ensure a straight spine over a level pelvis. In ambulatory or very active patients who play recreational activities, such as wheelchair basketball, the pelvis may be spared with the knowledge that a later revision may be required.

Various options are available for instrumentation to the pelvis. The Galveston modification of Luque rods is a commonly used system, although it may not provide as much stability as the Warner-Fackler modification in correcting kyphosis. As previously described, the Warner-Fackler method involves two 90-degree bends in the distal end of a Luque rod, allowing the rod to pass through the S1 foramina and lever against the anterior aspect of the sacrum (see Fig. 28.11).[84] In a small series of nine patients treated with kyphectomy and this method of pelvic fixation, Thomsen and colleagues[159] reported excellent correction and maintenance of kyphosis correction at an average of 28 months of follow-up. The authors described two instances of complications (loss of rod connection and migration), both at about 32 months after surgery, and concluded that this technique, although effective, should be limited to patients weighing less than 30 kg. McCall described a similar technique with Luque rods passed through the S1 foramina and bent once to 20 to 40 degrees depending on sacral inclination. In his series of 16 patients, McCall[85] reported good correction of kyphosis and excellent maintenance after 57 months of follow-up. Iliac screw fixation has also been shown to afford equivalent maintenance of pelvic obliquity and scoliosis correction compared with the Galveston technique.[83,84]

True fusion to the pelvis (to the wing of the ilium rather than just to the sacrum) can be achieved by suturing the

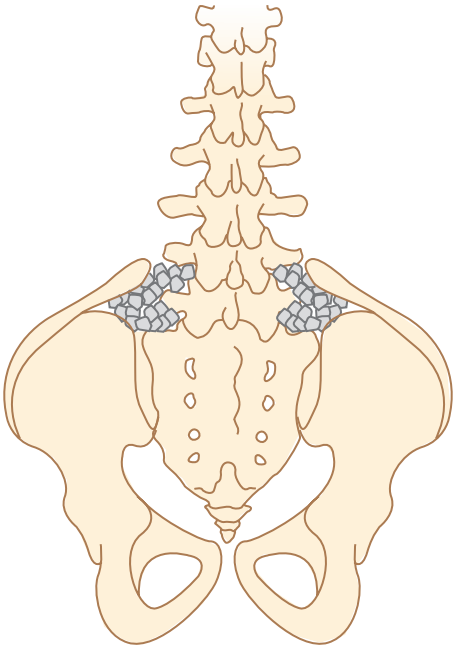

FIG. 28.22 This bone grafting technique increases the chance of stable fusion by including the wing of the ilium and the sacrum.

FIG. 28.23 Lumbar gibbus on a patient with thoracic-level myelomeningocele caused sitting difficulties and loss of trunk height before he underwent kyphectomy and spinal fusion.

detached iliac crest apophysis to the transverse process of the spine at L3 or L4 and filling the created triangle with bone graft (Fig. 28.22). Pseudarthrosis is common in fusions to the pelvis, and the authors still advise a conservative immobilization protocol.

Major and minor complications are more common in myelomeningocele patients than in other patients with neuromuscular scoliosis. Reports of the incidence of wound infections range from 19% to 43%.[160] Many patients have minor complications, such as urinary tract infections or minor wound dehiscence. Major complications, including massive blood loss and instrumentation failure, are more common in myelomeningocele scoliosis than in idiopathic scoliosis or other neuromuscular conditions.[155,160] Pseudarthrosis rates range from 16% to 50% in the literature.[155,161] In addition, the proximity of procedures to the dural sac and the abnormal anatomy increase the risk of shunt compromise and failure. By attending to detail and applying all that is currently known about myelomeningocele scoliosis surgery (careful anterior and posterior fusion, segmental attachment, cautious remobilization), the major complication rate can be reduced to 15% or less.

Kyphosis Treatment

As already noted, bracing is extremely difficult in the severe kyphosis associated with myelomeningocele. Kyphosis is relentlessly progressive (3–8 degrees per year) and can become pathologic in 20% of patients. Because surgical correction is complex and difficult, many children are left untreated and seem to function reasonably well, although skin breakdown over the kyphosis, pressure on abdominal contents, and loss of trunk height remain problems. Indications for surgery include progressive kyphosis, skin breakdown over the kyphosis, respiratory compromise, and concern regarding the effect of severe trunk shortening (Fig. 28.23).[85,162]

Kyphosis in myelomeningocele can be corrected, but intraoperative or perioperative death is frequent enough to give pause to all who treat this disorder. Death can occur from uncontrolled bleeding or problems with cerebrospinal fluid (CSF) dynamics. The advent of segmental spinal instrumentation has made kyphectomy with fusion at least moderately predictable. The segmental attachment must extend well into the thoracic spine to control the large sagittal plane bending moments.

Basic principles include a long midline posterior approach with exposure of five or six levels of normal closed laminae proximally and distal exposure down to the midsacral level. The sac and cord are retracted or resected, with care being taken to repair the dura slightly distal to and separate from the cord transection to avoid tying off the central canal and disturbing CSF dynamics.[163] In most cases, retracting the scarred thecal sac allows sufficient exposure.[162] The spine is prepared for segmental attachment by passing laminar wires or hooks through all normal laminae proximally. The distal segments can be attached by pedicle screw fixation or by screws placed directly into the vertebral bodies. Because the bleeding encountered with osteotomy may force a rapid finish, complete preparation is essential for a successful instrumentation.

The vertebral bodies making up the cranial two-thirds of the kyphosis are excised, allowing one to "fold in" the remaining proximal and distal spinal segments (Fig. 28.24). Care must be taken when the vertebrectomy is performed because the kidneys may be present in the concavity of the deformity and may sustain inadvertent injury. Often, ribs 10 to 12 must

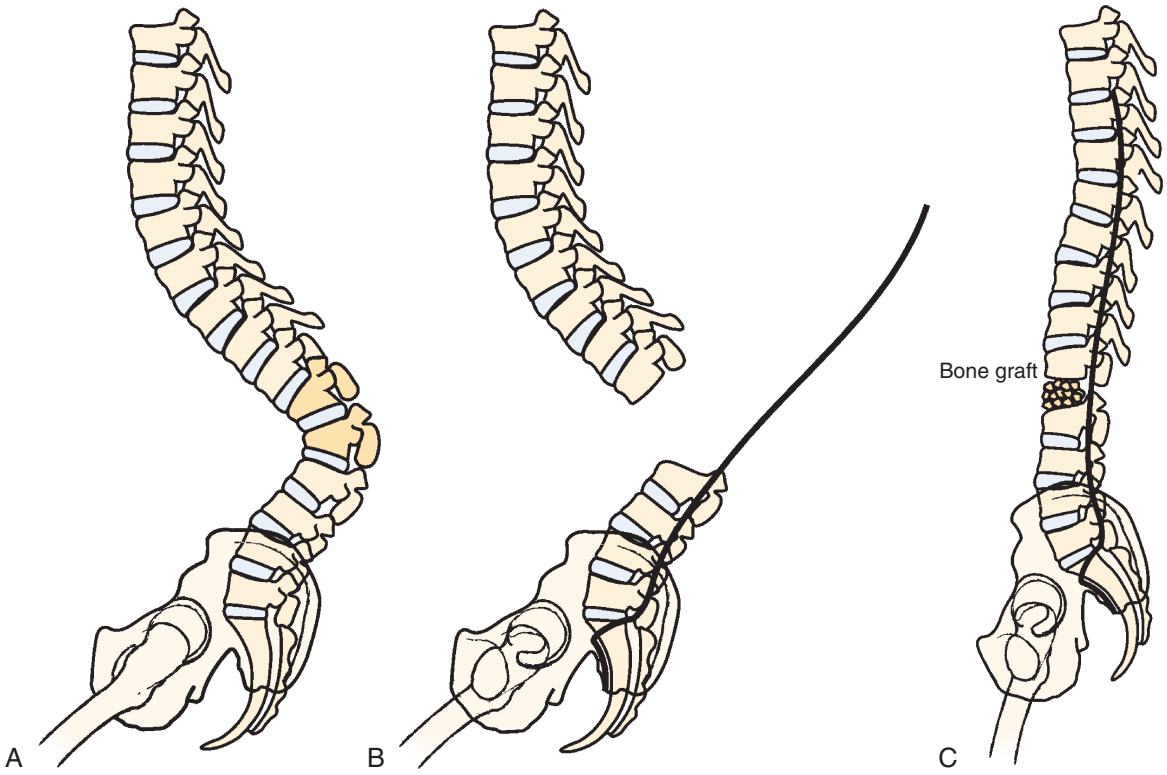

FIG. 28.24 Sagittal diagram describing sequence for performing kyphectomy. (A) The spine is exposed, the dural sac is tied off or retracted, and the kyphotic segment of the spine is excised. (B) To improve mobility of remaining segments, discs can be excised, and the lower two to three pairs of ribs can be sectioned from their origins. (C) Two segments of the spine are "folded inward," bone grafted (from the excised segments), and wired to previously contoured rods.

be transected bilaterally to free the proximal segment enough so that the spine folds inward. The rods are positioned posterior to the infolded segments and secured in place. Posterolaterally placed polyaxial screws may be used to augment wiring and provide greater construct rigidity (Fig. 28.25). In a study of seven myelomeningocele patients, Kocaoglu and colleagues[164] found that the addition of polyaxial screws provided greater correction capacity and a low instrumentation profile in patients with a kyphectomy and Luque instrumentation. The excised vertebrae provide adequate bone graft, applied anteriorly and posteriorly.

Spinal Muscular Atrophy

Affecting 1 in 11,000 newborns, SMA is a fairly common autosomal recessive disorder that is characterized by varying degrees of degeneration of the anterior horn cells, resulting in a symmetrical muscle paralysis of the trunk and proximal musculature. The etiology of SMA has been linked to an autosomal-recessive disorder resulting from a homozygous deletion or mutation of the *SMN1* gene on the 5q13 chromosome. All patients with SMA lack a functioning *SMN1* gene, making them dependent on their *SMN2* gene in order to produce the SMN protein. The severity of the disease is inversely correlated to the *SMN2* gene copy number.[6] Absence or deficiency of this inhibitory protein allows increased motor neuron death that leads to progressive muscle paralysis, eventually causing respiratory insufficiency and scoliosis (Fig. 28.26).[148] Although there are more severe forms, 80% of patients live to adulthood and achieve sitting balance.[165]

Spinal Muscular Atrophy Types

SMA is broken down into three types. First described in the 1890s, type I is also known as Werdnig-Hoffman disease or acute infantile SMA. In this form, children are born with a normal appearance but by 6 months begin to show signs of muscle weakness with poor head control, absent reflexes, and respiratory insufficiency, which is the cause of death by 2 to 3 years of age.[166] Children with type II SMA—the chronic infantile or Dubowitz form—experience the onset of muscle weakness between 6 and 19 months of age but do not have the same severity of symptoms. They attain sitting balance but rarely are able to walk independently. Although respiratory impairment is not as severe as in type I, respiratory complications are common. Type III SMA is also called the chronic juvenile form of the disease or Kugelberg-Welander syndrome and is characterized by onset after 2 years with milder impairment. Most children develop the ability to walk at some time, although many lose this ability around puberty.[167]

Scoliosis in Spinal Muscular Atrophy

The natural history of scoliosis in SMA depends on whether the patient has type I, II, or III. However, these types represent

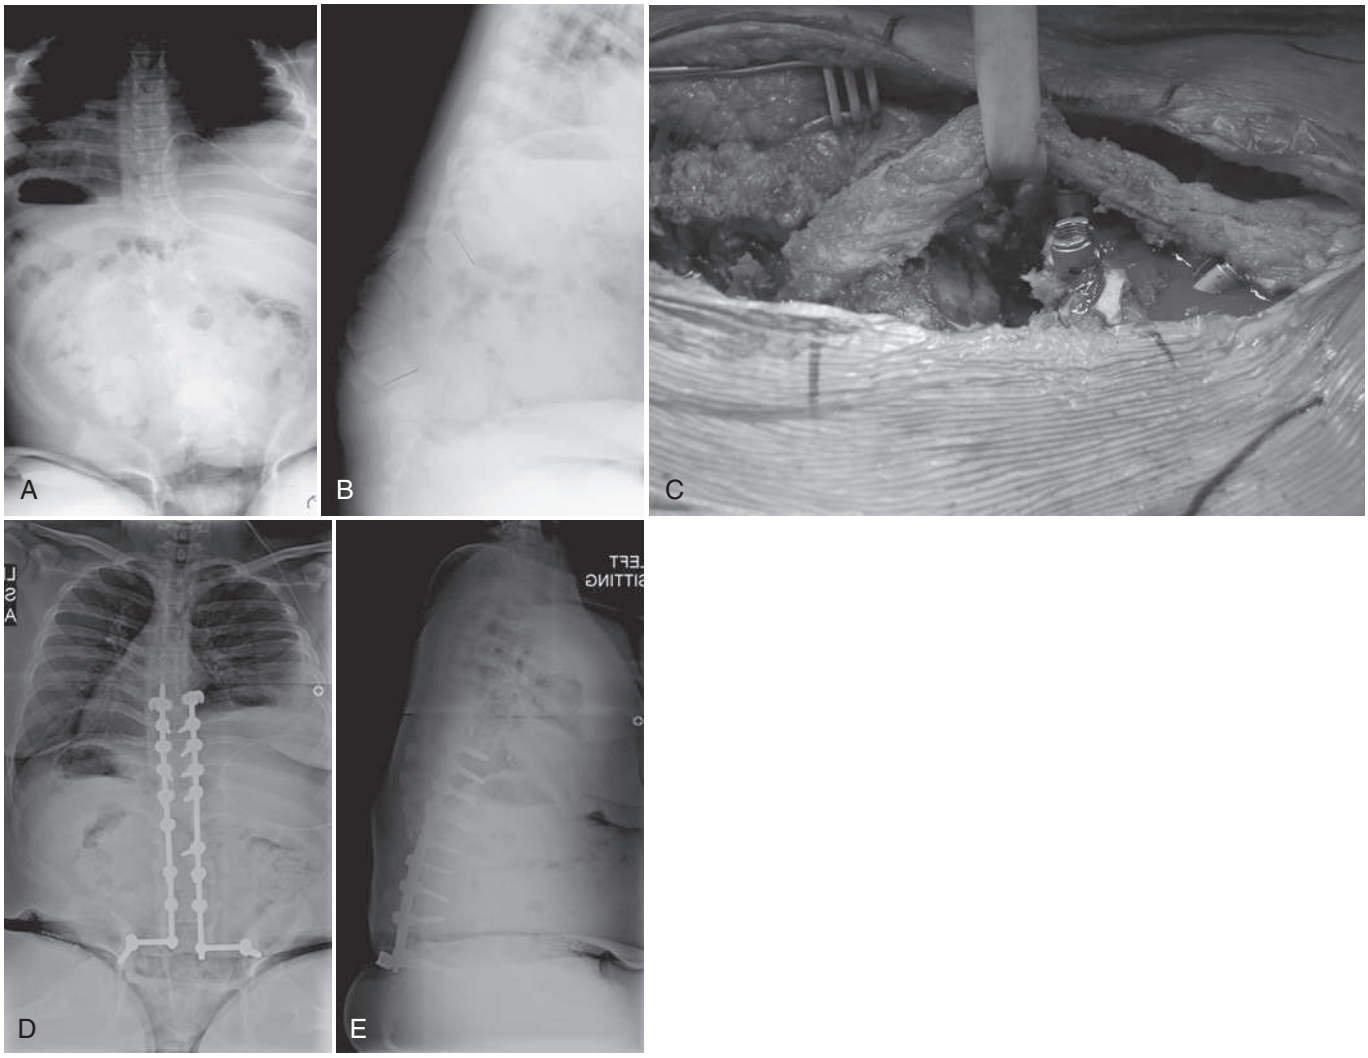

FIG. 28.25 (A–B) A young patient with spina bifida was missing posterior elements from T11 to the sacrum with 103-degree focal lumbar kyphosis with no associated scoliosis. (C) Kyphectomy was performed with excision of L2 and L3 vertebrae. (D–E) Posterior instrumentation and fusion were used from T7 to the pelvis.

a spectrum of disease, and the distinctions between types may not be absolute. One should be guarded in making unqualified predictions of prognosis based on type.

All patients with type I SMA develop curves greater than 15 degrees. Surgical intervention is not warranted in these patients because of their short life span; a body jacket provides good support for balanced and comfortable sitting. Patients with type II also develop curves greater than 15 degrees, although the onset of spinal deformity occurs later, between 2 and 4 years of age. Most of these patients do not ambulate and are likely to experience rapidly progressive scoliosis. The prevalence of spinal deformity in type III patients is varied, but it typically develops in about half of patients.[168] Some of these patients are independent walkers and more likely to escape spinal deformity.[166,169,170]

Scoliosis in SMA tends to progress. In 52 cases of SMA, Granata and colleagues[171] found an increase in curve magnitude of 8 degrees per year, despite brace use. They likewise showed a significant increase in curve progression when a patient with mild involvement stopped walking. In 13 nonwalking SMA patients, these investigators found a 3-degree per year curve progression. Walking patients with mild involvement showed only a 0.6-degree per year progression. The curve most often seen with SMA is a C-shaped thoracolumbar curve. Kyphosis can also be seen with these spinal deformities, but is typically not severe.

Treatment Options

Bracing

As with other neuromuscular diseases, bracing is mainly a temporizing measure to aid in sitting while patients attain more trunk height and vertebral size before surgical intervention. The effectiveness of bracing depends on the type of SMA, the severity of the deformity, and the remaining growth of the patient. Early studies reported delay of progression in a limited subset of patients with milder forms of SMA.[166,170] No studies have documented correction of deformity with dynamic bracing, however, because many patients do not

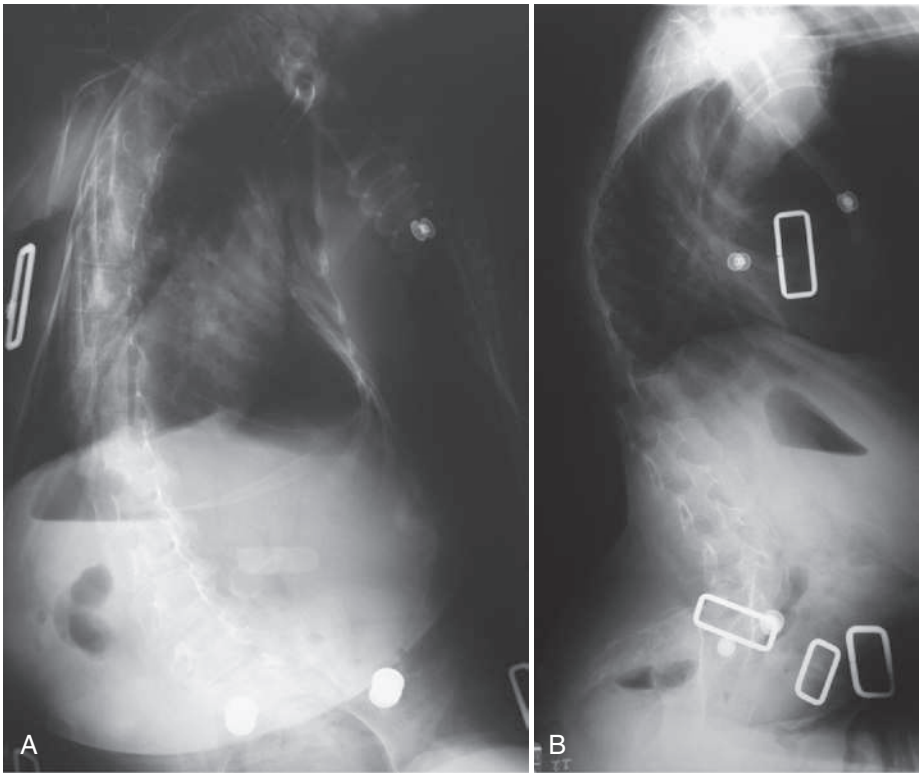

FIG. 28.26 This patient's bell-shaped thoracic cage, characteristic of spinal muscular atrophy, has been compromised further by severe scoliosis.

have the muscular control to pull away from the sides of the brace. The evidence for brace application is still inconclusive because no current studies stratify their results based on age and SMA type. When bracing is elected to provide support for comfortable, balanced sitting before or in lieu of surgery, pulmonary function must also be considered. SMA patients are abdominal breathers because the disease affects intercostal muscle and diaphragmatic function. Because bracing significantly restricts abdominal movement and tidal volume, pretreatment pulmonary function should be a consideration in choosing this treatment modality.[167]

Surgical Management

Several studies have supported the use of segmental instrumentation to the pelvis for the definitive management of scoliosis in SMA. Brown and colleagues[172] evaluated 40 patients with SMA who were treated with posterior fusions and concluded that there were fewer complications and better maintenance of correction with Luque instrumentation compared with Harrington instrumentation. A study by Bentley and colleagues[173] reported a 51% surgical correction rate of coronal deformity in 33 SMA patients with good maintenance of correction. Fusion should be performed before the patient's curve becomes too stiff; periodic bending films and examinations are important for the timing of fusion.

Spinal fusion almost always results in a loss of function. Evaluating 40 patients with preoperative and postoperative functional and strength testing, Furumasu and colleagues[174] found that the straight but rigid spine was not always an immediate advantage to patients. The increased length of the spine creates a longer lever arm against which weakened proximal muscles have to work. These investigators reported an increased use of assistive devices, such as mobile arm supports, reachers, and lapboards. In this study, stronger patients were still able to maintain function, but weaker patients lacked the strength and flexibility to move their trunk in daily activities. Other studies have also noted a postoperative loss of function[70,164,175,176]; Aprin and colleagues[176] noted increased preservation of preoperative function in 22 patients who underwent preoperative and postoperative physical therapy. Spinal fusion does not stabilize pulmonary function. In a study of eight patients—4 with SMA type II and 4 with SMA type III—Chng and colleagues[177] reported a continued decline in pulmonary function at 44 months after spinal fusion and instrumentation. These authors noted that this decline was less marked than the natural history of SMA and that it was most likely secondary to the progressive neuromuscular weakness of the disease.

Ultimately, spinal fusion limits the progressive decline in spinal deformity and pulmonary function that characterizes SMA. A straight spine over a level pelvis allows comfortable sitting and the use of upper extremities in daily functions, and is undoubtedly a great benefit to these patients. The timing of fusion should be an individual decision that takes into account the patient's comfort, functional status, and overall health. As with DMD, fusion needs to be performed before pulmonary function has declined to a level at which pulmonary complications are prohibitive. In the past decade, the treatment of collapsing scoliosis experienced in children with

severe and intermediate forms of childhood SMA (types I and II) has been aided through the use of GRs. Early fusion in these patients has been demonstrated to limit trunk height and inhibit lung growth, exacerbating the pulmonary difficulties associated with SMA. GRs provide for continued trunk growth and lung growth, while at the same time controlling the spinal deformity. McElroy et al,[178] from analysis of a multicenter database, reported 15 nonambulatory patients with SMA treated with GRs and was able to show improvement in the deformity of the major curve, spinal growth (T1 to S1), and lung volumes with reasonable operative morbidity. However, GRs could not halt rib collapse in these patients. Further studies will be needed with greater patient cohorts to fully determine how effective and helpful GRs can be in treating patients with this debilitating subtype of neuromuscular scoliosis.

Our Recommendations

We use bracing in early flexible curves as soon as progression is documented. The goal in bracing is to temporize, allowing the child to achieve as much sitting height as possible. Spinal fusion may be delayed until approximately 10 to 12 years of age, unless the curve is uncontrollable by bracing and is greater than 40 degrees. Surgical intervention with posterior spinal instrumentation and fusion to the pelvis is the method of choice. In very young Risser 0 patients, anterior fusion without division of the diaphragm rarely may be considered to prevent the crankshaft phenomenon, but must be weighed against the pulmonary risk. Most patients are treated by posterior-only methods, particularly if pedicle screws can be inserted.

Duchenne Muscular Dystrophy

The most common hereditary neuromuscular condition, DMD is a sex-linked recessive disorder that affects 1 in 3500 boys. A deficiency of the muscle cell membrane stabilization protein dystrophin results in cell membrane leakage and gradual deterioration with fatty infiltration.[179] These patients typically present with progressive muscle weakness at 3 to 5 years of age. DMD patients are young boys with delayed onset of walking, a wide-based gait, a wide-based stance with pronounced lordosis, and pseudohypertrophy of the calves. Gower sign of DMD is a characteristic way in which these patients rise up from the floor using all four limbs to get into a "bear position" and then pushing off of their thighs with their upper extremities to force hip extension and right the trunk. In this manner, these children overcome their proximal muscle weakness. Elevated creatine kinase level (5000 to 15,000 U/L) is a good screening test. Definitive diagnosis is established by either a genetic analysis or a muscle biopsy specimen revealing decreased levels or absence of dystrophin.[180-182]

The clinical course of these patients is fairly predictable. Patients usually use a wheelchair full-time by 10 to 12 years of age. The incidence of spinal deformity and rate of scoliosis progression in these patients are controversial. Several studies have found that DMD scoliosis increases at a rate of 15 to 30 degrees yearly and may exceed 100 degrees if untreated (Fig. 28.27).[183-186] In contrast, a 10-year retrospective study of 123 DMD patients by Kinali and colleagues[187] found a highly variable rate of the presence and the progression of scoliosis in children with DMD. Despite this inconsistency, skeletally immature patients with a Cobb angle progression to greater than 20 degrees generally continue to progress. The association of the severity of spinal deformity and decline in pulmonary function has been well described. Respiratory failure generally leads to death in the late teens or early 20s, although advances in treatment have improved prognosis.[188]

Scoliosis in Duchenne Muscular Dystrophy

More than any other form of neuromuscular disorder, pulmonary function and life expectancy are directly correlated with spinal deformity. FVC begins to decline at the age that

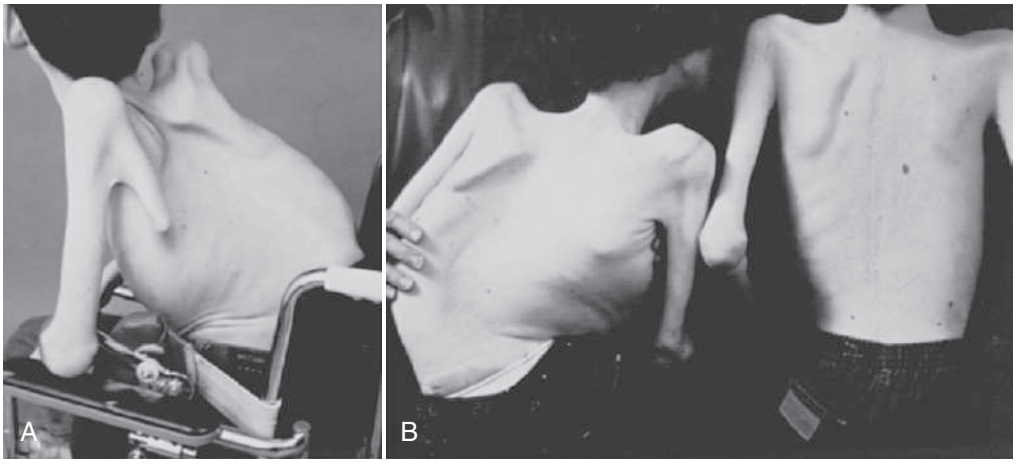

FIG. 28.27 Two brothers with severe scoliosis secondary to muscular dystrophy. (B) The younger boy underwent a successful posterior spinal instrumentation and fusion, achieving good sitting balance. (A) His older brother had already lost too much pulmonary function to tolerate surgery. He is unable to sit well, even with support.

patients stop standing. From that time, the restrictive effects of thoracic cage deformity and loss of respiratory muscle function cause pulmonary function to decline 4% for each 10 degrees of deformity and each year of age (Fig. 28.28).[175] Smith and colleagues[186] reviewed the natural history of DMD in 51 boys and found that the rate of progression of scoliosis was inversely related to the age of death. Although most studies have failed to identify a protective role of spinal surgery on pulmonary function,[187-189] Galasko and colleagues[190] reported a stabilization of pulmonary function at 3-year follow-up. They compared 32 patients who underwent spinal fusion and 23 patients who refused surgery. The FVC remained stable for 3 years postoperatively in the fused group compared with an 8% per year average decline in patients not operated on. Although the impact of spinal surgery on pulmonary function is unknown, the relationship between pulmonary decline and progression of scoliosis has been shown by Kennedy and colleagues[189] to be 3% to 5% per year. When scoliosis progression has reached 20 to 30 degrees, many authors recommend surgery (Fig. 28.29).[29,191,192] Glucocorticoid treatment seems to be affecting the natural history of this condition, but it is unclear how the surgical indications for spinal fusion should be modified.

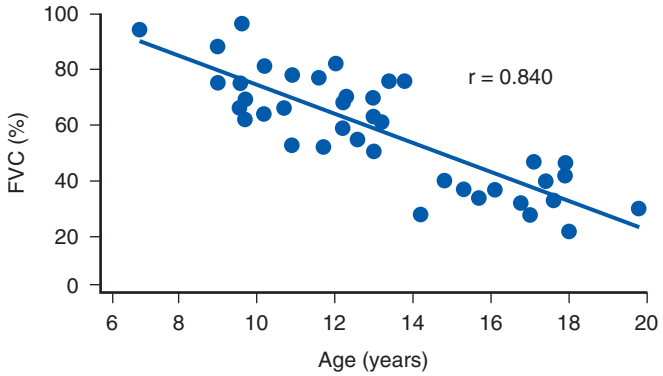

FIG. 28.28 Percentage of forced vital capacity (FVC) vs age in patients with Duchenne muscular dystrophy. FVC percentage was found to be the parameter of pulmonary function that most strongly correlated with age and thoracic Cobb angle measurement. (From Kurz LT, Mubarak SJ, Schultz P, et al. Correlation of scoliosis and pulmonary function in Duchenne muscular dystrophy. *J Pediatr Orthop.* 1983;3:347.)

Treatment Options

The preoperative evaluation of DMD patients must take into account other comorbidities of their disease. Pulmonary function testing should be done before surgery to assess the severity of preoperative respiratory compromise. Although more recent studies have reported successful spinal surgery at FVC of less than 35%,[193] previous work associated this lowered FVC value with increased postoperative morbidity.[192] Similar to the progressive decline in pulmonary function over time, the severity of cardiac dysfunction also increases with age. DMD patients are likely to develop cardiomyopathy and arrhythmias in the second decade of life, and an electrocardiogram, a chest radiograph, and an echocardiogram should be done to screen for cardiac problems. Despite the fact that many of these patients are obese, they should be evaluated for malnutrition because wound healing complications and increased infection rates have been reported.[194] DMD is also associated with a tendency for increased blood loss caused by

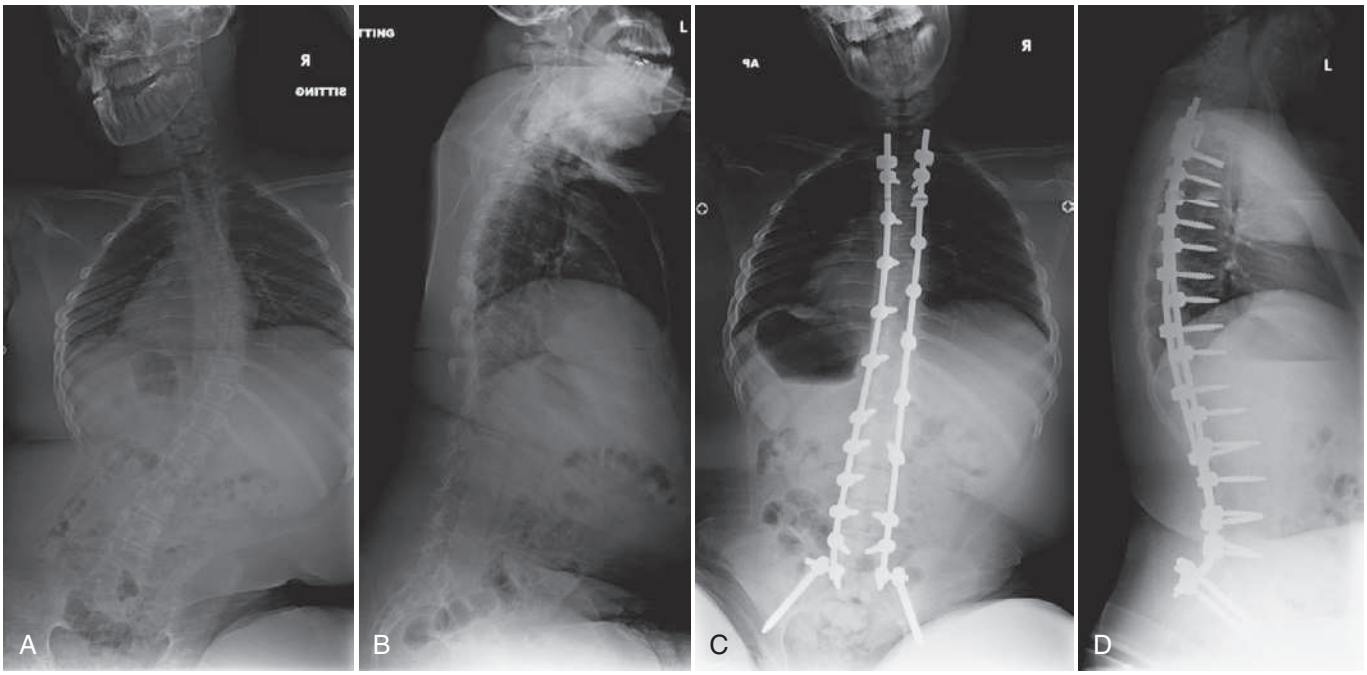

FIG. 28.29 Preoperatively, this boy with Duchenne muscular dystrophy had 20 degrees of scoliosis and 30 degrees of thoracolumbar region kyphosis. He underwent posterior instrumentation and fusion from T3 to L5 at age 13 years to retard further progression of spinal deformity. Treating the patient early allowed stopping short of the pelvis.

poor vasoconstrictive function owing to a lack of dystrophin in vessel smooth muscle; preparation for major operative blood loss should be made.[195] Additionally, patients with dystrophic myopathies have an increased risk of malignant hyperthermia.[196]

Surgical Management

Long fusions from T2 to either L5 or the pelvis are recommended. The distal extent of the fusion has been an area of much research and remains a controversial subject. Mubarak and colleagues[192] determined that instrumentation and fusion to L5 was effective in mild deformities with pelvic obliquity less than 15 degrees at 34-month follow-up. Sengupta and colleagues[197] found similar results in their review of posterior fusions in 50 patients, and concluded that fusion to L5 with pedicle screw instrumentation is adequate if done soon after patients lose walking ability. These results were supported further by McCall and Hayes,[74] who found that fusion to L5 was a viable alternative to fusion to the pelvis in patients with less than 15 degrees of L5 tilt.

Takaso and colleagues[198] supported the argument that the caudal extent of the fusion in DMD patients can be stopped at L5 if the degree of L5 tilt is less than 15 degrees.

Given the limitations of a minimal curve size and pelvic obliquity, fusion to the pelvis is the most common method of spinal fixation in DMD patients. Luque rods with the Galveston technique of pelvic fixation is a well-studied technique that offers acceptable results. Brook and colleagues[199] reviewed results of Luque and Luque-Galveston instrumentation in 17 patients and found an average of 63% correction as well as good maintenance of correction. Bentley and colleagues[173] reviewed 64 patients treated with posterior fusion and reported a 47% correction rate with good maintenance of correction. The authors recommended fusion to T4, stating that the lower level of fusion allows more freedom of movement for feeding and upper extremity use. Unit rods have also been evaluated in DMD patients and provide acceptable results; however, placement of the rods into the iliac wings makes this technique challenging.[199] The Dunn-McCarthy technique with S-shaped rods looped over the sacral alae has been shown to provide good results in DMD patients. This technique has gained popularity because of its dependable fixation in patients with osteopenia and ease of placement in the kyphotic lumbar spine that is often seen in DMD patients.[83,191]

More recent advances in segmental pedicle screw fixation have resulted in their promotion as an alternative to more traditional hook-wire and Galveston pelvic fixation techniques. Hahn and colleagues[200] reported results of 20 DMD patients treated with pedicle screw–alone fixation and concluded that pedicle screws combined with iliac screws provided a stable construct that eliminated the need for a combined anterior procedure at minimum 2-year follow-up. These authors found that this technique limited blood loss compared with sublaminar wiring, had no implant loosening, and allowed early mobilization, resulting in no pulmonary complications. These findings were supported by Mehta and colleagues,[201] who reported their cohort of 36 patients with DMD instrumented from upper thoracic level to L5 or the pelvis if the pelvic tilt was 15 degrees or greater (10 patients), unlike the study performed by Hahn et al.,[200] who instrumented the pelvis regardless of the pelvic tilt. All patients in the group were able to achieve a balanced sitting posture and a significantly improved lumbar lordosis. Also, the patients who underwent pelvic fixation had a significantly improved pelvic tilt following surgery compared to preoperative measurements.[201] Pedicle screw fixation with a free-hand technique has been shown to be as safe and accurate as in other conditions.[202]

Our Recommendations

In patients with DMD, spinal fusion is performed when curves reach 20 degrees and FVC is greater than 40%. Preoperative FVC of less than 30% to 35% is correlated with a high incidence of major respiratory complications. The surgical technique recommended by the authors is segmental instrumentation (mainly with pedicle screws) and posterior fusion from the high thoracic level (T2 or T3 down to L5). Usually, the ICU stay is 2 days, and the average hospital stay is 8 days. If the pelvic obliquity is greater than 10 degrees or the scoliosis curve is greater than 40 degrees, the authors consider instrumentation to the pelvis to correct this obliquity and ensure a level pelvis. The ultimate goal in the treatment of deformity in DMD is the maintenance of upright sitting balance and maximal pain-free function. Many of the authors' patients are now older than 20 years with an upright posture, minimal wheelchair difficulties, and improved quality of life.

Rett Syndrome

Rett syndrome is a developmental disorder of unknown etiology that occurs in 1 in 20,000 females. The syndrome is linked to a mutation in the *MeCP2* gene located on the X chromosome, which encodes a deacetylator that regulates the transcription of certain genes. Patients appear normal at birth but begin the stepwise deterioration characteristic of Rett syndrome. The syndrome has four stages. In the first stage, generally occurring when patients are 6 to 18 months of age, signs of the syndrome include developmental stagnation, slowed head and brain growth, and generalized hypotonia. From approximately age 1 to 3 years, patients begin to regress developmentally and exhibit autism-like symptoms. In the third stage, between ages 2 and 10 years, patients have seizures, exhibit ataxia, exhibit mental retardation, and perform stereotypical gestures such as repetitive hand wringing. During this phase, scoliosis and spasticity can be seen. In the fourth stage, patients exhibit upper and lower motor neuron signs with increased rigidity and muscle wasting. Scoliosis is most likely to develop in this final stage (Fig. 28.30).[203]

Scoliosis in Rett Syndrome

The incidence of scoliosis increases as patients get older: 8% of girls with Rett syndrome have scoliosis at age 5, 40% have it by age 11, and 80% have it by age 20. The deformity can be

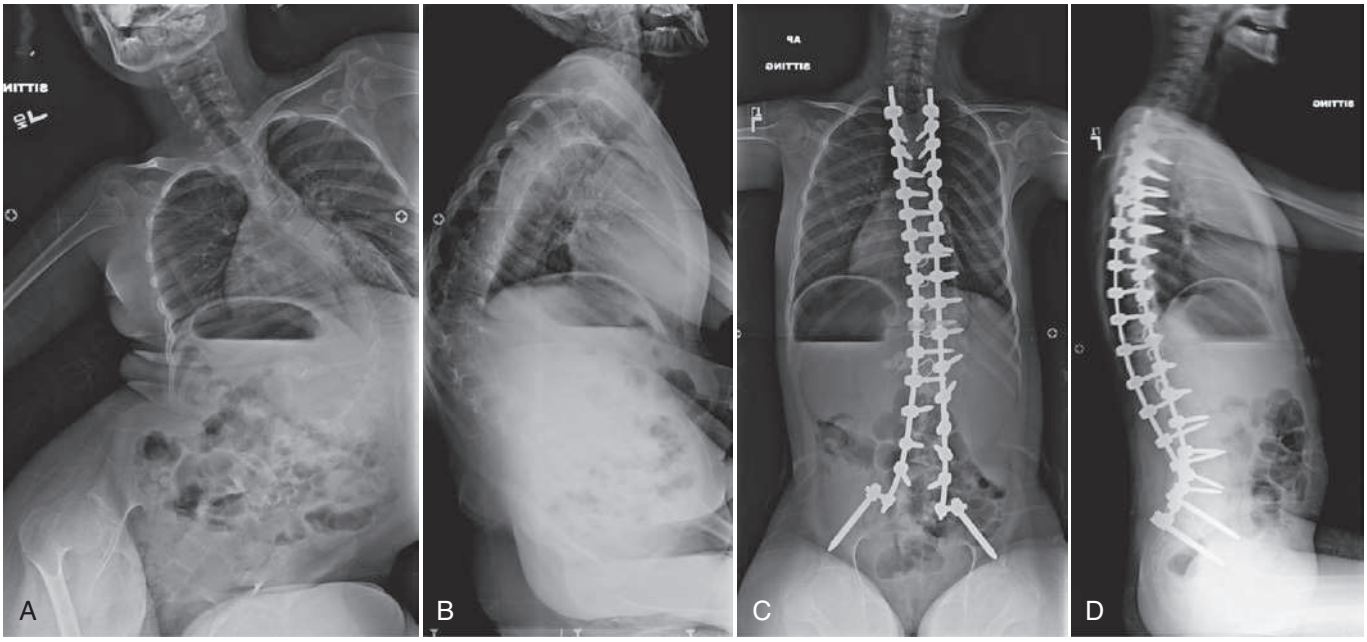

FIG. 28.30 A 9-year-old girl with Rett syndrome had 80 degrees of spinal deformity, despite bracing. Because her triradiate cartilage remained open, she underwent anterior thoracoscopic release and posterior instrumentation from T2 to the pelvis.

rapidly progressive; Lidstrom and colleagues[204] reported on 78 patients with Rett syndrome and reported progression rates of 20 to 41 degrees per year in the 10 most severe cases. Because scoliosis in Rett syndrome has this potential for progression, yearly evaluation of the spine should be conducted after the age of 5 years.[205]

The treatment for Rett syndrome is similar to treatment for CP. Bracing has a limited role in treatment, although it may provide support for comfortable sitting until surgery is performed.[206] As with CP, the authors recommend that if sitting comfort and balance become compromised, treatment with segmental instrumentation is indicated. Spinal surgery is indicated when the curve exceeds 40 degrees. Long-term outcome of surgery in patients with Rett syndrome has shown good results. In a prospective study of 23 girls with Rett syndrome and neuromuscular scoliosis, Larsson and colleagues[207] found improved seating position and patient satisfaction at 6-year follow-up. These authors reported that all patients who could walk preoperatively maintained ambulation postoperatively. They also noted that patients and parents reported an overall improvement in well-being with better sitting posture and improved breathing. As with all patients with neuromuscular disorders who undergo scoliosis surgery, spinal cord monitoring is advocated.[208]

PEARLS

1. Neuromuscular spinal deformities are often complex, multiplanar, and rigid.
2. Segmental instrumentation reduces the risk of progression. Hooks and screws add to construct rigidity compared with sublaminar wires alone.
3. Hyperkyphosis increases the risk of implant failure or junctional kyphosis, or both. Segmental posterior compression instrumentation reduces this risk.

PITFALLS

1. Blood loss should be anticipated. The surgeon should minimize blood loss during exposure and consider use of a pharmacologic agent to reduce blood loss during surgery. Transfusion should be done early, and clotting factors should be replaced (fresh frozen plasma) before coagulopathy develops.
2. The surgeon needs to be aware of infrapelvic causes of obliquity, such as hip contracture.
3. Preoperative nutritional supplementation, often via a gastrostomy tube with fundoplication, should be considered.
4. Postoperative intensive care unit support is crucial to negotiating major spinal surgery safely in these medically compromised patients.

29 CHAPTER Thoracoscopic Approach for Spinal Conditions

Peter O. Newton
Kuan Wen Wu
Burt Yaszay

Thoracoscopic Anterior Release and Fusion

Mack et al.[1] and Rosenthal et al.[2] first introduced video-assisted thoracoscopic surgery (VATS) as a therapeutic modality for various spinal disorders such as anterior release for deformities, discectomy, and vertebral body biopsy in the 1990s. VATS has since been widely developed to perform anterior thoracic or thoracolumbar reconstruction in cases of spinal tumors or fractures, drainage of vertebral abscess, and anterior instrumented fusion for the treatment of idiopathic scoliosis and other spinal deformities.[1-3] The goals of VATS are fundamentally the same as those of open surgery but is performed in a minimally invasive manner.

The adoption of thoracoscopic surgery in idiopathic scoliosis aims to improve the spinal alignment and balance in all planes comparable to that obtained with an open thoracotomy. In addition to idiopathic scoliosis, VATS has also been used to perform anterior spinal column release (discectomy) in scoliosis and kyphosis, as well as hemiepiphysiodeses or hemivertebrectomies in congenital scoliosis. As such, VATS may be executed alone or performed as an adjunct to posterior surgery.

The thoracoscopic approach potentially offers several advantages over an open anterior approach, including reduced postoperative pain, decreased intraoperative blood loss, lower pulmonary morbidity, access to multiple vertebral levels, and better cosmesis due to its less invasive nature. However, it is apparent that even after several series reported, VATS continues to be technically demanding and is associated with a significant learning curve. This may be the reason that VATS remains in limited use among spinal surgeons. Although the posterior approach continues to be the most familiar access for surgical treatment in the majority of spinal diseases, VATS may have an important role in a subset of spine patients.

Indications

Scoliosis

Anterior spinal surgery had been frequently used as a means for multiple discectomies and fusion in severe scoliosis or kyphosis, with the aim to bring greater curve flexibility and to prevent the "crankshaft" phenomenon in immature patients. Although no definite guidelines on the magnitude and flexibility of the spinal curvature necessary for anterior release have been established, it has been generally accepted that curves with a Cobb angle greater than 70 to 75 degrees and a bending correction lower than 50% are considered appropriate indications. When sufficient segmental mobility of the released vertebra has been achieved, posterior instrumentation and fusion is performed to make final correction of the deformity (Fig. 29.1).

In 2003, Lenke[4] reported the outcomes of adolescent idiopathic scoliosis (AIS) treated with a VATS anterior release and fusion followed by posterior instrumentation. The mean preoperative curve was 82 degrees (range, 41–125 degrees) and was corrected to a mean postoperative curve of 28 degrees (range, 5–60 degrees) resulting in a mean correction rate of 70%. In another consecutive series studied by Newton and coworkers,[5] 112 pediatric spinal deformity cases with an average preoperative curve of 80 degrees who underwent a combined anterior released fusion and posterior instrumentation surgery were found to have radiographic evidence of a solid anterior arthrodesis in 75% of the disc spaces. The scoliosis correction rate showed a nonsignificant difference between three diagnostic groups, though idiopathic scoliosis seemed to have a trend toward greater percent correction (67%) compared with patients with neuromuscular (52%) and other diagnoses (50%).

With the modern improvement on posterior spinal instrumentation techniques and increased popularity of Ponte osteotomies, more recent authors have started to question the necessity and indication of anterior release.[6,7] Suk et al.[6] found an average correction of 66% with posterior all-pedicle-screw instrumentation to treat severe scoliosis up to 110 degrees. Although modern pedicle screw constructs offer powerful correction, we still believe that thoracoscopic anterior release remains valuable to optimize coronal and axial plane correction and to improve sagittal alignment by increasing thoracic kyphosis in the most severe cases of scoliosis.[8]

Progressive scoliosis in children with open triradiate cartilage is known to be at risk for crankshaft deformity when

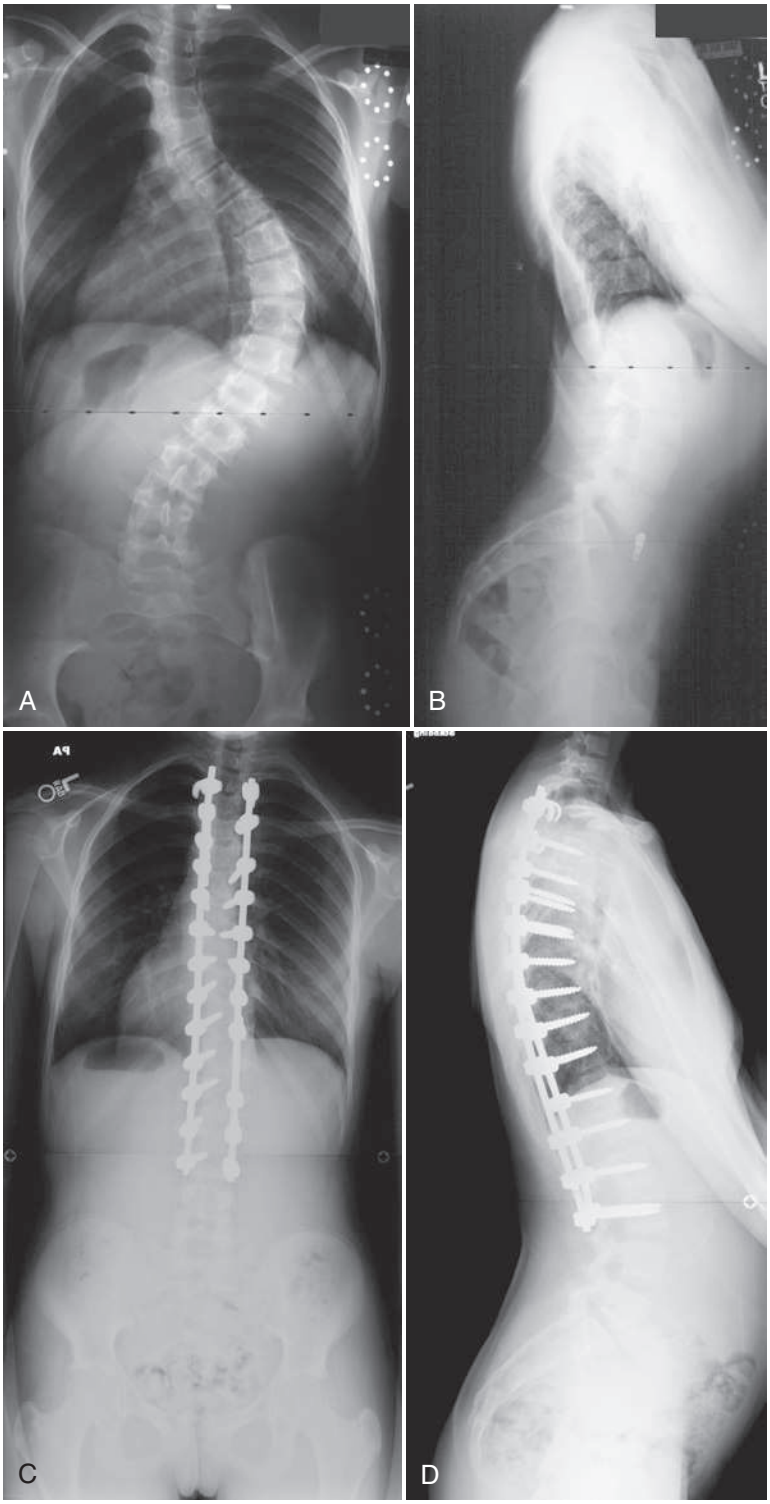

FIG. 29.1 Preoperative (A) posteroanterior and (B) lateral radiographs of large stiff curve. Postoperative (C) posteroanterior and (D) lateral radiographs. Thoracoscopic anterior spinal release and discectomy and combined posterior spinal instrumentation and fusion provide acceptable correction.

treated with a posterior fusion alone.[9] The phenomenon was more commonly encountered for children using hook and wire fixation, but less in those with modern pedicle screw instrumentation. Sarlak et al.[10] reported a 5-year follow-up series on seven idiopathic scoliosis children (average age, 7.4 years) who were treated with all-posterior–pedicle screw instrumentation. The authors found a 57% correction rate without evidence of crankshaft phenomenon in four patients. However, they also found a slight increase of curve angle in one patient and a significant increase in angle of trunk rotation (ATR), suggesting crankshaft phenomenon in two patients.[10] Given the lack of clear evidence on the appropriate treatment of these cases, thoracoscopic anterior fusion may be a viable option to limit anterior growth and prevent this

late-presenting deformity in these youngest of patients.[11-14] Furthermore, the thoracoscopic procedure has been used in other diagnoses to prevent pseudarthrosis. Previous studies have suggested circumferential fusion with autogenous bone graft for certain syndromes, such as Marfan syndrome, neurofibromatosis, and prior spinal irradiation, because these conditions are susceptible to an increased risk of pseudarthrosis following posterior fusion alone.[5,8]

Kyphosis

Scheuermann kyphosis used to be a common indication for anterior spinal fusion and instrumentation.[15–17] Papagelopoulos et al.[18] and Sturm et al.[19] found that posterior fixation with hook or hybrid constructs alone did not yield adequate strength to maintain correction in patients with progressive kyphosis. Therefore, combined anterior and posterior approaches have been investigated to treat such kyphotic deformity. In a retrospective analysis of 32 patients with Scheuermann kyphosis, Lowe and Kasten[20] found that a combined approach resulted in a 51% correction of the deformity without major postoperative complications. Afterwards, Herrera-Soto et al.[21] specifically investigated the use of VATS in kyphosis patients and found similar benefits as those in scoliosis patients, including reduced blood loss and less morbidity, compared with open thoracotomy.

Given the benefits of modern posterior instrumentation, Lee et al.[16] performed a comparative study between the posterior thoracic segmental pedicle screw construct and a combined anteroposterior approach in a series of 39 patients. The authors found a similar correction rate between both techniques; however, they found increased complications in the combined technique group. In our institution, with the increasing utilization of Ponte osteotomies and improved spinal instrumentation and fixation techniques, we gradually undertook the posterior-only method and have limited indications for a combined anteroposterior approach to those with the severe rigid nonangular form of kyphosis.[8]

Congenital Deformity

Various operative methods have been used for management of congenital scoliosis, depending on the types of vertebral anomaly, location, associated conditions, and age of the patient. Even more of a concern in this younger group of patients than older children with AIS, reports have identified the crankshaft phenomenon, a progression of scoliotic deformity after a region of solid posterior arthrodesis, to be a particularly difficult problem with the surgical treatment of congenital deformity.[9] In a study with 12 years of follow-up in patients with congenital scoliosis, Kesling et al.[22] found that 15% of 54 patients who received a posterior-only arthrodesis subsequently developed a crankshaft deformity.

As a result of the unfavorable results with posterior-only surgery in the past, VATS has been advocated in the treatment of congenital scoliosis.[5,13,23] Anterior arthrodesis and growth-modifying hemiepiphysiodesis are both technically possible through an endoscopic approach. First introduced by Roaf,[24] hemiepiphysiodesis has been detailed more recently by Samdani and Storm,[25] who suggested that a convex anterior and posterior hemiepiphysiodesis is ideally performed on children older than 5 years with a short curve less than 40 degrees involving five or fewer vertebrae. In this combined hemiepiphysiodesis procedure, the convex halves of the discs were removed anteriorly, followed by a posterior arthrodesis and casting.[26] In addition, hemivertebrae at a lower thoracic level may occasionally be indicated for excision. In such a situation, performing a thoracoscopic surgery anterior hemivertebra excision is feasible in a combined-approach fashion. It should be noted that for children who are younger than 5 years who require anterior fusion over few levels of the spine, the benefit from a thoracoscopic approach may be limited. The use of VATS in these small patients must be considered on an individual basis.

Contraindications

As mentioned, the small size of the patient is a relative contraindication to thoracoscopy. Lung deflation is more difficult in these cases because standard-size double-lumen and bronchial blocking endotracheal tubes are too large. Another restriction is the markedly reduced working distance between the chest wall and the spine. In severe cases of scoliosis, the reduced distance limits the field of vision (in that the endoscope is too close to the spine to obtain any perspective) and the maneuverability of the working instruments. A minimum distance of 2 to 3 cm of working space between the rib cage and the spinal column is required to provide adequate visualization. If the distance is less than 2 cm, thoracoscopy is not advised. Body weight of less than 30 kg is a relative contraindication because the relative benefits of VATS seem to be reduced in small patients.[27]

Visualization of the surgical field is mandatory in all surgical approaches, and it may be compromised in VATS by incomplete deflation of the lung or pleural adhesions that preclude collapse away from the chest wall and spine. Pleural adhesions (Fig. 29.2) can be anticipated in patients with a history of prior ipsilateral thoracic surgery or significant

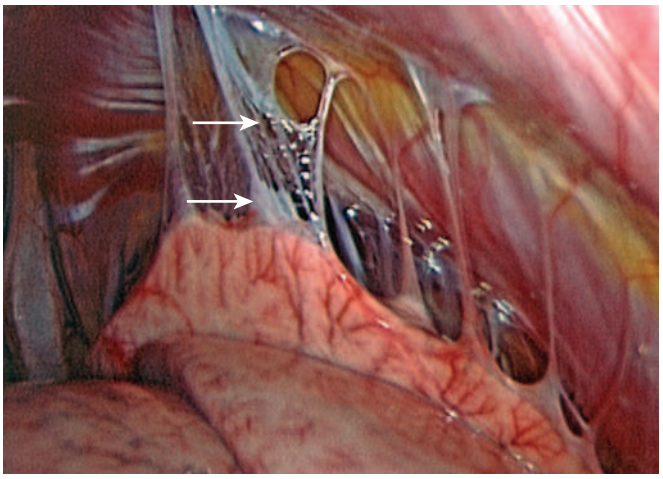

FIG. 29.2 Endoscopic view of pleural adhesions (*arrows*).

pulmonary infection, both of which may prevent the surgeon from safely using the thoracoscopic approach.

Surgical Technique

There are a number of special equipment needs for the safe performance of thoracoscopic surgery. High-quality endoscopes (10-mm diameter and 0-, 3-, and 45-degree angled optics), video camera, light source, and monitor have become standard in nearly all modern operating rooms. We prefer to have the surgeon and assistants stand anterior to the patient. An endoscopic suction-irrigation device, an ultrasonic dissector, and electrocautery are positioned at the head of the operating table. The operating table must be compatible with use of the image intensifier.

The patient is secured in a direct lateral position over an axillary roll with the convex side of the scoliosis up (Fig. 29.3). Some authors have suggested that prone positioning may be possible in select cases, which avoids the need to reposition the patient for the posterior procedure and allows anterior release and posterior instrumentation simultaneously.[28–30] Although the ability to convert to an open approach may be restricted, it has been shown that the prone position does not adversely affect postoperative pulmonary function.[31] This approach necessitates a more posterior portal placement strategy that may limit the anterior extent of spinal exposure and disc excision.

The role of the anesthesiologist is crucial in the success and safety of thoracoscopic surgery.[32] Spinal cord monitoring is advised using somatosensory and transcranial motor evoked potentials. Complete ipsilateral lung deflation is essential to prevent lung parenchymal injury from passing instruments and to allow visualization of the spine. Double-lumen endotracheal tubes are preferred in patients large enough (>45 kg) to accept these devices. In children (<45 kg), selective intubation of a single lung is often required as an alternative. A small balloon advanced into the main stem bronchus blocks ventilation to the lung on the operative side. In nearly all patients with normal preoperative pulmonary function, single-lung ventilation can be tolerated. The surgeon and anesthesiologist should be aware of the increased risk of developing postoperative mucous plugs as a result of single-lung ventilation.

After lung deflation, plastic tubular portals are established through the chest wall (Fig. 29.4). The orientation of these portals may vary depending on the pathology, although in most cases of deformity release and fusion, they are best placed in a linear relationship along the anterior axillary line. Owing to the site of diaphragm insertion, the inferior portals require a slightly more posterior placement to maintain an intrathoracic position. Initial exposure of the spine often requires gentle retraction of the lung, at least until it becomes completely atelectatic (Fig. 29.5). A fan retractor is often required early in the procedure before complete atelectasis of the lung has occurred. The vasculature, including the azygos vein and subclavian artery, is identified before the introduction of surgical instruments to prevent inadvertent injury (Fig. 29.6). The vertebral levels are selected by identifying the first rib partially hidden beneath the subclavian artery, counting down distally (Fig. 29.7) and confirming with a radiographic

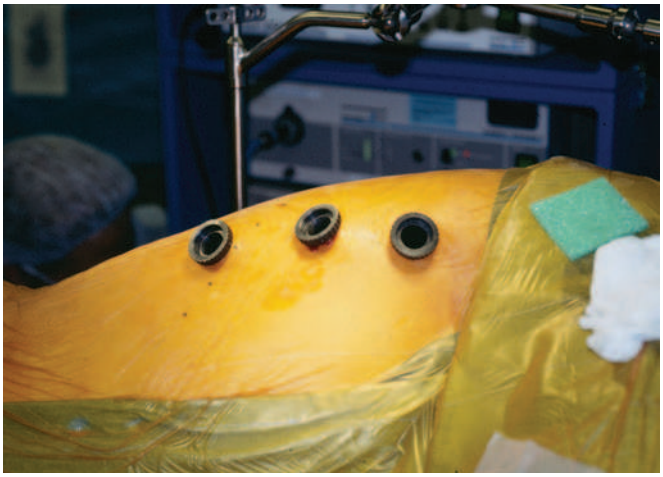

FIG. 29.4 Proper placement of portals is necessary for multilevel discectomies with the patient in the lateral position.

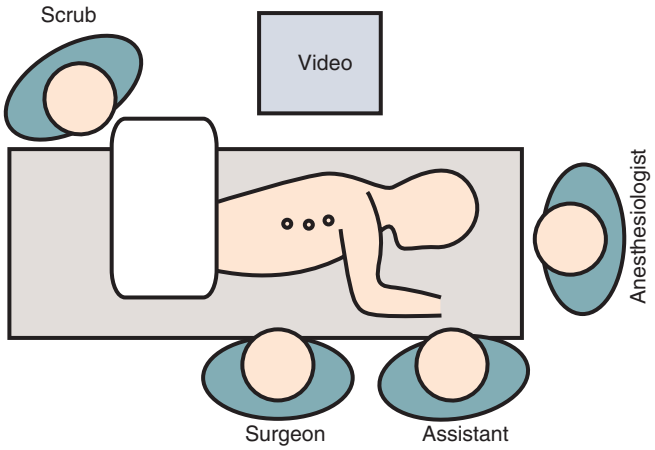

FIG. 29.3 Diagrammatic setup in the operating room shows position of surgeon, assistants, scrub nurse, and monitor for endoscopic surgery.

marker. Division of the pleura overlying the spine may be performed either longitudinally, over the length of the spine to be fused, or transversely, at each disc space.

Treatment of the segmental vessels (Fig. 29.8) may be individualized with either division or preservation, depending on the needs of the case or preference of the surgeon. In most cases, we prefer a longitudinal pleural exposure with division of the segmental vessels using harmonic coagulation. Division of the segmental vessels allows greater anterior spinal exposure for more complete circumferential annular release. Blunt dissection of the pleura to the contralateral side of the spine is performed, exposing approximately 270 degrees of the disc perimeter. After division of the pleura, any remaining areolar tissue is divided, and packing sponges are used to create a space between the anterior spine and the pleura.

The accessible levels through thoracoscopy are T2–L1. Exposure of the T12–L1 disc and L1 vertebral body requires division of a small segment of the diaphragm insertion that can be accomplished by extending the pleural incision distally into the diaphragm. The proximal thoracic spine in the right chest is often covered by the confluence of the segmental veins, which may appear daunting at the T3 and T4 levels. With slow, cautious use of the ultrasonic devices, these vessels can be sealed and divided safely, exposing the upper thoracic spine. Disc excision techniques are similar to techniques used in open surgery. An annulotomy is performed with the electrocautery or ultrasonic scalpel. A rongeur is an excellent tool for most of the disc excision. Specially designed endoscopic rongeurs are available in extended lengths with various angles (straight, up, right, left) to reach the depths of each disc space (Fig. 29.9).

Awareness of the discectomy path is vital to avoid damage to the neural elements and to prevent excess bone excision that can cause increased bleeding and suboptimal visualization. An angled curette may also be used to remove residual endplate cartilage and expose the cancellous bony surface required for fusion. Bleeding from the bone can be limited by using the avascular plane of dissection between the cartilage endplate and the vertebral body in immature patients. The key to a comprehensive discectomy is optimal visualization deep into the disc space; this not only allows complete removal of all disc tissue, but also prevents injury to the posterior longitudinal ligament and neural elements.

When the discectomy is complete, either allogeneic cancellous or autogenous (rib or iliac crest) bone graft is placed into the disc space with an endoscopic tubular plunger (Fig. 29.10). The method and type of bone grafting also seems to be important to the success of arthrodesis. This may be crucial only in selected cases. However, all patients are at some risk for pseudarthrosis after posterior instrumentation and fusion procedures. In a study of 112 patients treated with an anterior release followed by posterior instrumentation, Newton et al.[5] compared the grade of arthrodesis between patients who received autogenous versus allogeneic bone graft. The authors found that the disc space was fused in 88% of the autograft group compared with 72% of the allograft group at 2-year follow-up.[5] If autograft is not available, either allograft bone or demineralized bone matrix may be used because they have been shown to result in similar fusion rates.[5,33]

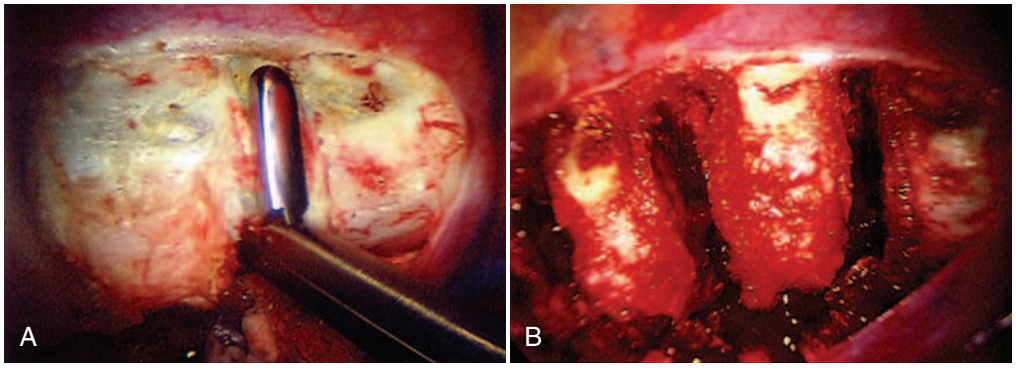

FIG. 29.9 (A) Discectomy can be done with a rongeur or curette or both, with complete removal of the anulus fibrosus, nucleus pulposus, and both endplates of cartilage. (B) Appearance after multilevel discectomies completed. Empty disc space can be temporarily packed with Surgicel for hemostasis control before application of bone graft.

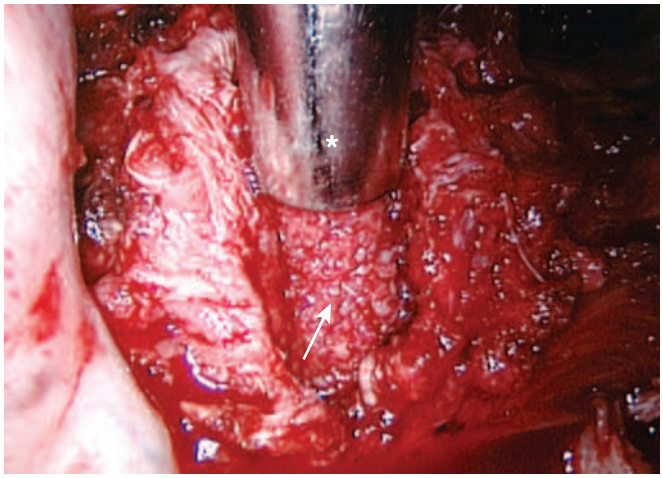

FIG. 29.10 Morcellized bone graft (*arrow*) is introduced into the disc space using a tubular plunger (*asterisk*).

Outcomes

Due to its minimally invasive character, thoracoscopic approach to the spine for an anterior release and fusion has several advantages over the more traditional open thoracotomy approach while achieving similar results in experienced hands. These advantages include less pulmonary morbidity, reduced recovery period, and improved cosmesis. However, the learning curve appears to be steep and operative times significantly longer when compared with open anterior or posterior technique.[14] Several studies have been conducted to evaluate the learning curve associated with VATS.[13,34,35] Newton et al.[13] found that there was a slight decrease in operative time throughout the course of the first 65 patients treated at their institution and concluded that VATS had a steep, but not prohibitive, learning curve. In a more recent study by Son-Hing and coworkers,[34] the learning curve was found to be short with appropriate training and resulted in an excision of a greater amount of disc tissue and a decrease in operative time, while providing similar curve correction to an open thoracotomy.

Several experimental studies have been done to analyze the extent of disc excision possible with thoracoscopic techniques. Biomechanical evaluations of the instability resulting from discectomy were equivalent between open and endoscopic approaches in various animal models.[35–38] The extent of endplate bony exposure has also been shown to be similar with the two approaches experimentally.[35,39]

The clinical results of VATS anterior release and fusion in patients with spinal deformity have been generally favorable but poorly controlled.[40] Although there was a trend in the use of this method during the 1990s, it has since declined in popularity with the widespread adoption of posterior segmental pedicle screw instrumentation. Luhmann et al.[6] and Suk et al.[7] investigated the severe and rigid scoliosis with a main thoracic curve between 70 degrees to 100 degrees and an average flexibility of 45%. Both authors concluded that posterior segmental pedicle screw fixation without anterior release in severe scoliosis had satisfactory deformity correction and prevented significant loss of curve correction. However, these studies did not address the extremely large and stiff deformities, such as curves more than 100 degrees and less than 25% flexibility. In a more recent study of 21 patients with an average preoperative Cobb angle greater than 110.5 degrees and flexibility of 13%, Yamin et al.[41] found a staged anteroposterior procedure to provide safe and effective treatment with a mean correction rate of 65.2%. These authors recommended that patients with a Cobb angle more than 80 degrees and flexibility less than 20% should be treated with a staged anterior release and posterior pedicle screw instrumentation with adjuvant halopelvic traction to gradually correct the deformity.[41] Despite recent studies calling the necessity of this technique into question for large and stiff curves, there is likely a subset of patients who continue to benefit from this procedure, particularly if a three-column osteotomy can be avoided.[6,7,41]

The time to perform VATS anterior release has ranged from 90 minutes to 4 hours, with a decrease in operative time as surgeons gain familiarity. The operative time per disc level excised averages 20 to 40 minutes in experienced hands.[13,34] The reported blood loss and chest tube drainage have been comparable to open procedures, with blood loss generally averaging less than 300 mL.[13,34,42,43] In cases of excessive blood loss, sometimes conversion to open surgery may be required. The incidence of major complications for either VATS or open thoracotomy is less than 1%.[13,34,44] The most common complications associated with VATS anterior release are pulmonary, such as atelectasis, pleural effusions, pneumothorax,

and excessive chest tube drainage.[13,34,43,44] As with all anterior spinal surgery, these risks exist and must be minimized. There are few studies that compare the effect of variable surgical approaches to the thoracic spine on pulmonary function. Faro et al.[45] compared pulmonary function after an open surgery versus a VATS and found that pulmonary function recovered more quickly with VATS; this difference was maintained after 2 years of follow-up. A large series from Newton and coworkers[46] also showed that 2 years after anterior thoracic scoliosis correction, the VATS group was superior with regard to both absolute pulmonary function test volumes and percentage predicted values as compared with the open thoracotomy group that included a thoracoplasty. Although the instrumentation, techniques, and support for VATS continue to improve, proper training is essential to the success of this procedure.

Thoracoscopic Anterior Scoliosis Instrumentation

Anterior scoliosis instrumentation and fusion surgery has been recognized as an alternative to posterior surgery in isolated thoracic curves because it has the potential to save distal fusion levels, prevent crankshaft phenomenon, increase thoracic kyphosis restoration, and improve spontaneous correction of the unfused lumbar and cephalad thoracic curve.[5,44,47,48] Based on the principles of open thoracic anterior instrumentation, VATS anterior instrumentation has been developed to combine the advantages of the anterior approach and minimally invasive surgery simultaneously. Since the first thoracoscopic instrumented fusion of idiopathic scoliosis was accomplished in 1996, this technique has attracted considerable attention for the treatment of thoracic idiopathic scoliosis. Later, several authors also reported good scoliosis correction (mean, 55–65%) and cosmetic outcomes via this minimally invasive technique.[48–51] However, the superiority of VATS instrumented surgery over conventional surgery has not been clearly proven because of concerns with regard to implant failure, pseudarthrosis, and pulmonary complications. Furthermore, given the learning curve, VATS instrumentation has significantly longer operative times.[48,49]

Although the thoracoscopic approach was shown to have advantages over the open anterior approach because of less postoperative pain and pulmonary compromise, these advantages are less distinct compared with the current posterior techniques.[48,49] Thoracoscopic anterior instrumented fusion is an accepted alternative to treat spinal deformity. Nevertheless, careful patient selection and the potential benefits and risks must be balanced before such surgery.

Indications

Anterior instrumented fusion has been thought to allow greater restoration of sagittal alignment and might be beneficial for thoracic scoliosis with significant hypokyphosis. In general, AIS with a right single thoracic curve (Lenke type 1 curves) and those double-curve patterns in which only the thoracic component is structural can be considered for selective thoracoscopic anterior instrumented fusion (Fig. 29.11).[48,49] Ideal cases are relatively small to moderate magnitude and flexible curves requiring thoracic-only instrumentation between T4 and T12.[48–52] The upper limits of curve magnitude and rigidity for which the thoracoscopic approach can effectively be performed is unknown, although it is generally recommended to limit the procedure to patients with a structural scoliosis curve less than 70 degrees and thoracic kyphosis less than 40 degrees.[48,49] In fact, these cases are also candidates for a posterior all-pedicle-screw technique by current criteria. The decision relating to the best approach for each subject remains debatable and requires more substantial research.

Contraindications

The general contraindications for thoracoscopic instrumentation are similar to those described earlier for anterior release and fusion. The procedure is contraindicated if the patients have substantial restrictive lung disease, particularly in patients with marked hypokyphosis or pulmonary symptoms. Previous abscess, pneumonia, and ipsilateral thoracic surgery may result in extensive pleural adhesions that would obstruct thoracoscopic visualization. Additionally, large and stiff curves (scoliosis >70 degrees or thoracic bending >35 degrees) are relative contraindications. Patients with poor vertebral bone stock or insufficient vertebral size to accommodate the anterior screws are also inappropriate for this technique. Patients with a seizure disorder or mentally disabled patients who are unlikely to comply with postoperative instructions are poor candidates because of concerns about implant loosening with a single-rod construct. Since the visual field of thoracoscopy is limited from T4 to L1, secondary structural curves in the cephalad thoracic and thoracolumbar regions that might require instrumentation beyond these endpoints should be ruled out.[52–54]

Surgical Technique

The operating room setup and surgical instruments are similar to the VATS released procedure. The patient is held in a direct lateral decubitus position over an axillary roll with the convex side of the scoliosis up. After the patient has been properly positioned, a portable fluoroscopy unit is brought into position to ensure that adequate radiographic visualization is possible. Prior to preparation, fluoroscopy is used to plan the position of the skin incisions for thoracoport placement. The three posterior portals are placed in the posterior axillary line that allows screw placement in the posterior aspect of the vertebral bodies. Two or three vertebrae are accessible through each portal. One or two anterior portals are placed in the anterior axillary line to allow access to the discs for discectomy and for the scope as well as to assist in the application of spinal instrumentation.

After the portals are placed, a thorough discectomy and endplate preparation are performed as described previously for the VATS released fusion technique. Spinal instrumentation and curve correction is performed under the guidance of

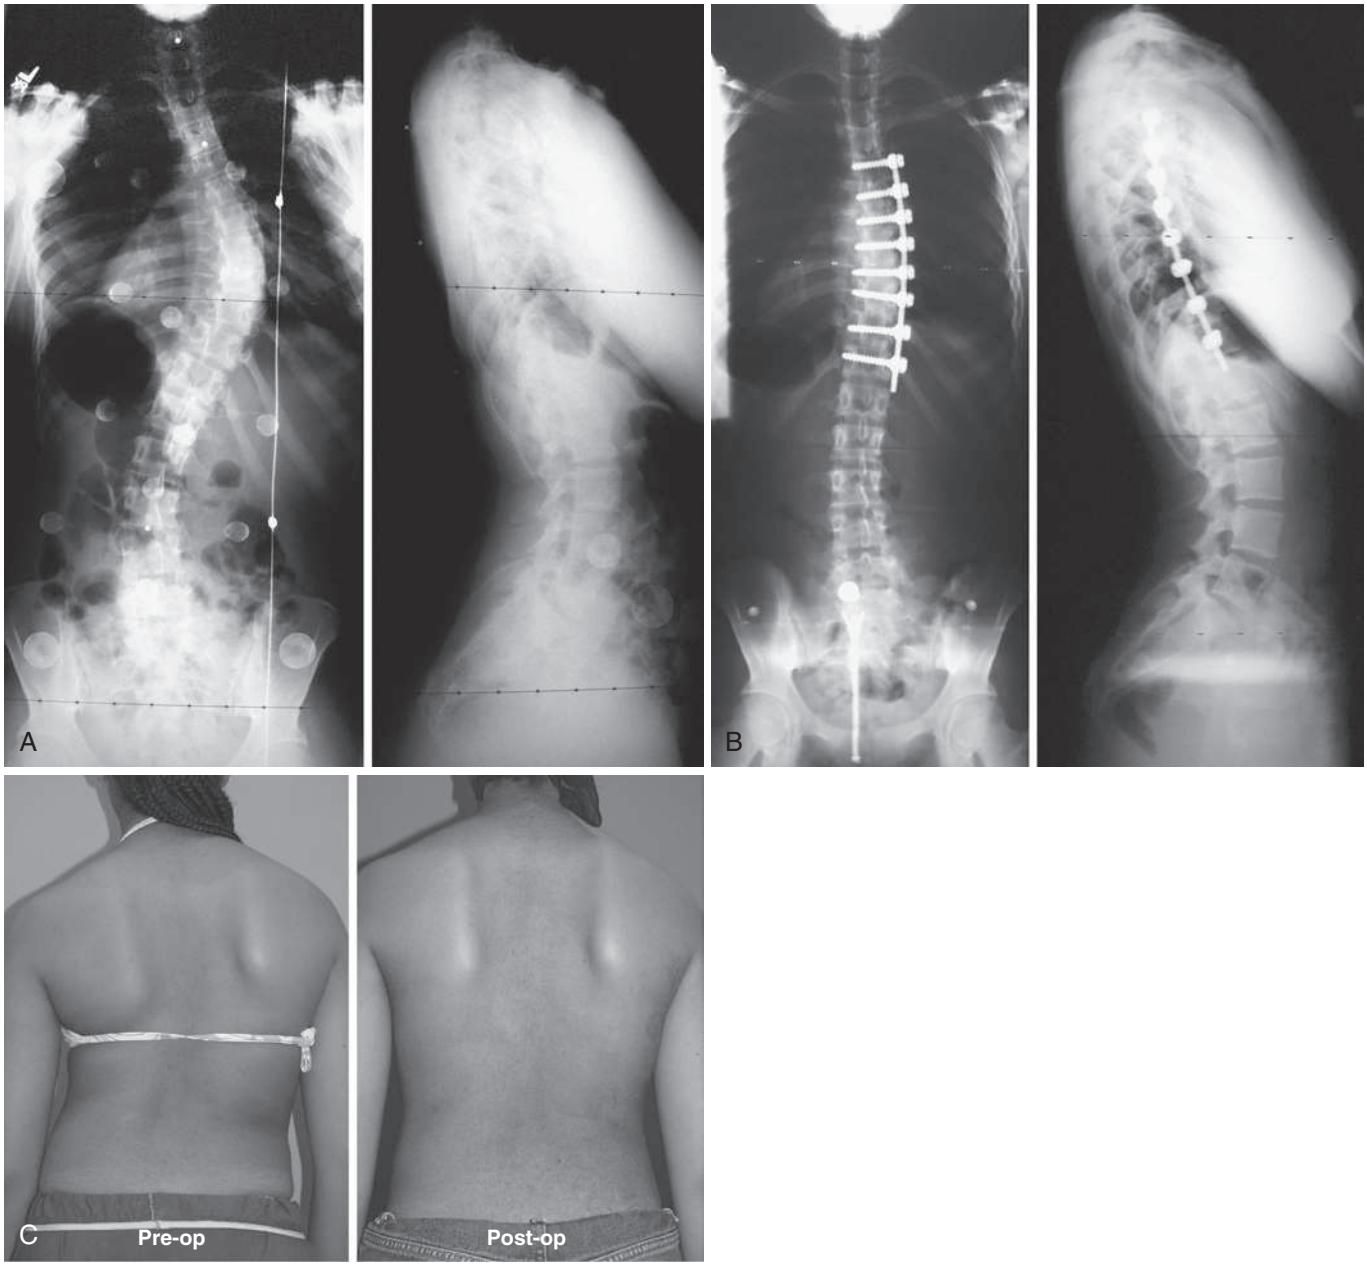

FIG. 29.11 (A) Preoperative posteroanterior and lateral radiographs of a patient with adolescent idiopathic scoliosis. (B) Postoperative posteroanterior and lateral radiographs after thoracoscopic instrumentation from T5 to T12 with correction of deformity. (C) Clinical appearance of the patient before and after thoracoscopic anterior instrumentation and fusion with excellent trunk balance and shoulder symmetry.

fluoroscopy and endoscopy. Either a single-rod or dual-rod system may be used depending on the size of the vertebrae, concerns for rod breakage, and experience of the surgeon. Single-rod systems offer a greater ease of implantation. However, biomechanical studies have suggested that dual-rod constructs are more stable than single-rod constructs.[55,56] The length of the cephalad-most screw is templated on the preoperative posteroanterior radiograph (usually 27.5 or 30 mm); this screw is placed first. A screw path is initiated with an awl and tap, with the entry site in the middle of the vertebral body just 1 to 2 mm anterior to the rib head and approximately 10 degrees of anterior angulation. Penetration of the far cortex greatly enhances the fixation and is mandatory at the proximal levels to reduce the risk of screw pullout. The posterior portals are adjusted to each interspace, allowing screws (typically 6 mm in diameter) to be placed at each desired level parallel to the superior and inferior endplates of the vertebra (Fig. 29.12). Care must be taken to avoid placing successive screws increasingly anterior in the vertebral body because this may negatively affect fixation and restoration of kyphosis. It also potentially places the aorta at increased risk of iatrogenic injury.[57] Although there have been concerns regarding vertebral body screws placed thoracoscopically, Qiu et al.[58] showed that there is no statistically significant difference in the accuracy of vertebral body screw placement in thoracoscopic versus mini-open thoracotomy approaches.

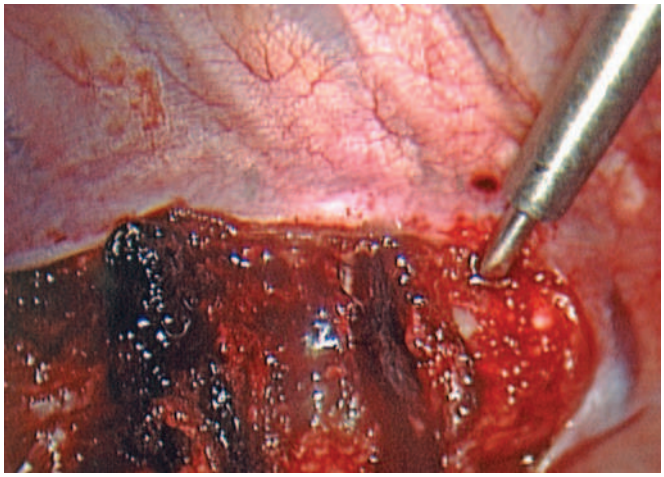

FIG. 29.12 Screws are placed along the path parallel to the endplates.

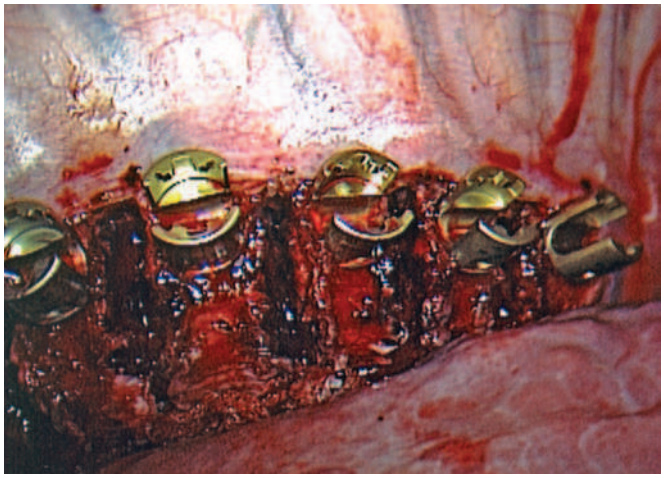

FIG. 29.13 Care must be taken in screw placement to ensure that screws are aligned to accept the rod.

After all the screws are placed (Fig. 29.13), the length of the rod is determined with a calibrated rod-measuring device. A rod of appropriate length is cut and contoured to the desired level of postoperative scoliosis and kyphosis. The rod is sequentially loaded into the screws and secured with locking nuts (Fig. 29.14). Fully seating the rod into the screws may be accomplished with either a rod pusher or the use of a reduction device. Several styles of compressors have been developed to compress between levels. This compression is an important component to the anterior correction of scoliosis but must be performed in a gentle manner, particularly at the upper levels, where screw fixation may be tenuous. Bone grafting is crucial to the success of this procedure. As previously mentioned in the section on thoracoscopic release, autogenous graft provides the optimal base for a solid fusion and is recommended.[5,33]

After completion of the instrumentation procedure, wound closure is initiated. An endoscopic suturing device is utilized to perform a running closure (2-0 suture) of the pleura. The chest is irrigated, and a chest tube is placed prior to closure of the skin incisions. The patient is instructed to wear a thoracolumbosacral orthosis when out of bed for 3 months postoperatively.

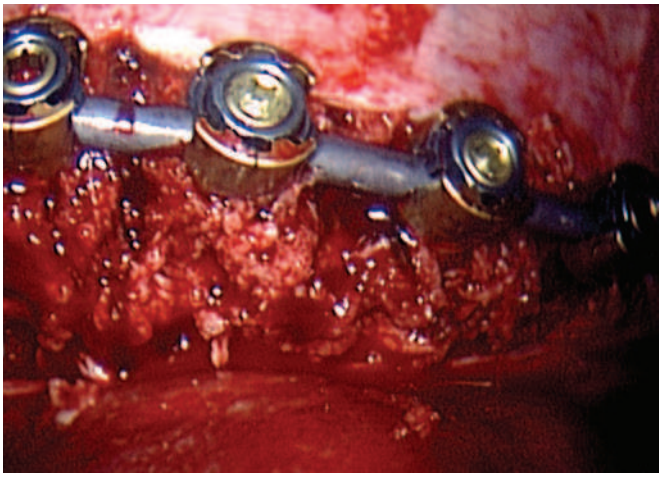

FIG. 29.14 Endoscopic view of a locked single-rod anterior screw and rod construct.

Outcomes

In 1998, Picetti et al.[59] were the first to report a clinical case of multilevel anterior scoliosis correction performed thoracoscopically. Early studies reported high rates of pseudarthrosis, implant failure, and loss of fixation.[54,60,61] After surgical experience grew, comparable results have been reported between thoracoscopic anterior procedures and open anterior and posterior techniques.[47–50,62] In a series of 45 patients with AIS, Norton et al.[3] found an overall curve correction of 87.3% (51.6 degrees preoperatively to 6.6 degrees postoperatively), an average hospital stay of 2.9 days, and a return to school after 2 to 4 weeks. Newton et al.[48,49] reported that radiographic findings, pulmonary function, and clinical measures remained stable between 2 and 5 years of follow-up in their series of 23 patients treated with VATS instrumented fusion. Both series found no significant loss of correction after an average 4.6-year (Norton series) and 5.3-year (Newton series) follow-up.

Although operative time is longer in VATS cases compared with an open anterior or posterior procedure, operative time does decrease with experience. Lonner et al.[62] reported a significant reduction in operative time from 6 hours in their first 28 cases to 4 hours and 30 minutes in the last 15 cases. Studies by Lonner et al.[14] and Wong et al.[63] compared VATS with standard posterior procedure and found a decrease in intraoperative blood loss and a reduced hospital stay in the Lonner study and a reduced intensive care unit stay in the Wong study. When pulmonary function is evaluated, VATS has been shown to result in better recovery of pulmonary function compared with open technique and similar return to function as in standard posterior technique.[14,45] Similarly, in regard to shoulder girdle function, Ritzman et al.[64] found that VATS was comparable to posterior instrumentation, which were both better than open anterior surgery. Further comparison by Lonner and coworkers[65] of the impact of VATS versus posterior spinal instrumentation and fusion on the patients' quality

of life using the SRS-22 instrument revealed that patients who underwent VATS scored higher in the self-image, mental health, and total domains despite similar curve corrections.

In all of the aforementioned studies, VATS was compared with a mix of posterior spinal fusion instrumentation anchors (wires, hooks, screws). Although many of these past studies focused on the outcomes of thoracoscopic instrumentation compared with open anterior or posterior hybrid instrumentation, VATS has been directly compared more recently with posterior segmental pedicle screw constructs. Lonner et al.[47] performed a matched-pair analysis of 34 patients with AIS with single thoracic curves of approximately 50 degrees. The patients had equivalent radiographic results, patient-based clinical outcomes, and complication rates with the exception that the posterior thoracic pedicle screw group had a slightly better major curve correction (63.8% vs 57.3%). These authors concluded that VATS offers the advantages of reduced blood loss (371 vs 1018 mL), fewer total levels fused (5.9 vs. 8.9), and preservation of nearly one caudal fusion level. The disadvantages included increased operative time (325 vs 246 minutes) and slightly less improved pulmonary function. Similar findings were described by Lee et al.[66]; the VATS group had a relatively lower correction rate (66% vs 72%), longer operative time, and less blood loss compared to posterior all-pedicle-screw constructs. There was no difference at the last follow-up in terms of pain score and satisfaction between groups, but a loss of correction was significantly higher in the VATS group.[66]

The evidence supporting which AIS patients would be the best candidates for VATS is unclear. Since posterior pedicle screw instrumentation with Ponte osteotomies has gained popularity, the role of thoracoscopic surgery in the surgical treatment of AIS has been reduced.[66,67] The best indication today seems to be in selected patients who strongly desire minimally invasive surgery.

Treatment of Other Thoracic Spine Conditions

The thoracoscopic approach has been widely applied to thoracic and thoracolumbar reconstruction in cases of metastatic tumors, fractures, herniated discs, and infection. The clinical benefits compared with open thoracotomy include the following: (1) direct lesion visualization intraoperatively, (2) less postoperative pain, (3) reduced impairment of immediate postoperative pulmonary function, (4) shorter hospitalization, and (5) cosmetic advantages. The technical demands of treating these conditions may be greater; theoretically, however, any anterior lesion that causes compression of the spinal cord can be addressed with this technique.

Tumor

Of all spinal tumors, approximately 70% are located within the thoracic spine; 85% of these tumors predominantly invade the ventral vertebral body and anterior epidural space.[68,69] With the goals of decreasing pain, maintaining function, and decreasing tumor recurrence, vertebrectomy via posterior only or combined anterior and posterior approaches has been advocated by some surgical oncologists.[70–72] Patchell et al.[73] found that significantly more patients who underwent direct surgical decompression followed by radiation were capable of walking than patients who received radiotherapy alone. The advantages of the anterior approach is that it offers an extensive exposure for tumor resection with direct cord decompression, larger interbody reconstruction footprint and stabilization, and a lower rate of wound complications than posterior incisions.[69] Traditional open transthoracic approach is most commonly used. Nevertheless, it is associated with significant morbidity, yielding an opportunity for thoracoscopic techniques in select cases.[74]

Technologic advances in expandable interbody cages have made the wide resection of tumors and immediate stabilization of the spine possible through a VATS approach.[69,75] The minimally invasive nature substantially benefits these compromised patients, including reduced postoperative pain, shorter hospital stay, faster return to activity, and lower pulmonary complication rates.[69–75] Although data on large series are pending, VATS can be a valuable treatment modality for patients with a life expectancy greater than 8 to 12 months.

Apart from metastatic tumors, few studies report experience of VATS in the treatment of primary spinal tumors.[76,77] With the advent of navigation systems (NAVs) to guide the anatomic orientation and to define the tumor margin, the VATS-NAV combination may have the potential to achieve accurate spinal tumor localization and excision without unnecessary vertebral bony removal through a minimally invasive access approach.[78]

Trauma

The principles of surgical treatment in traumatic thoracic spinal injuries (e.g., compression fractures, burst fractures, Chance fractures, or dislocations) involve correction of alignment, decompression of the spinal canal, and stabilization. However, loss of kyphosis correction and chronic pain have been demonstrated in some patients treated with posterior instrumentation alone.[79] To address these pitfalls, additional ventral column stabilization and fusion may be of benefit in some cases.[80] Beisse et al.[81] reported 371 patients who underwent VATS anterior reconstruction and fusion with instrumentation for spinal trauma. The average duration of surgery was 6 hours, which gradually decreased to an average of 2.5 to 3 hours as the surgeons gained experience and skill. An 85% to 90% fusion rate was observed via the VATS technique; Beisse et al.[81] believed it was comparable with the posterior approach.

With the evolution of implant technologies and imaging tools, the use of VATS corpectomy followed by short segment percutaneous instrumentation has been described as an option in managing thoracic and thoracolumbar fractures.[82] Theoretically, the combination of two minimally invasive techniques can achieve the goals of anterior reconstruction and posterior stabilization while lessening the morbidities related to the open surgeries. Twenty-six patients with acute burst fracture were included in the series and 23 of 26 patients (88.5%) had radiographic fusion at 2 years follow-up. There was no case

that required revision surgery due to metal failure, loosening, or adjacent segment problems.[82]

Thoracic Disc Herniation

Disc herniation has been estimated to occur in approximately 11% to 37 % of the population as diagnosed by magnetic resonance imaging (MRI) and postmyelographic CT scanning.[83] Despite a relatively low incidence of disc herniation in the thoracic spine compared with the cervical and lumbar spine regions, a symptomatic thoracic disc herniation may present with any combination of back pain, radiculopathy, and myelopathy from nerve root and/or spinal cord compression. Most patients resolve with nonoperative treatment, but for those with refractory radicular pain and progressive myelopathy, surgical intervention may be recommended. Current approaches for resection of symptomatic herniated thoracic disc include posterolateral and anterolateral (open thoracotomy or thoracoscopy). By convention, the posterolateral approach is most suitable for the small and lateral herniated disc, while an anterolateral approach is ideal for wide-based and central lesions.[84] With increased familiarity of VATS techniques and cumulative experience, favorable results and acceptable complication rates of VATS discectomy have been shown over the past decade.[85–89]

The endoscope provides a magnified view of the entire ventral surface of the spine and spinal cord. Excision of the rib head and herniated disc provides access to the spinal canal, which allows clear visualization to ensure adequate decompression. A systematic review of 12 articles reported complete resolution of symptoms in 79% of the patients and improvement but with residual symptoms in 10.2%. The overall complication rate was 24% with intercostal neuralgia (6%) as the most common, followed by atelectasis (2.8%).[90] The authors concluded that thoracoscopic discectomy was the best treatment in the single soft and centrally located disc between the T4 to T11 level because of its less invasive nature, whereas those with large calcified discs, likely dural adhesions, or multilevel involvement are preferably treated with open surgery.[90]

Infection

Spinal tuberculosis (Pott disease), accounting for 50% of the cases of extrapulmonary involvement, still remains a major health issue in both developed and developing countries. The hematogenous route is the most common pathway for vertebral inoculation. The thoracic spine is predominantly involved.[91] Although antituberculous drugs and bracing are the mainstays of treatment for spinal tuberculosis, they are not applicable for those with worsening neurologic deficit and spinal instability. The mass effect of paraspinal abscess and marked sagittal malalignment due to extensive anterior column destruction are responsible for direct and indirect compression of adjacent neural structures. Through the radical debridement of the necrotic bone debris and abscess drainage, surgical intervention aims to obtain tissue diagnosis confirmation, adequate neurologic decompression, and facilitate fusion with bone grafting. The conventional surgical method to decompress the tuberculous thoracic spine is either the anterolateral extrapleural or open transthoracic transpleural approach.[92] Both approaches are valuable methods for thorough decompression and graft implantation, but high morbidity (10% to 50%) and prolonged hospital stays have been reported.[93]

In the last 2 decades, some authors have suggested VATS as an alternative to treat tuberculous spine infections, reporting encouraging results.[92,94–97] The surgical goals—including decompression, bone grafting, and even screw/rod instrumentation—can be achieved with a VATS approach and provide the advantages of lower perioperative morbidity and early recovery due to minimally invasive access. The rate of neurologic recovery to ambulatory status in the available literature ranges from 82% to 95%, which was thought to be equivalent to the rates following open surgery.[92,94–97]

Although VATS was found to be an effective and reliable approach, there is a tendency for increased kyphosis postoperatively.[92,94,95] Sasani et al.[98] thus recommended the use of an iliac crest bone graft rather than a rib graft to bear more load over the anterior column, and none of their patients encountered the kyphotic deformity at the 2-year follow-up. Excluding inappropriate cases such as pleural adhesions and severe kyphotic instability, the minimally invasive anterior approach to treat spinal tuberculosis has shown promising results in many institutions if performed by experienced thoracoscopic surgeons.

Future of Thoracoscopic Spinal Surgery

The utilization of VATS in treating thoracic and upper lumbar spinal pathology continues to evolve since it appeared more than 25 years ago. It is currently used in a wide spectrum of therapeutic indications, including spinal deformities, thoracic disc herniation, spinal tumors, infections, and other pathologic processes if the lesion position is amenable to an anterolateral approach. Recent technologic advances, including topical hemostatic agents for controlling bleeding and modified bone graft materials for accelerating fusion, have improved the safety and efficiency of VATS fusion procedures. Successful incorporation with high-tech imaging systems, such as intraoperative navigation, has been useful in conjunction with the VATS technique to reinforce the location accuracy. Although VATS anterior instrumented fusion is losing its role in the surgical correction of AIS, the VATS instrumented technique may still be valuable in spinal growth modulation for juvenile idiopathic scoliosis. Gradual correction of a scoliotic deformity has been achieved with anterior vertebral growth modulation using a 4.5-mm-diameter polyethylene spinal tether, a procedure in which the VATS approach may be preferred.[99] Such cases are being undertaken in several centers (Fig. 29.15). This technique holds promise but remains relatively early in development. Presently, the implants are not approved by the US Food and Drug Administration for this indication, and long-term outcome studies are lacking.

When done well in properly selected patients, the VATS approach has clear advantages over open thoracotomy.

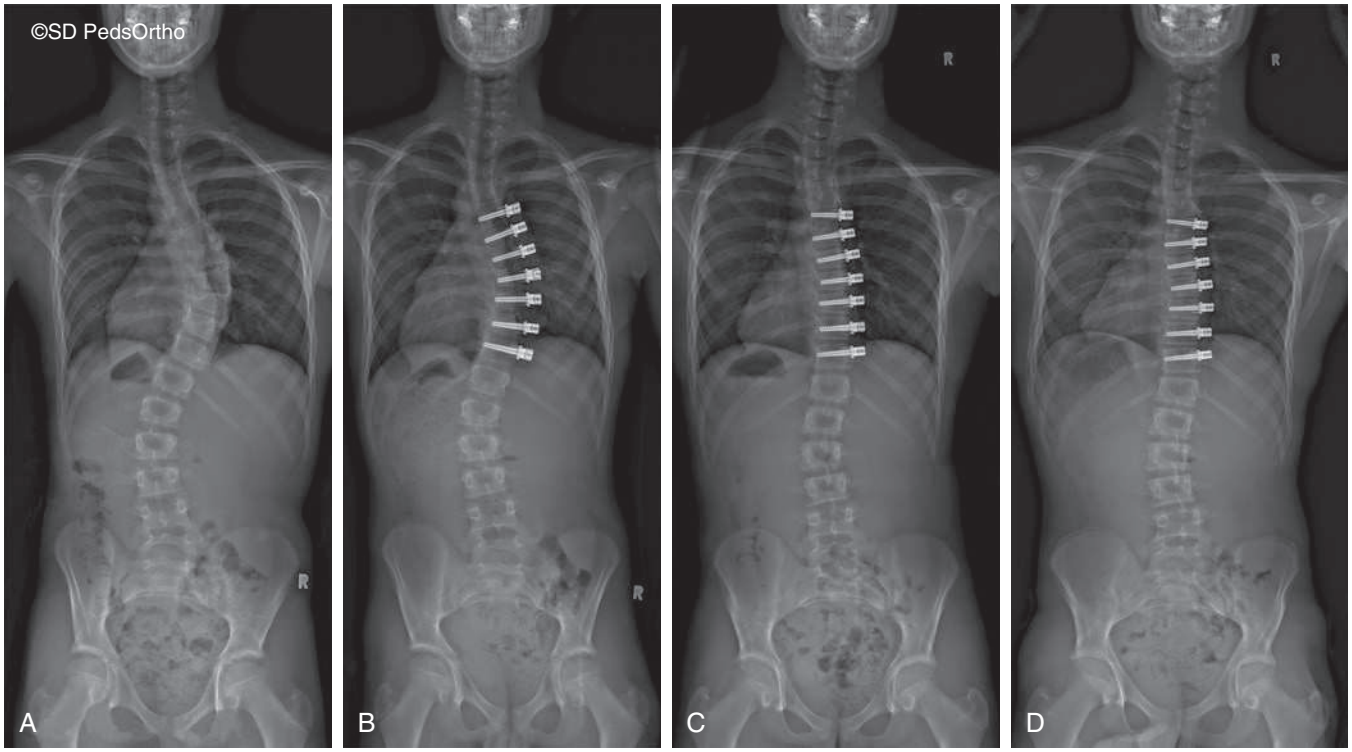

FIG. 29.15 A 13-year-old girl with adolescent idiopathic scoliosis Lenke 1a curve, showing Risser 0 and a T5–T12 Cobb angle of 53 degrees. She underwent spinal growth modulation surgery through anterior thoracoscopic instrumentation, then was tethered by a polyethylene flexible cord. (A) Preoperative posteroanterior (PA) standing radiograph. (B) PA standing radiograph immediately after surgery. (C) PA standing radiograph 2 years after surgery. (D) PA standing radiograph 3 years after surgery. The scoliotic curve continued improvement over time as the spine grew.

However, substantial experience and comprehensive judgment are required. Midterm reports show favorable outcomes using these techniques in a variety of spinal disorders, but further research remains to define which pathologies and patients are the optimal candidates for a VATS procedure.

PEARLS

1. Careful patient selection is the first step in reaching success with VATS.
2. Positioning of the patient is crucial; otherwise, the surgeon may be misled about spinal orientation and misplace instrumentation.
3. Portal placement should be optimized to facilitate the working range of the surgical instruments.
4. Adequate visualization can be obtained by complete lung deflation and meticulous hemostasis.
5. Surgeons should master anterior released discectomy and fusion before attempting to use fully endoscopic anterior instrumentation.

PITFALLS

1. Parenchymal lung injury can result from incomplete atelectasis.
2. Loss of perspective or orientation within the chest can be avoided by looking through the portal directly.
3. The surgeon can control bleeding from segmental vessels with a HARMONIC scalpel (Ethicon), bone bleeding with wax, and bleeding from epidural veins with bipolar cautery and topical hemostatic agents.
4. A mini-open approach should be a back-up plan to ensure safe completion of the procedure.
5. Pseudarthrosis can be avoided by performing a thorough discectomy and endplate excision. Complete autogenous bone grafting (if possible) is recommended.

KEY POINTS

1. Thoracoscopic spinal procedures are technically demanding.
2. Although performed through relatively small incisions, thoracoscopic surgeons must have substantial experience to perform similar procedures via a mini-open approach in properly selected cases.
3. Visualization is the key to performing surgery safely and effectively. This is critical in thoracoscopic surgery as well.
4. The addition of a current navigation-guided system with VATS assists in target localization and is potentially applicable for thoracic discectomy, spinal tumors, infection, and ossification of the posterior longitudinal ligament.

CHAPTER 30

Pediatric Kyphosis: Scheuermann Disease and Congenital Deformity

SECTION IV

Steven S. Agabegi
Dinesh P. Thawrani
Alvin H. Crawford

The normal adult spine has four curves in the sagittal plane: cervical lordosis, thoracic kyphosis, lumbar lordosis, and sacrococcygeal kyphosis. In utero and at birth, there are two primary kyphotic curves in the thoracic spine and sacrococcygeal region. The lordotic curves in the cervical and lumbar spine are compensatory curves and develop as a child holds the head upright and begins to stand and walk.[1]

Lordotic curves are considered secondary and compensate for the degree of kyphosis in the primary curves to allow a balanced spine in the sagittal plane. There is great variability in defining the normal range of thoracic kyphosis. As measured by the Cobb method, the normal range of thoracic kyphosis is 20 to 45 degrees.[2,3] Normal kyphosis increases with age and is slightly greater in women.[3] Thoracic kyphosis is measured on a lateral radiograph using the Cobb method from the superior endplate of T2 to T5 depending on visibility to the inferior endplate of T12. The thoracolumbar junction is normally neutral or slightly lordotic (0–10 degrees of lordosis). Any degree of kyphosis at the thoracolumbar junction is considered abnormal. Lumbar lordosis is measured from the superior endplate of L1 to the superior endplate of S1, and normal values are 40 to 65 degrees.

The importance of achieving a neutral sagittal balance has been emphasized in recent years in the evaluation and treatment of various kyphotic deformities. The C7 plumb line, that is, the sagittal vertical axis (SVA) is a vertical line drawn from the midpoint of the C7 vertebral body. This should fall through the posterosuperior corner of the L5–S1 disc space. If it falls anterior to this point, there is positive sagittal balance; if it falls posterior to this point, there is negative sagittal balance. Jackson and McManus[4] reported values in asymptomatic adults with a mean sagittal vertical axis offset of 0.5 cm (±2.5 cm standard deviation). According to these data, offset greater than 2.5 cm anteriorly or posteriorly is considered beyond the normal range. A positive sagittal balance is poorly tolerated because intradiscal pressures increase in the lumbar spine and the posterior spinal musculature is placed at a mechanical disadvantage, leading to back pain.

Scheuermann Disease

In 1921, the Danish radiologist Scheuermann described a pathologic condition and distinguished it from passively correctable postural humpback when he noted the development of painful fixed kyphosis in 105 children.[5] Scheuermann likened the entity to the femoral head abnormality described by Calvé and Perthes, and named it *osteochondritis deformans juvenilis dorsi*. Several terms have been used in the past to describe this entity, including *kyphosis dorsalis juvenilis,* but *Scheuermann disease* and *Scheuermann kyphosis* are the most common.[6]

Scheuermann disease is the most common cause of severe thoracic kyphosis in adolescents, with a reported prevalence of 1% to 8%.[7–9] The prevalence is approximately equal in boys and girls. Approximately one-third of patients have concomitant scoliosis, which is usually mild.[10]

In 1964, Sorensen[11] defined the radiographic criteria that have now become widely accepted for diagnosing Scheuermann disease: anterior vertebral wedging greater than 5 degrees on three or more consecutive vertebrae or greater than 15 degrees combined over three vertebrae at the apex of the curve. Associated radiographic findings include endplate irregularities and Schmorl nodes (herniation of a disc into vertebral endplates). Schmorl nodes are not specific to Scheuermann disease and can be found in various conditions. Scheuermann disease is typically diagnosed at age 10 to 12 years. Sorensen's criteria are typically not present in patients younger than age 10 because the ring apophysis has not ossified before this age.

There are two curve patterns in Scheuermann disease. The thoracic type is most common, and its apex is located between T7 and T9 (Fig. 30.1). The thoracolumbar type has also been referred to as "atypical" Scheuermann disease; its apex is located between T10 and T12, and it is more likely to become symptomatic in adult life.[10] Vertebral endplate changes, Schmorl nodes, and disc space narrowing are much more common in the thoracolumbar form of Scheuermann disease.

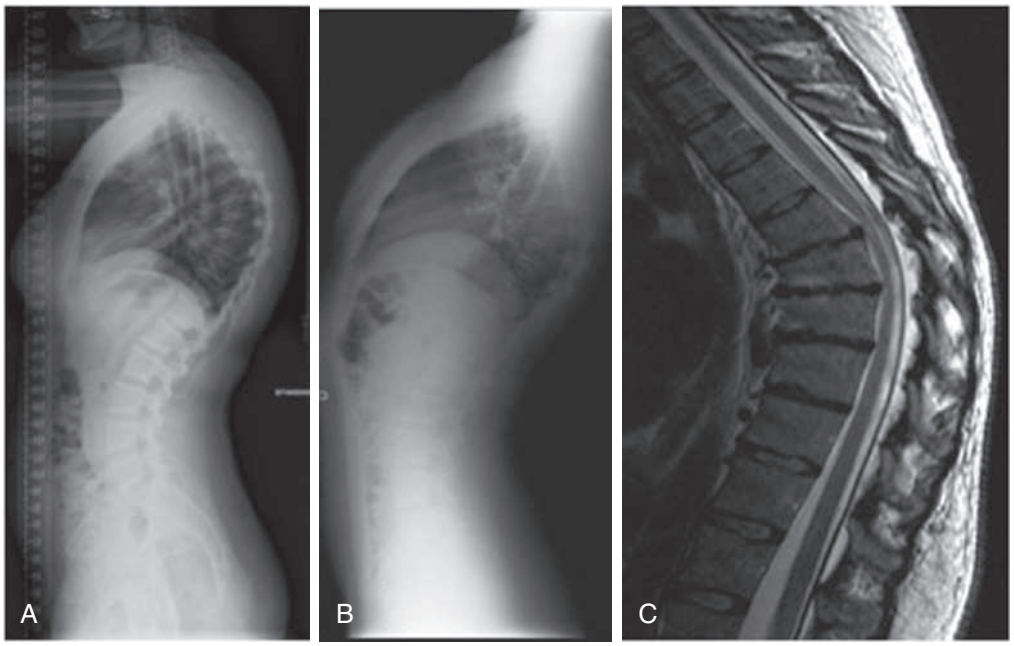

FIG. 30.1 (A) Standing lateral radiograph of a 15-year-old female with arms at a right angle illustrating typical thoracic Scheuermann kyphosis. (B) Supine cross-table hyperextension lateral radiograph. (C) Magnetic resonance imaging showing typical endplate changes at the midapical region with a bulging disc indenting the dural sleeve.

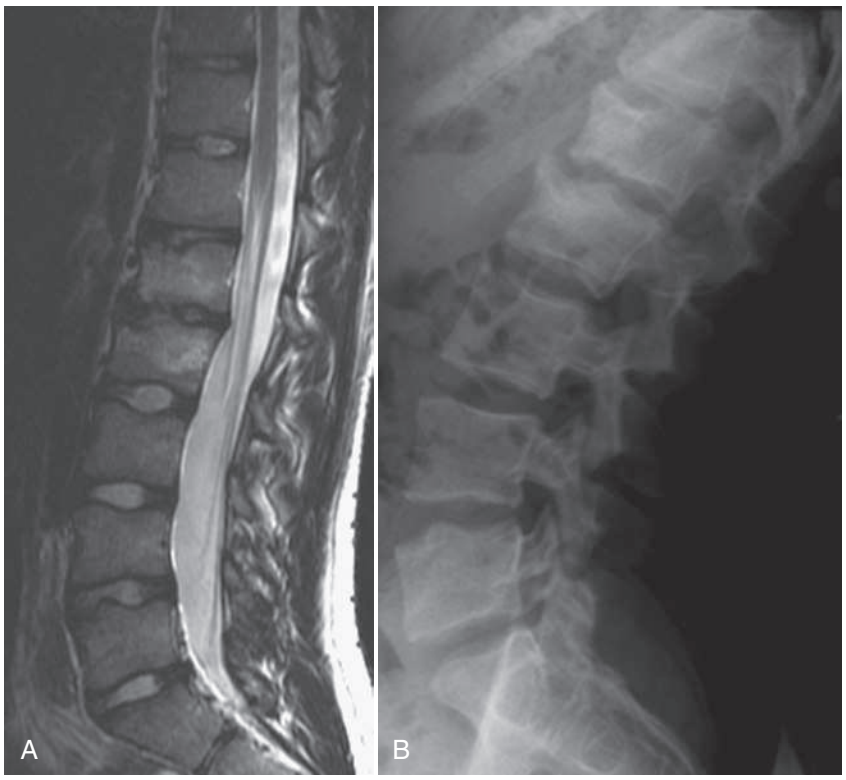

FIG. 30.2 A 16-year-old female with back pain and lumbar Scheuermann disease, with typical endplate changes at T12–L1 and L1–L2. (A) Sagittal cuts of lumbar spine magnetic resonance imaging. (B) Plain radiograph lateral view of lumbar spine.

Sorensen's criteria (three consecutive wedged vertebrae) are unnecessary to diagnose the thoracolumbar form of Scheuermann disease.

Lumbar Scheuermann disease is a distinct entity in which significant degenerative changes are present in the lumbar spine (typically L1–L4) without vertebral wedging or significant kyphotic deformity (Fig. 30.2). Schmorl nodes and endplate irregularities are common. Lumbar Scheuermann disease is more common in males, especially laborers who engage in heavy lifting activities.

Other causes of kyphosis include congenital kyphosis, postlaminectomy kyphosis, myelomeningocele, posttraumatic kyphosis, neuromuscular kyphosis, infections, tumors, and various metabolic conditions. The main differential diagnosis in patients with Scheuermann disease is postural kyphosis, that is, "juvenile roundback," in which the spine is flexible without structural vertebral wedging.

Etiology

Although the etiology of Scheuermann disease is unknown, several theories exist. Scheuermann's initial description suggested that the condition results from avascular necrosis of the vertebral ring apophyses, which leads to a premature growth arrest with resultant wedging of the anterior portion of the vertebral bodies, and mentioned that it resembled Legg-Calvé-Perthes disease of the hip.[5,6] Schmorl and Junghans[12] hypothesized that herniation of disc material into the vertebral body endplates occurred as a result of inherent weakening of the cartilaginous endplate, with resultant damage to the endplate causing growth disturbance and kyphosis. Schmorl nodes are not specific to kyphotic deformities, however, and are found in normal spines.

Genetic factors have also been proposed. An autosomal-dominant inheritance pattern with incomplete penetrance and variable expression in families with Scheuermann disease has been described.[13–15] Three cases of Scheuermann kyphosis in monozygotic twins have been reported in the English literature,[11,16,17] supporting the genetic etiology hypothesis.

Other etiologies of the deformity have been attributed to defective endplates, upright posture, juvenile osteoporosis, increased release of growth hormone, defective formation of collagen fibrils with subsequent weakening of vertebral endplates, strenuous manual labor, trauma, vitamin A deficiency, epiphysitis, poliomyelitis, prolonged sitting, and osteochondrosis.[18–23] Mechanical factors have also been proposed to play a role in pathogenesis, owing to partial reversal of vertebral wedging with brace treatment and thickening of the anterior longitudinal ligament.[10,24]

Clinical Evaluation

The clinical evaluation begins with a complete history and physical examination. The deformity is often attributed to poor posture in an adolescent, delaying diagnosis and treatment.[10] One should inquire about the onset of the deformity and the location of pain. If the patient has pain, it is usually mild and aggravated by prolonged sitting or exercise, and typically is near the apex of the kyphotic deformity.[10] Spondylolysis and spondylolisthesis have been noted with an increased incidence in patients with Scheuermann disease and can be a source of low back pain.[25] There is a 50% incidence of spondylolysis in Scheuermann kyphosis, presumably resulting from increased stress on the pars interarticularis in the lower lumbar spine as a result of hyperlordosis.[25] With significant deformity, the erector spinal musculature is placed at a mechanical disadvantage, which may also contribute to the pain that is common with this condition.

The Adams forward bending test is used to evaluate any deformity in the coronal plane. On the Adams test, the deformity of Scheuermann disease is sharply angulated compared with the harmonious curve of a postural kyphosis. The flexibility of the deformity should be assessed with a prone hyperextension maneuver. Typically, the kyphosis is fixed and remains visible with spine hyperextension, and patients cannot voluntarily correct the deformity.

Increased lumbar lordosis is often noted in these patients as compensation for the kyphotic deformity to maintain overall sagittal balance. It is important to assess coronal and sagittal balance. Lowe and Kasten[26] studied the sagittal contour of 24 patients with Scheuermann kyphosis and found that most patients with Scheuermann kyphosis have negative balance before surgery and slightly more negative balance after surgery. Lumbar hyperlordosis was reduced from an average of 75 degrees before surgery to 55 degrees after surgery.

Tightness and contracture of pectoral and hamstring muscles is common.[27] One should look for cutaneous lesions, foot deformities, or muscle contractures. These may signal an underlying neurologic problem. A complete neurologic examination should be performed. Although neurologic findings are rare in Scheuermann disease, spinal cord compression has been reported.[18,28–31] Causes of cord compression include thoracic disc herniation, dural cysts, or severe kyphosis.

Imaging Studies

Routine radiographs include standing posteroanterior and lateral 36-inch films. Sorensen's criterion (three consecutive wedged vertebrae of ≥5 degrees) is used as the diagnostic criterion. On the lateral view, the fists are placed in the supraclavicular fossa to visualize the upper thoracic spine better. Arm position has a tendency to displace the C7 plumb line. Patients with Scheuermann kyphosis typically have normal or negative sagittal balance, however. It is important to be consistent with the methods used when obtaining radiographs in the preoperative and postoperative periods. A supine hyperextension bolster lateral view is useful in assessing the flexibility of the deformity and can help differentiate it from postural kyphosis.[32] Other radiographic abnormalities that may be present—such as spondylolysis, scoliosis, disc space narrowing, and endplate irregularities—should be noted.

All patients with a rapidly progressive kyphosis, neurologic abnormalities, or any evidence of congenital kyphosis should undergo magnetic resonance imaging (MRI). One report showed transient paraparesis owing to thoracic spinal stenosis and recommended preoperative MRI in patients undergoing surgical correction.[33] Thoracic disc herniations are known to occur with increased frequency in patients with Scheuermann disease.[34,35] The issue of whether all surgical patients should undergo MRI preoperatively is controversial; our practice is to obtain MRI in all patients before surgery to rule out stenosis, disc herniation, or other pathologies. A retrospective study performed by Abul-Kasim et al. showed significantly higher spinal epidural lipomatosis at T7 level in patients with Scheuermann kyphosis as compared to a control group.[36] Further, degree of kyphosis in patients with Scheuermann

kyphosis was correlated to the amount of epidural fat. These authors concluded that spine MRI should be routinely performed to screen each Scheuermann kyphosis patient to avoid impending neurologic injury during the surgery.[36]

Natural History

Several early studies suggested an ominous natural history for Scheuermann disease, with significant back pain, embarrassment about physical appearance, interference with social functioning, and cardiopulmonary failure.[11,37–41] Ponte and colleagues[37] showed in their series that all curves greater than 45 degrees in skeletally immature patients progressed during the adolescent growth spurt and continued to increase after age 30 years. Sorensen[11] reported a 50% incidence of pain during the adolescent growth spurt, and a high rate of pain was noted in patients with kyphosis greater than 60 degrees.[38] Other studies noted the often unremitting and incapacitating nature of the pain, progressive nature of the deformity, risk of cardiopulmonary failure, and unacceptable appearance of the deformity in untreated adults.[39–41] Aggressive surgical treatment was recommended to prevent these problems in the future.[41]

In 1993, Murray and colleagues[18] provided the first long-term follow-up study on the natural history of untreated Scheuermann disease in patients with an average age of 53 years and average kyphosis of 71 degrees. These investigators found that 64% of patients (compared with 15% of controls) reported back pain. The proportion of patients who had pain that interfered with their daily lives was not significantly different from control subjects, however. Their data suggested that, although patients with Scheuermann disease may have some functional limitations, they do not have major interference with their lives. Murray and colleagues[18] also found that their patients adapted reasonably well to this condition and recommended that surgical treatment should be carefully reviewed. Other reports have also suggested the generally benign natural history of this condition.[42–44]

The natural history is more favorable when the deformity is in the thoracic spine rather than the thoracolumbar spine. Back pain is more common in the latter. It is believed that thoracic kyphosis, compared with thoracolumbar kyphosis, has a lower incidence of progression because of the support provided by the surrounding rib cage.[45] When a thoracolumbar kyphosis exceeds 50 to 55 degrees, the deformity is readily apparent, especially in thin patients, and pain is common.[45] The thoracolumbar spine is typically neutral to slightly lordotic, and any degree of kyphosis may be clinically apparent. In adults, degenerative disc disease is frequently seen at the apical segments of the kyphosis and may be a source of back pain.[46,47]

Although progression of deformity can be rapid during the adolescent growth spurt, it is unknown whether the deformity would progress after skeletal maturity is reached. Thoracic curves greater than 80 degrees and thoracolumbar curves greater than 55 to 60 degrees may be at risk of progression after skeletal maturity, although the true incidence of progression is unknown.[10,45] If nonsurgical treatment is chosen for curves of this magnitude, periodic follow-up is recommended into adulthood.

Pulmonary failure secondary to severe deformity is very rare. Murray and colleagues[18] found that lung volume, lung mechanics, and diffusing capacity were not significantly affected and were normal in patients with curves less than 100 degrees. They found that as the deformity reaches 100 degrees, restrictive lung disease occurs more often when the curve apex is between T1 and T8.

Nonsurgical Treatment

Nonoperative treatment consists of observation, exercise, and physical therapy, or bracing and casting. As is the case with the management of all spinal deformities, diligent observation is the mainstay of nonoperative treatment. In a skeletally immature patient with a mild deformity, periodic observation every 6 months is recommended to document progression. Exercise and physical therapy are useful to treat associated back pain and to improve muscle tone and posture. There is no evidence that exercise improves the kyphotic deformity or reverses endplate changes. Adolescents with kyphosis less than 60 degrees are treated with a physical therapy and exercise program, with periodic radiographs until the patient is skeletally mature. Most adults with untreated Scheuermann disease respond well to a back exercise program if the kyphosis is not severe.

Applying a brace to a patient with Scheuermann kyphosis tends to be more challenging than applying one to a patient with idiopathic scoliosis. The apex of a typical thoracic Scheuermann kyphosis is usually at or above T8; a traditional thoracolumbosacral orthosis (TLSO) does not extend high enough to provide substantial corrective forces. The Milwaukee brace or serial hyperextension casts are the most effective in this regard but are poorly tolerated because of appearance issues. The Milwaukee brace is most effective in a skeletally immature patient with a flexible kyphosis greater than 55 to 60 degrees, who is highly motivated and has the appropriate body habitus. Patients with larger curves, patients with vertebral wedging greater than 10 degrees, and skeletally mature patients do not usually respond to bracing. An underarm TLSO is indicated when the apex of the curve is at or below T11, but in the senior author's experience (A.H.C.), relief of symptoms as opposed to correction is the main indication for a TLSO in these patients.

The use of the Milwaukee brace for the treatment of scoliosis was first reported by Blount and colleagues in 1958.[48] In 1959, Moe began treating Scheuermann kyphosis with the Milwaukee brace.[39] In 75 patients who completed treatment, the kyphosis improved by 40%, and the vertebral wedging improved by 42%. Bradford and colleagues[39] reported that factors that limited the amount of correction included kyphosis greater than 65 degrees, skeletal maturity, and vertebral wedging averaging more than 10 degrees. Sachs and colleagues[32] found that curves less than 74 degrees in skeletally immature patients can be successfully treated in a Milwaukee brace. They reported 120 patients with Scheuermann disease who were treated with the Milwaukee brace with more than 5 years of follow-up; 76 patients had improvement in kyphosis, 10 patients had no change in kyphosis, and 24 patients had worsening of deformity compared with initial studies.

One-third of patients with an initial kyphosis of 75 degrees or greater subsequently underwent surgery. Results showed that treatment with the Milwaukee brace consistently improved kyphosis by approximately 50% during the active phase of treatment, but some loss of correction occurred over time. The final result showed improvement in 69% of patients.

Gutowski and Renshaw[49] reported 75 patients treated with either a Milwaukee or Boston brace. For compliant patients, the average improvement in kyphosis was 27% in the Boston orthosis group and 35% in the Milwaukee orthosis group, despite the fact that patients in the former group were younger and had smaller, more flexible curves. Compliance with orthosis wearing was twice as likely with the Boston orthosis (61% compliance vs 29% compliance for the Milwaukee orthosis). Results in patients who wore their orthoses at least 16 hours per day were equal to results in patients with 23 hours of daily wear. The Boston brace provided satisfactory correction in curves less than 70 degrees and had better compliance. For larger curves, a Milwaukee brace was recommended.

Ponte and colleagues[37] reported on 1043 patients treated with casts for 8 to 16 months, followed by a Milwaukee brace and physical therapy until skeletal maturity. Patients had a mean initial curve of 57 degrees and at 3-year follow-up had a mean 62% wedge improvement and 40% curve correction.

Before considering brace treatment, a hyperextension cross-table lateral radiograph over a bolster (patient supine with the bolster at the apex of the deformity) is helpful to assess the potential efficacy of a brace. If the deformity is flexible, a brace may help. If the deformity is totally rigid, a brace is unlikely to be helpful, and casting may be better. A lateral radiograph in the brace should show correction of the kyphosis to within the normal range (<45 degrees).

If bracing is chosen, physical therapy should be initiated for trunk stabilization and postural exercises and to stretch the pectoral and hamstring muscles. The brace should be worn for 23 hours a day. To get a meaningful correction with brace treatment in Scheuermann disease, correction of the vertebral wedging deformity by bone remodeling is necessary. In contrast to scoliosis, in which bracing does not correct the curve, bracing in Scheuermann disease may help achieve some curve correction. After 12 to 18 months of bracing, partial reversal of anterior wedging of vertebral bodies is often noted.[10] Loss of correction can occur, however, after discontinuation of the brace. Montgomery and Hall[24] reported an average loss of correction of 15 degrees in 21 patients 18 months or more after they stopped wearing the brace. Brace treatment initially leads to some correction by opening the disc spaces, which close down again unless sufficient time is allowed to reverse the wedging of the vertebral bodies.

We consider a brace for curves of 55 to 70 degrees in skeletally immature patients (Risser 0 to 2) with the proper body habitus and motivation to wear a Milwaukee brace. A preliminary hyperextension plaster cast can be used to improve flexibility before application of a Milwaukee brace. We generally consider a brace or cast only if the deformity is flexible enough to allow at least 40% correction. In a skeletally immature patient with flexible deformities, we have developed the "four 6's" program, consisting of a hyperextension Risser cast for 6 weeks, Milwaukee brace for 6 months, weaning out of the brace for 6 weeks, and only sleeping in the brace for 6 months. This contract with teenage patients has resulted in improved compliance and satisfactory outcomes.

During bracing, follow-up radiographs are taken at 4- to 6-month intervals, and patients are followed to skeletal maturity. Patients and parents should expect a gradual loss of correction after the brace is discontinued.

Indications for Surgery

Surgical indications for patients with Scheuermann kyphosis are controversial because the true natural history of the disease with regard to curve progression has not been defined. Controversial issues are the importance of cosmesis, degree of pain and disability that warrants surgical intervention, and various opinions on the natural history of curves 65 to 80 degrees. These factors must be weighed against the risks of surgical intervention. Treatment decisions should be individualized after a thorough discussion with the patient and parents.

Despite controversy, generally accepted surgical indications include a progressive thoracic kyphosis greater than 75 to 80 degrees in a skeletally immature patient or severe thoracic hyperkyphosis associated with pain; thoracolumbar kyphosis exceeding 50 to 55 degrees that is associated with pain unresponsive to conservative treatment; progression of deformity despite bracing; and cosmetic deformity that the surgeon, patient, and family consider significant and unacceptable. Other factors to consider are patient age, location of the kyphosis, and extent to which the kyphosis is sharp and angular. If the apex is at the thoracolumbar junction, the deformity typically appears more significant clinically and is more likely to be disabling into adulthood because of the inability of the lumbar spine to compensate for the deformity. If the deformity is very sharp and angular, more consideration should be given to surgical treatment. Generally, pulmonary or neurologic compromise does not occur until the curve is greater than 100 degrees, and these are rarely indications for surgery.

Neurologic compromise is an indication for surgery, but it rarely occurs in Scheuermann disease. Cord compression may be due to disc herniation at the apex, severe kyphosis, and extradural cysts.[34] Similarly, pulmonary compromise is rare and does not occur until the curve is greater than 100 degrees.[7,18,41,44]

Surgical Treatment

The surgical options for Scheuermann disease include posterior-only correction and fusion, combined anterior and posterior fusion, and anterior-only procedures. Historically, the surgical treatment of Scheuermann disease consisted of apical anterior release and fusion followed by posterior fusion. This approach originated from work by Bradford and colleagues[50] in 1975, in which they found an unacceptably high rate of correction loss after posterior-only fusion with Harrington compression instrumentation. These investigators reported a 9% pseudarthrosis rate and 23% risk of instrumentation complications. In 1980, work from the same institution

showed solid fusion and good maintenance of correction with anterior release and fusion followed by posterior compression instrumentation in 24 patients.[40]

The efficacy of combined anterior release and posterior fusion is well documented in the literature.[40,51–53] Anterior release traditionally has been recommended for patients with severe, rigid deformities that do not correct to less than 50 degrees on a hyperextension lateral radiograph. With the use of modern pedicle screw instrumentation and posterior osteotomies, the indications for performing an anterior release are less common, however, and even severe deformities are being successfully treated with a posterior-only approach.

The anterior release can be performed through an open thoracotomy or thoracoabdominal approach depending on the location of the apex of the deformity, or can be performed through a video-assisted thoracoscopic surgery (VATS) approach.[54,55] The senior author has achieved excellent results with simultaneous video-assisted thoracoscopic release and posterior fusion and instrumentation in the prone position (Figs. 30.3 and 30.4). The levels requiring anterior release typically include six to eight segments centered around the apex of the deformity. In general, vertebrae that fail to correct over hyperextension bolster radiographs are indicated for anterior release. The anterior longitudinal ligament and entire disc are removed, and the space is packed with fibular structural allograft bone. In very severe deformities, an intervening period of halofemoral traction may be considered between the anterior and posterior procedures.

Anterior release and fusion ensures that correction is reliably achieved and solid fusion is obtained. There is, however, the obvious morbidity of the additional operating time and reported complications, including hemothorax, pneumothorax, and pulmonary embolism.[7,51,56] There may be potential negative effects on pulmonary function, which may not return to baseline even at 2 years postoperatively.[57–59] Although anterior surgery has benefits in achieving correction of severe deformities, the additional surgery is not without consequence.

Over the last 3 decades, several studies have shown good results with posterior-only fusion and instrumentation with various constructs.[38,56,60–63] Speck and Chopin[38] found posterior-only fusion to be adequate in skeletally immature patients, but that combined anterior and posterior surgery is needed for skeletally mature patients.

In 1984, Ponte and colleagues[64] described shortening of the posterior column by employing multiple osteotomies and posterior compression instrumentation and fusion. The Ponte osteotomy (PO) is similar to the Smith-Petersen osteotomy except that it is performed at multiple levels in the thoracic spine (Figs. 30.5 and 30.6). Smith-Petersen's original osteotomy was in the lumbar spine, at one level, in patients with rheumatoid arthritis.[65] After Ponte's description in 1984,[64] this procedure did not gain popularity for many years, especially among North American surgeons, until pedicle screw instrumentation became popular in the thoracic spine. As pedicle screws became more widely used and the ability to obtain strong, three-column fixation in the spine became possible, several studies have documented successful results with posterior-only treatment of more severe deformities.[66–68]

The PO opens the anterior column (disc space), hinges on the middle column, and closes the posterior column by the amount that is removed posteriorly. Essentially, it is necessary to have a potentially open disc space to achieve correction

FIG. 30.3 A 17-year-old male underwent simultaneous prone video-assisted thoracoscopic surgery release and posterior spinal fusion with excellent correction of kyphosis. (A) Intraoperative image showing FlexiPort on patient's right side adjacent to midline surgical wound. The monitor at the top shows thoracic anatomy. (B) Preoperative and (C) postoperative lateral standing radiographs.

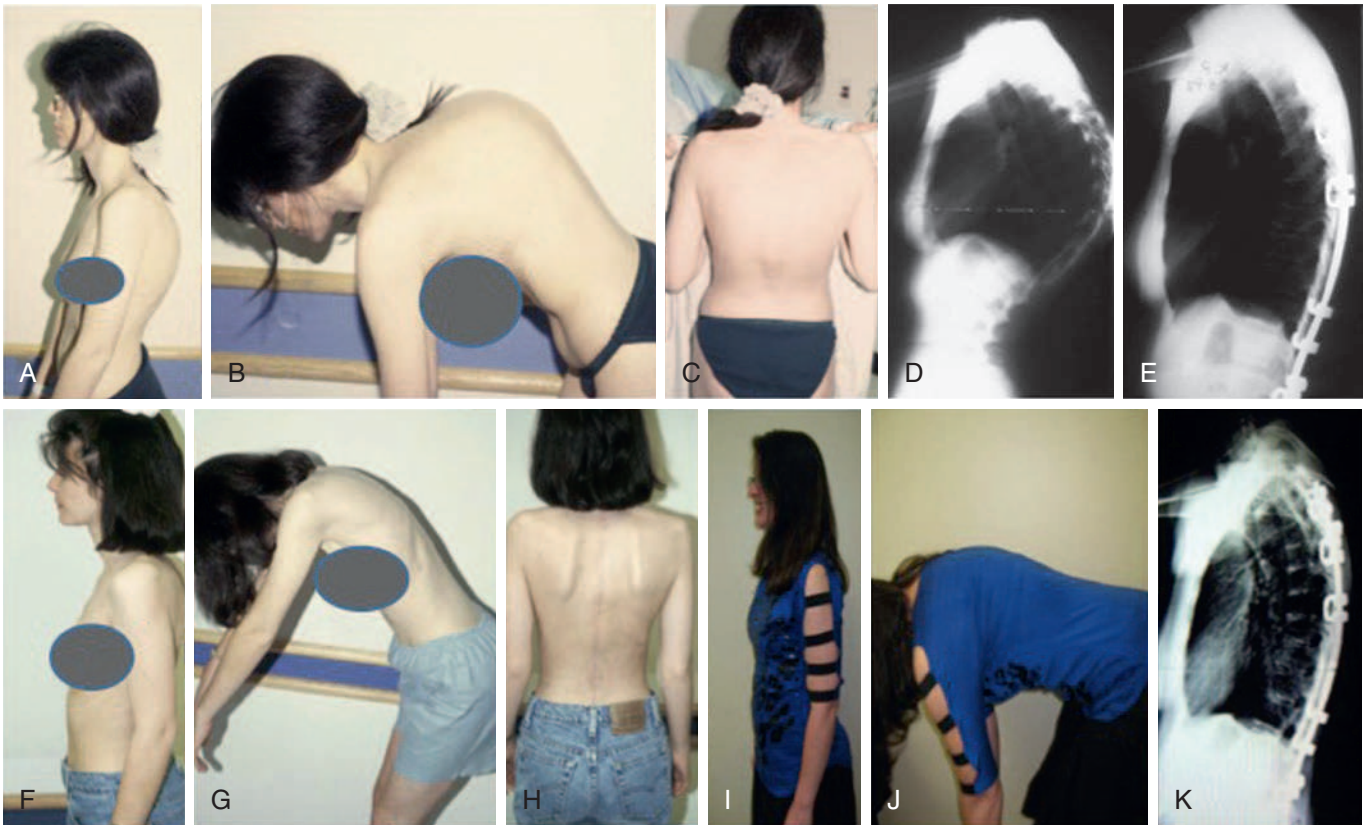

FIG. 30.4 (A–C) Preoperative clinical images of a 14-year-old female with Scheuermann kyphosis. (D) Preoperative standing lateral radiograph showing typical Scheuermann kyphosis. (E) One year postoperative standing lateral radiograph following video-assisted thoracoscopic surgery (VATS) along with posterior spinal fusion with instrumentation. (F–H) One year postoperative clinical pictures. (I–J) Twenty years postoperative clinical pictures. (K) Twenty years postoperative standing lateral radiograph illustrating fusion at the intervertebral disc spaces that were filled with allograft through VATS.

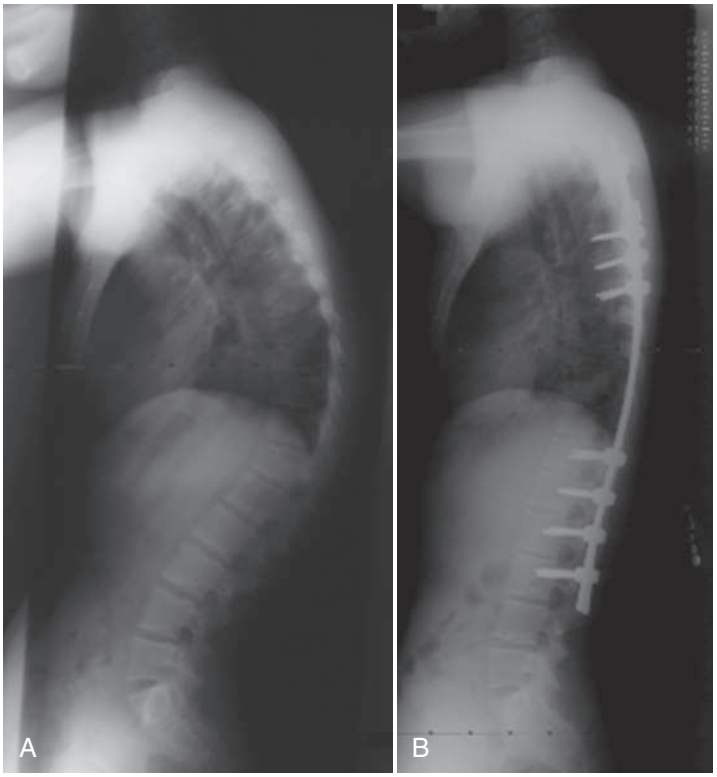

FIG. 30.5 A 15-year-old male with Scheuermann kyphosis, significant midback pain, and progression underwent posterior-only correction with multilevel Ponte osteotomies and pedicle screw instrumentation. (A) Preoperative and (B) postoperative standing lateral radiographs.

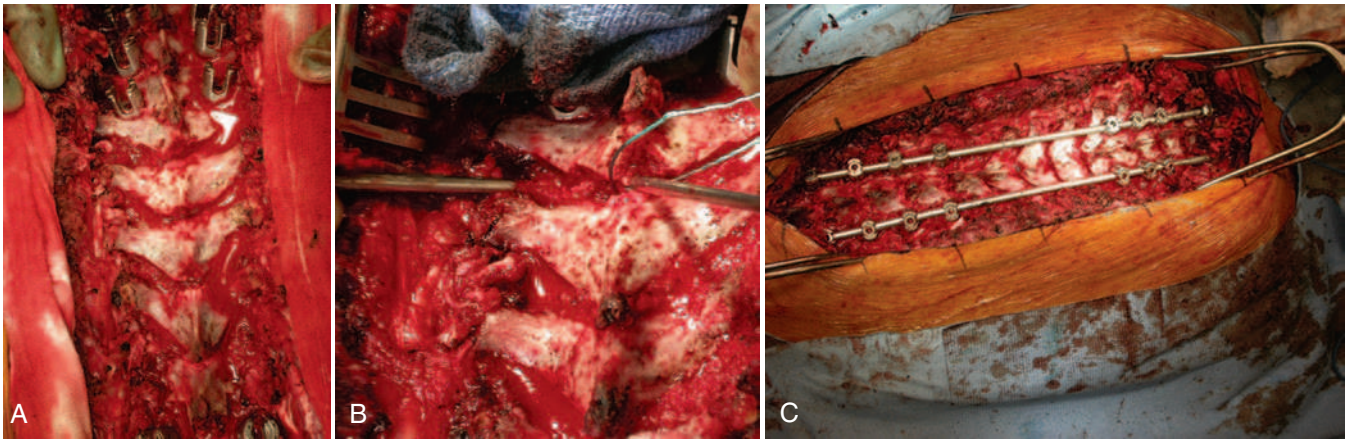

FIG. 30.6 Multiple Ponte osteotomies performed at the apex of the curve on the patient shown in Fig. 30.5. (A) Exposure of facet joints. (B) Excision of entire facet joint (inferior as well as superior articular process) and identification of nerve roots, as pointed out with a blunt instrument. (C) Intraoperative image after instrumentation.

with a PO. Critical review of radiographs of Scheuermann kyphosis patients will show that even discs at the apex of the curve or compromised in height have potential to open with a PO. The anterior longitudinal ligament in an unfused spine is not violated in common execution of a PO. This also reduces the risk of neurologic or anterior spinal vascular injury. Each segment undergoing PO can contribute between 5 and 15 degrees of correction. Multilevel PO is considered an ideal procedure for correcting Scheuermann kyphosis. However, there is no consensus regarding the number of levels or exact location where PO should ideally be performed. For example, Geck et al. reported performing osteotomies at each level of the intended instrumentation and fusion.[67] However, given that each level of PO contributes between 5 and 15 degrees of correction, we do not believe that PO is necessary at each level undergoing fusion. We routinely perform three to five levels of PO at the apex of the deformity, but this varies depending on the rigidity of the deformity and the angle of kyphosis. Emphasis should be given to performing a true PO in which the entire facet joint, including the superior articular process of the inferior vertebra, is completely removed and one can clearly visualize the underlying nerve roots on both sides. In addition to improving the degree of correction, removal of the superior articular process helps to avoid any impingement on the nerve roots during closure of the osteotomy. Care should also be taken to get a symmetrical opening at the osteotomy level on both sides to avoid any postoperative coronal plane deformity.

Lee and colleagues[68] compared posterior-only fusion (18 patients) with combined anterior-posterior fusion (21 patients) and found better correction and fewer complications in the posterior-only group at a mean 2-year follow-up. The anterior-posterior group did not have Ponte osteotomies, and hybrid hook and screw constructs were used, whereas the posterior-only group had Ponte osteotomies (in 67%) and had all-pedicle-screw constructs.

Geck and colleagues[67] obtained good correction in 17 patients, employing multiple osteotomies and pedicle screw fixation, averaging 9.3 degrees of correction per osteotomy across the apex. There is growing evidence that anterior release may be unnecessary to obtain satisfactory correction of even severe deformities if multilevel segmental osteotomies are performed in conjunction with pedicle screw fixation.[67–69] Hosman and colleagues[69] suggested that posterior-only correction is often adequate for correcting up to a 100-degree kyphosis to a physiologic range of 40 to 50 degrees without an anterior release.

In general, most patients with Scheuermann kyphosis can be managed by posterior fusion and instrumentation alone. A combined anterior-posterior procedure also has a longstanding successful track record. For very severe deformities (>100 degrees) that are rigid, an anterior release performed through an open or thoracoscopic approach is preferred to obtain some flexibility of the spine.

An alternative approach in the most severe and rigid deformities is either the eggshell decancellation procedure, also called vertebral column decancellation (VCD; Figs. 30.7 and 30.8) and/or vertebral column resection (VCR; Figs. 30.9 and 30.10) at the apical kyphotic segments.[70–72] VCD and VCR procedures are described later in this chapter. Instrumentation options include all pedicle screws or a hybrid construct of hooks and pedicle screws, depending on the preference of the surgeon. Successful results have been obtained regardless of the type of instrumentation. Behrbalk et al. found no differences in the efficiency in low- or high-density pedicle screw constructs.[73] We prefer to use pedicle screws bilaterally at most levels above and below the apex with correction achieved by cantilever forces and by compression. Shortening the posterior column is an important component of surgical treatment. Prebending the rods depending on the apical angle seen on hyperextension bolster films serves as a rough guideline on how much correction should be targeted.

Surgical Principles

Degree of Deformity Correction

Surgical treatment of Scheuermann kyphosis should aim to correct the thoracic kyphosis to the high-normal range of thoracic kyphosis (40–50 degrees). Overcorrection of a kyphotic deformity can lead to neurologic complications, postoperative sagittal malalignment, and proximal junctional kyphosis. The

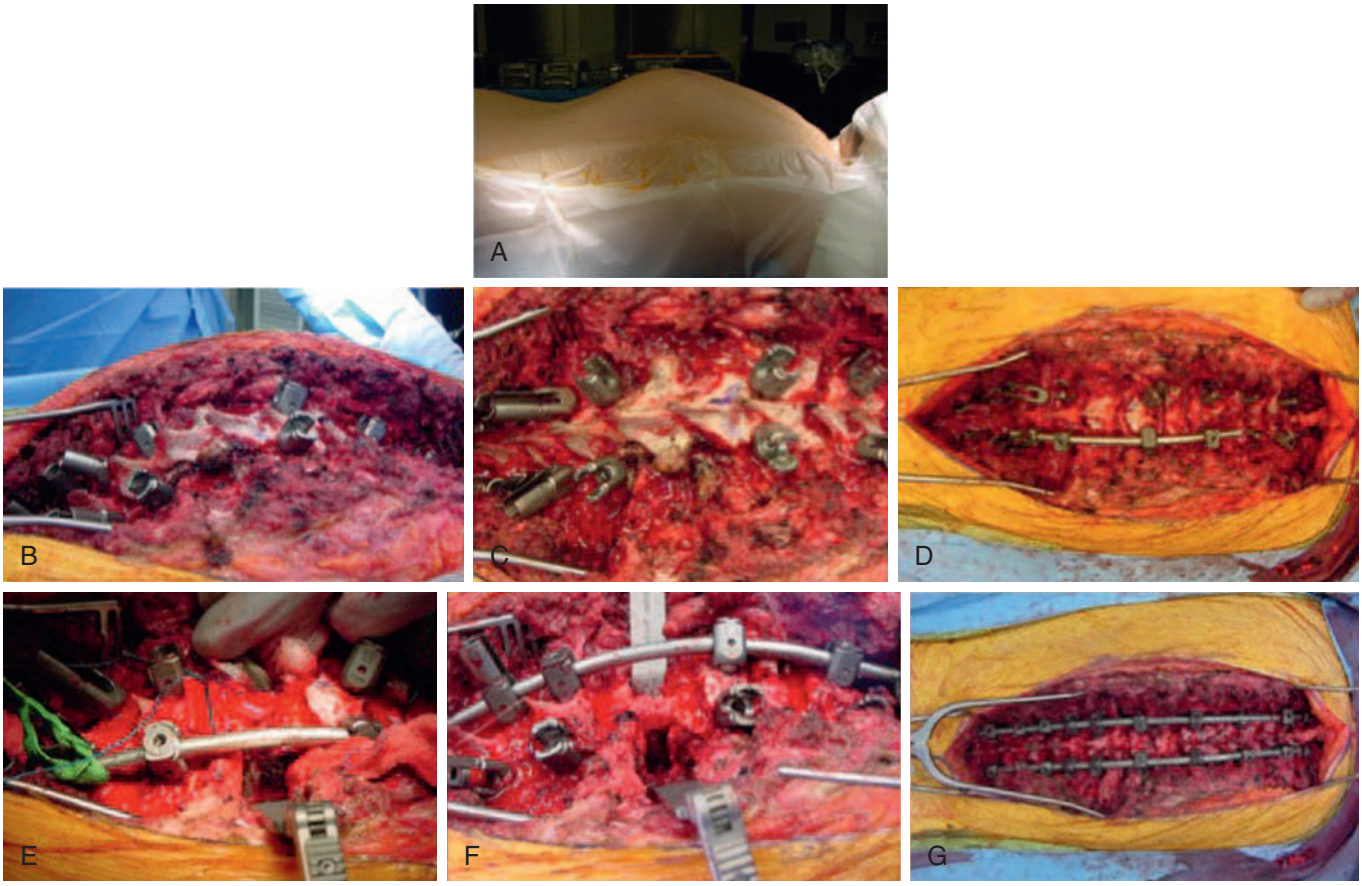

FIG. 30.7 (A) Cross-table lateral prone clinical image illustrating clinical kyphosis in a 16-year-old male. (B–C) Screw placed in apical vertebrae; note reduction screws in lumbar vertebrae and multiaxial in thoracic levels. (D) Single rod placed on one side to allow bony work from the other side. (G) Intraoperative image after instrumentation.

last condition may occur as a result of forces being transferred to the proximal junction after an aggressive corrective maneuver.[10,52,69] Lowe and Kasten[26] recommended that no more than 50% of the preoperative kyphosis be corrected and that the final kyphosis should never be less than 40 degrees. These authors also found that the negative sagittal balance is worsened postoperatively, which may predispose patients to junctional kyphosis.[26]

Selection of Fusion Levels

Proper selection of fusion levels is crucial to avoid complications related to junctional decompensation. The proximal extent of the fusion should be the proximal end vertebra in the measured kyphotic deformity.[7,26,56,74] There has been considerable debate regarding the optimal distal extent of the fusion. Traditionally, it has been suggested to extend the distal fusion level to the first lordotic disc beyond the end vertebra to minimize risk of junctional kyphosis.[26,61] Some authors have advocated inclusion of L1[20] or the inferior neutral vertebra, whereas others have advocated including L2 in the fusion. Poolman and colleagues[75] advocated the inclusion of the second lordotic disc below the kyphotic deformity. More recently, Cho and colleagues[76] emphasized the importance of the sagittal stable vertebra, defined as the most proximal vertebra touched by the posterior sacral vertical line. The posterior sacral vertical line is a line drawn vertically from the posterior-superior corner of the sacrum on the lateral upright radiograph. Cho and colleagues[76] found that distal junctional problems were more common when the fusion level was to the first lordotic vertebra rather than down to the sagittal stable vertebra. They recommended extending the distal end of the fusion to the vertebra that touches the posterior sacral vertical line. There is growing evidence to include sagittal stable vertebra in distal fusion to achieve a stable sagittal balance and prevent the distal junctional kyphosis.[77,78]

Spinopelvic Alignment

In the last decade, attention has been directed at the overall alignment of the spine in relation to the pelvis and lower extremities. For the assessment and reconstruction of global spinal alignment, several spinal and pelvic parameters can be measured on the lateral radiograph obtained in the standing position with the knees fully extended. Three commonly used pelvic parameters are pelvic tilt (PT), sacral slope, and pelvic incidence. PT is defined as an angle between the vertical line and a line through the midpoint of the sacral endplate to femoral head axis. PT is a major compensatory mechanism. When there is sagittal imbalance, pelvic retroversion is a

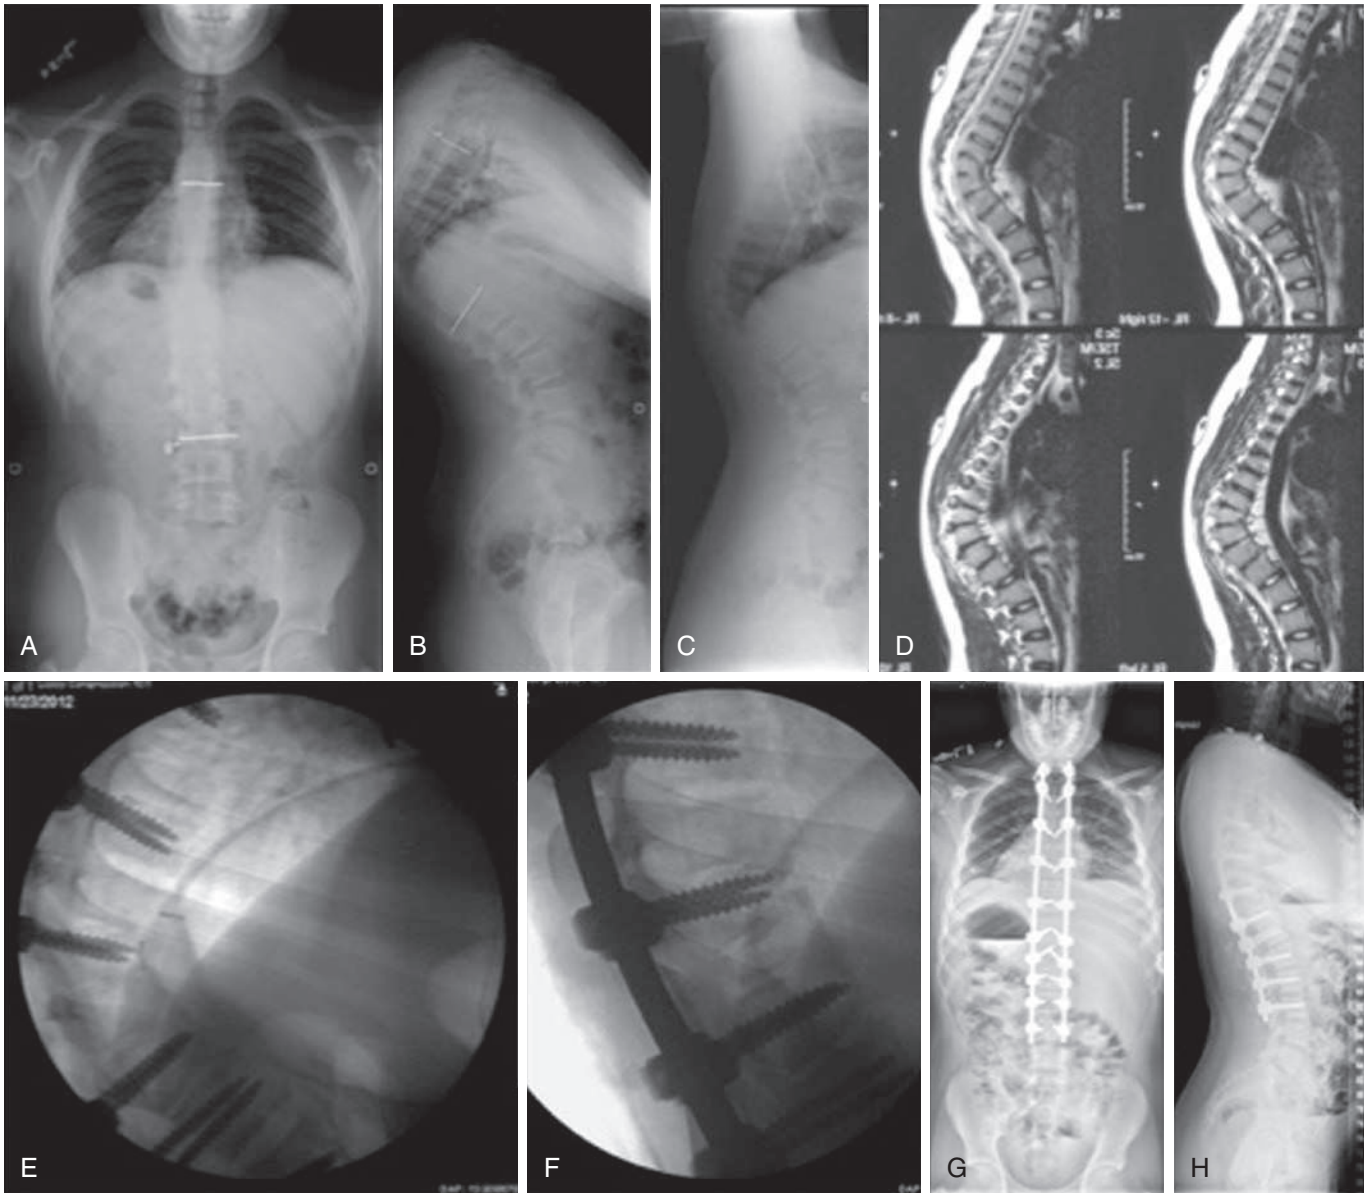

FIG. 30.8 (A) Standing posteroanterior radiograph of a 16-year-old male whose intraoperative images are shown in Fig. 30.7. (B) Standing lateral radiograph showing significant kyphosis. (C) Cross-table hyperextension lateral radiograph; note very little correction at the midapical region. (D) Sagittal magnetic resonance image showing bridging across the intervertebral spaces at the midapical region. (E) Intraoperative C-arm images showing lateral view following screw placement prior to the curve correction. compensatory mechanism to improve sagittal balance. PT measures the degree of pelvic retroversion. Sacral slope (SS) is defined as the angle between the horizontal and sacral endplate. Pelvic incidence (PI) is defined as the angle between the line connecting the center of the femoral head axis to the center of the S1 endplate and the line perpendicular to the S1 endplate. PI is a stable anatomic parameter that is unique to each individual once maturity is achieved; it is constant and does not change with the position of the pelvis.

PI in patients with Scheuermann disease is lower than that reported for healthy adults and adolescents, and is not significantly different from PI reported for healthy children. Further, PI of patients with atypical Scheuermann disease is lower than PI of typical Scheuermann disease patients.[79] However, at this point, literature does not authenticate whether impaired spinopelvic parameters are the cause or result of Scheuermann disease. Nevertheless, in general, PI is the sum of PT and SS (PI = PT + SS).

Faldini et al. studied Scheuermann kyphosis patients who underwent posterior spinal fusion with PO and found that posterior spinal fusion for Scheuermann kyphosis significantly improved thoracic kyphosis and lumbar lordosis but did not affect the pelvic parameters.[80] In essence, while trying to achieve Scheuermann kyphosis correction, care should be taken to match the lumbar lordosis correction. As PI is constant for an individual and not going to change after surgery,

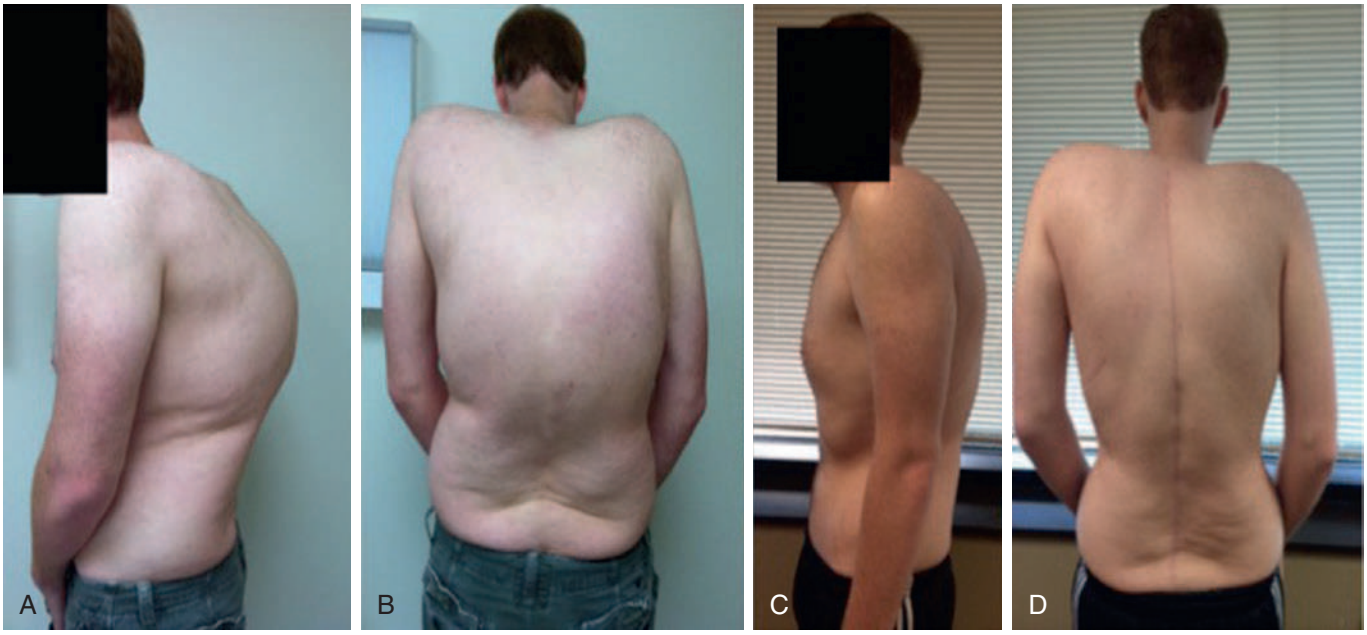

FIG. 30.9 (A–B) Preoperative clinical sagittal and coronal images of a 26-year-old male with significant Scheuermann kyphosis. (C–D) Postoperative clinical images showing curve correction.

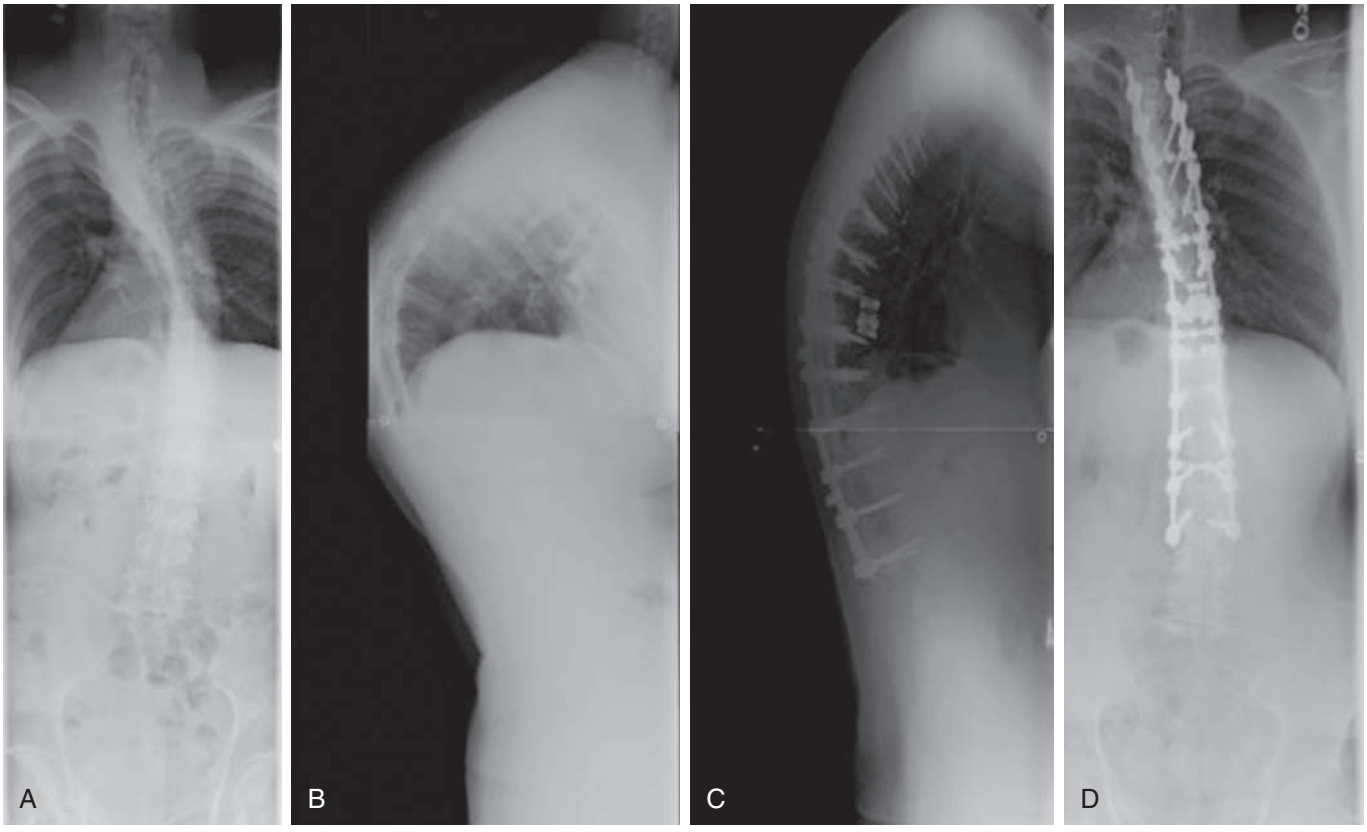

FIG. 30.10 (A–B) Standing posteroanterior and lateral radiographs of the patient shown in Fig. 30.9 illustrating more than 100-degree Scheuermann kyphosis. any mismatch obtained by overcorrecting one over the other will lead to poor sagittal balance. Any suboptimal results will require compensatory actions from adjacent levels, leading to junctional problems or compensation by flexing hips or knees, which will lead to fatigue and discomfort.

Complications

The most worrisome complication of surgical treatment of Scheuermann disease is neurologic deficit. The 1999 Morbidity and Mortality Report of the Scoliosis Research Society reported the risk of neurologic injury during surgery for

Scheuermann disease to be 1 per 700 cases. Surgical treatment of kyphotic deformities is associated with a higher incidence of neurologic complications than treatment of coronal deformities because the spinal cord is lengthened anteriorly after correction, which may compromise its anterior vascular supply.[81]

Neurologic complications during deformity surgery can be caused by direct trauma to the neural elements (during instrumentation or osteotomies); stretch injury to the spinal cord during corrective maneuvers; or a vascular insult to the spinal cord, whether secondary to stretch or disruption of vascular supply or secondary to hypotension.[82–84] A preexisting spinal canal stenosis may increase the risk of neurologic injury during correction,[33] and although controversial, we believe that preoperative MRI should be obtained to rule out any compressive lesions. Overcorrection of a kyphotic deformity is hazardous to the neural elements because the spinal cord is lengthened; no more than a 50% correction (from preoperative kyphosis) should be attempted.

Distraction has been shown to induce spinal cord injury in feline studies by a reduction in cord perfusion.[85,86] Cantilever forces used during corrective maneuvers increase the length of the anterior column, which may have the same effect as distraction. Caution should be taken during correction, which should ideally be a gentle combination of cantilever forces and compressive forces to shorten the posterior column. We find the use of reduction pedicle screws at lumbar levels to be helpful in the correction maneuver.

Intraoperative neuromonitoring is an essential component of the surgery to lower the neurologic risks and safely execute the correction maneuver. Multimodality spinal cord monitoring with some type of motor tract assessment usually creates a safer, optimal intraoperative environment. Cheh et al. found a 35.7% true-positive rate of loss of intraoperative neurogenic mixed-evoked potential (NMEP) data sometime during the Scheuermann kyphosis correction surgery while concomitant somatosensory sensory-evoked potential (SSEP) remained within acceptable limits of baseline values.[81] Most of the cases showed loss of signals during the closure of the osteotomies. All patients had an intervention performed in the form of release of correction and/or blood pressure elevation. NMEP data returned following intervention ranging from 8 to 20 minutes. Normal intraoperative (Stagnara wake-up test) and postoperative neurologic examination results were reported.[81]

Junctional Kyphosis

Proximal junctional kyphosis (PJK) is defined as kyphosis measured from one segment cephalad to the upper end instrumented vertebra to the proximal instrumented vertebra, with an abnormal value defined as 10 degrees or greater (Fig. 30.11).[87] Similarly, distal junctional kyphosis (DJK) is defined as kyphosis measured from one segment caudal to the end instrumented vertebra to the distal instrumented vertebra, with abnormal value again being 10 degrees or more of kyphosis (Fig. 30.12).[87] In a retrospective multicenter review of 78 patients with Scheuermann kyphosis treated surgically, there was a 32% incidence of PJK and 5% incidence of DJK.[87] The investigators found that PJK was related to stopping the fusion caudal to the proximal end vertebra and is influenced by PI. DJK was always associated with fusion cephalad to the sagittal stable vertebra. Despite the high rate of PJK, the problem was clinically problematic or required reoperation in only 5.1% of cases.

Lowe and Kasten[26] reported a radiographic rate of PJK of 30%, ranging from 12 to 49 degrees and of DJK of 28%, ranging from 10 to 30 degrees. In their study, PJK was related to greater than 50% correction of the curve magnitude in 5 of 10 patients who developed PJK. PJK was also related to fusing short of (caudal to) the proximal Cobb end vertebrae by one or two levels. These authors recommended correcting kyphosis to no less than 40 degrees. Lonner et al. compared the combined anterior-posterior and posterior-only approaches

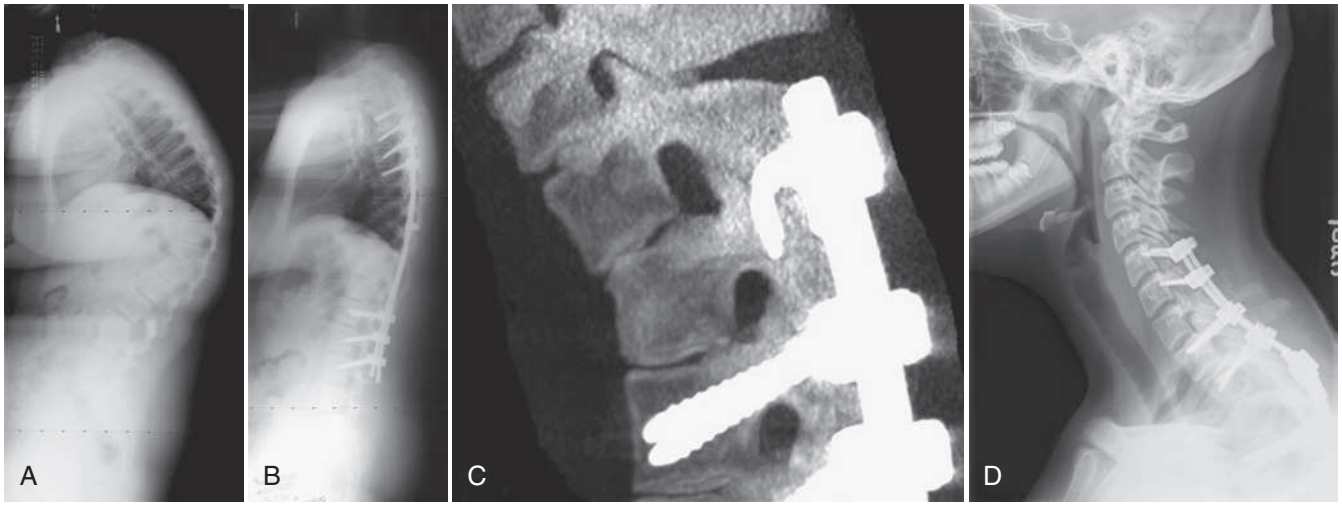

FIG. 30.11 An 18-year-old female noticed prominence of her neck 1 year postoperatively. She had developed proximal junctional kyphosis, which was revised with extension of fusion to the cervical spine. (A) Preoperative lateral standing radiograph. and found no difference in the development of symptomatic PJK between the groups.[87]

Recent biomechanical studies showed that using transverse process hooks at the upper instrumented fusion level instead of pedicle screws provides a gradual transition from a rigid pedicle screw construct to the mobile normal adjacent spine.[88,89] Similarly, a finite element model study suggested that the use of a transition rod of lesser diameter at the proximal end of a long posterior spinal fusion construct minimizes the adjacent level abnormal pathomechanics, therefore possibly avoiding the development of PJK.[90]

To prevent PJK, we take the following precautions. (1) Always involve proximal end vertebra in fusion. Preoperative radiographic conditions when a proximal end vertebra is not clearly visualized, "best fit line" as was proposed by Denis et al.,[91] is recommended. (2) Preserve the interspinous and supraspinous ligament complex at the proximal two levels of the fusion that works as a tension band to minimize PJK. (3) We prefer to place transverse process hooks one level above the end instrumented vertebra for the gradual transition of forces to the adjacent level. In addition, the use of transverse process hooks requires less soft tissue dissection and produces less damage to the adjacent facet joint compared with pedicle screw insertion. (4) Aim to bring the curve correction into the upper normal physiologic range without overcorrecting the deformity. Do not do overcorrection.

Although earlier studies reported a high incidence of pseudarthrosis with a posterior-only procedure,[40,50] the use of modern instrumentation and techniques has resulted in a low rate of pseudarthrosis in adolescents. The tensile forces applied to a kyphotic deformity likely increase the incidence of pseudarthrosis in patients with Scheuermann disease as opposed to patients with idiopathic scoliosis, but this is unproven. Thorough preparation of the fusion bed with decortication and use of allograft bone is recommended. We do not use iliac crest autograft, but it is a viable option if other risk factors for pseudarthrosis exist.

Other reported complications include pulmonary embolus, pleural effusion, persistent back pain, instrumentation failure, and superior mesenteric artery syndrome.[9,26,50,53] Daniels and colleagues[92] reported a case of acute celiac artery occlusion resulting in necrosis of the stomach after combined anterior and posterior fusion with 50% correction of the curve.

Congenital Deformity

The first description of congenital kyphosis in the English language was by Greig[93] in 1916, who reported a 2-year-old child with a posterior hemivertebra. In 1932, Van Schrick[94] differentiated failure of vertebral body formation versus failure of segmentation as the cause of congenital kyphosis in four patients.

By definition, a vertebral anomaly is present at birth, but the clinical deformity may not manifest until much later. Congenital kyphosis develops prenatally as a result of growth deficits of the centrum occurring during the late stages of chondrification and ossification, leading to hypoplasia or aplasia of the vertebral body.[95,96] The defect is thought to be due to inadequate vascularization of the vertebral body during fetal development. Most vertebral malformations occur between days 20 and 30 of fetal development.[97]

Congenital kyphosis is less common than congenital scoliosis, but it is associated with a higher risk of neurologic compromise and progression of deformity if untreated.[98] Congenital kyphosis and kyphoscoliosis are not separate entities, but rather a spectrum of spinal deformities caused by vertebral anomalies. If one side of the vertebra is involved more than

the other, concomitant scoliosis may develop. In most cases, the deformity involves the coronal plane to some extent.

Classification

Van Schrick[94] was the first to classify this condition into failure of vertebral body formation and failure of segmentation. Winter and colleagues[99] described three types in 1973 based on their classic review of 130 patients with kyphotic deformity of the spine owing to congenital vertebral anomalies. They classified the deformities as type I, congenital failure of vertebral body formation; type II, congenital failure of vertebral body segmentation; and type III, mixed failure of formation and segmentation. Type I was the most common, predominantly in the thoracolumbar region, followed by the upper thoracic region, and the least frequent in the lumbar spine. Failure of segmentation was symmetrical and produced pure kyphosis. Failure of vertebral body formation was often asymmetrical, producing scoliosis and kyphosis. In the series by McMaster and Singh,[100] 65% of patients had anterior failure of vertebral body formation, 20% had segmentation defects, 10% had mixed anomalies, and 5% could not be classified (Fig. 30.13).

Type I deformity is due to partial failure of vascularization of the cartilaginous centrum of the vertebral body.[100] These deformities are the most common type. The absence of two growth plates anteriorly with continued growth of posterior elements results in a sharp angular kyphosis and can lead to spinal cord compression. The prognosis is considerably worse than the unsegmented type (type II). The natural history involves relentless progression if untreated.

McMaster and Singh[100] further classified type I deformities into four patterns of malformations: posterolateral quadrant vertebra (35%), posterior hemivertebra (7%), butterfly vertebra (13%), and anterior wedged vertebrae (5%). If the failure of formation is purely anterior, a pure kyphosis results. More commonly, the defect is anterolateral with a posterior corner hemivertebra (posterolateral quadrant type), resulting in kyphoscoliosis. McMaster and Singh[100] noted that the posterolateral quadrant vertebra has the worst prognosis, progresses relentlessly, and has a high rate of spinal cord compression. This anomaly is due to a complete failure of formation of the anterolateral portion of the vertebral body, leaving a posterolateral fragment of bone of varying size attached to one pedicle and the neural arch.[100] Defects of formation are treated surgically because of the high risk of progression and potential neurologic complications if left untreated.

Dubousset[101] classified type I deformities into two types: a well-aligned spinal canal and a dislocated canal. Shapiro and Herring[102] and Zeller and colleagues[103] used the terms *congenital vertebral displacement* (Shapiro and Herring) and *congenital dislocated spine* (Zeller and colleagues) to describe deformities in which anterior and posterior elements were abnormal and there was posterior displacement of anomalous vertebrae. Zeller and colleagues[103] described the "step-off" sign as the loss of continuity of the posterior cortex of adjacent vertebral bodies as a half of a congenital dislocated spine.

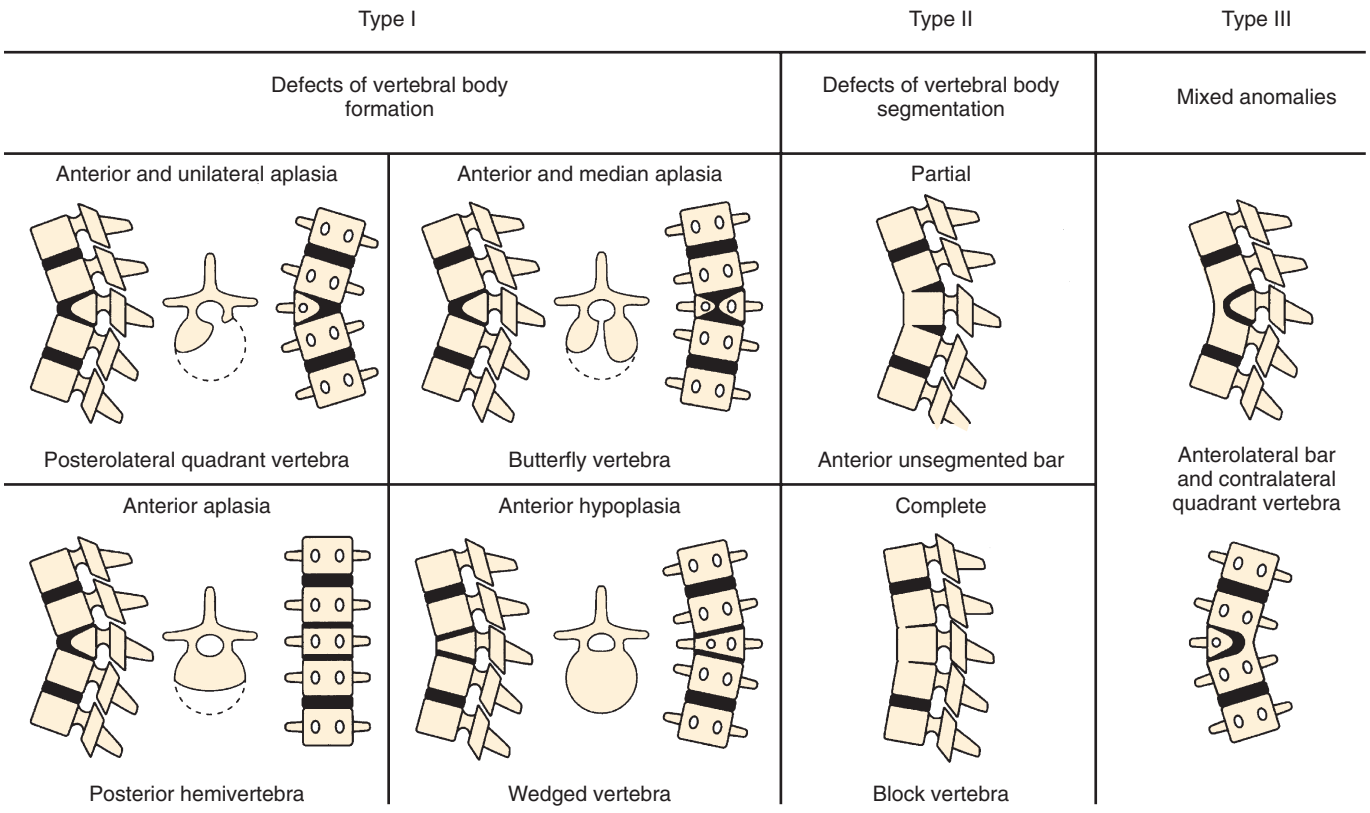

FIG. 30.13 Congenital kyphosis type I results from defects in vertebral body segmentation, and congenital kyphosis type III results from mixed anomalies. (From McMaster MJ, Singh H. Natural history of congenital kyphosis and kyphoscoliosis. *J Bone Joint Surg Am.* 1999;31:1369.)

Patients with type II deformity have a better prognosis in terms of rate of progression of deformity and neurologic complications. This deformity is secondary to bony metaplasia in the anterior portion of the anulus fibrosus, resulting in an anterior unsegmented bar.[100] There is no longitudinal growth, but posterior growth continues, resulting in a kyphotic deformity. The rate of progression is slow, and spinal cord compression does not occur.[100] McMaster and Singh[100] subdivided defects of vertebral body segmentation into partial (anterior unsegmented bar) or complete (block vertebrae) failure of segmentation.

Imaging Studies

In younger children, vertebral anomalies may be difficult to appreciate on plain films because of incomplete ossification. Computed tomography (CT) scans with three-dimensional reconstructions are useful for precisely defining the nature of the deformity. Flexion and extension lateral radiographs are useful to assess flexibility of the deformity. MRI is recommended preoperatively in all cases to rule out intraspinal anomalies, which can be present in 5% to 37% of patients with congenital kyphosis and scoliosis.[104,105] MRI is also useful in identifying cord compression or cord signal changes that may result from the angular kyphosis.

Clinical Evaluation

Numerous associated anomalies can accompany congenital spinal deformities, including renal and cardiopulmonary anomalies, chest deformities (pectus carinatum or excavatum), intraspinal anomalies (e.g., diastematomyelia, tethered cord, Arnold-Chiari malformation, syringomyelia). Proper workup of congenital deformities includes renal ultrasound, cardiac echocardiogram, and MRI of the brain and entire spine.

Progression can be insidious; thus, at each follow-up examination, the initial radiograph, previous radiograph, and present radiograph should be reviewed, using the same levels for comparison. Failure to recognize progression can lead to a severe deformity, requiring more extensive surgery with higher risks. During periods of rapid spinal growth (birth to 5 years and during the adolescent growth spurt), more frequent evaluation (every 6 months) is wise. During the "dormant" phase of growth (5 to 10 years), yearly evaluation is adequate. Even if the absolute magnitude of the kyphotic deformity is not increasing, its flexibility may worsen over time, which may be an indication for earlier surgery.

A complete neurologic examination is crucial. Before surgery, urodynamic testing should be considered in patients with large curves because it may detect subtle preexisting myelopathy in high-risk patients (especially young children).

Natural History

The natural history of congenital kyphosis depends on the type of deformity, age of the patient and amount of growth remaining, and location of the deformity. Winter and colleagues[99] found type I deformities to have the worst prognosis and to progress rapidly, followed by type III and type II. McMaster and Singh[100] found the most rapid progression to occur in type III deformities, followed by type I and II. The posterolateral quadrant vertebra has the worst prognosis.

Kyphosis resulting from defects of formation progresses an average of 7 degrees per year and is most rapid during the adolescent growth spurt.[99] Progression is most likely to occur during rapid periods of growth (birth to 3 years and adolescent growth spurt). Type II deformities progress an average of 5 degrees per year.[106] Progression rate is slower in type II deformities because bony bar formation of the anterior disc occurs later in childhood, and the growth discrepancy between the posterior and anterior elements is not as great as type I deformities.

Neurologic involvement and spinal cord compression occur primarily with anterior failure of vertebral body formation (type I or III) because of the acute angular kyphosis over a short segment. The rate of neurologic involvement has been estimated to be around 18%.[100] This rate would likely be much higher if all patients were untreated. Neurologic compromise is most common during the adolescent growth spurt, when progression is most rapid. The greatest risk of spinal cord compression occurs when the apex is at the midthoracic region (T4–T9) because this is a vascular watershed area. The onset of cord compression can occur at any age, but is most common during the adolescent growth spurt. All patients who develop neurologic deficit progress to paraplegia if left untreated.[100] Progressive neurologic deficit should be immediately treated surgically.

Type II deformities (failure of segmentation) produce a more rounded kyphosis compared with the angular gibbous deformity that occurs with failure of formation.[99,106] These deformities occur most often in the lower thoracic and thoracolumbar region. They are less likely to progress and rarely cause neurologic compromise because of the more gradual kyphosis that is spread out over several segments (as opposed to the sharp angular kyphosis of type I deformities).

Nonoperative Treatment

Nonoperative treatment in congenital kyphosis primarily consists of diligent observation to document progression of the deformity (Fig. 30.14). Bracing and casting are believed to be ineffective in congenital kyphosis.[99,107] Progression can be insidious, and radiographs may show small degrees of progression over months that may be deemed insignificant. However, over a 2- to 3-year time frame, the progression may be much more significant. At each follow-up evaluation, current radiographs should be compared with the initial radiographs to document progression more precisely. In all cases of congenital kyphoscoliosis, especially with type I deformities, it is crucial to obtain a posteroanterior radiograph and a lateral radiograph at each visit because the scoliosis may appear to be stable but the lateral view may show significant progression of the kyphosis owing to a hemivertebra. We refer to such a hemivertebra as a "snake in the grass" (Fig. 30.15).

The importance of observation was highlighted by a more recent report by Campos and colleagues,[108] who described

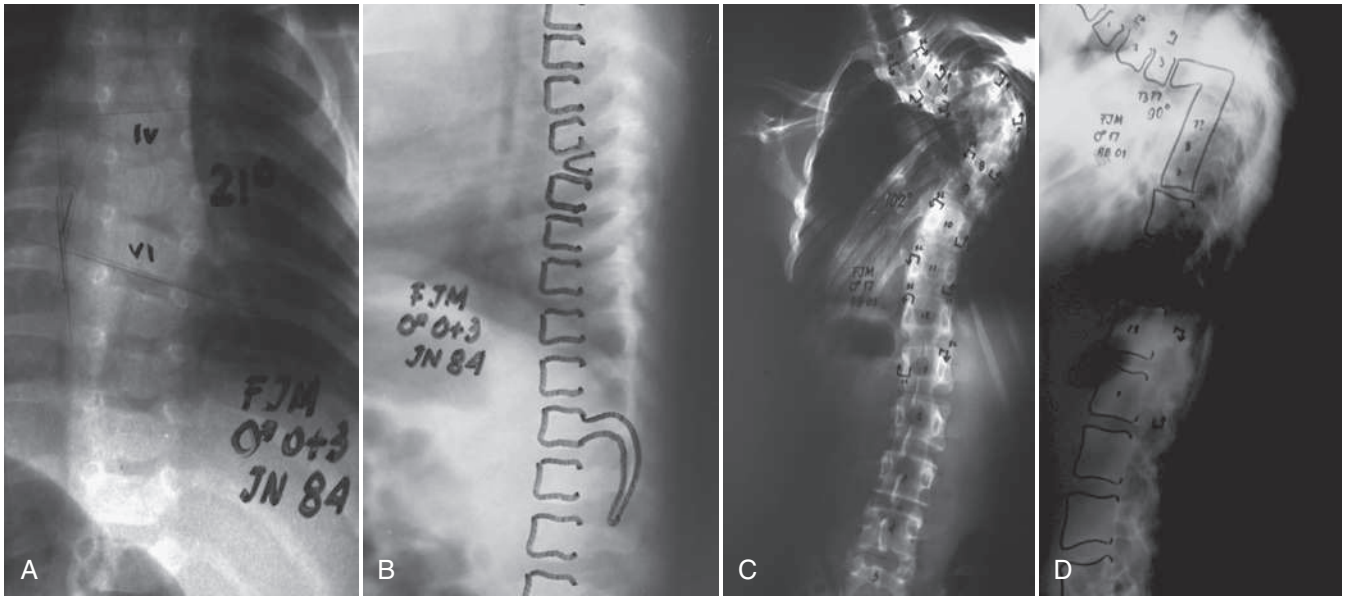

FIG. 30.14 T5 hemivertebra initially diagnosed at age 3 months. The patient was not followed up until age 17 years, when he became paraplegic and wheelchair dependent with severe spinal deformity. (A) Anteroposterior and (B) lateral radiographs of entire spine at 3 months of age. (C) Anteroposterior and (D) lateral radiographs of entire spine at 17 years of age. (Courtesy R. Maenza, MD, Italian Hospital, Buenos Aires, Argentina.)

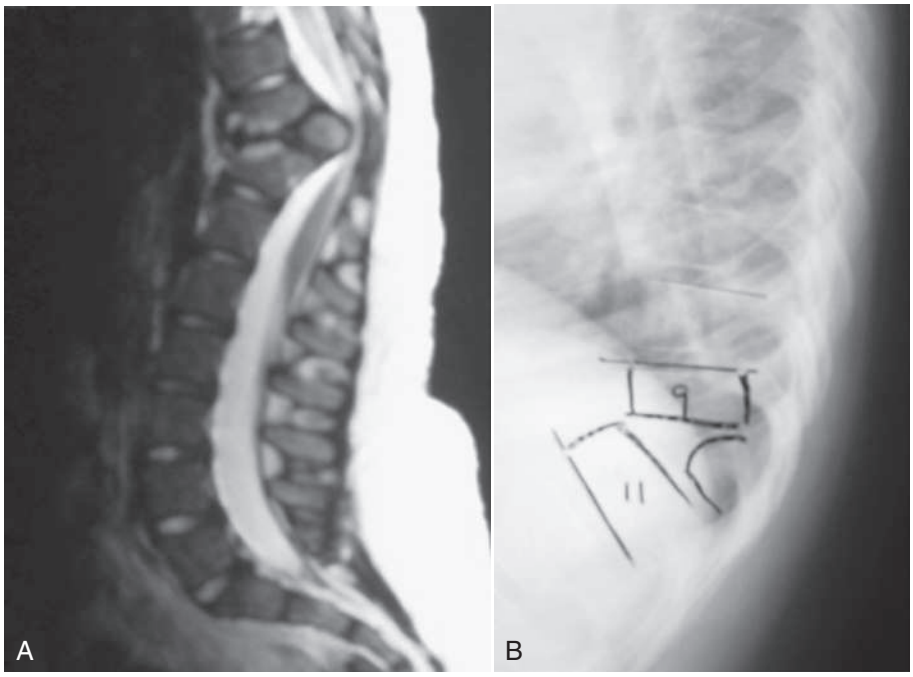

FIG. 30.15 Hemivertebra causing severe cord compression. This deformity is often not well appreciated on the posteroanterior view and can be missed if proper imaging is not performed. We refer to such a "hidden" anomaly on the posteroanterior view as a "snake in the grass." (A) Sagittal magnetic resonance cuts. (B) Lateral radiograph of spine.

seven patients with early thoracolumbar kyphosis associated with single lumbar vertebral hypoplasia, which appeared similar to a failure of formation (Fig. 30.16). All patients had spontaneous correction of alignment over time. In all seven patients, the anomaly was limited to one lumbar level (L1 or L2), and the defect was limited to the superior portion of the anterior half of the vertebral body without posterior malformations. The investigators recommended a brief period of observation to document progression versus spontaneous correction. If progression was documented or if the deformity persisted at age 3 years, further workup was recommended.

Surgical Treatment

The guiding principle of operative treatment of congenital kyphosis is early fusion to prevent severe deformity and to allow for some correction with growth.[98] If curves with a bad

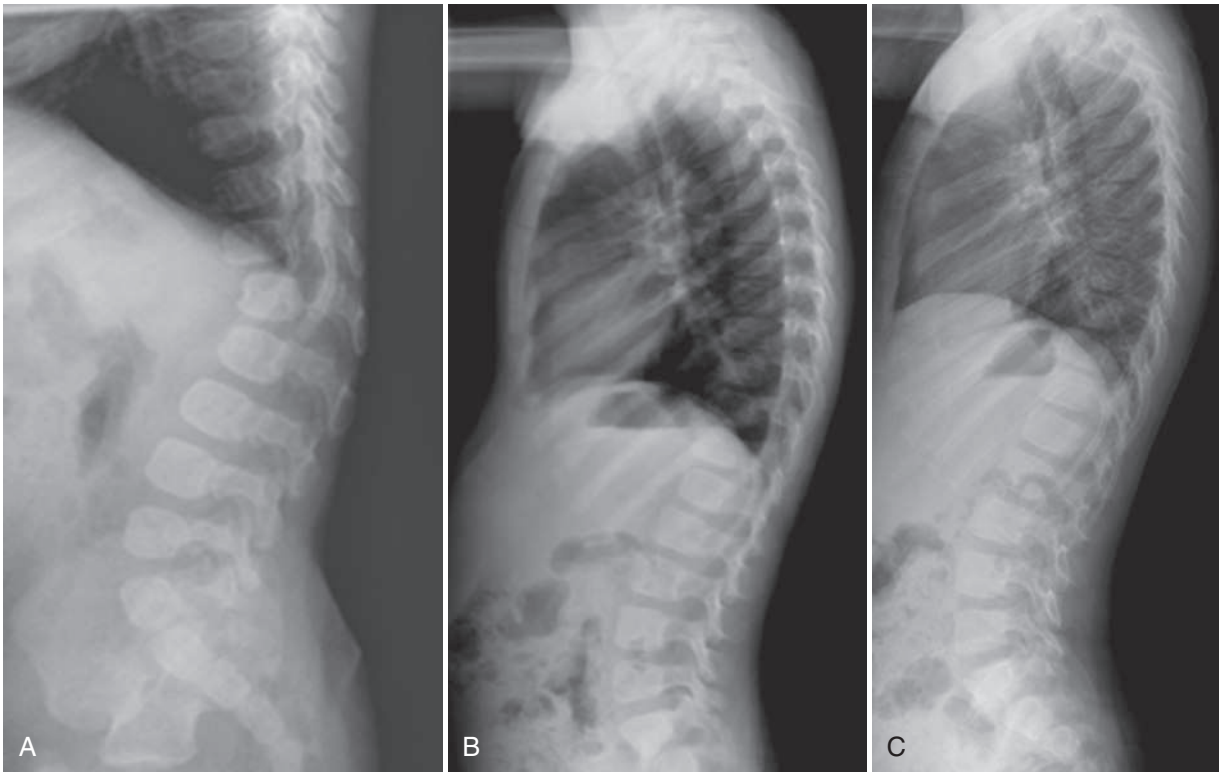

FIG. 30.16 A 6-month-old boy with wedging deformity of L1 vertebra, which spontaneously corrected over time. The patient was braced with a thoracolumbosacral orthosis. Lateral radiographs show deformity at (A) 6 months of age, (B) 3.5 years of age, and (C) 4.5 years of age. This case highlights the importance of diligent observation of all congenital deformities and performing surgery only if progression is documented.

prognosis are recognized at an early age, simple prophylactic surgical treatment can prevent progression and neurologic complications. The surgical treatment of congenital kyphosis can be challenging, and many factors must be considered when deciding on the operative plan, such as type of vertebral anomaly, patient age and amount of growth remaining, severity of deformity, and presence or absence of spinal cord compression or neurologic deficits, or both.[98]

All operations should be performed with spinal cord monitoring, including motor evoked potentials, somatosensory evoked potentials, and electromyography monitoring. Traction without anterior release is contraindicated because of the high incidence of neurologic complications.[99,109] Because of the rigidity of the kyphosis at the apex, traction primarily causes correction of the ends of the curve, which are more flexible. This correction lengthens the spine and pulls the spinal cord against the unforgiving apical bone, which may lead to more compression of the cord and resulting neurologic complications.

The treatment of type I deformities is almost always surgical because of the high risk of progression and neurologic sequelae if deformities are left untreated.

The presence of a posterolateral quadrant vertebra mandates early prophylactic surgical treatment before the child is 5 years of age and before the kyphosis is 50 degrees.[100] Traditionally, this treatment was best achieved by a posterior growth arrest procedure, which is essentially a posterior (convex) hemiepiphysiodesis. More recently, hemivertebra excision performed through an all-posterior approach has been used for these deformities, discussed later in this chapter. In situ fusion can be done with or without instrumentation, extending one level above to one level below the abnormal vertebra. If the deformity is less than 50 to 55 degrees, and there is growth potential anteriorly, creating a posterior tether allows some gradual correction in the presence of continuing anterior growth. This also eliminates the risk of spinal cord compression.

Early on, surgeons did not use instrumentation. Pseudarthrosis rates were relatively high and reexploration of the fusion mass was routinely recommended for this reason. Earlier reports recommended prolonged bed rest (up to 6 months) after surgery. The use of spinal instrumentation, specifically pedicle screw instrumentation, has been shown to be safe and effective in very young patients with congenital spinal deformities[110,111] and improves the fusion rate, making reexploration and prolonged bed rest unnecessary. We prefer to use allograft bone because fusion rates tend to be high in young patients. The fundamental principles of fusion surgery, including facet excision and thorough decortication, must be adhered to for optimal results. Postoperatively, we immobilize very young children in a brace, given their inability to restrict their activities.

The surgical treatment of older children (>5 years) with more severe deformities (>55–60 degrees) has traditionally been a combined anterior and posterior fusion. Several studies have documented the inefficacy of posterior fusion alone for these patients,[98,112,113] and a combined anterior and posterior fusion with or without instrumentation has been recommended.[24,99,109] Winter and colleagues[99] made this recommendation in a review

of 94 patients in whom progressive congenital kyphosis had been treated after the age of 5 years. Some degree of vertebral resection is necessary to obtain satisfactory correction. McMaster and Singh[98] recommended anterior strut grafting and instrumented posterior fusion because of the substantial rate of pseudarthrosis and deformity progression with posterior fusion alone. Large curves place posterior fusion at a mechanical disadvantage in the absence of anterior fusion, leading to a high pseudarthrosis rate. Older children (>5 years) also lack sufficient spinal growth to produce an appreciable correction. Other studies have corroborated that posterior fusion alone, with or without instrumentation, is insufficient for a type I or type III kyphotic deformity greater than 50 degrees.[24,109] McMaster and Singh[98] recommended fusing the entire deformity in older patients with large curves (longer fusion than in younger patients with smaller curves).

The anterior and posterior procedures can be done in 1 day or can be staged, depending on the preference of the surgeon. The anterior procedure is done through a transthoracic, transthoracic-retroperitoneal, or purely retroperitoneal approach depending on the location of the deformity. When exposure is obtained, the segmental vessels are ligated, and periosteal flaps are created. The segmental vessels should be ligated as anteriorly as possible to avoid disruption of the collateral circulation, which lies closer to the foraminal regions. Complete discectomies are performed. Rib strut grafts are placed from end vertebra to end vertebra, creating slots in the vertebral bodies.

These studies were completed before pedicle screw instrumentation became widely used. The superior three-column fixation that is obtained with pedicle screws may obviate the need for an anterior surgery in many patients, even patients with severe deformities.

An alternative to early in situ posterior fusion for a hemivertebra is complete resection of the hemivertebra. Traditionally, hemivertebra excisions have been done through combined anterior and posterior exposures. More recent reports have shown this procedure to be safe and effective through a posterior-only approach,[114–116]; thus, this is our preference. Shono and colleagues[117] reported on one-stage posterior hemivertebra resection and fusion and instrumentation in 12 patients 8 to 24 years old with kyphoscoliosis. Satisfactory correction of the scoliosis (from 49 to 18 degrees) and the kyphosis (from 40 to 17 degrees) was obtained, without neurologic complications or pseudarthrosis. Ruf and Harms[110,114] described a similar approach in children 15 months old, mostly in congenital scoliosis, with successful outcomes. The location of a hemivertebra in congenital kyphosis or kyphoscoliosis (at the apex of kyphotic deformity) makes it amenable to resection from a posterior approach with visualization of the spinal cord during correction. This approach allows for correction and short-segment fusion without concern regarding continued growth of the anterior column that may lead to future progression or crankshaft phenomenon.

Patients with spinal cord compression and neurologic deficits require decompression of the spinal cord. This decompression can be done either from an anterior approach or posteriorly from a costotransversectomy approach. Laminectomies alone are contraindicated because the compression is from the ventral aspect of the cord, and laminectomies create further mechanical instability. If the deformity is severe and spinal cord compression exists, the apex of the deformity may be so far posterior that cord decompression may be more feasible from a posterior approach. In such cases, a vertebral body resection is performed through bilateral costotransversectomies or a transpedicular approach. After the body is resected, the spinal column is shortened in such cases to obtain some bony apposition anteriorly. In severe gibbous deformities, decompression is technically more feasible from a posterior approach. A cage can be inserted anteriorly if the deformity allows it.

With surgical treatment of kyphosis, some lengthening of spine usually results. The kyphotic apex is stiff; thus, the normal, flexible spine corrects and lengthens around a relatively fixed deformity. This can cause significant stress on the vascularity of the spinal cord. Every effort should be made to shorten the spine with correction.

A type II kyphosis does not require immediate surgical treatment unless the deformity is already sufficiently severe to require correction or the curve is shown to be progressive under observation.[98] If a type II deformity is detected early and has been noted to be progressive, but the curve is not severe and is within acceptable limits, a posterior fusion alone (one level above to one level below the congenital kyphosis) is sufficient to prevent further progression.[24,99,106,109] These deformities have no potential for anterior growth because of ossification of anterior disc spaces. For more severe curves, in which substantial correction is necessary, traditionally an anterior approach has been recommended to perform osteotomies of the unsegmented areas, discectomies and fusion, and posterior fusion and instrumentation.[106] All patients who undergo surgical treatment should be observed to skeletal maturity because adding on of additional vertebrae above and below the fused segment can occur during the adolescent growth spurt.

For relatively mild deformities, such as those from a wedge vertebra or failure of formation hemivertebra excision, a posterior column-shortening osteotomy, such as Ponte or pedicle subtraction, is sufficient. For severe, rigid deformities, three-column resection osteotomy, such as VCR, is often needed. Initially, VCR was performed through a combined anterior and posterior approach. To minimize the anterior approach–related morbidity, Suk et al.[116] described execution of VCR using the posterior-only approach. Lenke et al. then popularized posterior VCR with a comprehensive surgical technique.[70,72] The purpose of VCR is to circumferentially decompress the neural elements, correct the deformity, and do 360-degree fusion with instrumentation (see Figs. 30.9 and 30.10). It is a highly technically demanding procedure. Neurologic complications still remain the biggest challenge. The overall complication rate is reported to be as high as 59%.[71] The location of the apex of the deformity directly influences the neurologic complications. The thoracic (T6–T9) level apex carries higher intraoperative and postoperative risk for neurologic complications as compared to thoracolumbar or lumbar apex.[118] Several preoperative and intraoperative

measures have been found helpful to minimize complications and optimize outcomes. A thorough understanding of the deformity with three-dimensional CT and/or with a three-dimensional spine model is an essential step in the preoperative planning. The nutritional optimization of the patient should be considered. During the procedure, sufficient height of anterior reconstruction, avoiding the sagittal translation of the upper and lower vertebrae, keeping a temporary rod in position at all times and intraoperative neuromonitoring, may help to improve the safety. Care should also be taken to control epidural bleeding and keeping the mean arterial blood pressure equal to or above 80 mm Hg during the correction maneuver to prevent neurologic complications.

An alternative to VCR for rigid, sharp complex deformities is the eggshell decancellation procedure, also called vertebral column decancellation (VCD).[119] The VCD technique does not require 360-degree exposure of the spinal cord; therefore, it reduces the instability-related complications, has low intraoperative blood loss, requires less surgical time, and causes less neurogenic complications. The decancellation of the vertebral body is executed through the pedicle in inside-to-outside order, reducing the exposure and damage to segmental vessels. VCD is a close-opening technique and the hinge of the correction is adjustable, often located at the junction of the anterior and middle column (see Figs. 30.7 and 30.8). The residual bone in the VCD technique may obviate the need for metal mesh needed in the VCR technique.[119–121] Although VCD is relatively safer than VCR, it still needs experience and high technical expertise to execute safely.[119]

Complications

Pseudarthrosis and Progressive Deformity

Techniques to obtain a solid fusion more reliably include combined anterior and posterior fusion, use of instrumentation, proper facet decortication, and use of autogenous bone graft. With use of modern spinal instrumentation and proper technique, pseudarthrosis rates are low in young children even with allograft and posterior-only fusion.[111,122] Pseudarthrosis typically leads to progression of the deformity; if any progression is noted in the postoperative period, reexploration of the fusion mass is recommended. For severe curves (>55–60 degrees), the most reliable means of avoiding these complications is by performing a combined anterior and posterior fusion.

Neurologic Complications

The rate of neurologic complications is higher in the surgical treatment of congenital kyphosis than other spinal deformities, especially in older patients with large deformities.[109] As mentioned previously, traction is contraindicated in the treatment of congenital kyphosis. Neurologic complications are more likely to occur if attempts are made to obtain maximum correction of the curve with use of instrumentation. Partial correction is preferable; the goal is to obtain a balanced spine in the coronal and sagittal planes, rather than maximal correction. Spinal cord monitoring is mandatory—the use of the wake-up test is recommended if the patient can cooperate.

PEARLS

1. Surgical correction of Scheuermann kyphosis can be accomplished in most cases by posterior-only fusion with multilevel POs. Complete removal of the inferior and superior facets and ligamentum flavum allows the posterior column to be shortened.
2. A combination of cantilever forces and compression is used to obtain correction in Scheuermann kyphosis. Intraoperative use of reduction screws in lumbar levels is often helpful.
3. MRI is recommended before surgical correction of Scheuermann kyphosis. The presence of stenosis or disc herniation may alter the operative plan.
4. In a very young child with congenital deformity, fusion should be as short as possible. In an adolescent patient, the entire deformity should be addressed.
5. Although bracing and casting are not very effective in congenital deformities, alternating with casting may be considered in a very young infant as a temporizing measure to allow further growth before surgery is performed.
6. Overcorrection of a kyphotic deformity can lead to neurologic injury because the spinal cord is lengthened. No more than 50% correction (from preoperative kyphosis) should be attempted.
7. Avoiding overcorrection, selection of proper fusion levels, and preservation of the supraspinous ligament at the proximal end of the construct have been found to be helpful to prevent a junctional kyphosis. The possibility of a junctional kyphosis should be discussed with the patient and family preoperatively.
8. All patients with congenital kyphosis require diligent observation. Not all patients experience progression, and early surgery in the absence of documented progression should be avoided.
9. In patients with congenital scoliosis, the lateral radiograph should be critically examined. The scoliosis may appear to be stable, but the kyphosis may be progressing.

KEY POINTS

1. The natural history of Scheuermann disease is generally benign, and most patients do not experience significant disability in adulthood.
2. A Milwaukee brace is recommended in skeletally immature patients with curves of 55 to 70 degrees.
3. Surgical indications include a progressive thoracic kyphosis greater than 75 to 80 degrees in a skeletally immature patient; thoracolumbar kyphosis exceeding 50 to 55 degrees that is associated with pain unresponsive to conservative treatment; progression of deformity despite bracing; or cosmetic deformity that the surgeon, patient, and family consider significant and unacceptable.
4. Patients diagnosed with congenital kyphosis should undergo MRI of the entire spine to rule out intraspinal anomalies.
5. Diligent periodic observation of all patients with congenital kyphosis is crucial; without such observation, severe deformities with neurologic sequelae may develop.
6. The natural history of congenital kyphosis, particularly type I deformities, is unfavorable. Insidious progression of the deformity can occur with growth, and surgery is recommended if progression is noted.
7. Goals of treatment are early fusion to prevent severe deformity, halt progression, and achieve head and trunk balance.
8. In a very young child, fusion should be as short as possible. The entire deformity should be addressed in adolescent patients.

9. Postoperatively, patients should be followed to skeletal maturity to ensure that progression of the primary or compensatory curves does not occur.

31 CHAPTER Spondylolysis and Spondylolisthesis

Suken A. Shah

Spondylolysis is defined as a defect in the pars interarticularis of the posterior vertebral arch and is a common cause of back pain and disability.[1] In addition, spondylolysis may lead to instability of the spinal column and result in anterior translation of the vertebral body relative to the level inferior to the defect. This translation in the setting of spondylolysis is termed *spondylolisthesis,* from the Greek roots, *spondylos,* meaning "vertebrae," and *olisthesis,* meaning "to slip."[2] Even in the absence of symptoms from the pars defects themselves, spondylolisthesis may lead to clinically significant radiculopathy and progressive neurologic deficits secondary to nerve root impingement. Both conditions vary in their presentations and require judicious application of conservative and surgical treatment strategies.

The clinical syndrome of spondylolisthesis was first described in 1782 by the Belgian obstetrician Herbiniaux[3] before an understanding of its pathophysiology. Herbiniaux reported a bony prominence anterior to the sacrum that created an impediment to vaginal delivery in a cohort of his patients. In 1853, the German physician Robert[4] reported on specific defects in the pars interarticularis; these defects were first labeled spondylolysis by Killian in 1854.[2] Killian[2] proposed that forces imposed by the body's weight caused subluxation of the lumbosacral facets and subsequent vertebral body subluxation. A short time later, in 1855, anatomic studies by Robert and Lambl revealed that a neural arch defect typically preceded the subluxation.[5] Robert freed the fifth lumbar vertebra successfully of surrounding soft tissue and showed that a neural arch defect was required for slippage to occur.[6]

In 1881, Neugebauer[7] detailed the clinical and anatomic manifestations of the deformity and suggested that lysis, elongation, and angulation of the pars interarticularis could lead to spondylolisthesis. In his travels through Europe in 1888, Neugebauer came across 10 specimens in which there was gross displacement of the fifth lumbar vertebra. He aptly termed this phenomenon *spondyloptosis,* from the Greek *ptosis,* meaning "falling off or down," to indicate a vertebra that is completely dislocated. Neugebauer initially attributed the deformity to traumatic injury; however, he later proposed that it was due to a congenital abnormality of neural arch ossification. This theory of abnormal ossification was questioned by Lane, who, in 1893, posited that spondylolisthesis was due to modification of the interarticular part of the fifth lumbar vertebra by pressure from the inferior facet of L4 superiorly and from the superior sacral process inferiorly.

Pathophysiology

As understanding of spondylolisthesis increased, classifications of common subtypes emerged. The most widely used classification system today was described by Wiltse.[8–11] This system represents a further development of the classification described by Newman and Stone,[12] who, in 1962, reported the long-term outcomes of 319 patients with spondylolisthesis. In their series, spondylolisthesis was classified in terms of radiographic appearance and proposed etiology.

Wiltse separated spondylolisthesis into five main groups (Table 31.1). Type I, also known as *congenital* or *dysplastic spondylolisthesis,* is secondary to a congenital defect of the superior sacral facet or the inferior L5 facet or both, with gradual anterior translation of the L5 vertebra. Type II, also known as *lytic* or *isthmic spondylolisthesis,* involves a defect in the isthmus or pars interarticularis. Type II is classified further into three subtypes. Type IIA represents a spondylolysis or a stress fracture of the pars region. Type IIB represents an intact but elongated pars caused by repeated stress and bony remodeling. Type IIC represents an acute traumatic fracture of the pars leading to anterolisthesis; this is the rarest of the subtypes. It is not the pars defect itself but the anterior translation that allows the lesion to be termed *spondylolisthesis*. Type III is degenerative in origin and is a disease of older adults that develops as a result of facet arthritis and remodeling. Such long-standing intersegmental instability can lead to either anterolisthesis or posterolisthesis. As the disease progresses, the articular processes may become more horizontally shaped, creating the potential for rotational deformity as well. Type IV is a posttraumatic disruption of posterior elements other than

TABLE 31.1 Spondylolisthesis Classification by Wiltse[18]

Type	Description
I	Congenital dysplastic
II	Isthmic: defect at pars interarticularis
IIA	Spondylolytic: stress fracture of pars interarticularis
IIB	Elongation of pars interarticularis
IIC	Acute or traumatic fracture of pars interarticularis
III	Degenerative: long-standing intersegmental instability
IV	Posttraumatic: defects of posterior elements (aside from pars interarticularis)
V	Pathologic

TABLE 31.2 Spondylolisthesis Classification by Marchetti and Bartolozzi[13]

Type	Features
Developmental	
High dysplastic	Interarticular lysis Elongation of pars interarticularis
Low dysplastic	Interarticular lysis Elongation of pars interarticularis
Acquired	
Traumatic	Acute or stress fracture
Postsurgical	Direct or indirect effect of surgery
Pathologic	Local or systemic pathology
Degenerative	Primary or secondary

the pars (as in type IIC). This disruption is a gradual event and not an acute fracture–dislocation, as seen in type IIC. Type V involves the destruction of the posterior elements in the setting of a pathologic process, such as malignancy, Paget disease, tuberculosis, or giant cell tumors. Additionally, an iatrogenic spondylolisthesis may occur after facetectomy.

Wiltse type I and type II constitute most cases, which are the focus of this chapter. Although the classification schemes described allow for the systematic study of these disparate disease entities, they are of no proven prognostic value in the prediction of deformity progression.

The extent to which spondylosis depends on genetic or developmental factors is controversial. In 1982, Marchetti and Bartolozzi[13] divided spondylolisthesis into developmental and acquired subtypes. Developmental etiologies included elongation of the pars, lytic lesions, and traumatic events, whereas acquired etiologies included iatrogenic, pathologic, and degenerative conditions. In 1994, a revised classification system subclassified the developmental group further into high or low dysplastic. In these two subgroups, the pars interarticularis was described as being either osteolytic or elongated. Traumatic lesions were incorporated into the acquired group and the iatrogenic etiology was relabeled as postsurgical (Table 31.2). Although developmental abnormalities of the posterior arch are typically insufficient to cause spondylolysis in the absence of other inciting factors, they may play a significant role in the predisposition to spondylolysis and subsequent spondylolisthesis.

A significant genetic predisposition is suggested by the observation that spondylolysis occurs in 15% to 70% of first-degree relatives of individuals with the disorder.[14-22] Spondylolisthesis also shows a strong familial association, with an incidence in first-degree or second-degree relatives of approximately 25% to 30%.[5,9,11,23] A radiographic study by Wynne-Davies and Scott[15] showed that dysplastic spondylolisthesis has a familial incidence of 33%, whereas the isthmic variant has a familial incidence of 15%. Compared with the incidence in the general population, this represents a fourfold and twofold increased familial risk in patients with dysplastic and isthmic spondylolisthesis, respectively. Wynne-Davies and Scott[15] suggested a multifactorial autosomal dominant pattern of inheritance with incomplete penetrance. Wiltse[22] suggested, however, that a cartilaginous defect in the vertebrae may be of autosomal recessive inheritance with varying expressivity. Additionally, the correlation between spina bifida occulta and spondylolisthesis strengthens the suggestion of a hereditary contribution.

In combination with developmental susceptibilities, certain activities are risk factors for spondylolysis because of the nature of the biomechanical stresses imparted on the pars interarticularis. Biomechanical analyses have shown that hyperextension and persistent lordosis increase shear stresses at the neural arch.[24–27] Wiltse and colleagues[28] hypothesized that most cases of isthmic spondylolysis should be considered fatigue fractures caused by repetitive load and stress as opposed to a single traumatic event, although a traumatic event may lead to completion of a fracture already in development. Farfan and colleagues[29] hypothesized that a single event leads to the initial microfracture in the pars, with fractures occurring as a result of repetitive overload. As a result of these biomechanical data, activities that involve hyperextension of the lumbar spine—such as gymnastics, weightlifting, diving, football, and volleyball—have been implicated as causative factors in the development of spondylolysis.[27,30–32]

Persistent lumbar lordosis may also increase susceptibility to spondylosis; Ogilvie and Sherman[14] reported a 50% prevalence of asymptomatic spondylolysis in patients with Scheuermann kyphosis. The tendency toward progression of slippage during adolescence and the observation that girls are several times more likely to have an increase in deformity are also suggestive of a hormonal role in the development of spondylolisthesis.[23]

Epidemiology

The exact prevalence of spondylolysis is uncertain because it is asymptomatic in a large proportion of patients. Reports regarding the prevalence of spondylolysis are based primarily on painful or symptomatic spondylolysis or cases associated with listhesis. The prevalence in whites has been reported as 3% to 6%, with a male-to-female ratio of 2:1.[33–35] Roche and Rowe[35] examined 4200 cadaveric specimens and found an overall prevalence of spondylolysis of 4.2%. Considerable

ethnic variability exists in the prevalence of spondylolysis, with a lower prevalence in blacks (1.8%–2.4%) than in whites (5.6%).[36–39] The highest prevalence has been reported in the Eskimo population, with rates of 13% in adolescent patients and 54% in adults.[40] Although this prevalence may suggest a genetic predisposition, it has also been posited that Eskimos, who carry their infants in a papoose, place undue stress on the pars interarticularis.[36]

The reported incidence of isthmic spondylolisthesis ranges from 2.6% to 4.4%.[5,41–43] In the largest prospective radiographic study, Fredrickson and colleagues[41] evaluated 500 patients at age 6 years with a 20-year follow-up. A pars defect was appreciated in 4.4% of 6-year-old children. By age 12 years, 5.2% of the cohort was noted to have the defect (85% participation rate). This increased to 6% by age 18 years; however, most of the nonaffected patients had dropped out of the study (34% participation rate). Back pain had developed in only four of the patients, and one patient required an operative procedure to decompress a herniated disc at a level cephalad to the spondylolisthesis. Pars defects at L5 were noted to be bilateral in 78% of cases, with most of these progressing to spondylolisthesis. As a corollary to this study, Fredrickson and colleagues[41] also evaluated 500 newborns and found no evidence of spondylolysis or spondylolisthesis. The only reported case of a pars lesion in a newborn has been published by Borkow and Kleiger.[44] Isthmic spondylolisthesis is rare in children younger than 5 years old, with only a few reported cases.[43,45,46]

In spondylolysis, the pars interarticularis defect may be unilateral or bilateral. If the defect is bilateral, the chance of progression to listhesis is greater. The most common location of a spondylitic defect is L5 (85%)[47] and the defect may be observed as high as L2; multilevel defects are seen infrequently. Rarely, multiple defects may be seen at the same level. Ariyoshi and colleagues[48] reported a case of spondylolysis at three sites in L5 involving the bilateral pars interarticularis and the center of the right lamina.

The most common site of isthmic spondylolisthesis is at the L5–S1 level secondary to osteolysis at L5. Estimates show that this lesion is located at the L5 pars interarticularis in 90% of type II cases, at L4 in 5%, and in more cephalad vertebrae in the remaining 5% of cases.[11] Additionally, authors have reported spina bifida occulta at the same level in 30% of patients with pars lesions. The incidence of spina bifida associated with spondylolisthesis has been reported to range from 24% to 70%.[9,23,49,50] Age at presentation with isthmic spondylolisthesis follows a bimodal distribution. One peak occurs between the ages of 5 and 7 years, and the second occurs in the teenage years.[9,19,49,51] The incidence in athletes who subject themselves to excessive lumbar posturing, such as gymnasts, soccer players, pitchers, cricket bowlers, and divers, is higher than in the general population.[52–59]

In pediatric patients, dysplastic and isthmic are the most commonly encountered subtypes, with the latter representing 85% of the cases. As with spondylolysis, isthmic (type II) spondylolisthesis is two times more frequent in boys than girls.[35] Dysplastic spondylolisthesis, similar to its isthmic counterpart, is also most commonly found at the L5–S1 junction. The incidence is two times higher in girls[60,62] and, based on more recent published reports, it accounts for 14% to 21% of total cases.[61,62]

History and Physical Examination

Spondylolysis may be discovered incidentally or may manifest with low back pain typically in the teenage years.[63] In approximately half of cases, the onset of low back pain is associated with a history of trauma or an inciting event.[23,64,65] Usually, these patients complain of focal low back pain, only rarely radiating to the buttocks or posterior thigh, which becomes worse with activity or on hyperextension of the spine.[31,66–69] Lifting and weight bearing can exacerbate the pain, and a forced lumbar extension often intensifies the symptoms. Neurologic involvement is rare in isolated spondylolysis. Medical professionals who have little experience with spondylolysis often assume the defect to be a sequela of trauma requiring immediate immobilization and surgical intervention. In these cases, it is the responsibility of the spine surgeon to offer reassurance that imminent neurologic compromise is highly unlikely.[70,71]

Physical examination of the lumbar spine reveals focal tenderness in acute cases and mild discomfort in chronic cases. Patients maintain a full range of forward flexion (unless the hamstrings are tight) that is usually painless, but hyperextension movement leads to an exacerbation of symptoms, as does lateral bending or rotation. Other associated physical signs are an antalgic gait, increased lumbar lordosis, and hamstring tightness. A single-leg hyperextension test is used for the diagnosis and differentiation of unilateral spondylolysis from bilateral lysis. This test is performed by the patient bearing weight on one leg with the hip and knee of the other leg flexed while hyperextending the lumbar spine. This maneuver is performed on both sides; asymmetrical low back pain indicates unilateral spondylolysis. Bilateral lesions show symmetrical or asymmetrical pain with this maneuver.[72,73] The neurologic examination in isolated spondylolysis is generally normal, with radicular findings suggestive of foraminal stenosis owing to inflammation or instability.

Spondylolisthesis may manifest in a similar fashion but is also typically associated with hamstring tightness. This tightness manifests as a muscle spasm of the posterior thighs associated with a fixed flexion at the hip and knees. An increased popliteal angle is present on straight-leg raise. An increased popliteal angle is almost always observed universally, even in low-grade spondylolisthesis. Electromyographic and neurologic abnormalities are typically absent; this suggests that there is not a neurologic basis for the hamstring tightness but that it likely results from the patient's attempts to maintain global sagittal balance.[62,74] Other authors hypothesize that tightness results as a sequela of chronic nerve root irritation from the instability and micromotion of the involved segment.[74–77] Patients often ambulate and stand with increased flexion at the hips and knees, also known as the Phalen-Dickson sign.[75] This flexed posturing increases as the amount of slippage increases. The patient may also exhibit a shuffled or short-stepped gait.[77]

Patients with spondylolisthesis may initially present with focal neurologic deficits or radiculopathy, although this is uncommon. Bilateral radicular symptoms are more commonly observed than unilateral radiculopathy. Typically, the L5 root is involved, with pain radiating to the buttocks and posterior thigh or weakness of the extensor hallucis longus. Constant loading of the pars defects may hinder bony healing, resulting in a fibrous union that may be a persistent source of pain. Local expansion of fibrocartilaginous scar tissue within the area of the pars defect may cause nerve root compression. Tension on the nerve root also increases with progression of olisthesis, increasing further the likelihood of radicular symptoms with disease progression.[71] In higher-grade subluxations, traction of the cauda equina over the sacrum may exist. This traction may lead to signs and symptoms of cauda equina compression, such as perineal paresthesia, decreased sphincter tone, and urinary retention. Additionally, traction of the cauda is thought to create a reflex spasm of the hamstrings.[78,79]

Higher-grade spondylolisthesis results in a palpable step-off over the spinous processes. In isthmic spondylolisthesis, the step-off is typically found at the L4–L5 junction, as the neural arch of the L5 vertebra does not translate anteriorly with the body but remains within its geographic location in relation to the sacrum. In dysplastic spondylolisthesis, the neural arch is still attached to the vertebral body and slides anteriorly with the body, producing a palpable step-off that is typically appreciated at the lumbosacral junction. Lumbosacral kyphosis with a retroverted sacrum results in heart-shaped, flattened buttocks. In severe cases, the trunk appears grossly shortened, and the rib cage lies within close proximity to the iliac crests.

Scoliosis also may be associated with spondylolisthesis.[12,25,80–84] The incidence has been reported to be 60%. Scoliosis may result because of a combination of hamstring and paraspinal muscle spasm, rotational deformity, or truncal asymmetry. If scoliosis is secondary to spondylolisthesis (nonstructural), it usually resolves after treatment of the olisthesis. The patient may also have an adolescent idiopathic curve with a low-grade spondylolisthesis that was detected incidentally on radiographic evaluation.

Radiographic Evaluation

Many imaging modalities may be useful in the diagnosis and evaluation of spondylolisthesis. Radiographic evaluation of spondylolisthesis begins with plain radiographs, including lateral, anteroposterior, and oblique views.[85] The anteroposterior view should be angled 15 degrees to the inclination of the L5–S1 disc (Ferguson view). This view not only allows for visualization of the presence of sacral spinal bifida, but also evaluates the size of the lumbar transverse processes and height of the disc.

The defect in isthmic spondylolysis is visualized as lucency in the region of the pars interarticularis. The lucency is commonly described as having the appearance of a collar or a "broken neck on the Scotty dog" seen in lateral oblique radiographs. A spot lateral view is able to identify only 19% of pars defects,[33,86] whereas oblique lateral views can detect the pars defect in 84% of cases.[87] It is important to take right and left oblique views because pars defects may be unilateral in some cases, and the collar may be visible in only one projection.

Although oblique views are most sensitive in diagnosing spondylolysis, the lateral view is optimal for appreciating the degree of olisthesis in spondylolisthesis. The lateral view should be performed with the patient standing. Flexion-extension views may assess for the presence of associated instability. This subtle movement may be an important pain generator and is essential for further treatment planning. Additionally, these views show the extent of postural reduction of the lumbosacral angulation and translation that may be obtained without formal release.

Because the sensitivity of plain radiographs is limited, radionuclide (technetium-99m) bone imaging may be a good option in cases of suspected spondylolysis with negative plain radiographs. A bone scan identifies pars interarticularis stress fractures that can be missed in oblique radiographs because a stress reaction may be present without a bony defect. Patients who have had a recent trauma or performed strenuous activity and are symptomatic have a bone scan showing increased uptake in the spondylolytic area; however, patients with chronic low backache can have normal bone scans if the defect is chronic, is sclerotic, and has lost its blood supply. Single photon emission computed tomography (SPECT) is more sensitive and provides more details than plain radiographs and technetium bone scan.[88,89] A "hot" scan insinuates increased activity and the patient may benefit from orthotic immobilization, whereas a "cold" scan suggests a chronic lesion that is not metabolically active and is unlikely to respond to immobilization alone.[71]

Thin-cut axial computed tomography (CT) is highly accurate at visualizing osseous anatomy and is superior to plain radiography in its ability to show dysplastic facets and pars defects. CT may also be used after plain radiographs or bone scan to assess the healing potential of an identified pars defect.[90] In addition to showing spondylolysis accurately, CT may identify changes in the apophyseal joints associated with degenerative and reverse spondylolisthesis and can show minimal degrees of spondylolisthesis by the presence of a pseudo-bulging disc.[91]

Magnetic resonance imaging (MRI) is a highly sensitive imaging technique that allows for additional visualization of soft tissue and neural structures and is recommended in all cases associated with neurologic findings. MRI offers the distinct advantage of being able to image the spine in any plane without exposure to ionizing radiation. Sagittal thin slices (3-mm slice thickness for T1-weighted images and 4-mm slice thickness for T2-weighted images) are able to identify 95% of pars defects, with T1-weighted images being more sensitive than T2-weighted images.[92] In the early course of the disease, MRI helps in identifying the stress reaction at the pars interarticularis before the end-stage bony defect.[93,94] In more acute presentations in which plain radiographs may be negative, a fat saturation technique can be applied to minimize signal from fat and to bring out signal from fluid

TABLE 31.3 Meyerding Classification[a]

Grade	Percentage of Slippage (A/B)
0	0 (spondylolysis)
I	0–25%
II	25–50%
III	50–75%
IV	75–100%
V	Vertebral body completely displaced (spondyloptosis)

[a]Grades 0 and V were added later.

structures, such as bone edema. MRI also allows for evaluation of the spinal cord and its associated elements with greater anatomic detail and without the procedural risks associated with CT myelography. MRI may show the degree of impingement of neural elements by fibrous scar tissue at the spondylolytic defect. Additionally, involvement of adjacent discs should be evaluated because abnormal biomechanics can lead to early degenerative changes at adjacent levels.

The most commonly used radiographic grading system for spondylolisthesis is the one proposed by Meyerding in 1932.[95] The degree of slippage is measured as the percentage of distance the anteriorly translated vertebral body has moved forward. On the lateral radiograph, a line is drawn along the posterior sacral border. A line perpendicular to this is drawn at the superior part of the sacrum. The anterior translation or displacement of the inferior border of L5 as a proportion of the width of S1 is expressed as a percentage. The Meyerding classification grades increasing olistheses from I to IV (Table 31.3). Spondyloptosis, in which the fifth lumbar vertebra has slipped forward over 100% of the gliding plane past the sacral promontory, is referred to as grade V. Spondylolysis without olisthesis is referred to as grade 0.

Although the Meyerding classification system quantifies translational subluxation in the anteroposterior plane, it does not quantify the sagittal rotation of a vertebral body that may coexist in spondylolisthesis. This angular displacement is referred to as the *slip angle* and, as with the Meyerding grading system, the erect lateral radiograph is the basis for measurement. The slip angle is calculated by measuring the angle formed by the intersection of two lines: (1) a line perpendicular to the posterior cortex of the sacrum and (2) a line paralleling the inferior endplate of L5. In the normal spine, slip angle values should be close to zero. The slip angle quantifies the lumbosacral kyphosis and was shown by Boxall and colleagues[62] to be the most useful tool in determining the risk of the progression in a skeletally immature patient. A slip angle greater than 55 degrees is associated with a high probability and increased rate of progression.

Sacral inclination, or pelvic tilt, refers to the vertical position of the sacrum. It is the angle formed by the intersection of two lines: (1) a line perpendicular to the floor and (2) a line parallel to the posterior cortex of the sacrum. Normal values are greater than 30 degrees. With an increasing slip, lumbosacral kyphosis is increased and the sacrum is forced into a more vertical orientation, decreasing the pelvic tilt.

In 1983, Wiltse and Winter[96] proposed a classification that separated the tangential movement seen in low-grade slips (grades I and II) from the angular and tangential movement that was appreciated in high-grade slips (grade III or higher). The three measurements that were factored were degree of slip, vertebral wedging, and sacral rounding. These authors recommended that the forward displacement of the fifth lumbar vertebra in relation to the sacrum be measured as an actual percentage, as first described by Taillard[42] and later recommended by Laurent and Osterman.[97] It was stressed that even a small degree of progression should be measured, and this was not quantifiable on the Meyerding scale. Sacral tilt as described previously and sagittal rotation or slip angle were also used. The method for measuring slip angle, which Wiltse and Winter[96] termed *sagittal rotation,* was modified by measuring the angle formed by the intersection of two lines: (1) a line extending off the anterior cortex of the L5 vertebral body and (2) a line off the posterior border of the first sacral vertebra. Wiltse and Winter[96] believed the endplates of the L5 and S1 bodies to be unreliable osseous structures secondary to osseous hyperplasia.

Nonoperative Management

Treatment of spondylolysis mainly focuses on pain relief, core muscle strengthening, and restoration of full lumbar range of motion. Achieving these goals enables the patient to return to normal activity without any restrictions. Management of spondylolysis depends on the severity of the symptoms and level of activity. Initial conservative management in the form of activity restriction and bracing (for pain relief) relieves symptoms in patients with spondylolysis. It is likely that most lesions do not heal with bone but become a stable fibrous union that remains relatively asymptomatic.

In the pediatric population, nonoperative management of spondylolysis includes restriction of activity, rehabilitation with strengthening of the abdominal and paraspinal musculature, minimization of pelvic tilt, and perhaps antilordotic bracing.[98] Nonoperative management protocols also depend on several factors, such as disease involvement (spondylolysis vs. spondylolisthesis), level and laterality of the defect (unilateral vs. bilateral pars defects), duration since injury (acute vs. chronic), and age of the patient.[99] Many authors prefer to use a total-contact, low-profile polyethylene orthosis, which is designed to maintain an antilordotic posture and extends from just below the nipples to 1 inch above the greater trochanter. The brace is worn for 23 hours/day for a minimum of 3 to 6 months.[100] If clinical symptoms improve, the brace can be gradually weaned through a period of part-time wear.

Excellent clinical outcomes have been reported with a course of activity restriction and bracing that prevents repetitive hyperextension movements at the lumbar spine.[100–103] Good to excellent results with brace therapy have been shown in 80% of patients with grade 0 or I spondylolisthesis.[100,104,105] Bell and colleagues[104] showed prevention of increased slip angle and 100% reduction of pain in 28 patients with grade I or II spondylolisthesis after a mean brace treatment of 25

months. In a series of 82 symptomatic patients with various degrees of spondylolisthesis, Pizzutillo and Hummer[105] reported that nonoperative treatment of grade II or less was shown to relieve pain reliably in two-thirds of patients. A study by Steiner and Micheli[100] showed radiographic evidence of healing pars defects in 12 of 67 patients with spondylolysis or grade I spondylolisthesis after treatment in a modified Boston brace. Excellent or good results were achieved in 78%, with return to full activities. Patients with spondylolysis and grade I spondylolisthesis may return to full activity and sports with resolution of symptoms and documented lack of slip progression. Controversy exists regarding post-brace activity level for patients with grade II spondylolisthesis. The general consensus is that after successful brace treatment, a child with grade II spondylolisthesis may return to sports that do not involve hyperlordotic posturing.[18,26,27]

Patients with acute pars interarticularis fractures are best treated with immediate initiation of bracing for pain relief and restriction from athletic activity, with continued mobilization for activities of daily living. Anderson and colleagues[106] used clinical evaluation and SPECT imaging to compare the rate of response to early versus late initiation of bracing. In this study, patients with early bracing showed rapid relief of symptoms, a short bracing time, and rapid reduction of SPECT ratio. Patients showing a spondylolytic defect on plain radiography but whose bone scans were negative were determined to have inactive (terminal) spondylolytic defects, pseudarthrosis, or old unhealed fractures.[72,107] Athletes with low back pain and increased uptake on SPECT scan at the pars interarticularis but no defect on radiographs typically respond to a period of rest and active rehabilitation; very few athletes develop defects or persistent back pain.[108]

As the understanding of spinal biomechanics has progressed, Panjabi[109] posited the concept of specific training of lumbar muscles in chronic low back pain. According to his concept, specific training of muscles around the lumbar spine improves the dynamic stability and controls segmental spinal motion. The local muscular system that controls the lumbar spine consists of lumbar multifidus, internal oblique, and transverse abdominis.[109] A randomized trial by O'Sullivan of 44 patients who were treated with two different protocols showed that a specific strengthening program was more effective than generalized back strengthening exercises.[98] Along with exercises that target specific core muscle groups with the spine in neutral position, strengthening of hip flexors and hamstring stretching are important and recommended.[100,101,110]

Patients with low-grade dysplastic spondylolisthesis are less likely than patients with isthmic spondylolisthesis to respond to conservative measures,[5] but conservative therapy is still recommended as the initial modality. The importance of radiographic and neurologic follow-up should be stressed to these patients because they are at a higher risk for slip progression owing to facet hypoplasia. Radiographic follow-up is recommended at least annually until skeletal maturity and more frequently during peak height velocity before puberty. Documentation of slip percentage, angle, sacral inclination, wedging, and pelvic tilt is recommended as part of proper documentation of progression of the deformity.

Surgical Treatment

Surgical intervention is indicated for patients with persistent pain, progressive spondylolisthesis, or neurologic symptoms who fail conservative management. Treatment approach is influenced by the level of spinal maturity, degree of slippage, symptoms, the patient's activity level, and expected progression. In contrast to a comparable adult, an asymptomatic adolescent may be a candidate for surgical intervention because of expected progression of deformity in a high-grade slip, which may lead to mechanical and neurologic dysfunction. In a skeletally immature patient with slippage greater than 50% or a mature adolescent with a slip greater than 75%, operative intervention is recommended even if the patient is asymptomatic.[111-113] Surgical decompression is also indicated when a patient has neural compromise, with a radiculopathy or bowel or bladder dysfunction.[114–116]

Surgical treatment options may be broadly divided into two categories: direct repair of the pars defects versus arthrodesis of the involved segments to prevent slip progression with or without decompression of affected neural structures. Procedures for direct fixation of pars defects include the Buck technique,[117] Scott wiring,[118] and repair with an ipsilateral pedicle screw and hook.[119,120]

Fusion of the involved level has been widely advocated as treatment of symptomatic spondylolysis.[111,121] The long-term effects of fusion in a young patient must be considered, however, owing to the potential for adjacent-segment degeneration.[122,123] Based on their simulated lumbar fusion studies in cadavers, Weinhoffer and colleagues[124] concluded that increased intradiscal pressure at the level of fusion could lead to accelerated degeneration at the adjacent discs. Kinematic studies of adjacent vertebra after fusion have shown disc degeneration, increased stress at the facet joints, hypertrophy of the facets, and hypermobility at the adjacent level.[123,125,126] Based on these kinematic studies and the goal of preserving motion when possible, isolated repair of the pars interarticularis defect is the preferred treatment for symptomatic pars defects in patients with no slip or disc degeneration at that level and relief from the diagnostic injection. Fusion is an option if an attempt at pars repair is unsuccessful, the lamina is dysplastic, the defect is very large, or disc degeneration or listhesis is present. Some authors maintain that results for fusion are better at L5 because of the narrow lamina at L5 and the steep lordotic angle that may be present.[127]

To increase the probability of response to surgical treatment, Wu and colleagues[128] reported on the use of preoperative diagnostic pars injection at the site of the defect. In their series of 100 patients who had failed conservative management, the pain generator was confirmed by injecting 1.5 mL of bupivacaine (Marcaine) into the lytic area. Reproduction of similar pain and pain relief of at least 70% of the usual pain quality for more than 6 hours were considered as a positive response; these patients subsequently showed an excellent outcome after repair of the defect.[128]

Buck fusion is an open technique in which the fibrous tissue at the pars defect is identified, thoroughly debrided, and

stabilized with a 4.5-mm stainless steel cortical screw in compression.[117] Buck[117] concluded that this technique was indicated only in cases in which the gap was smaller than 3 to 4 mm. Various studies showed 88% to 100% defect healing and satisfactory results with his technique.[129–131] Direct repair using a screw is a demanding procedure, however; owing to the narrowness of the lamina, a minimal displacement or malposition of the screw can lead to implant failure or complications such as nerve root irritation, injury to the posterior arch or dura, or pseudarthrosis.[132,133]

In the Scott technique, a stainless steel wire is looped from the transverse processes to the spinous process of the level involved and tightened in conjunction with local iliac crest bone graft.[118] This wire creates a tension band construct, placing the pars defect under compression, and holds the bone graft in place. Bradford and Iza[134] reported 80% good to excellent results and 90% radiographic healing of the defects. This technique requires greater surgical exposure, with extensive stripping of the muscles to expose the transverse process. Complications such as wire breakage are common with this technique. Salib and Pettine[135] modified this technique by passing a wire around the cortical screws introduced into both pedicles and tightening it beneath the spinous process. Biomechanical tests show that fixation of the wire to the pedicle screw does not increase the stiffness of the system.[136] Both cerclage techniques have good defect healing rates of 86% to 100%.[118,135,137,138] Songer and Rovin[139] modified this construct by replacing the wire with a cable tied up to a pedicle screw and then passed and wrapped around the contralateral lamina. This system provides solid fixation; the authors reported excellent outcome in five of seven patients and 100% solid union in all patients.

Morscher and colleagues[140] introduced a new technique to repair the pars defect with a laminar hook, which is loaded with compression by a spring placed against a screw threaded in the articular process. Healing rates with this technique range from 56% to 82%.[140–144] The major drawback of this procedure is screw penetration to the inferior articular process of the cephalad vertebra, which can lead to screw loosening or breakage.[145] Gillet and Petit[146] introduced the concept of the rod screw construct, in which the rod is firmly fixed to the spinous process, and published excellent outcomes in 6 of 10 patients.

Taddonio, using the Cotrel-Dubousset system, first introduced a repair using pedicle screw fixation.[146a] Tokuhashi and Matsuzaki[127] reported excellent outcomes with the Isola pediculolaminar system. Kakiuchi[147] reported similar results using the Texas Scottish Rite Hospital instrumentation system; with this technique, hooks are fixed at the lamina and connected with a rod to an ipsilateral pedicle screw after compression. Roca and colleagues[148] reported 92% excellent results with their new pedicle screw hook construct system in adolescents, but they have not recommended this technique for patients older than 20 years. Pellise and colleagues[149] advised 1-mm thin cuts to assess the pars anatomy, but 2.5-mm cuts help in assessing bone healing after direct repair in spondylolysis.

Our preferred technique for pars repair is to use minimal access tubes or retractors to obtain exposure of the pars defect and debride the fibrous tissue and hypertrophic nonunion with a burr and curettes to bleeding bone, but care must be taken not to enlarge the defect further and destabilize the segment. Iliac crest bone graft is placed into the defect and a cannulated laminar screw is placed percutaneously over a predrilled guidewire from the ipsilateral inferior lamina across the defect to engage the cortical bone of the pedicle or superior endplate for compression, avoiding the facet joint. Additional graft (or bone graft replacement) is placed over the defect, extending from the lamina to the junction of the transverse process. The patient is immobilized in a low-profile thoracolumbosacral orthosis for 12 weeks (hip joint locked with a leg extension for the first 6 weeks) and then progressed to rehabilitation. Healing is checked at 6 months and the patient is allowed to resume all sports.

For a pediatric patient with grade I or II spondylolisthesis, dysplastic spondylolisthesis at the lumbosacral junction, or a slip secondary to a defect of the L5 pars who has failed conservative treatment, posterior in situ fusion is recommended from L5 to S1. With the widespread use of pedicle screws and the myriad screw options that are available, numerous studies have been performed supporting the use of transpedicular fixation. Transpedicular fixation has been shown to increase the rate of fusion, and a positive correlation has been reported between successful fusion and clinical outcome.[150–156] Other series have not shown a statistically significant difference between instrumented and noninstrumented posterior fusions.[157,158] In one study of 10 patients in a cohort who had the working diagnosis of spondylolisthesis, 5 underwent instrumented fusion, 4 of whom achieved an excellent or good outcome, compared with 2 of 5 who underwent a noninstrumented fusion.[159]

Lenke and colleagues[160] performed noninstrumented in situ fusions in 56 pediatric patients with isthmic spondylolisthesis. Based on radiographic evidence, only 50% showed a solid fusion mass, whereas 33% showed radiographic changes highly unlikely or with no evidence of a fusion mass. Despite poor fusion rates, overall clinical improvement was noted in greater than 80% of the cohort with preoperative symptoms of back or leg pain or hamstring tightness. A trend for improved clinical outcome with increased rigidity of fixation has been noted.[151] Pedicle screw fixation systems have been shown to be mechanically superior to other fixation while allowing for the selective segmental force without extension to adjacent levels.[161] Additionally, the use of instrumentation obviates the need for postoperative casting in a compliant patient. If exposure of midline structures and decompression is not warranted, the paraspinal approach described by Wiltse and colleagues[11,162] is recommended because it avoids neural arch defects, minimizes soft tissue trauma, and improves visualization of posterolateral structures. It also helps maintain the position of the bone graft and may promote fusion. During surgical dissection, care must be taken to protect facets at levels cephalad to the proposed fusion because this may create instability or degeneration later on. Minimally invasive techniques are available.

The method of immobilization after an in situ posterior fusion ranges from bed rest to bilateral pantaloon spica casts for 6 months. Literature can be found to support either end

of the spectrum.[112,163–169] Boxall and colleagues[62] and Sherman and colleagues[170] compared in situ patients who were immobilized in a cast or orthosis with patients who were treated with bed rest.[62,170] Each study showed no statistical difference in the fusion rate based on immobilization methods.

Decompression is warranted in patients with neurologic findings. Patients with low-grade spondylolisthesis generally do not have significant neurologic symptoms. In an adult patient with radiculopathy, it may be acceptable to perform only a decompressive procedure, as described in 1955 by Gill and colleagues.[114] The removal of loose posterior elements and cartilaginous tissue can increase vertebral column instability and further progression of deformity, however—an unacceptable risk in the pediatric spine.[171,172] Although a wide decompression may be warranted, it should be augmented with spinal fusion in a growing child.[114] Studies have also shown an increased risk of progression of deformity in patients with L5 laminectomy and posterior fusion versus patients with posterior fusion alone.[172–174]

Treatment of high-grade spondylolisthesis is a topic of great debate. Symptomatic patients with high-grade spondylolisthesis tend to fare poorer with nonoperative treatment compared with their counterparts with low-grade spondylolisthesis.[175] In high-grade spondylolisthesis, correction of the slip angle rather than the degree of anterior listhesis should be addressed. Although studies show that patients with greater than 50% of slippage may not have a poor nonoperative outcome,[176] fusion is the general treatment of choice among spinal surgeons. In determining the most appropriate procedure, one must take into account all presenting symptoms, neurologic function, radiographic findings, clinical deformity, patient's age, and the surgeon's experience.

As with low-grade spondylolisthesis, in situ fusion was a described treatment for pediatric patients with high-grade spondylolisthesis; however, cranial extension is recommended.[165] A Wiltse approach is suggested unless decompression is warranted. As reported by Pizzutillo and colleagues,[177] bone graft placement at the level of or anterior to the transverse processes extending to the sacral ala helps to ensure a large posterolateral fusion mass, which can effectively counteract shear forces at the lumbosacral junction. Allograft or autograft (or both) may be used, balancing the rate of successful fusion versus the potential for donor site pain and morbidity.[173,178–181]

Postoperative progression of deformity has been appreciated in patients and has been attributed to pseudarthrosis, lack of postoperative immobilization, lack of graft consolidation or maturation, or deterioration of the solid fusion mass. Progression has been appreciated in patients with a solid fusion mass, as evidenced by radiography. Patients with a greater preoperative deformity are at higher risk.[165,168,172,182,183] The advance of slippage is usually minor in these cases, and studies have shown that radiographic evidence of pseudarthrosis does not always lead to pain.[62,160,184] Studies with long-term follow-up of patients with high-grade spondylolisthesis show in situ fusion to be a viable solution in maintenance of symptom relief and prevention of degenerative arthrosis of mobile cephalad spinal segments.[163,185–187]

Grzegorzewski and Kumar[168] found no radiographic pseudarthrosis in 21 patients with high-grade spondylolisthesis treated with in situ fusion, postoperative immobilization in a pantaloon spica cast, and 4 months of bed rest. Although five patients showed evidence of slip progression, two of whom showed an increased slip angle within the first year, only four patients had symptoms of back pain after postoperative follow-up of almost 13 years. Overall reports show radiographic evidence of successful fusion to range from 71% to 100% and relief of back pain and neurologic symptoms to range from 74% to 100% in patients after in situ fusion.[1,165,170,175] Patients with high-grade spondylolisthesis who are at risk of developing pseudarthrosis require a wide decompression secondary to L5 radiculopathy or sacral root symptoms, and patients with excessive mobility at the L5–S1 junction require fusion with pedicle screw instrumentation. Patients with hypoplastic transverse processes, spina bifida, and sacral malformation are also at risk of pseudarthrosis.

Transsacral fusion using either a fibular graft or mesh cage has been shown more recently to be a viable treatment option. By providing an anterior column support and fusion bed, increased structural stability can be achieved. Smith and Bohlman[188] suggested a modification to posterolateral fusion to decrease the incidence of pseudarthrosis and progression of deformity. Eleven patients with high-grade spondylolisthesis were treated in a single-stage procedure involving spinal decompression, in situ posterolateral arthrodesis with autologous iliac crest graft, and anterior arthrodesis with a fibular graft inserted from the posterior approach. A cannulated drill was used to develop a transsacral osseous tunnel extending into the L5 vertebral body. A mid-diaphyseal fibular graft was harvested, trimmed, and inserted into this tunnel, acting as a dowel in the lumbosacral junction. Preoperative neurologic findings were sensory deficits in all but one patient and cauda equina syndrome in five patients. Six patients had prior spinal operations that had failed. The average duration of follow-up was 64 months, showing a solid fusion mass with complete or major neurologic recovery in all patients. Average time to solid fusion was 12 weeks.

In a patient with sagittal balance and high-grade spondylolisthesis, an in situ procedure or partial reduction can be performed, and a cage or fibular dowel can be inserted anteriorly from L5 into S1 or posteriorly with a retrograde direction from S1 into L5. Posterior insertion of the transvertebral cage or fibular graft is advantageous because it obviates the need for an anterior approach to the lumbosacral region, which has its own drawbacks. There is less blood loss and less risk of injury to great vessels. Because the entire procedure can be done with the patient in one position and with one incision, operative time is also greatly reduced. A partial reduction can be performed by use of concave rods, and fusion should be augmented with posterior instrumentation.

Mahmood and colleagues[189] presented a case series in which a transsacral mesh cage was used in lieu of a fibular strut graft. Partial reduction was accomplished with a pedicle screw curved-rod construct, after which an osseous tunnel was established and a transsacral cage impregnated with bone graft was inserted from a posterior approach. A distinct benefit

of using a cage is increased biomechanical stability, as studies have shown fibular strut resorption, deformation, and even fracture.[189–191] Additionally, the use of a cage avoids potential donor site morbidity.[192,193] Average radiographic and clinical follow-up of these patients was 38 months, showing evidence of fusion and relief of symptoms.

There is no clear indication for when reduction of a high-grade spondylolisthesis is necessary as opposed to performing a fusion with mild correction of the slip angle. Many authors suggest that an in situ fusion or mild correction is indicated for patients who exhibit sagittal balance and acceptable slip angle. When considering reduction, improvement of slip angle should be the primary objective rather than improvement of grade of listhesis. In patients with a high-grade slip, a larger slip angle correlates with increased risk of progression of deformity.[74,76] Reduction of spondylolisthesis results in improved sagittal balance, improvement in cosmesis, and a biomechanically stable fusion mass. In addition, by reducing the deformity, canal stenosis is improved, and tension on nerve roots and the cauda equina is reduced. Improvement of overall sagittal alignment leads to improved posture, improved gait, and increased function. Reduction of spondylolisthesis in skeletally immature patients is recommended for patients with a high slip angle (>45 degrees), patients with severe sagittal imbalance, and patients who are at high risk of developing a pseudarthrosis with in situ fusion.[62,163,194]

Numerous methods of reduction have been described. The earliest reported reduction was published in 1936 by Jenkins,[195] who used longitudinal traction followed by anterior fusion; however, the reduction could not be maintained. Since his initial report, variations of Jenkins's described technique have been published.[163,185,196–206] Reduction techniques may be as minimally invasive as external casting after bone graft placement or as complex as staged procedures involving multiple posterior and anterior approaches.

Reduction with external casting is particularly beneficial in young patients, in whom pedicle screw fixation is not feasible. After an open procedure in which posterior elements are decorticated and bone graft is placed around the proposed fusion site, the surgical wound is closed. The patient is placed on an antilordotic frame or spica table with extension of the spine to reduce the lumbosacral kyphosis. The patient should be awake for this part of the procedure to report any changes in neurologic function. If this is impossible, the use of neuromonitoring may help in the neurologic assessment during the reduction. To hold the reduction, the spica cast should be extended to the trunk and incorporate at least one thigh. Burkus and colleagues[166] showed that the use of pantaloon spica cast immobilization led to a decrease in sagittal translation of more than 5% in three-quarters of patients treated with cast immobilization and a decrease in the slip angle of more than 5% in 58% of patients treated with cast immobilization. Of the patients who did not undergo cast immobilization, 45% had an increase in sagittal translation of more than 5% and 56% had an increase in slip angle of more than 5 degrees.

In patients in whom instrumentation can be placed, reduction followed by instrumentation for stability is recommended. Published procedures include halo-femoral or halo-pelvic traction and anteroposterior fusion followed by application of a pantaloon spica cast to apply anteriorly directed pressure.[163,200] Other authors have described anterior release with partial reduction and anterior interbody fusion,[207] intraoperative closed reduction followed by instrumented posterior fusion,[208] and a two-stage procedure with a posterior decompression and halo-skeletal traction followed by interbody fusion.[209] Drawbacks to these procedures included lengthy preoperative hospitalization for traction and lengthy postoperative immobilization in a cast. The study by Burkus and colleagues[166] compared patients treated with a pure in situ fusion with patients who underwent posterior fusion and were reduced postoperatively in a pantaloon spica cast. Reduction was found to be safe and fusion rates were noted to be higher in addition to less chance of late slip and slip angle progression in patients who were treated with a reduction.

Mehdian and Arun[211] published a three-stage procedure using a combined anterior and posterior approach performed in one operative sitting. In the first stage, a laminectomy of L5 is performed with wide decompression of the L4–S1 nerve roots. L5–S1 discectomy was performed next, followed by an osteotomy of the posterosuperior aspect of S1. The second stage consisted of a transperitoneal approach to the L5–S1 level, allowing removal of the anterior disc protrusion and associated thickened anulus fibrosus, effectively allowing posterior translation of the superior body. In the final stage, the patient is repositioned prone and instrumented from L4 to S1. Bilateral pedicle screws are initially placed at L4 and S1, and a reduction can be performed with the assistance of curved rods, after which bilateral L5 pedicle fixation points can be established. Cages may be inserted in the L5–S1 interspace to promote a solid arthrodesis.

Our preferred method for treating high-grade slips with significant lumbosacral kyphosis is postural reduction with positioning under anesthesia and a wide decompression of the L5 and S1 nerve roots bilaterally. The dysplastic L5–S1 disc is removed with a transforaminal approach, and the dome of the sacrum is osteotomized (sacroplasty) to facilitate gentle reduction. Reduction pedicle screws are used to reduce the slip gently, an interbody graft is placed, and the construct is compressed posteriorly to obtain lordosis.

Treatment of severe deformity, including spondyloptosis, can be challenging to the most experienced spine surgeon. The natural history of spondyloptosis is unclear because of its rarity and because it is frequently not reported separately from high-grade spondylolisthesis (grades III and IV). Most authors agree that in a symptomatic patient, benign neglect is not a viable option. The surgical management of spondyloptosis in children is variably documented in the literature. Some authors propose that posterior fusion in situ with or without decompression is a safe and reliable procedure,[168] whereas others suggest that reduction of the slipped vertebra may prevent some of the adverse sequelae of in situ fusion, which include nonunion, bending of the fusion mass, and persistent or increasing lumbosacral deformity.[191,211–214] Many investigators advocate a combined anterior and posterior fusion using instrumentation. An in situ circumferential fusion, as described by Smith and Bohlman,[188] has the lowest risk for iatrogenic nerve injury.

Resection of the L5 vertebra with reduction of L4 onto S1 was initially described by Gaines and Nichols in 1985.[215] The initial stage of the procedure involves an anterior L5 vertebrectomy, in which the L5 body is removed to the base of the pedicles. The second stage is performed through a midline posterior approach involving resection of the now loose L5 posterior elements, decompression, and instrumented reduction through transpedicular instrumentation of L4 onto S1.[214,215] Lehmer and colleagues[216] performed a retrospective review evaluating indications, techniques, results, and patient satisfaction. Of patients, 25% were found to require reoperation secondary to delayed union or instrumentation failure. Three-quarters were noted to have early postoperative neurologic deficits, more than half of which were present preoperatively, and most resolved. All three patients with preoperative cauda equina syndrome recovered postoperatively, and patient questionnaires revealed a high patient satisfaction rate.

As with other lumbar fusion surgery, the most common complication from an operative intervention is pseudarthrosis. Reported rates vary from 0% to 39%,[82,164,166,169,217] and pseudarthrosis occurs more frequently in fusions performed for lytic (type IIA) spondylolisthesis.[218] Radiographs often show lucency around pedicle screws, instrumentation failure, progression of slip angle, or increased vertebral displacement.

Reports exist of increase in spondylolisthesis even with an uninstrumented solid arthrodesis as shown radiographically.[8,62,106,168,169,177] In most of these reports, radiographs and not CT were used to assess fusion mass; many of these cases may have been pseudarthroses. Increased slip was reported in noninstrumented fusions, providing a sound argument for instrumented fusion.

As per the 2003 mortality and morbidity report of the Scoliosis Research Society, the incidence of neurologic complications with lytic spondylolisthesis surgery is 3.1%.[219] Radiculopathy is the most common surgical complication after reduction. Intraoperative manipulation can cause direct dural trauma, injuring multiple sacral and lumbar nerve roots and resulting in postoperative deficits. The L5 nerve roots are most commonly involved and reports show variable rates of resolution, with the highest risk associated with aggressive reductions of high-grade listhesis.[220–222]

Cauda equina syndrome is a potentially disastrous complication that can occur as a result of intraoperative technique, as a result of postoperative conditions, or with no apparent antecedent cause.[208,223–226] Schoenecker and colleagues[116] described 12 cases after in situ arthrodesis for grade III or grade IV L5–S1 spondylolisthesis. During the procedures, there was no evidence of compromise of the cauda equina. Of 12 patients, 5 showed complete recovery and 7 had permanent residual deficits manifested by bowel and bladder dysfunction. Although the exact etiology is unknown, it may be related to vascular phenomena, transient anterior displacement of L5 during the surgical exposure causing laminar impingement on the sacral dome, or a period of hyperextension during patient positioning.[226] With reduction of the deformity, the risk is far greater. If cauda equina syndrome is suspected, surgical decompression is imperative. Sacroplasty and resection of the adjacent disc or lamina of L5, or both, is recommended because it is thought to facilitate neurologic recovery.[116]

With surgical advances in technique and instrumentation, new biologic and mechanical fusion adjuvants, neuromonitoring, and advanced imaging, it is hoped that further reductions in complication rates may be achieved despite the risks inherent to these highly invasive procedures.

Summary

The treatment of patients with spondylolisthesis can be a challenge for the most experienced spinal specialists. With an increasing number of pediatric athletes and improvements in diagnostic imaging techniques, more patients with spondylolisthesis are presenting to the clinician's office. To address the patient's needs best, one first must establish a proper diagnosis, quantify the deformity, and understand properly the etiology of the disease and its risk of progression.

Most pediatric patients with low-grade slips can be treated effectively with nonoperative modalities such as immobilization, activity and sports restriction or modification, analgesia, and physical therapy. Severe spondylolisthesis in adolescents can be cosmetically and functionally debilitating and poses a challenge to the treating spinal surgeon. Management of high-grade spondylolisthesis often requires larger procedures with increased associated risks. In addition to fusion with or without instrumentation, reduction of the listhesis may be beneficial in certain high-grade lesions. With the increased risks and complexity of the reduction procedure, strict selection criteria must be applied to select proper surgical candidates. Improvement of the slip angle should be the primary objective in considering a patient for deformity reduction. Additionally, sagittal alignment and overall balance should be considered during the decision-making process. All risks must be thoroughly communicated to the patient and family before the decision is made to proceed with surgical intervention.

I thank Faisal Mahmood, K. Durga Nagraju, and Andrew J. Milby for their contributions to this chapter in previous editions of this text.

PEARLS

1. Spondylolysis is often discovered incidentally. In asymptomatic cases, patients may need no treatment other than monitoring for progression to spondylolisthesis.
2. Various surgical options have been described for direct fixation of the pars interarticularis in spondylosis and for decompression and fusion for spondylolisthesis. The risks and benefits of each of these options must be carefully considered before recommending surgical treatment.

PITFALL

1. Spondylolisthesis may be associated with neurologic findings attributable to canal stenosis or nerve root impingement. MRI is

recommended in cases with neurologic findings. Surgical intervention may be required even in asymptomatic cases if progressive translation is observed.

KEY POINTS

1. Spondylolysis is defined as a defect in the pars interarticularis and is likely multifactorial in etiology with activity-related, degenerative, and genetic components.
2. Spondylolysis is a common cause of back pain, particularly in young adults and athletes engaging in repetitive hyperextension activities.
3. Most cases of symptomatic spondylolysis respond to conservative management, including bracing, activity modification, and analgesia.
4. Spondylolisthesis is defined as the anterior translation of a superior vertebral body relative to an inferior vertebral body and may occur as a result of insufficiency of the pars interarticularis (isthmic spondylolisthesis), following spondylolysis, or in the absence of spondylolysis (degenerative spondylolisthesis).

32 CHAPTER Cervical, Thoracic, and Lumbar Spinal Trauma of the Immature Spine

Jesse E. Bible
J. Alex Sielatycki
Joon Yung Lee
Clinton J. Devin

Epidemiology

Spine injuries involve 1% to 5% of children admitted to trauma centers, making these injuries relatively uncommon in pediatric patients.[1,2] The true incidence may be higher given the challenges of obtaining a reliable examination and necessary images in children compared with adults.[1–3] A high index of suspicion is warranted in children with polytrauma, particularly those who have sustained a head injury given that 40% to 50% of children with a head injury also have a cervical spine injury.[3,4]

The cervical spine is most commonly involved in injuries in pediatric patients. The levels of cervical spine involvement and mechanisms vary with age. Due to a disproportionately larger head and inherent mobility, children younger than 8 years of age are more susceptible to upper cervical spine injuries. As the spine develops adult characteristics between the ages of 8 to 10 years, children older than this age more commonly sustain subaxial cervical spine injuries.[5] Similarly, thoracic and lumbar spine injuries also increase in incidence as children age and the spine takes on the biomechanical characteristics of an adult.[5]

Traffic-related incidents account for nearly one-third of all pediatric spine injuries; however, other mechanisms of injury are unique to particular age groups.[5] In neonates, birth trauma is the most common cause of spine injury, with an incidence of 1 in 60,000 live births.[6] Excessive distraction or hyperextension of the cervical spine is thought to be the mechanism, occurring in breach deliveries and large neonates.[7] Spinal cord injury should be considered in neonates with hypotonia or cardiopulmonary instability. In infants and young children, particular injuries should also raise suspicion for nonaccidental trauma, including avulsion fractures of the spinous processes or multilevel compression fractures in conjunction with rib fractures, long bone fractures, cutaneous lesions, and other characteristic injuries of abuse.[8,9] In older children and adolescents, sports-related injuries and diving accidents become more frequent.[5]

Developmental Anatomy and Biomechanics

Understanding the developmental anatomy allows identification of normal radiographic variants and synchondroses opposed to true pathology. The atlas (C1) and axis (C2) undergo unique development, whereas the subaxial cervical spine, thoracic spine, and lumbar spine follow a similar pattern of maturation. The atlas (C1) develops from three primary centers of ossification: the anterior arch and two neural arches[10] (Fig. 32.1). The two neural arches are visible at birth and develop into the lateral masses. The anterior arch is radiographically visible at birth in only 20% of infants; in the remaining infants, it ossifies over the subsequent year. Measuring the atlanto-dens interval (ADI) is therefore unreliable in infants younger than 1 year old. Posteriorly, the synchondrosis between the two neural arches closes by age 3 years, while the ossification between the anterior arch and the two neural arches occurs by age 7 years.[11]

The axis (C2) is formed by five primary centers of ossification. The odontoid process is formed by two parallel ossification centers that fuse in utero during the seventh fetal month. A secondary ossification center occurs at the tip of the odontoid, called the *os terminale,* arising between ages 3 and 6 years and fusing by age 12 years. The remaining three primary centers of ossification are the body and two neural arches. The body typically fuses with the odontoid by age 6 years, but this synchondrosis can persist until age 11 years (Fig. 32.2). The neural arches fuse anteriorly to the body by age 6 years and with each other posteriorly by age 3 years, similar to the atlas.

The subaxial cervical spine (C3–C7), thoracic spine, and lumbar spine all develop in a similar fashion. There are three primary ossification centers: the body and two neural arches. The neural arches typically fuse to the body anteriorly by age 6 years and to each other posteriorly by age 3 years. However, closure of the neurocentral synchondroses can remain incomplete until early adulthood, especially in the thoracic region.[12] Secondary centers of ossification can exist at the tips of the

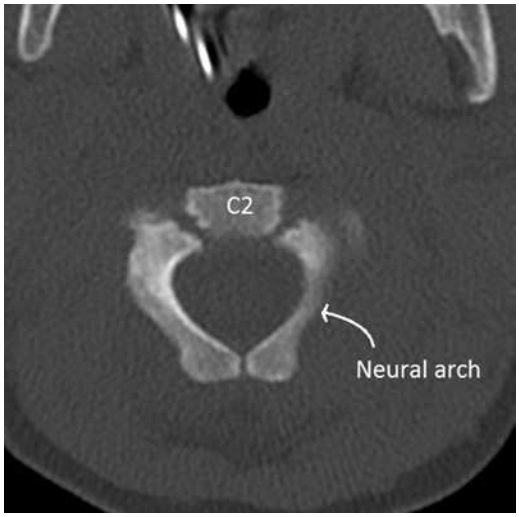

FIG. 32.1 Axial computed tomographic scan of C2 in an 18-month-old child demonstrating the ossification centers of the vertebral body and paired neural arches.

FIG. 32.2 Coronal computed tomographic reconstruction in the cervical spine of an 18-month-old child, showing the C2 body *(A)*, dens *(B)*, and neural arch *(C)* ossification centers.

transverse processes, spinous process, and superior and inferior aspects of the vertebral body. These areas ossify in early adulthood and can be mistaken as a fracture.[10,11] The vertebral bodies of the subaxial cervical, thoracic, and lumbar spine grow in height by endochondral ossification that progresses in posterior to anterior direction over time until the body takes on its characteristic rectangular shape by age 7 years. Until age 7, it is acceptable to have anterior wedging of the subaxial cervical vertebrae, which should not be confused with anterior compression fractures. This normal wedging can be most profound at C3.[13]

The spine typically assumes adult characteristics and size by ages 8 to 10 years. Therefore, spine injuries can typically be divided by age: younger or older than 8 years old. From birth until age 8 years, children are usually more susceptible to upper cervical spine injuries. In addition, it is more common for children in this younger age group to have a neurologic injury and subluxation or complete dislocation rather than a fracture, due to increased generalized laxity.[2,14–17] Proposed reasons for the increased incidence of upper cervical spine injuries in this younger age group are listed in Box 32–1. These unique characteristics, especially disproportionate head size, are important to keep in mind when transporting and evaluating a young child.

BOX 32.1 Risk Factors in Children <8 Years Old for Developing Upper Cervical Spine Injuries

Disproportionately large heads and weak neck muscles
Fulcrum of movement centered at C2–C3
Ligamentous and joint capsule laxity
Horizontal orientation facet joints
Increased cartilage/bone ratio with relative anterior wedging of vertebrae and incomplete ossification of odontoid process

Transport and Evaluation

Proper care of pediatric spine injuries begins at the scene of the accident. In a child with polytrauma, a spine injury must be assumed until proven otherwise, and all appropriate precautions and immobilization must be utilized. Children should be initially placed in a well-fitting cervical collar and immobilized on a spine board. Commercial collars often do not fit appropriately, preventing adequate immobilization. In this case, sandbags can be placed on each side of the head to prevent motion.

Herzenberg and colleagues[18] were the first to note that the transport of young children (< 8 years old) on a standard adult spine board tended to cause excessive flexion of the cervical spine. It was noted in all cases that the cervical spine was forced into relative kyphosis because of the disproportionately large head relative to the chest. This flexed position could potentially jeopardize the cervical cord if the mechanism of injury was a flexion force, which is often the case in motor vehicle accidents. To obtain a neutral position, Herzenberg and colleagues[18] recommended pediatric spine boards with a cutout for the occiput. Alternatively, a standard spine board can be used with a towel roll placed under the shoulders, allowing the head to drop into mild extension (Fig. 32.3). Several other studies have demonstrated that young children with suspected cervical spine injuries should be transported with relative chest elevation to allow for more anatomic alignment of the cervical spine. One should evaluate the child's cervical spine clinically after immobilization, looking from the side to ensure that the external auditory meatus is in line with the shoulder.[19,20]

Clinical evaluation of a child believed to have a spine injury is often hampered by an inability to obtain an accurate history and thorough physical examination. The clinician should have a heightened suspicion of spine injury in nonverbal children,

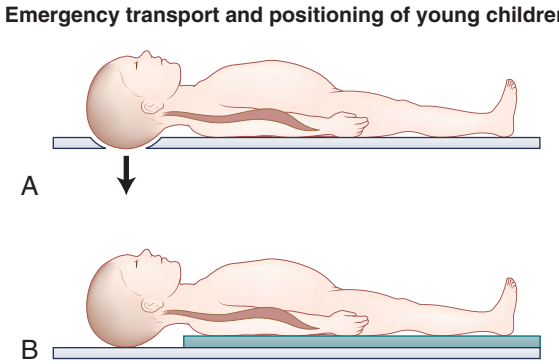

FIG. 32.3 The proportionally larger occiput in children requires a cutout from the spine board in emergency transportation. (From Herzenberg JE, Hensinger RN, Dedrick DK, et al. Emergency transport and position of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg Am.* 1989;71:15–22.)

with a reported 23-fold increased likelihood of missing a cervical spine injury in this group.[21] The mechanism of injury should be taken into account when considering the likelihood of an occult spine injury. Additionally, the presence of associated injuries, including facial trauma, head injuries, thoracic wall injuries, and abdominal injuries, increases the likelihood of spine trauma.[22] Abdominal injuries, particularly injuries of the small bowel, are associated with flexion distraction injuries of the thoracolumbar spine.[23] Spinal injuries can occur at multiple levels, with noncontiguous fractures occurring in 16% of cases.[24]

For examination purposes, the cervical collar should be temporarily, carefully removed, with an assistant stabilizing the head and cervical spine during the log-roll maneuver. Cervical inline traction should be avoided in young children because of the increased risk of ligamentous and atlanto-occipital injuries. The entire spine is visually inspected and palpated for malalignment, asymmetry, interspinous widening, tenderness, abrasions, or other abnormalities. Careful spine precautions should be maintained until injury is ruled out.

A thorough baseline neurologic examination, as discussed in detail in other chapters, should be carefully documented. If a neurologic deficit is identified, frequent examinations should be performed to detect a change in the deficit. Throughout the sensory, motor, and reflex examination, the contralateral extremity should always be used as a comparison to detect subtle injuries. Also, given that an accurate examination can be difficult at times due to a child's age or altered mental status, close observation during other parts of a child's workup can be valuable, such as looking for withdrawal from painful stimuli or diaphragmatic breathing without assistance of accessary muscles.

Plain Radiography of the Cervical Spine

Imaging of the cervical spine should be performed if a child meets any of the following criteria (Box 32.2): (1) The child is nonverbal secondary to age or altered mental status, (2) intoxication is present, (3) a neurologic deficit (persistent or transient) is present, (4) neck pain is present, (5) there is a high-risk mechanism of injury, (6) physical signs of neck trauma or lap belt trauma are present, or (7) painful distracting injuries are present.[25] Additionally, unexplained cardiorespiratory instability can be an indication of a high cervical spine injury, and should be evaluated appropriately with imaging of the cervical spine.[26]

BOX 32.2 Criteria for Imaging the Cervical Spine in Pediatric Trauma

Child is nonverbal (secondary to age or mental status)
Intoxication is present
Persistent or transient neurologic deficit
Neck pain
High-energy mechanism
High-risk mechanism (i.e., fall onto head from a height)

The three-view cervical spine series may not be applicable in pediatric patients with polytrauma, but likely still has a role in patients without polytrauma. The supine lateral cervical radiograph has a reported sensitivity of 79% to 85% in pediatric patients.[27] This sensitivity is dependent on seeing all seven cervical vertebrae, including the occipitocervical and cervicothoracic junction. Lally and colleagues[28] found that all seven cervical vertebrae were seen in only 57% of children on the initial cervical spine series. The addition of the anteroposterior and open-mouth odontoid views increases the sensitivity to approximately 94% if ideal images can be obtained, although this can be extremely challenging in an uncooperative child.[29] Buhs and colleagues[30] showed that the open-mouth odontoid view did not provide additional information in children younger than 9 years that was not already appreciated on the anteroposterior and lateral views. In its place, these authors recommended use of computed tomography (CT) from the occiput to C2.

The use of flexion and extension radiographs during the initial evaluation has come into question. Ralston and colleagues[31] disputed the need for these dynamic studies in the acute setting. These investigators had blinded radiologists retrospectively review static and flexion-extension radiographs on 129 children. They found that if the static radiographs were normal, the flexion-extension views would reveal no abnormality. Additional studies have confirmed these findings and recommended against acute flexion-extension views.[32] Dynamic views may still be useful in evaluating for instability in the subacute outpatient setting after acute pain and muscle spasms have subsided.

Interpretation of the cervical spine series requires an understanding of the normal anatomy and the anatomic variants of the immature spine that can mimic trauma. Special attention should be given to the upper cervical spine, including the atlantoaxial and atlanto-occipital region given the propensity of injuries to this area in children and the subtle radiographic findings.[33] Several methods for evaluating the craniocervical junction using a lateral radiograph have been described. The "rule of twelves" is thought to be the most sensitive method (Fig. 32.4), whereby the distance between the basion and tip of the odontoid process should be 12 mm or less, and a line drawn parallel along the posterior aspect of the body of C2, including the odontoid, should come within

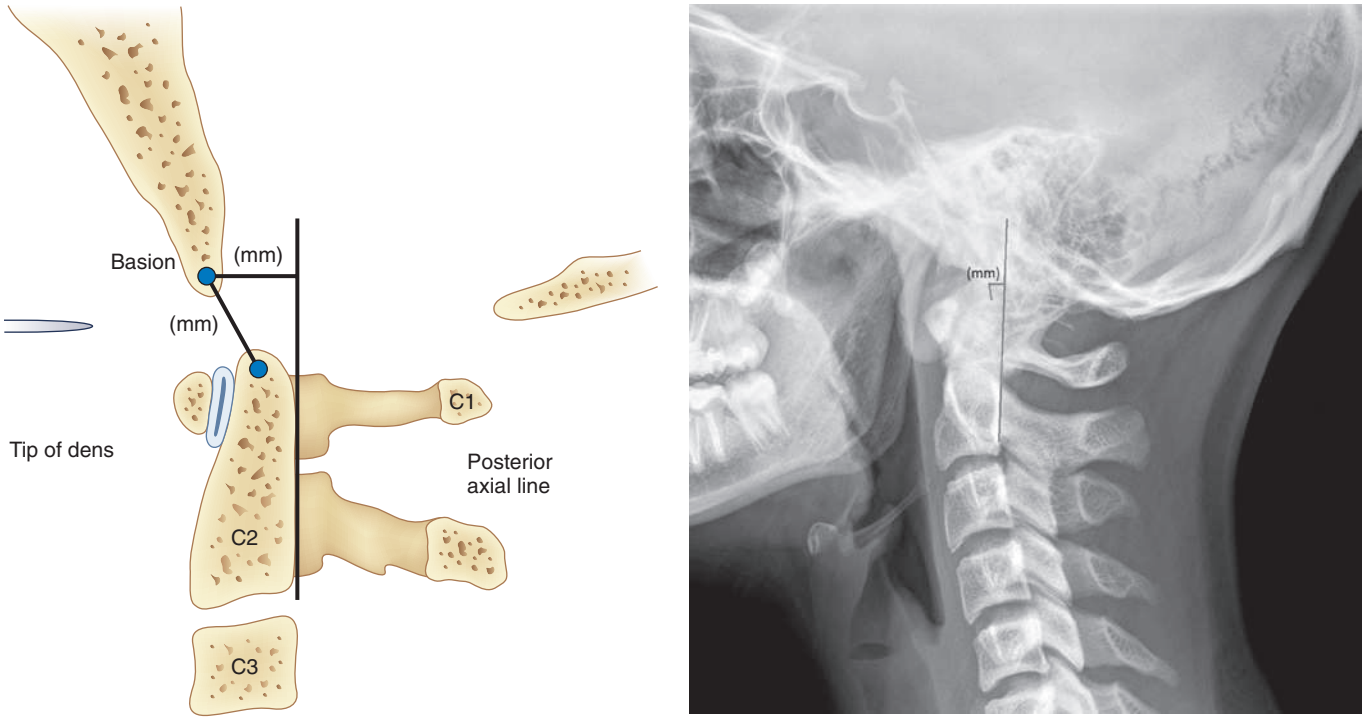

FIG. 32.4 Schematic illustrating the measurements required for the "rule of twelves" (*left*). Lateral radiograph of a teenager without a cervical spine injury with measurement lines superimposed (*right*).

12 mm of the basion. The former, tip of the odontoid to the basion distance, is unreliable in children younger than 13 years because of incomplete ossification of the odontoid. However, the line drawn parallel to the back of the C2 body and odontoid peg should be less than 12 mm from the basion.[24] Furthermore, a gap of more than 5 mm from the occipital condyle to the C1 facet articulation also represents a disruption of the occipitocervical junction.[34]

The atlantoaxial articulation is best evaluated with the atlantodens interval (ADI). In children, the normal ADI can be up to 5 mm. If the ADI exceeds 5 mm on lateral flexion and 4 mm on lateral extension, the transverse atlantal ligament is likely disrupted.[35] When the ADI exceeds 10 to 12 mm, the alar and apical ligaments have failed, with a high risk of cord compression.[36] The extent of cord compression at the atlantoaxial joint can be determined using Steel's rule of thirds,[37] which is based on dividing the inner diameter of the C1 ring into thirds. One-third of the space should be occupied by the odontoid, one-third by the spinal cord, and one-third by the space available for the cord. When the dens migrates posteriorly by greater than one-third of this space, the transverse ligament has been disrupted, and the spinal cord is likely being compressed.

Many normal anatomic variants should be recognized so as to not be confused with a "true" traumatic injury (Box 32.3). A normal finding on extension radiographs in 20% of children is overriding of the anterior arch of the atlas on the odontoid. This finding represents incomplete ossification of the dens.[38] Another common variant noted on cervical spine radiographs in an immature spine is pseudosubluxation of C2 on C3 and less commonly C3 on C4. Cattell and Filtzer[38] were the first to appreciate this normal finding in a study involving 160 pediatric patients with no history of cervical spine trauma. Pseudosubluxation can be differentiated from traumatic subluxation by evaluating the continuity of the spinolaminar line drawn along the posterior arch from C1–C3 (also known as the Swischuk line); with physiologic subluxation, this line should pass within 1 mm of the anterior cortex of the posterior arch of C2, while a distance greater than 1.5 mm should raise concern for injury (Fig. 32.5). On dynamic radiographs, 46% of children younger than 8 years showed 3 mm of anteroposterior motion of C2 on C3; 14% of children had radiographic pseudosubluxation of C3 on C4.[38,39] Based on this study and others, up to 4 mm of translation is considered normal.[6,31,38,40,41]

The absence of cervical lordosis on static lateral radiographs can be a normal finding in 14% of children up to age 16 years.[24] This normal variant can be differentiated from a more ominous sign of posterior ligamentous injury by assessing the posterior interspinous distance. Each interspinous distance should not be more than 1.5 times greater than the interspinous distance directly above and below a given level. The only exception to this rule is the C1–C2 interspinous distance, which can be

BOX 32.3 Common Radiographic Variants in Pediatric Spine Trauma

Anterior wedging of vertebral bodies in children ≤7 y
Pseudosubluxation of C2 on C3, or C3 on C4
Lost cervical lordosis
Atlanto-dens interval <5 mm on flexion views in children <8 y
Persistent synchondrosis
Increased retropharyngeal space (≤7 mm) in the crying child
Overriding of the anterior arch of the atlas on the odontoid

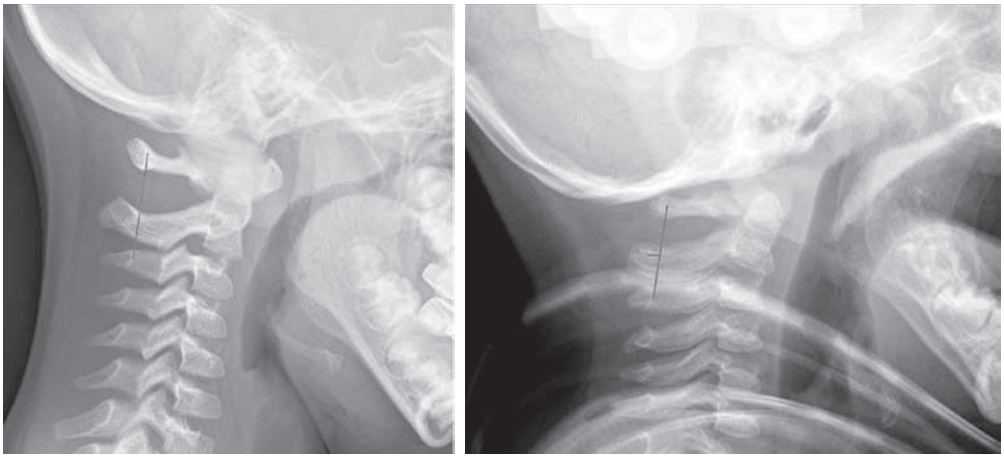

FIG. 32.5 Flexion radiograph of an uninjured cervical spine in a 6-year-old demonstrating pseudosubluxation and a congruent C1–C3 spinolaminar line (*left*). Upright radiograph in a 3-year-old child with traumatic subluxation of C2 on C3 (*right*).

greater than 1.5 times the distance of the level below. The increased mobility at this level is thought to be secondary to the stout posterior ligaments linking C1 to the occiput.[42,43]

Another challenge unique to the developing spine is differentiating a synchondrosis that has not yet ossified from a true fracture. A synchondrosis typically shows well-corticated sclerotic margins. Another helpful aid in differentiating a subtle fracture from a synchondrosis is evaluation of the prevertebral soft tissues. The retropharyngeal space at C2 should be less than 7 mm and the retrotracheal space at C6 should be less than 14 mm in children (as opposed to <22 mm in adults). In simplistic terms, the retropharyngeal space should be one-half the anteroposterior distance of a cervical vertebral body, and the retrotracheal space can be up to a full cervical vertebral body. The retropharyngeal soft tissue can be falsely increased with expiration, such as in a crying child.[44]

Computed Tomography and Magnetic Resonance Imaging of the Spine

The use of helical CT has replaced conventional radiography as the screening tool of choice for the adult cervical spine in the setting of blunt trauma.[45,46] CT of the chest, abdomen, and pelvis, originally targeted for evaluation of the thoracic and abdominal contents, has been shown to be very sensitive at screening for thoracolumbar spine injury. Multiple prospective studies have shown a higher sensitivity for CT (93–100%) compared with plain radiography (33–74%) with improved interobserver variability.[39,47-49] Thus, CT of the spine in high-energy trauma patients has been touted as the standard of care in the adult literature.[50] This information can potentially be extrapolated to pediatric patients, but further studies need to be performed before CT scans with sagittal and coronal reconstructions replace conventional radiography for thoracolumbar spine evaluation in children. As of 2007, the American College of Radiology Appropriateness Criteria advocates for plain radiographic imaging in children 14 years and under with suspected spinal trauma.[51] Additional studies advocate the judicious use of CT scan in children, with some recommending magnetic resonance imaging (MRI) over CT scan in children under 5 years with suspected spinal injury given the relatively high rate of ligamentous versus bony injury in the very young.[52,53] In 2001, Keenan et al. showed that adding CT of the cervical spine in the setting of head trauma decreased the occurrence of multiple additional radiographs, particularly when the patient was intubated.[54] In 2009, Rana et al. reported the sensitivity and specificity of CT to be 100% and 98%, respectively, as compared to plain radiographs showing sensitivity and specificity of 62% and 1.6%, respectively, in a review of 318 pediatric trauma patients.[55] Following practices in the adult population, the use of CT as a screening for spinal trauma in children continues to expand. Adelgais et al. found an increase in the use of CT of the cervical spine in pediatric trauma: from 2002 to 2011, use of cervical spine CT increased from 3.5% to 16.1% of traumas seen at pediatric trauma centers, and from 6.8% to 42% at general emergency departments.[56] Another study showed an increase in the proportion of pediatric fall patients receiving CT from 5.3% in 2001 to 16.6% in 2010. Cervical spine CT is the preferred screening method at our institution in the setting of high-energy trauma.

The increased radiation exposure and increased risk of thyroid cancer is of concern, particularly in the pediatric population. Studies have estimated that CT exposes patients to four times the radiation dose compared to plain radiographs.[57,58] Muchow et al.[59] calculated the radiation exposure to the thyroid after CT and estimated the median excess relative risk of thyroid cancer to be 13% in males and 25% in females for CT scan versus 0.24% in males and 0.5% in females after one radiograph. Based on this data, the increase in the absolute risk of thyroid cancer after CT in males is estimated to be 5.2 to 5.8 per 100,000 and 15.2 to 19 per 100,000 in females. Of note, radiation exposure from any particular CT scan is dependent on the specific scanner and imaging protocol used[60]; thus, advances in technology may allow radiation doses to decrease.

Whether the specificity and sensitivity of CT is sufficiently superior to radiography to justify the increased cost and radiation risk has not been firmly established. Studies in adult trauma have estimated the cost-effectiveness ratio (cost per quality-adjusted life-year [QALY]) of CT to range from $20,000 to $50,000/QALY in high-risk patients and up to $80,000/QALY in low-risk patients.[61] To our knowledge, there are no high-quality studies specifically investigating the cost-effectiveness ratio of spine CT in pediatric trauma. Analyses that also account for the added risk of cancer from radiation exposure are warranted in the pediatric trauma population. Based on available data, either CT or plain radiography may be used to screen for cervical spine injuries.

MRI is useful for evaluating a neurologic deficit and soft tissue involvement. MRI in this age group can be difficult because these young patients often need sedation to prevent movement during data acquisition. MRI should be obtained in patients with evidence of a persistent or transient neurologic deficit. A transient deficit can be an indication of a more serious ligamentous and neurologic injury, thus subsequent need for immobilization.[62]

MRI can also be especially helpful in clearing the cervical spine in obtunded patients. Frank and colleagues[63] showed the effectiveness of MRI at decreasing time to cervical spine clearance, length of time in the pediatric intensive care unit (ICU), and length of time in the hospital. In a meta-analysis of diagnostic imaging studies, Muchow et al.[59] advocate that a normal MRI is the gold standard for cervical spine clearance in obtunded trauma patients. In their meta-analysis, they identified five level I studies, inclusive of a total of 464 obtunded trauma patients with cervical spine MRIs at least 72 hours after admission. Patients with spinal cord injuries were excluded. Clinical follow-up awake examination and imaging was the gold standard comparison to MRI. There were zero false-negatives, yielding a negative predictive value of 100%; the positive predictive value was calculated at 90.2%. Thus, they concluded that a negative MRI can reliably be used to clear the cervical collar in obtunded patients. Also in this study, 97 (20.9%) of the 464 patients had abnormalities identified by MRI that were not seen on plain radiographs or CT; unfortunately, the nature of the injuries missed were not reported in any of the available studies. Of note, 15 of the 464 patients had spine injuries requiring surgical treatment, although all 15 of these injuries were also seen on CT or plain radiography. Thus, the literature suggests that MRI can be used to rule out cervical spine injury in the obtunded patient. There are case reports of spinal cord injuries in patients whose collar was "cleared" by a normal CT scan[64]; however, the incidence of significant spine injuries missed by CT or radiographs has not been firmly established. Fisher et al. performed a retrospective review of 277 patients, reporting that MRI detected an injury requiring intervention in 7 (3%) of patients with a negative CT scan.[65] Five of those 7 required longer-term use of a cervical collar, and 2 (0.7%) had injuries warranting surgical stabilization. Importantly, 4% of their patients had fracture seen on CT that were *not* seen on MRI, suggesting that both CT and MRI are needed to rule out a significant spine injury in obtunded patients.[66]

Spine Clearance

Early cervical spine clearance has multiple benefits as cervical collars have known complications. These include skin breakdown around the neck, dysphagia, pulmonary complications, and increased intracranial pressure.[40,67,68] After a cervical collar has been placed on a child, formal clearance must be obtained before it can be removed. Clinical clearance of the cervical spine has been evaluated using the National Emergency X-Radiography Utilization Study (NEXUS), which was originally developed for adults. NEXUS has been used as a decision-making instrument to determine the need for radiography. The criteria in adults for clinical clearance are absence of the following: neck pain, neurologic symptoms, distracting injuries, or altered mental status (owing to injury, age, or intoxication). If any one of these four criteria is present, the patient is considered to be high risk and must be radiographically cleared. If none of these criteria is present, the collar can be cleared without further imaging.

Application of NEXUS criteria in pediatric patients was studied in a prospective multicenter study. All 30 cervical spine injuries were placed correctly into the high-risk group, and, more important, no cervical spine injuries were noted in the low-risk group. Additionally, use of NEXUS criteria decreased pediatric cervical spine imaging by 20%.[69] These rules cannot be safely applied in children too young to cooperate with an examination, in children in the presence of a high-energy mechanism, or in children with associated injuries that heighten the suspicion of a spine injury. The Canadian C-spine rule (CCR) has gained popularity in the adult literature, showing a higher sensitivity than NEXUS (99.4% vs. 90.7%) and a higher specificity (45.1% vs. 36.8%).[70] According to the CCR, imaging is recommended if an adult patient is high risk (>65 years old, dangerous mechanism, or extremity paresthesias) and if the patient is unable to actively rotate the neck 45 degrees in each direction (tested only in low-risk patients).

In young children, however, the Canadian C-spine rule may not be as sensitive owing to potentially poor cooperation with exam or inability to communicate important symptoms.[71] The efficacy of the Canadian C-spine rule and NEXUS in young children was investigated by Ehrlich et al. in 2009. In a study of children 10 years and younger, the investigators retrospectively applied the NEXUS and CCR rules based on the initial history and physical, and compared these against the patients' imaging findings. With this method they reported that, if applied, the NEXUS had sensitivity of 43% and specificity of 96%, and the CCR showed a sensitivity of 86% and specificity of 94%.[72] We are not aware of any prospective studies specifically investigating clinical decision rules for spine imaging in young children.

It has been shown that an efficient, multidisciplinary approach can facilitate rapid clearance of the cervical spine, decreasing the average time to 7.5 hours in nonintubated patients and 19.4 hours in intubated patients.[25] This rapid clearance is dependent on a system that is safe and user-friendly enough to allow the primary admitting team to perform the clearance. Anderson and colleagues[73] evaluated

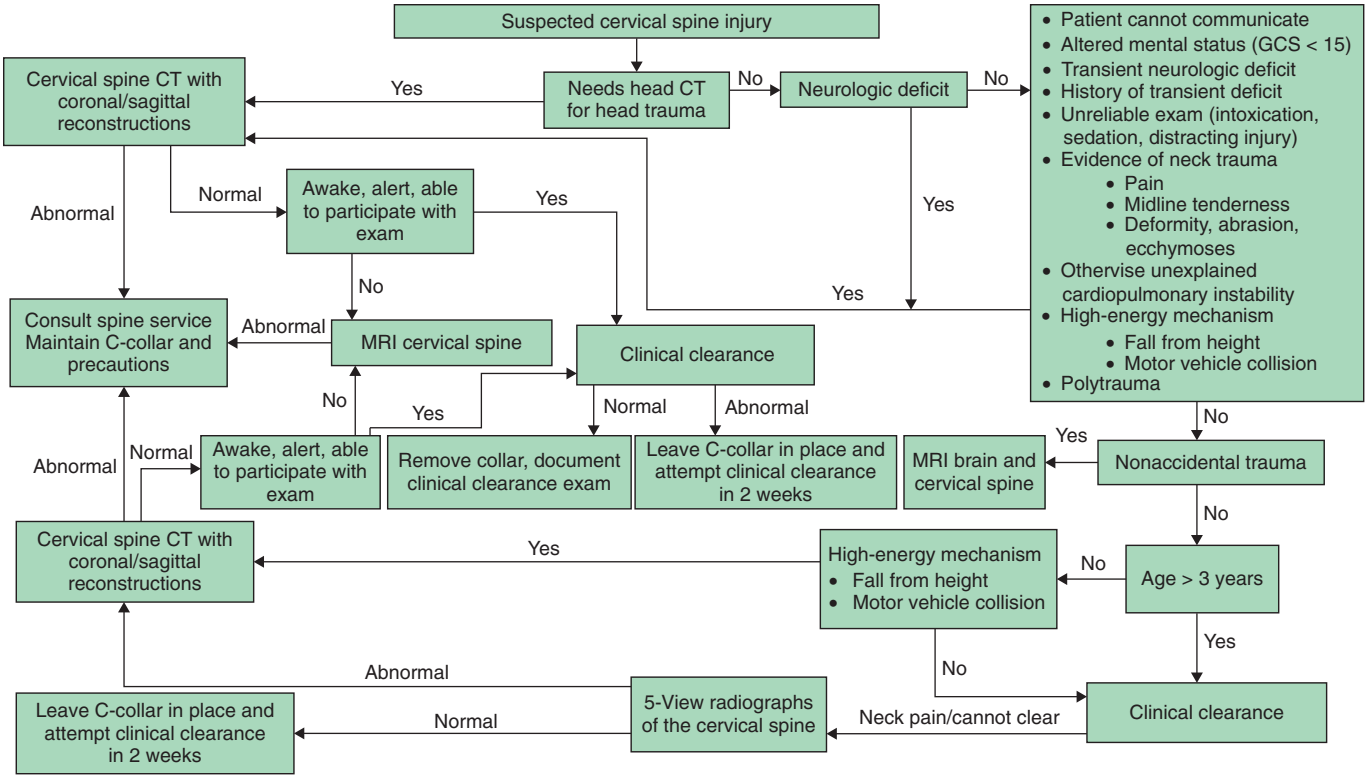

FIG. 32.6 Cervical spine clearance algorithm in pediatric trauma. CT, computed tomography; GCS, Glasgow Coma Scale; MRI, magnetic resonance imaging.

the percentage of cervical spines cleared by spine specialists before versus after the initiation of a clearance protocol, noting a 60% increase in spines cleared by nonspine physicians without any late injuries detected.

A spine clearance protocol should incorporate a thorough history and physical examination with judicious use of imaging modalities. If a low-risk/low-energy injury mechanism took place and there is cervical tenderness on examination, imaging should begin with plain anteroposterior and lateral radiographs. An open-mouth odontoid view should be obtained in children older than 8 years who have the ability to cooperate; otherwise, a CT scan from occiput to C2 should be performed. Children undergoing a CT scan to evaluate for head injury should have the cervical spine with reconstructions included. In the setting of high-risk/high-energy trauma, we recommend CT imaging as the screening tool of choice if a cervical spine injury is suspected. Children with no evidence of injury on plain radiography or CT scan who have persistent pain should remain in the cervical collar with later clearance in the clinic with dynamic radiographs. In the presence of a neurologic deficit or a history of a transient deficit before arrival, MRI of the entire spine should be obtained. If spinal cord injury without radiographic abnormality (SCIWORA) is suspected, the cervical collar should remain in place, spine precautions should be continued, and the patient should be admitted for observation to monitor for potential delayed neurologic deterioration.[74,75]

Clearing the cervical spine in an unconscious patient can be facilitated by a standard protocol. If the patient returns to a normal mental status, the protocol for a conscious patient can be used. There have been reports of delayed neurologic deterioration in patients with altered mental status and unrecognized ligamentous injury that subluxed on mobilization.[76] The two modalities available for evaluating ligamentous injury in an obtunded patient include fluoroscopic flexion-extension and MRI. Fluoroscopic flexion-extension examination can be labor intensive, and in an adult series it was difficult to visualize the cervicothoracic junction.[77] Because of these problems, MRI is superior for evaluating ligamentous injury. Fig. 32.6 presents a cervical spine clearance protocol in line with the best evidence available to date regarding collar clearance and cervical spine imaging.

MRI has been found to be most sensitive for detecting a ligamentous injury at postinjury day 2 or 3.[78] Stassen and colleagues[79] used MRI within their protocol at a level I adult trauma center for assisting in cervical spine clearance. All obtunded patients with a negative CT scan of the cervical spine underwent MRI on postinjury day 3 if they could not be clinically cleared. MRI allowed clearance of the cervical collar in 60% of subjects, and there was no delayed neurologic sequela. The remaining patients were treated in a cervical collar for 6 weeks without complication.

Equivocal MRI findings can be evaluated further with flexion-extension radiographs, or the physician can forgo further study and treat the patient with a collar for 6 weeks. At the termination of the 6-week period, the patient should undergo a flexion-extension series to ensure adequate healing. Expedient clearance of the thoracolumbar spine in a child with polytrauma is also very important to prevent skin breakdown, respiratory complications, and ileus. At our institution,

the CT traumagram, with sagittal and coronal reconstructions, is used to augment the clinical examination and clear the thoracolumbar spine. Future work is needed to prospectively investigate the sensitivity and specificity of clinical decision rules applied in very young children. Such rules should make adjustments for the difficulties with history and physical examination in small children.[71]

Spinal Cord Injury in Children

In the United States, the annual incidence of spinal cord injuries in children has been reported at 19.9 injuries per one million, which translates into roughly 1400 spinal cord injuries per year.[2,80] Spinal cord injury most often occurs after motor vehicle accidents (56%), falls (14%), firearm injuries (9%), and sports injuries (7%).[80] In children, there is a 5% to 10% mortality rate during the first year after spinal cord injury, and death within the first year is reported to be five times more likely in children under age 11 years.[81] The mechanism of spinal cord injury differs depending on age.[24] Children younger than 8 years more often sustain spinal cord insult involving the upper cervical spine secondary to ligamentous injury with no discernible bony changes. This is in contrast to children older than 8 years who have spinal cord injuries with associated fractures secondary to biomechanics of the spine that more closely mirror those of an adult. A thorough neurologic examination should be performed to determine the level involved and whether the lesion is complete or incomplete. It is important to note whether there is sacral sparing as indicated by sensation at the anal mucocutaneous junction (S4–S5 dermatome) on the left and right side, ability to contract the anal sphincter voluntarily, and deep anal sensation. This sacral sparing indicates continuity of long tracts with improved likelihood for return of neurologic function.[82] As in adult injuries, the American Spinal Injury Association (ASIA) Impairment Scale is most frequently used in pediatric patients to provide a standardized description of injury.

Damage to the spinal cord has been categorized into primary and secondary injury. Primary injury occurs at the time of the trauma, leading to structural damage of the neural elements and supporting blood supply. This primary insult is irreversible. Secondary injury occurs within minutes of the trauma, setting off a cascade of events that result in ischemia, increased cell membrane permeability, pathologic electrolyte shift, edema, and production of free radicals.[83] This process continues to evolve over subsequent days, and medical and surgical strategies are directed at mitigating secondary injury. Current acute treatments of interest include support of spinal cord perfusion, intravenous corticosteroids, and early (versus delayed) decompression. Many pharmacologic therapies have been investigated for spinal cord injury, including corticosteroids, GM_1 ganglioside,[84] sodium channel blockers (Riluzole),[85] minocycline, Rho antagonists (Rho is a signaling molecule for myelin and extracellular matrix inhibitors of neural regeneration),[85] and mesenchymal stem cells.[86] There is no single "cure" for spinal cord injury, and the majority of the available treatment strategies remain investigational, with varying results.

During transport and initial evaluation, it is crucial to prevent hypotension and keep oxygen saturations high in patients suspected to have a spinal cord injury to optimize spinal cord perfusion.[87] Animal and adult studies have shown improved outcome in subjects aggressively managed to prevent spinal cord ischemia.[88–90] Strategies to this end include admitting patients to the ICU and accurately monitoring volume status and blood pressure. The mean arterial pressure should be maintained to promote spinal cord perfusion. At our institution, the pediatric trauma ICU utilizes age-specific mean arterial pressure goals for children with spinal cord injuries: age younger than 3 years = 60 mm Hg; 3 to 12 years = 70 mm Hg; 13 to 16 years = 75 mm Hg; and older than 16 years = 80 mm Hg.

Steroids are stabilizing agents; they act as a powerful anti-inflammatory agent that decreases edema and scavenges oxygen free radicals. High-dose methylprednisolone used to be administered to older children based on initial data collected in adults (National Acute Spinal Cord Injury Studies). However, controversy persists surrounding the efficacy of steroids in the setting of an acute spinal cord injury after neurologic improvements were not reproducible in subsequent studies. Additionally, significant complications are associated with high-dose steroids, including gastrointestinal bleeding, hyperglycemia, sepsis, wound complications, pneumonia, myopathy, and respiratory failure.[91,92] To date, we are aware of six randomized controlled trials investigating the use of intravenous methylprednisolone in the setting of spinal cord injury.[93–98] Despite these, no firm consensus has been established for the use of methylprednisolone in spinal cord injury; as such, this therapy can only be considered a treatment option. In 2013, the joint American Association of Neurological Surgeons/Congress of Neurological Surgeons recommended against the use of steroids altogether for treatment of spinal cord injury, stating that the evidence of potential harm outweighs the evidence of potential for benefit.[99] It should also be noted that studies of steroid treatment in the setting of spinal cord injury have not been stratified by injury level to distinguish between the effect of steroid use in cervical as compared with thoracic cord injuries. Additionally, to our knowledge, there are no high-quality randomized controlled trials investigating the use of steroids in pediatric spinal cord injury; thus, in this age group, the use of steroids is not evidence based at the time of this writing.[74]

The indications for early operative intervention for pediatric patients with spinal cord injury include radiographic confirmation of spinal cord compression in the setting of an incomplete injury or progressive deficit, an open spine injury, and a grossly unstable spine in patients who are neurologically intact. Studies have demonstrated improved neurologic recovery for adult patients undergoing early (<24 hours from injury) versus late (>48 hours from injury) decompression in the setting of a cervical spinal cord injury and continued compression.[100,101] This information can potentially be extrapolated to the pediatric population. However, to our knowledge, there have been no well-designed, prospective studies specifically in pediatric patients evaluating the effect and timing of decompression.[102]

Functional outcomes depend on the level of injury and whether it is complete or incomplete. Patients with injuries above C4 may be dependent on a respirator, and phrenic nerve pacemakers can be implanted. Patients with C3 lesions can shrug their shoulders and often have neck motion, permitting operation of equipment with sip/puff controls, voice activation, eyebrow or eye blink, and head or chin controls. Patients with C6 lesions are often able to propel a manual wheelchair with the assistance of fusions and tendon transfers. At least partial recovery after a complete spinal cord injury has been reported in 10% to 25% of patients.[24,87,103,104] In a series reported by Wang and colleagues,[105] 64% of patients showed at least partial recovery after spinal cord injury. Of patients with complete injuries, 25% eventually became ambulatory. Recovery was seen up to 1 year after injury.

Complications unique to pediatric patients with a spinal cord injury are susceptibility to development of posttraumatic deformity and growth arrest.[106] Causes can be divided into intrinsic, extrinsic, and iatrogenic factors. Intrinsic factors include injury to the vertebral apophyses, resulting in abnormal growth and change in biomechanics from altered shape of the vertebral body and loss of posterior ligamentous support. This change in biomechanics can alter the forces on the vertebral apophyses, exacerbating the deformity further.[107] Extrinsic factors include weak trunk muscles in the setting of gravity and spasticity with a contracture. Iatrogenic factors include improperly instrumented segments and use of a laminectomy without fusion. The risk of developing a deformity in the setting of a laminectomy without fusion is approximately 50%, with a much higher incidence in the cervical and thoracic spine.[108] Nonoperative treatment with a brace can help slow the progression of deformity, and can temporize the situation to allow the child maximum time to grow before undergoing a fusion.[109] Performing surgical correction and fusion needs to take into account remaining growth. An estimate of remaining growth can be determined by multiplying 0.7 mm times the number of segments fused times the number of years of remaining growth.[110]

Posterior fusion in young children has the added drawback of the crankshaft phenomenon. This phenomenon occurs with continued growth of the anterior column in the setting of a fused posterior column. With continued anterior growth, the apical vertebral body rotates, producing a scoliotic curve.[111] However, this is less of a problem now with the use of pedicle screw instrumentation, which theoretically captures all three spinal columns. The goals of surgery include halting progression, obtaining correction, and balancing the spine and pelvis to equalize sitting skin pressure. Indications include a scoliotic curve of greater than 40 degrees and kyphotic curves of greater than 60 degrees. Anterior release may be needed if the deformity is rigid, as shown on bending films. Including the sacrum in the fusion construct is recommended if pelvic obliquity exists.

Spinal Cord Injury Without Radiographic Abnormality (SCIWORA)

The biomechanical differences in the spine of children younger than 8 years place them at risk of a SCIWORA.[24] This entity was first described by Pang and Wilberger[112] in 1982 before the use of MRI. The term SCIWORA was developed to describe spinal cord injuries without overt vertebral column disruption, as displayed by conventional radiographs, CT scans, myelograms, and dynamic flexion-extension radiographs. SCIWORA excludes injuries secondary to penetrating trauma, secondary to electrical shock, secondary to obstetric complication, and in association with congenital anomalies. The incidence of SCIWORA in patients with spinal cord injury for ages birth to 17 years was reported to be 35% in earlier literature.[75] As MRI has become more widely used, the incidence of SCIWORA with spinal cord injuries is reported to be 3%.[5] This change likely reflects an improvement in imaging quality and the ability to detect subtle injuries previously missed, rather than a change in actual injury type. More recently, Bosch and colleagues[113] found that recurrent SCIWORA was an uncommon entity, which occurred only in low-energy, sports-related injuries, resulting in transient neurologic symptoms, with full recovery in all cases.

MRI is the study of choice for evaluation of patients suspected to have SCIWORA. On MRI, there are both extraneural soft tissue changes and intraneural changes. The changes seen on MRI are secondary to edema and methemoglobin, a processed form of hemoglobin. Edema is seen as isointense on T1 and hyperintense on T2; extracellular methemoglobin is seen as hyperintense on T1 and hyperintense on T2. MRI changes in the extraneural tissues can be detected within hours of injury because the blood is quickly metabolized into a form easily seen on MRI. Intraneural changes can take days to be detectable because of the delayed metabolism of a hemorrhage into a form visible on MRI.[114,115] It is recommended that MRI be obtained at the time of presentation to rule out a compressive lesion that needs to be surgically addressed and at 6 to 9 days after injury to improve detection of intraneural injuries related to SCIWORA.[75]

The recommended duration of immobilization in a brace has been somewhat controversial, with the concern for delayed neurologic deterioration or reinjury motivating the recommendation for a brace. A meta-analysis by Launay and colleagues[74] showed that patients immobilized for 8 weeks had a 17% chance of developing recurrent SCIWORA, whereas no patients immobilized for 12 weeks had recurrent SCIWORA develop.

Atlanto-Occipital Dislocation

Atlanto-occipital dislocations were previously thought to be rare injuries that were fatal and usually found on autopsy.[116,117] More recently, this injury has been identified more frequently with a higher survival rate, particularly among children. Increased survival is possibly due to faster response by emergency personnel, improved cervical immobilization, and faster diagnosis upon arrival to the emergency department.[117–122]

The atlanto-occipital joint is a condylar joint with minimal bony stability that is stabilized primarily by ligaments. In children, the occipital condyles are less cup shaped and the articulation is more horizontal, potentially explaining the

higher incidence of dislocation among children compared with adults.[33,34,120] Ligamentous stability is provided primarily by the tectorial membrane, anterior longitudinal ligament, nuchal ligament, and paired alar ligaments.

Dislocation of the atlanto-occipital joint is usually due to a deceleration mechanism, such as a motor vehicle accident or pedestrian-vehicle accident, in which the head violently moves forward, causing separation of the condyles and the atlas. Diagnosing dislocation based on physical examination findings can be difficult because of varied presentation and concomitant traumatic brain injury. Neurologic function can range from a normal examination to flaccidity (early), absent deep tendon and sacral reflexes (early), poikilothermy, spasticity (late), urinary retention (late), priapism (late), and autonomic dysreflexia (late).

On lateral plain films, the "rule of twelves" should be remembered, looking at the dens-basion distance and distance from the basion to the line tangential to the dens posterior cortex. Additionally, the Powers ratio is the distance from the basion to the posterior aspect of the arch of the atlas divided by the distance from the anterior tubercle of the atlas to the rim of the foramen magnum, which is normally between 0.7 and 1, with a value greater than 1 indicating anterior atlanto-occipital dislocation.[123] The accuracy of these traditional radiographic criteria has been called into question, leading some to advocate using CT and MRI for diagnosis.[118,119,124] More recently, it has been suggested that a condyle–C1 interval of greater than 4 mm, as measured on a reformatted CT scan, is valuable in identifying atlanto-occipital dislocation.[124,125]

Although initial treatment of atlanto-occipital dislocation is immobilization in a halo or Minerva cast, most unstable injuries should be managed by posterior occipitoatlantal fusion with internal fixation. Wire fixation or fixation with a contoured rod and wires can be used from occiput to C1 to preserve C1–C2 motion. If the stability of the C1–C2 junction is questionable, fusion from occiput to C2, or C1 to C2, should be considered. Techniques have been developed to utilize occipital plates and lateral mass screw fixation to achieve successful fusion from the occiput to C2.[126] Harms described a technique for fusion of C1–C2 utilizing C1 lateral mass and C2 pedicle screws, with good fusion result.[127] This technique is considered a useful option for stabilization of the atlanto-axial complex, particularly in the setting of a fracture-dislocation when transarticular screws and wiring may not be an option due to subluxation of C1 on C2.

Fractures of the Atlas

A fracture of the ring of C1 is a rare injury in children that can occur when an axial load forces the occipital condyles into the lateral masses, resulting in fractures that involve the anterior and posterior rings (Jefferson fracture).[128–132] Children differ from adults because they can more often have plastic deformation of the ring and a single fracture with hinging on the contralateral synchondrosis. Instability exists when there is disruption of the transverse atlantal ligament. This disruption is determined on the anteroposterior cervical spine film (or coronal CT slice) by adding the overhang of the C1 lateral mass relative to the C2 lateral mass on the left and right sides. If the sum is greater than or equal to 8.1 mm on plain radiography or 6.9 mm on CT imaging, instability exists and should be treated with traction and a halo or Minerva cast. Cases with sums less than 7 mm can be treated with a well-fitting cervical orthosis.[132] Surgical stabilization of C1 fractures is rarely required in children[128,133]; if required, this can be accomplished with use of lateral mass screws in C1 and C2 connected by a cross link, as described by Tan et al.[134]

Atlantoaxial Instability

Instability at the level of C1–C2 can be secondary to traumatic ligamentous injury or chronic disease processes, including inflammatory diseases, malignancy, bone dysplasias, and congenital craniofacial malformations. An association with Down syndrome is well reported in the literature; there are other reports of atlantoaxial subluxation associated with Reiter syndrome, Larsen syndrome, juvenile rheumatoid arthritis, Morquio syndrome, and Kniest syndrome.[135–141] In traumatic atlantoaxial injury, the transverse atlantal ligament is disrupted, resulting in an increased ADI. The ADI is the distance as measured on a lateral cervical radiograph between the posterior aspect of the anterior ring of C1 and the anterior cortex of the dens. Active flexion views may be required to observe subluxation, and CT scans can show avulsion fractures at the insertions of the transverse ligament. In children, the upper limit for a normal distance is 4.5 mm; in adults, the upper limit is 3 mm. Acute rupture of the transverse ligament is rare in children.[142,143] Alternatively, the ligament itself may be intact, but can be avulsed from its attachment to C1. Surgical stabilization of C1–C2 after reduction in extension is generally recommended, followed by immobilization for 8 to 12 weeks in a halo brace, Minerva cast, or cervical orthosis. To document stability after treatment, flexion and extension views are recommended.

In Down syndrome, the frequency of atlantoaxial instability has been reported to approach 10% to 30% by adolescence.[136,144–147] Instability in patients with Down syndrome is attributed to laxity of the transverse ligament and C1–C2 joint capsules. Nearly 98% to 99% of patients are asymptomatic, but should be followed closely,[148–150] with some authors recommending yearly neurologic and dynamic radiographic examination.[151] Surgery is indicated in symptomatic and asymptomatic patients with an ADI greater than 10 mm or with less than 14 mm of space available for the spinal cord on lateral films.[152] There is a high reported surgical complication rate for these patients, including the risk of pseudarthrosis, wound infection/dehiscence, adjacent-level disease, and neurologic injury.[146,153]

Surgical fixation for atlantoaxial arthrodesis originated with posterior wire stabilization and structural bone grafting, as popularized by Gallie in 1939[154] and Brooks and Jenkins in 1978.[155] This technique requires the passage of wires into the spinal canal, with the potential risk of spinal cord injury.[156,157] Additionally, a wire construct often lacks sufficient stability[158,159] resulting in nonunion rates of 30% even with a halo

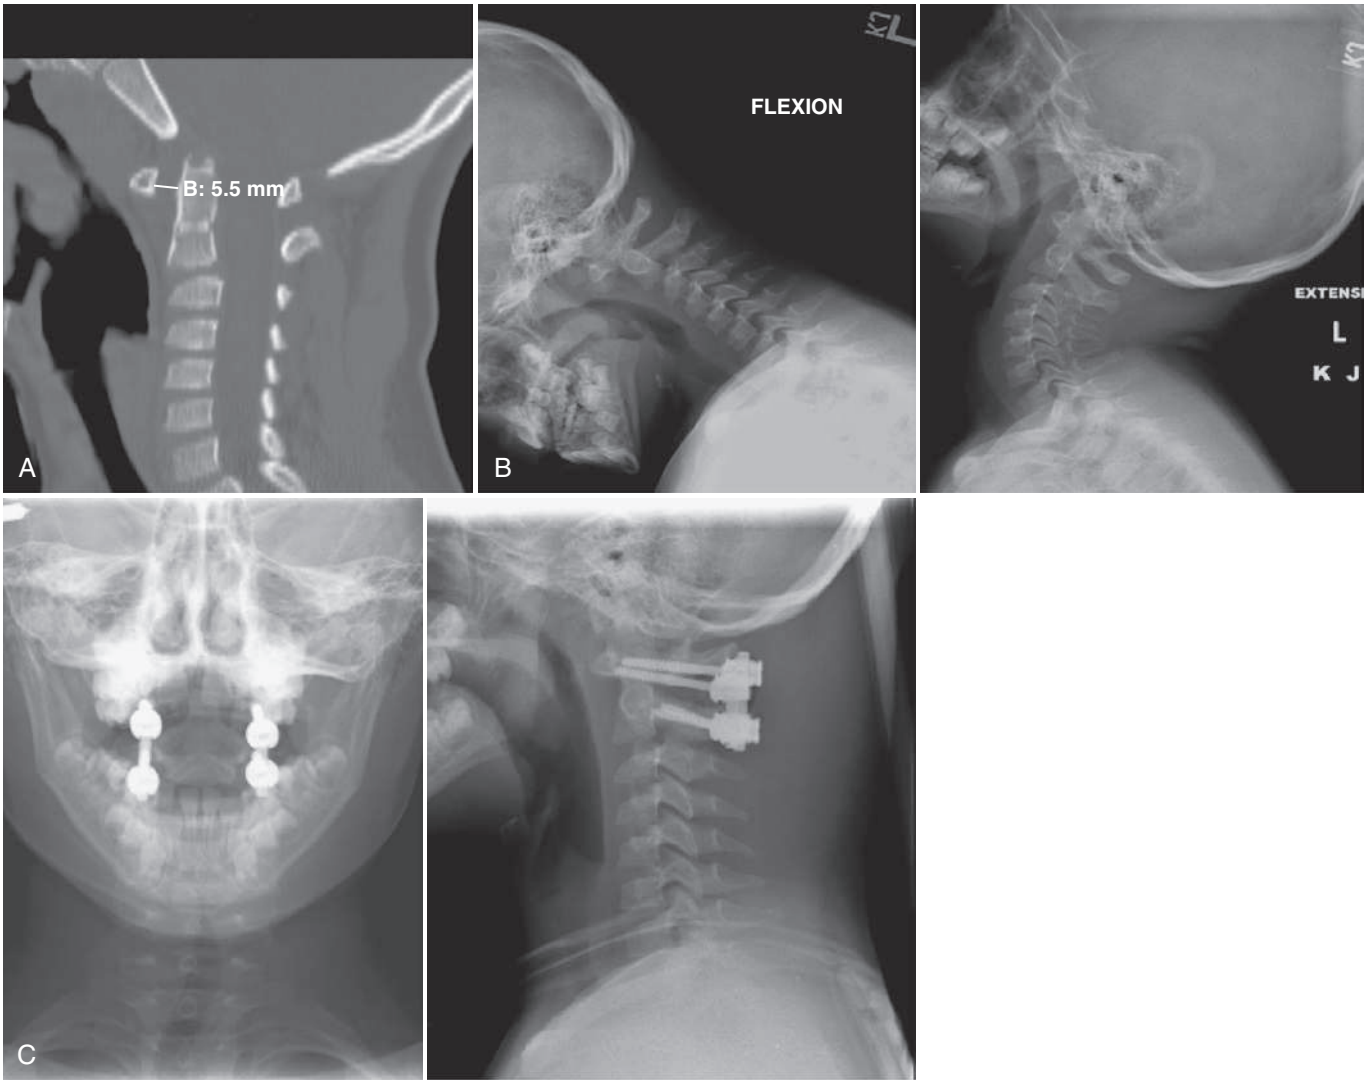

FIG. 32.7 Atlantoaxial subluxation. A 6-year-old boy was hit by a car. (A) A 5.5-mm atlanto-dens interval shown on lateral computed tomography reconstruction at the time of injury. (B) After 3 months of conservative treatment in a cervical collar, instability is shown on flexion and extension lateral cervical radiographs. (C) Postoperative radiographs after C1–C2 fusion.

vest postoperatively.[49,62,160–163] The C1–C2 posterior transarticular screw, or Magerl screw (1986), has a decreased rate of nonunion,[156,164–168] but carries the risk of injuring the vertebral artery.[169] Segmental C1–C2 fixation was introduced by Goel and Laheria in 1994[170] using a plate and lateral mass screws, and then by Harms and Melcher in 2001[127] using polyaxial C1 lateral mass screws and C2 pedicle screws with rod stabilization. This approach offers the distinct advantage of being able to insert the screws and then achieve the reduction compared with the Magerl screw technique, in which an anatomic reduction must be achieved before screw insertion. Fig. 32.7 shows a 6-year-old boy who had atlantoaxial subluxation.

Atlantoaxial Rotatory Subluxation

Atlantoaxial rotatory subluxation, also known as *atlantoaxial rotatory fixation,* if it has persisted for more than 3 months, is a frequent cause of torticollis in children. The most common etiologies are minor trauma and infection, although congenital and iatrogenic causes also exist. Patients present with neck pain, loss of cervical motion, and a "cock-robin" position, in which the head is tilted to one side and rotated to the contralateral side. In acute subluxations, movement is painful and accompanied by sternocleidomastoid spasms. In contrast to muscular torticollis, the sternocleidomastoid muscle is contracted on the same side to which the chin is rotated. This is likely due to a reactive muscle spasm attempting to reduce the subluxation. The child often has the ability to make the deformity worse, but cannot correct it. In fixed deformities, the pain subsides, but the lack of motion persists. Neurologic deficits are rare.[171]

The mechanism of injury is often trivial trauma, thus causing the diagnosis to be delayed.[172,173] The infectious etiology is known as Grisel syndrome and most commonly occurs after an upper respiratory tract infection, but can also occur after tonsillectomy, pharyngoplasty, or retropharyngeal

abscess.[174] Because of the anastomoses between the veins and lymphatics draining the pharynx and periodontoid plexus, inflammation in the pharynx can lead to attenuation of the transverse ligament or synovium or both surrounding C1–C2, resulting in subluxation.

Radiographic examination can be challenging because of the difficulty in positioning a patient with torticollis.[175] On the anteroposterior and open-mouth odontoid views, the lateral masses appear different in size because one is rotated anteriorly and one posteriorly, and the distances from the lateral masses to the dens are asymmetrical. On lateral view, with the cassette placed parallel to the skull, the two halves of the posterior arch of C2 will not be superimposed, with the spinal canal appearing narrowed. Two-dimensional and three-dimensional CT scans have largely replaced cineradiography, and can show superimposition of the atlas on the axis in a rotated position.[176,177] Some authors have endorsed dynamic CT, in which 3-mm cuts are taken with the head in neutral position, then with left and right rotation.[178,179] Although improved sensitivity has been reported using this technique, the significantly increased radiation exposure undoubtedly lessens its utility.

Treatment options depend on the timing of injury and duration of symptoms,[180] with some children likely never receiving medical attention because of spontaneous reduction. Patients whose symptoms have persisted less than 1 week can be treated with a soft collar, antiinflammatories, and home exercises. If spontaneous reduction does not occur after a week, the patients should be put in head halter traction and bed rest, which usually relieves the symptoms if they have persisted less than 1 month. In cases of atlantoaxial rotatory subluxations that have endured more than 1 month, reduction with head halter traction is unlikely, due to secondary changes that have developed within the atlantoaxial joint and surrounding soft tissues.[181] Halo traction can then be attempted, as can be used with the halo, while applying a rotation to the right and left to assist the reduction. Documentation of the reduction should be performed by CT scan; then, the patient must remain in the collar or halo vest for 6 weeks. Recurrent subluxation should be treated with prompt cervical traction until reduction is achieved, followed by a 3-month course in a halo. If initial reduction is unable to be maintained, posterior fusion of C1–C2 is recommended. Additionally, fusion is recommended if the halo immobilization fails after 6 weeks, if the subluxation has been present for more than 3 months, or if the patient has instability or neurologic compromise.[182]

Odontoid Fractures

Odontoid fractures are one of the most common cervical spine fractures in children, reported to represent up to 75% of all cervical spine fractures owing to the large head/body size ratio.[183] In children, the most common mechanism is falling; in young adults, the mechanism is typically high-velocity trauma, such as motor vehicle accidents. Fractures of the odontoid in children typically occur through the synchondrosis, which is a cartilage line at the base of the odontoid. Fractures that reduce spontaneously can look like a Salter-Harris I injury or appear to be normal on plain films. CT scans with three-dimensional reconstructions can assist in identifying minimally displaced odontoid fractures,[184] and MRI can show bone and soft tissue edema around a minimally displaced fracture. Most odontoid fractures are displaced anteriorly with an intact anterior periosteal sleeve that can help stabilize the fracture when immobilized in extension, and encourage healing.[177,185–187] Treatment of displaced fractures is by closed reduction via an extension maneuver with immobilization in a halo cast or Minerva jacket for children younger than 3 years. Most fractures heal uneventfully after 6 to 8 weeks, at which time documentation of stability with flexion-extension views is recommended. In cases that are difficult to reduce, head halter or halo traction—and, rarely, manipulation under general anesthesia—is necessary. The need for surgical fixation is unusual, as there are excellent results from closed treatment.[188–190]

Os Odontoideum

Os odontoideum is an unsupported round ossicle that is separated from the body of the axis by a transverse gap. Some authors propose that os odontoideum is due to an unrecognized fracture that is distracted by the alar ligaments and results in nonunion,[37,171,191–199] whereas other authors suggest that it is congenital because of its association with congenital syndromes.[200–202] Presentation ranges from asymptomatic to frank myelopathy. Diagnosis can usually be made on routine radiographs, with lateral flexion-extension views showing the degree of displacement of C1 on C2. Measuring the distance between C1 and the ossicle is not helpful because they typically move together. Instead, one should evaluate the space available for the cord or the relationship of the body of the axis to the posterior aspect of the anterior arch of C1. More recently, investigators have suggested using dynamic (real-time) MRI to aid in diagnosis of instability.[203]

There is debate in the literature regarding management of patients with os odontoideum. Some authors advocate conservative management with yearly clinical and radiographic evaluation of patients with a stable os odontoideum.[192,204–206] There are reports, however, of decompensation and death in asymptomatic patients who have been followed conservatively.[192,207,208] Some surgeons favor surgical stabilization of patients with an os odontoideum due to the potential instability risk leading to catastrophic injuries.[206,208–211] Options include methods for C1–C2 arthrodesis, as already discussed.[211–213]

Hangman's Fracture

A hangman's fracture, or traumatic spondylolisthesis, is a fracture of the bilateral pars interarticularis of C2. This name derives from the fact that the fracture resembles the injury associated with a judicial hanging. Because the fracture fragments separate and decompress the cord, neurologic injury is

unusual. Most of these injuries occur in children younger than 2 years, likely because of the large head size and poor muscle control. Radiographs often show anterior subluxation of C2 on C3, with lucency anterior to the pedicles of the axis. Persistent synchondroses of the axis have been reported that can be confused with hangman's fractures.[163,214–216] Treatment consists of immobilization for 8 to 12 weeks in a cervical orthosis, Minerva jacket, or halo. Pizzutillo and colleagues[217] reported healing in four of five children treated in a Minerva jacket or halo cast. If nonunion occurs, anterior or posterior arthrodesis can be considered for symptomatic patients.[182]

Lower Cervical (Subaxial) Spine Injuries

Traumatic injuries to the lower cervical spine (C3–C7) are rare in young children and infants, but are more common in adolescents and older children. Children younger than 9 years old account for only 22% to 31% of pediatric lower cervical spine injuries, whereas children older than 10 years account for 70% to 73%.[218] One should suspect a cervical spine injury if the patient is unconscious, has cervical rigidity, muscle guarding, neck pain, radicular pain, numbness, or neurologic deficits.[218] In infants, motor weakness and hypotonia should raise the suspicion of a cervical spine injury.

Compression Fractures

Compression fractures are the most common fracture in the pediatric lower cervical spine. Trauma causing flexion and axial loading leads to a loss of vertebral height. When evaluating a child, one must be careful not to mistake normal cervical wedging for a compression fracture. Ossification progresses in a posterior to anterior direction and remains incomplete until approximately age 8 years; thus, anterior wedging of the lower cervical spine until this age is considered normal. This wedging is usually most notable at the C3 vertebra.[219] Compression fractures are usually considered stable injuries and can be treated nonoperatively. With immobilization, these fractures normally heal in 3 to 6 weeks. Flexion and extension films should be obtained at 2 to 4 weeks to confirm stability and alignment of the fracture.

Facet Fractures and Dislocations

Facet fractures and dislocations are the second most common lower cervical spine injuries in children, and most commonly occur in adolescents.[182] Unilateral dislocations often affect the ipsilateral nerve root; bilateral dislocations affect the spinal cord.[220] The cartilaginous components are overlapped and locked, causing a "perched facet" on radiography, which indicates a true dislocation. Treatment for a unilateral dislocation is initially traction and reduction if the patient is awake and able to cooperate with an examination. The patient must be awake, cooperative, and able to provide a reliable examination in order for closed reduction to be done safely.[221] After reduction, surgical stabilization is typically needed. If the dislocation cannot be reduced, open reduction and arthrodesis is warranted. Similarly, bilateral facet fractures and dislocations are considered unstable; thus, reduction and stabilization is required.[182] Fig. 32.8 shows a 6-year-old girl with bilateral lumbar facet dislocations. If no disc herniation is present on MRI, either an anterior or posterior surgical approach can be used for reduction and stabilization of facet fracture-dislocations. The literature has not shown a clearly superior approach in terms of fusion rate, alignment, long-term complications, or neurologic recovery.[222] If a disc herniation is present, an anterior approach is preferable to allow direct removal of the impinging disc prior to reduction of the facet joints. In addition, the treating surgeon should assess the integrity of the posterior ligamentous complex (PLC) to determine whether an anterior-only procedure is adequate or whether a combined anteroposterior fusion is needed. In a cadaveric cervical corpectomy biomechanical study, anterior fixation with a static plate and cage adequately stabilized the injured level if the PLC was intact. If the PLC was sectioned, a combined anteroposterior approach was needed to achieve stability.[223]

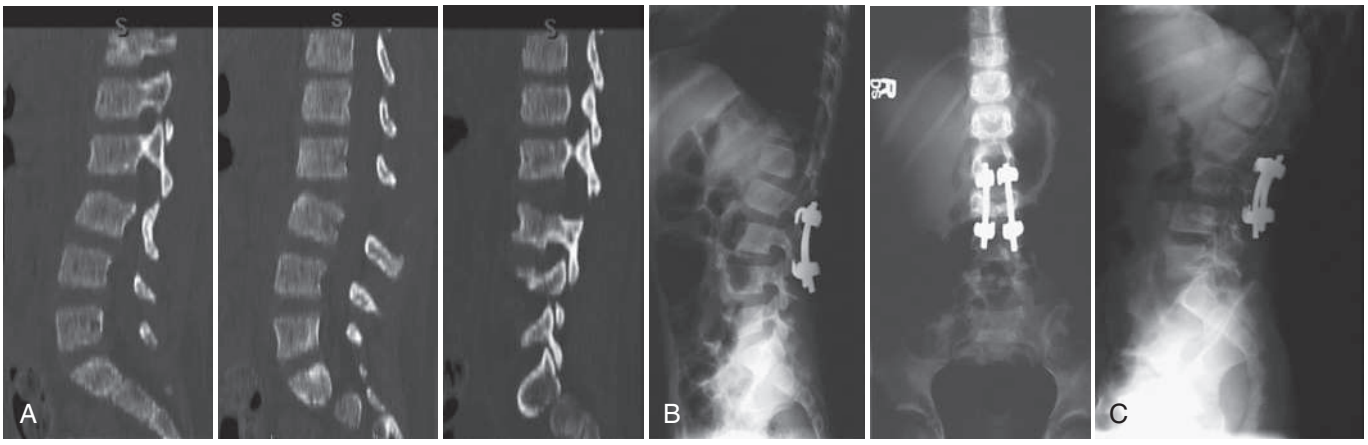

FIG. 32.8 Bilateral lumbar facet dislocation. A 6-year-old girl was in a motor vehicle accident. (A) Sagittal computed tomographic reconstructions show bilateral L2–L3 facet dislocations. (B) Postoperative image after L2–L3 fusion with pedicle hook instrumentation. (C) Image 3 years postoperatively.

Burst Fractures

Burst fractures in the subaxial spine are rare in pediatric patients. These injuries occur secondary to axial loading. Retropulsed fragments can compromise the spinal canal. CT is a useful modality in determining canal compromise and bony involvement. A burst fracture with no neurologic deficit and minimal spinal canal compromise can be treated by immobilization with a halo or rigid orthosis, depending on the level involved. If the patient has neurologic deficits due to significant canal compromise, surgical decompression and fixation is recommended. typically via anterior arthrodesis. This is one of the few instances in which anterior fusion is recommended in children because the need for stability outweighs the risk of developing a deformity secondary to destruction of the anterior growth plate. In older children and adolescents, anterior instrumentation can be used without as much risk of kyphotic deformity.[182] In cervical burst fractures that are more consistent with a flexion-distraction injury with posterior ligamentous disruption, an isolated posterior instrumented arthrodesis can be considered in those patients without active cord compression.

It is important to assess the integrity of the posterior ligamentous complex in the setting of burst fractures, as this can aid in determining whether the injury is stable or unstable.[224] Studies in the adult literature have shown that hyperintense signal on fat-suppressed T2-weighted MRI correlates with intraoperative confirmation of injury to the supraspinous ligament, interspinous ligament, and ligamentum flavum.[225] A detailed analysis by Vaccaro et al. reports the sensitivity of MRI in detecting PLC injury to range from 79% (facet capsule) to 90% (interspinous ligament).[226] More specific to the pediatric population, Sledge et al. also advocate MRI as a useful tool to assess the PLC in pediatric trauma based on a retrospective review of 19 MRI studies in children.[227]

Vertebral Growth Plate Fractures

In contrast to adults, lower cervical spine injuries in children can occur through the synchondrosis at the cartilaginous endplate. The primary ossification centers fuse by 7 to 8 years of age, but the secondary ossification centers can remain open until 25 years of age.[228] MRI can be used to assess the growth plate because it may be difficult to differentiate normal lucency of a synchondrosis from a traumatic lesion on radiography. Fracture of the synchondrosis can lead to anterior or posterior displacement of the endplate. Anterior displacement can be treated conservatively with a cervical orthosis until the fracture has healed. Posterior displacement of the endplate is treated with an anterior surgical approach to reduce the bony endplate, resulting in spinal decompression and alignment. The patient should remain in a cervical orthosis for 4 to 5 months.[229]

Pediatric Halo

Halo immobilization is often used in the treatment of pediatric cervical spine injuries, even in infants. Presized halos and vests are used in adults, which often work for adolescents. Prefabricated halos and vests are also available for children and infants, but because of the wide variability in size in children, custom vests and rings may be necessary. In some patients, CT can be helpful before pin placement to help determine bone structure. The pediatric skull is thickest anterolaterally and posterolaterally, and pins should be placed accordingly, with attention to the supraorbital and supratrochlear nerves.[230] The number of pins required varies with age. Children younger than 2 years require 8 to 10 pins, but by age 5 years, only 4 pins may be necessary.[220] Pins should be inserted perpendicular to the skull to improve pin-bone interface.[231] The amount of torque required during pin insertion decreases with age, with 2 to 4 inch-pounds required for younger children and standard torque of 6 to 8 inch-pounds in adolescents. There can be great variation in pressures with different torque wrenches, however, and they should be calibrated before any halo placement.[232] Pins should not be retightened at 48 hours in children. In adolescents, however, retightening can be performed at 48 hours.[182]

As in adults, complications are common with halo immobilizers in children. Dormans and colleagues[233] reported a complication rate of 68%, but noted that most complications were minor and all patients were able to wear the halo until fracture healing occurred. The most common complications include superficial pin tract infection and pin loosening. Serious, but less common, complications include dural penetration, supraorbital and supratrochlear nerve injury, pin scars, and deep pin infections.

Thoracolumbar Classification Systems

Thoracolumbar fractures in children are uncommon but can cause significant morbidity and mortality, requiring a high index of suspicion for these injuries. Two classification systems for thoracolumbar spine injuries are widely utilized: the Denis classification and the Thoracolumbar Injury Classification and Severity (TLICS) scale. These classification schemes are not specific to the immature pediatric spine; however, they are commonly extrapolated for use in pediatric spine trauma.[234] We are not aware of a classification scheme specific to thoracolumbar trauma in the immature skeleton, although recent studies have demonstrated that these classification systems have good reliability and validity in pediatric trauma.[235]

Denis[236] described a three-column classification system. The anterior column consists of the anterior ligament, anterior anulus fibrosus (AF), and anterior two-thirds of the vertebral body. The middle column contains the posterior longitudinal ligament, posterior AF, and posterior wall of the vertebral body. The posterior column comprises the supraspinous and interspinous ligaments, facet joint capsules, and ligamentum flavum. Denis[236] used this system to classify thoracolumbar injuries as compression fractures, burst fractures, flexion-distraction injuries, or fracture–dislocation injuries. He also classified the stability of these fractures based on the number of columns affected. If two or more columns failed, the fracture was considered unstable according to Denis.[236]

The Spine Trauma Study Group developed the TLICS scale. Although this classification system was developed in adult patients, recent studies have demonstrated reliability and validity of this system in pediatric trauma patients.[235] Three primary axes were identified to help analyze and manage fracture patterns: (1) injury morphology, (2) integrity of the posterior ligamentous complex, and (3) neurologic status. The three primary axes are divided further into subgroups. Morphology is determined from radiographs, MRI, and CT scan using one of three morphologic categories: (1) compression, which can be classified further with a burst component; (2) translation and rotation; and (3) distraction. The integrity of the posterior ligamentous complex is categorized as (1) intact, (2) disrupted, or (3) indeterminate. The neurologic status is categorized as intact, nerve root injury, complete spinal cord injury, or incomplete spinal cord injury. The TLICS score is based on these principles, and specific values are assigned to each subgroup with lesser point values for less severe injuries. These scores can help guide surgical treatment. Patients with a score of 3 or less are generally treated nonoperatively depending on the type of injury. Patients with a score of 5 or greater frequently require surgical fixation. Patients with a score of 4 fall in the intermediate zone, in which treatment is more ambiguous and up to the discretion of the surgeon.[219]

Compression Fractures

Compression fractures are the most common thoracolumbar fracture pattern.[182] The severity of the fracture is based on the percentage of height lost, but regardless of severity, these fractures are rarely associated with neurologic deficit. It is important to determine if the injury is acute or chronic because these injuries can commonly occur as a result of falls. Compression fractures are nearly always stable injuries, but one must be sure to examine the posterior soft tissues to rule out a flexion-distraction injury. Treatment options depend on whether the fracture is isolated or if contiguous fractures are present. Isolated compression fractures are best treated with an extension orthosis. These fractures usually heal in 4 to 6 weeks, but radiographs should be obtained to monitor alignment. Contiguous compression fractures can result in kyphosis. If kyphosis greater than 40 degrees is present, surgical treatment can be considered.[237] In the adult patient population, degree of kyphosis at the site of thoracolumbar compression fracture has not been shown to correlate with clinical outcomes in the setting of a normal neurologic exam.[224,238,239] In children, when kyphosis of 10 degrees or greater is seen on upright lateral radiographs, brace treatment has been shown to be more effective than no brace in terms of final alignment at skeletal maturity[240]; the clinical relevance of this finding has not been established. Finally, based on cadaveric studies, one must be careful to evaluate for injury to the PLC when 50% of the vertebral height is lost.[241]

Burst Fractures

Burst fractures involve, at a minimum, the anterior and middle columns.[236] These injuries are most common in the lower thoracic and upper lumbar region, due to this being the transition area from the stiff thoracic spine to the mobile lumbar spine. Spinal cord injury can occur with retropulsion of bony fragments at the thoracolumbar junction, resulting in conus medullaris or cauda equina syndromes. There have been few studies of burst fractures in immature patients. Most investigators believe that conservative treatment is warranted if the posterior ligament column is intact and there are no neurologic deficits. Treatment should include an extension molded cast or a thoracolumbosacral orthosis (TLSO). The goal is to allow the patient to maintain an upright position with ambulation while preventing progressive kyphosis and neurologic deficit.

If there is injury to the posterior ligamentous complex (PLC), surgical treatment may be used to protect the integrity of the spinal cord. Anterior and posterior approaches can be used.[238] The posterior approach is now more frequently utilized. The anterior approach allows direct canal decompression through corpectomy of the fractured vertebrae. When surgical stabilization of a burst fracture is deemed necessary, the surgeon should fuse as few motion segments as possible while still providing enough stability for healing and protection of the neural elements. Fig. 32.9 shows a 14-year-old boy with a lumbar burst fracture.

Chance Fractures

Chance fractures, or flexion-distraction injuries, are most often caused by lap belt injuries in motor vehicle accidents. With frontal impact, the lap belt causes the axis of rotation to be the anterior spine, causing distractive forces on the posterior spine and anterior vertebral compression. Owing to this mechanism, there is a high incidence of concurrent abdominal injury, which necessitates a thorough evaluation by a pediatric trauma specialist.[242] According to the Denis classification, this is a three-column injury and is unstable. The classic finding on radiography is an "empty facet" sign. The inferior articular process of the superior vertebrae is no longer in contact with the superior articular process of the inferior vertebrae, and the facet appears empty. Treatment of Chance fractures is based on severity of the injury. If only bony fractures are present, with no injury to the ligamentous complexes, a hyperextension cast can be used. If ligamentous disruption is present, surgical treatment is necessary. MRI should be performed to determine the integrity of the posterior ligamentous complex and guide management. Young children can be treated surgically with posterior wiring combined with a cast; older children and adolescents can undergo segmental fixation.[243] Fig. 32.10 shows a Chance fracture in a 5-year-old boy.

Fracture-Dislocations

Fracture-dislocations in the thoracolumbar spine are three-column injuries that are very unstable.[236] These injuries nearly always require surgical stabilization. If complete spinal cord injury is present, internal fixation is warranted because it may aid the rehabilitation process. Children younger than 10 years should undergo longer fusions to reduce the delayed development of paralytic scoliosis.[244,245]

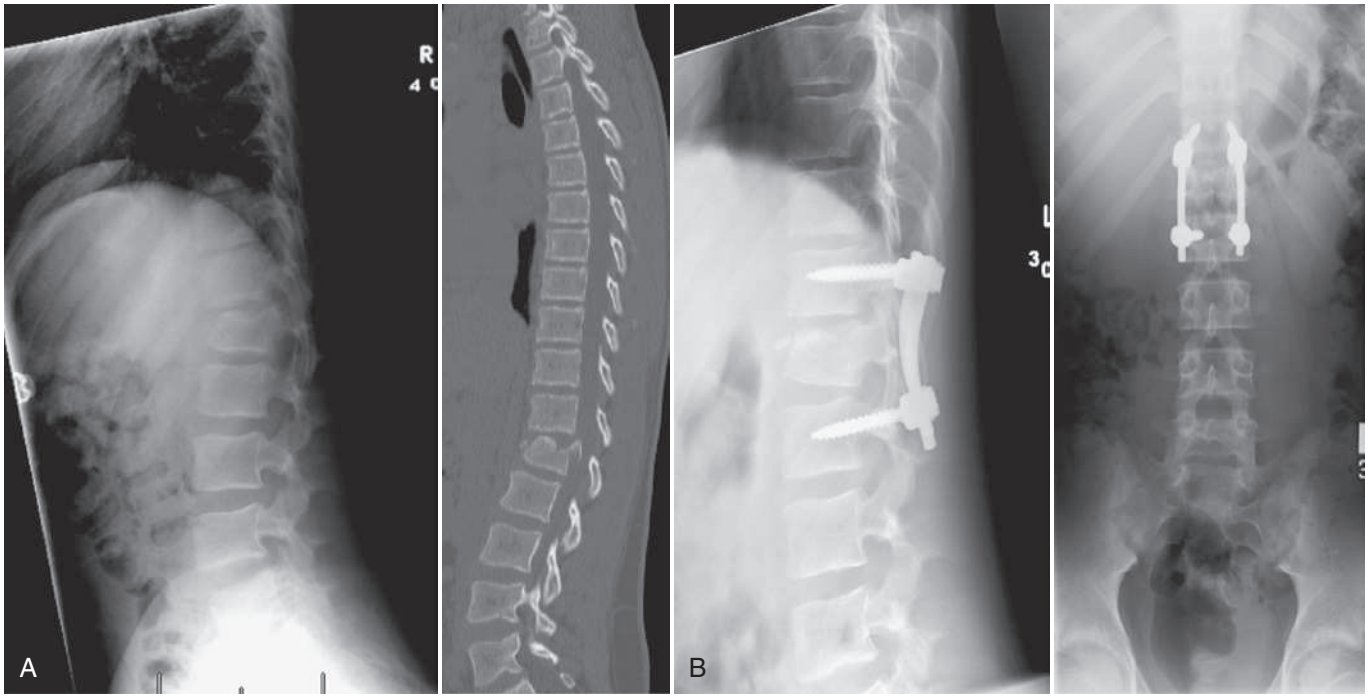

FIG. 32.9 Lumbar burst fracture. A 14-year-old boy was in a motor vehicle accident and had 50% retropulsion of the L1 vertebral body. (A) Lateral radiograph and sagittal computed tomographic reconstruction. (B) Postoperative result after decompression and fusion.

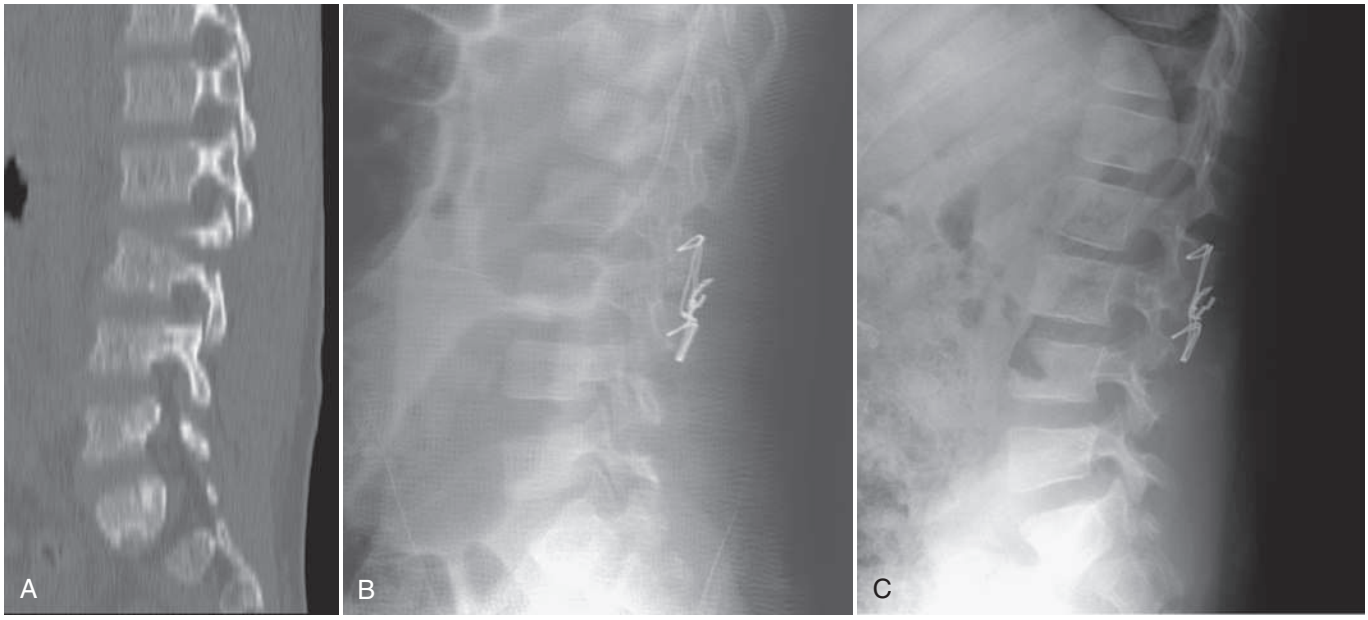

FIG. 32.10 Lumbar Chance fracture. A 5-year-old boy was restrained by a lap belt in a motor vehicle accident. (A) Sagittal computed tomographic reconstruction shows L2 Chance fracture. (B) Postoperative image after spinous process wiring. (C) Image 3 years postoperatively.

Limbus Fractures

Limbus fractures occur at the posterior vertebral endplate when disc material herniates between the unfused peripheral ring apophysis of the epiphyseal endplates and central cartilage (Fig. 32.11). These fractures often manifest as low back pain in adolescents and young adults, although they can be identified in older patients as well.[246] These lesions are usually located in the lower lumbar spine and appear on radiographs as a corner defect in the endplate and a wedge-shaped piece of bone posterior to the body or disc space. CT and MRI can help fully delineate the bony defect and disc injury. These injuries are less likely to resorb on their own and often require surgical decompression in symptomatic patients.

Depending on the size of the lesion, the disc (calcified or noncalcified) and bony fracture can be removed via an

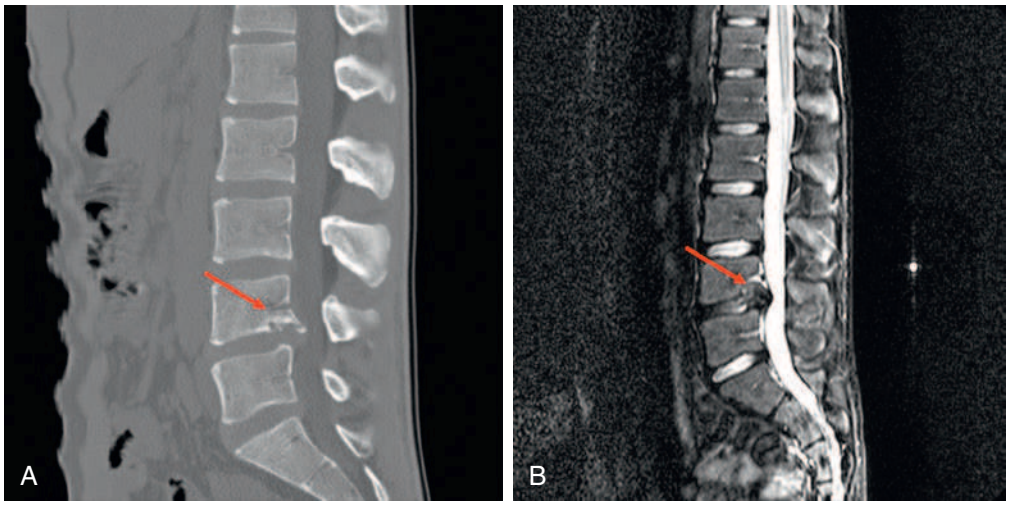

FIG. 32.11 (A) Computed tomographic and (B) magnetic resonance images showing a limbus fracture *(red arrow)* in a 17-year-old male with continued back pain 4 months after the initial injury.

extended laminotomy, hemilaminectomy, or laminectomy. In the absence of routine disc herniation, the discectomy can be performed in standard fashion, thus identifying the fracture as the endplate is exposed.[246]

KEY POINTS

1. Traumatic injury to the pediatric spine is relatively rare. Injuries in children younger than 8 years old typically affect the upper cervical spine because of the large head size; older children are more likely to sustain subaxial cervical spine injuries and thoracolumbar injuries as the spine takes on the biomechanical characteristics of an adult.
2. During transport, children younger than 4 years often require a cutout region for the occiput or elevation of the shoulders to accommodate the disproportionately large head and to keep the cervical spine in neutral alignment.
3. Spine imaging in an injured child should begin with a trauma radiographic series. Young children who cannot cooperate may require a CT scan from the occiput to C2. A CT traumagram—including sagittal and coronal reconstructions of the cervical, thoracic, and lumbar spine—is acceptable, and radiographs are not needed. MRI can be used to evaluate a neurologic deficit and determine if a ligamentous injury exists.
4. In spinal cord injury in pediatric patients, there is a susceptibility to development of posttraumatic deformity and growth arrest; surgical correction and fusion needs to take remaining growth into account.
5. Evaluation of cervical and lumbar trauma in children requires an understanding of developmental anatomy to differentiate trauma from age-appropriate findings. Evidence of soft tissue swelling and sharp edges at the suspected fracture are more indicative of trauma. Injuries that are unique to children include atlantoaxial rotatory instability, birth injuries, and limbus fractures. Generally, young children more often have ligamentous injuries; older children and adolescents have bony injuries as the spine takes on adult characteristics.

This article reports the increased prevalence of upper cervical spine injuries and SCIWORA in young children.
3. Bilston LE, Brown J. Pediatric spinal injury type and severity are age and mechanism dependent. *Spine*. 2007;32:2339-2347.
This article shows that injury is age and mechanism dependent. Falls are the most common mechanism in children younger than 8 years old, minor neck injuries are more common in children older than 8 years, and sporting injuries are most common in older boys. Motor vehicle accidents cause the most serious spinal trauma in children.
4. Vaccaro AR, Lehman RA Jr, Hurlbert RJ, et al. A new classification of thoracolumbar injuries: the importance of injury morphology, the integrity of the posterior ligamentous complex, and neurologic status. *Spine*. 2005;30:2325-2333.
The composite injury severity score derived from this classification system assigns 1 to 4 points to three critical components of an injury: integrity of the posterior ligamentous complex, injury morphology, and neurologic status. Fractures with scores of 3 points or less are considered nonoperative cases. Fractures with scores of 4 points can be considered for nonoperative or operative intervention. Fractures with scores of 5 or more points are considered surgical cases.
5. Mayfield JK, Erkkila JC, Winter RB. Spine deformity subsequent to acquired childhood spinal cord injury. *J Bone Joint Surg Am*. 1981;63:1401-1411.
This article found that children who had spinal cord injury before the adolescent growth spurt were much more likely to have progressive spinal deformity than children who were injured after the growth spurt.

33 CHAPTER The Immature Spine and Athletic Injuries

Jennifer J. Beck
Lyle J. Micheli

Most spine injuries in athletically active children and adolescents are chronic, resulting from repetitive demand on the immature spine during participation in sports. The most serious injuries are acute as a result of direct trauma. The age at which a child can be considered an athlete varies; a child may put on skis at 3 years old or begin to ride bulls at 10 years old (Fig. 33.1). Several sports—such as skiing, football, and horseback riding—involve increased risk of acute traumatic events, making spine fracture a significant concern when considering an adolescent athlete. Increase in pediatric involvement in nontraditional sports, such as cheerleading[1] and extreme sports,[2,3] have also increased sports-related injuries. In children, 32% of life-threatening injuries are sports related.[4] This chapter discusses the initial evaluation and on-field management of spine fractures; the complete treatment of spine fractures is covered elsewhere.

According to surveys of patients seen in sports medicine specialty clinics, the most common cause of back pain in adolescent athletes is stress fracture, or *spondylolysis*. Spine hyperextension and repeated twisting contribute to the high rate of spondylolysis seen in sports such as gymnastics, football, and weightlifting. The rate of spondylolysis in gymnasts is 20% compared with 5% to 6% in the general population.[5]

Less aggressive sports, such as golf, can also cause adolescent back pain and spine injury. The golf swing places significant torque on the spine and surrounding muscles, and can produce strains and sprains, which are minor injuries that interfere with performance. In all sports, appropriate strength training, routine stretching, and good technique are imperative for young athletes to avoid injury and to continue participation in sports throughout their lifetime.

The most effective technique in screening for serious disease is a good patient history; diagnosing spine injury is no exception. Although helpful, a radiograph is seldom definitive in diagnosing the cause of back pain. Radiography is imperative for diagnosis of an acute fracture, but back pain without a specific injury is usually treated on the basis of a careful history and a thorough physical examination.

Understanding the requirements of the particular sport and gaining knowledge of the training schedule of the athlete are important when performing the patient history. For example, a gymnast with no history of sudden trauma who practices 3 hours daily has a chronic stress that may account for the back pain. A young gymnast's developing spine, given insufficient recovery time, is highly susceptible to repetitive trauma.

Return to sport is a major goal for an athlete; the physician needs to be aware of the demands of the specific sport to determine when return to participation is reasonable. The physician should take heed of a young athlete who is reluctant to return to sport after an injury. Family dynamics often influence when a child is willing to resume activity.

Physical activity is the normal function of the musculoskeletal system. The American Academy of Orthopaedic Surgeons (AAOS) has encouraged physical activity as health promoting for all ages in its "Get Up, Get Out, Get Moving" program. The keys to maintaining a healthy spine are good nutrition and proper exercise. Good nutrition includes avoiding obesity and not smoking. Exercise programs should include strengthening for power and endurance, as well as stretching to improve joint range of motion (ROM) and muscle length.

Principles of Diagnosis

The initial treatment of low back pain usually begins without a specific diagnosis. A nonspecific diagnosis is satisfactory as long as the patient's condition improves. In contrast, the narrow area in which surgery offers reliable benefit to the patient requires a carefully determined, specific diagnosis. In children and adolescents, every attempt should be made to arrive at a specific diagnosis. Adults often have variable degrees of degenerative changes in the spine. In many such cases, treatment to restore ROM and strength of the spine and its associated structures is a first step.

History

A good patient history depends on effective patient-physician communication. When a patient presents with low back pain, the history is important to rule out serious diagnoses rather than leading to a definitive diagnosis. The physician brings knowledge of possible causes and treatments to the interview, and assembles a differential diagnosis. The patient wants to tell his or her story and brings knowledge of timelines and anecdotal details.

The term *interview* implies an interaction with the patient as opposed to the traditional notion of extracting information from the patient. When allowed to tell one's story, an adult patient takes an average of 90 seconds.[6] Adolescents tend to be more taciturn and talk less than the average adult. The average physician cuts off the patient with a question after 18 seconds because the physician has formed a differential diagnosis. Such interruption stops the flow of information, and often the patient is never permitted to relate pertinent facts.

The use of a visual pain scale facilitates consistent documentation. The patient's assessment of the intensity of the pain using a visual scale (Fig. 33.2) often stimulates a description of the circumstances that exacerbate or alleviate that pain. When making the differential diagnosis, the physician can classify the clinical syndrome into one of three categories: (1) nonmechanical back or leg pain (or both), (2) mechanical back or leg pain (or both), and (3) sciatica.

Warning signs for possible cancer include a history of cancer or constitutional symptoms, such as fever, weight loss, or night pain. Risk factors for infection include a history of recent bacterial infection, intravenous drug use, or an immunocompromised state. Patients with a spine cancer or spine infection often have pain that is not diminished by rest. Warning signs of possible spine fracture are major trauma (e.g., motor vehicle accident, blunt trauma, fall from a height), prolonged corticosteroid use, and osteoporosis. Symptoms suggestive of *cauda equina syndrome,* which requires urgent surgical consultation, include saddle anesthesia (found in 75% of patients); recent onset of bladder or bowel dysfunction (with urinary retention the most common symptom); and severe or progressive weakness of the lower extremities,[7] especially involving both lower extremities.

There are several findings to note when ascertaining psychosocial contributions to nonorganic back pain, as follows[8]:

1. *Superficial nonanatomic tenderness*. Lightly pinching or rolling the skin should not affect the deep structures, which might cause true pain.
2. *Patient's response to positive stimulation, such as axial loading*. Lightly placing one's hand on top of the head should not significantly increase pressure in the low back.
3. *Distraction*. One should look for a significant difference in straight-leg raising ability in the seated versus supine position.
4. *Overreaction*. An overly loquacious patient or behavior disproportionate to the stimulus should be noted.
5. *Disturbances in sensation or distribution of pain or weakness that do not follow anatomic patterns*.

Symptoms and signs that suggest back pain from nonmechanical causes—such as subclinical pyelonephritis, kidney stones, or dissecting aneurysm—should also be considered.

FIG. 33.1 This 10-year-old boy is following the traditions of ranch life in Colorado, where rodeo is a part of life. He won his first big belt buckle in competition at 8 years old.

Genetics

The wild card in the etiology of sciatic pain is genetics. Ala-Kokko[9] noted that scientific studies have identified specific versions of the genes encoding collagen, aggrecan, vitamin D receptor, and matrix metalloproteinase-3 that have significant associations with lumbar disc disease. Many other genes may also play a role in disc disease.[10–12] Although not a sports-related etiology, idiopathic adolescent scoliosis can be seen in adolescent athletes and is undergoing extensive research for genetic causes and predictors of curve progression.[13–15]

Physical Examination

The physical examination should take into consideration the three reasons for orthopaedic consultation: pain, deformity, and dysfunction. Although there is poor correlation between physical findings, symptoms, and treatment outcome, an examination of the patient's back is necessary. The purpose of physical examination is to confirm the impression gained from the history, if possible, and to look for surprises. Many obvious anatomic abnormalities can be visualized only when the patient's back is bare. The physical examination usually helps to exclude a serious disease rather than identify one. The

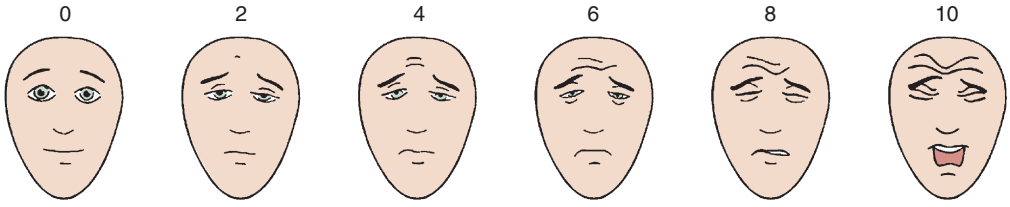

FIG. 33.2 Bieri faces. Drawings are neutral in terms of gender and ethnicity. The patient indicates a number that corresponds to his or her pain between 0 and 10.

three S's of an abnormal spine examination are apparent to observation: *spasm, scoliosis,* and *spondylolisthesis*.

Watching the patient move in flexion, extension, and rotation gives a visible assessment of pain. How a patient moves is as important to note as ROM. Whether the patient can bend to the knees, below the knees, or to the toes provides a rough measure of flexibility. Observing spinal rotation allows one to evaluate the facet joints.

After checking ROM and palpating for tenderness and muscle spasm, the physician should observe the rotational symmetry of the spine using the Adams forward-bend test and noting whether the pelvis is level. It is worthwhile to observe the effect of compression of the pelvis while the patient is lying on his or her back because this is a nonspecific test for sacroiliac joint disorders.

Observing standing posture in the coronal and sagittal planes is important to document evidence of deformity. Special tests, such as one-leg standing (the stork test) and compression tests for the neck (Spurling test), are indicated when one suspects spondylolysis or compression neuropathy. Anisomelia can be diagnosed by measuring limb lengths from the anterior superior iliac spine to the medial malleolus.

The neurologic examination requires close attention to detail and begins by having the patient heel walk and toe walk. Both functions demand strength, coordination, and cooperation one would expect from an athletic child. Testing deep tendon reflexes is important, especially if they are asymmetrical; testing the abdominal reflexes is essential to detecting hydromyelia.

The straight-leg raise test, or Lasègue sign, is a test for nerve root irritation or inflammation. A positive response is the reproduction of radicular pain. Pain on the opposite side or a positive cross straight-leg raise test is significant for diagnosis of a herniated disc. The straight-leg raise test can simultaneously provide evidence of sciatica and hamstring contracture.

Imaging

Modern imaging techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI) permit accurate visualization of anatomic defects in the spine. Although both techniques are powerful diagnostic tools, the defects revealed by CT or MRI are not always causative with regard to the patient's pain. The literature is replete with cases in which anatomic defects are present on MRI or CT in completely asymptomatic patients.

The Cochrane group performed a meta-analysis of the literature and concluded that there is no correlation between radiographic changes and back pain.[16] Contrary to that opinion, researchers in Tokyo reported a study in which they correlated preparticipation spinal radiographs with the incidence of back pain and disability among young football players.[17] They followed 171 high school and 742 college football players over a 1-year period. High school players with spondylolysis had a higher incidence of low back pain (79.8%) than players with no radiographic abnormality (37.1%). College players with spondylolysis, disc space narrowing, and spinal instability had a higher incidence of low back pain (80.5%, 59.8%, and 53.5%, respectively) than players with normal radiographs (32.1%). College players with spondylolysis had a higher incidence of low back pain than players with disc space narrowing and spinal instability.

How can this incongruence of findings be explained? It is believed that asymptomatic abnormalities in the general population, particularly abnormalities seen with aging, may become symptomatic with vigorous physical activity. Abnormal spine radiographs in a young athlete should be considered a risk factor for injury.

Magnetic Resonance Imaging of the Spine

MRI technology takes advantage of the high hydrogen content of the molecules that make up biologic tissues. Hydrogen atoms have a specific "spin" property associated with them; that "spin" state can be altered in the presence of a strong magnetic field. Alterations in the "spin" properties of hydrogen atoms in biologic tissues can be detected by MRI technology, producing highly sensitive visual images.

Although MRI is a very sensitive and accurate assessment of spinal anatomy, it cannot distinguish between painful and painless structures in the spine. A patient may have severe back pain and MRI may reveal no abnormalities, or the converse may be true. It can be difficult for the physician to correlate MRI findings with the patient's signs and symptoms to make a clinical diagnosis. Typically, it is unnecessary to obtain MRI at the onset of spine-related pain because most cases of back and neck pain resolve within 2 to 12 weeks with proper conservative treatment. MRI is indicated when more aggressive treatments (e.g., injections or surgery) are contemplated.

Bone Scintigraphy (Bone Scan)

Bone scintigraphy (Bone scan) is not as specific as MRI or CT, but is very sensitive to changes in metabolic activity of bone. Increased metabolic activity is seen with inflammation, infection, and tissue proliferation owing to tumors such as osteoid osteoma. Bone scintigraphy uses a short-lived radioactive pharmaceutical agent to label specific tissues or structures, ultimately to visualize them via scintillation-mediated imaging. Gamma emissions from the radiopharmaceutical are detected by a gamma camera, converted to light photons, amplified with photomultiplier tubes, and digitized via computer to present a high-resolution (4–6 mm) two-dimensional image.

Single-Photon Emission Computed Tomography

With single-photon emission computed tomography (SPECT), gamma camera detectors rotate around the patient in small increments (usually 3- or 6-degree steps), and emission data are obtained from different plane angles. Computer algorithms break the image into pixels, each of which represents an approximately 6-mm area of the planar image. Pixel data are used to render clinically useful volumetric images. Auerbach[18] showed that SPECT exceeded MRI or plain radiography in accurately defining spondylolysis in a series of 100 children with significant back pain.

Principles of Treatment and Rehabilitation

Acute Treatment

When pain onset is acute and severe, bed rest may be necessary for 2 or 3 days for initial pain control. A longer period of bed rest quickly becomes counterproductive. The key to recovery is modified activity within a minimal range to start, followed by gentle progression of activity. The sooner the athlete begins a level of tolerated activity, the quicker and more effective is the recovery. Research and experience have dispelled the notion that prolonged absolute rest is beneficial for treatment of back pain.[19]

Nonsteroidal antiinflammatory drugs (NSAIDs) can be potent when given with muscle relaxants, but the duration of medication should be no longer than 10 days. Opioid administration is rarely necessary for more than a few days. Local anesthetic injections into the facet joints or into trigger points can be useful treatments that may help to diagnose disease related to the facet joint or fibromyalgia.

Passive physical therapy modalities such as ice, massage, or heat can be helpful in initial treatment, but the athlete needs to begin active rehabilitation and assume responsibility for his or her recovery. Strengthening should begin as soon as possible, and bracing should be minimized.

Bracing

Bracing may be effective if used intermittently and primarily as a tool for returning to activity.[20] The Cochrane Collaboration reported a meta-analysis on the use of braces for low back pain in 2000.[21] There was moderate evidence that lumbar supports are no more effective for primary prevention than other types of treatment or no intervention. The authors found no data promoting the effectiveness of lumbar supports for secondary prevention. This opinion is consistent with the generally held concept that passive treatment such as bracing should be limited to acute pain relief and that active rehabilitation is an early goal for return to participation in sports and prevention of future injury. Lumbar function assessed by self-reported and objective measures does not seem to worsen with short-term use of nonrigid, inelastic bracing for low back pain.[22]

Traction

Traction has historically been used to treat low back pain. Current thought remains disparate, however, regarding the therapeutic value of traction.[23] A 2013 Cochrane Review on traction for low back pain with or without sciatica found traction alone or in combination with other treatments has little to no value in low back pain treatment.[24]

Rehabilitation

The rehabilitation program consists of stages that encourages building a foundation of fundamentals and moving through increasingly difficult levels of activity. Physical rehabilitation should be designed to be sport specific and diagnosis specific. A gymnast with spondylolysis needs a program avoiding hyperextension while the bone is allowed to heal. As rehabilitation goals, the gymnast needs to stay active in the maneuvers that do not stress the back and to maintain general fitness.

Generally, rehabilitation begins with flexion and extension cycles to reduce joint stiffness and relax elastic structures. There should be minimal loading of the spine during this stage. Hip and knee ROM exercises are added next to offload the spine, followed by specific muscle training. Focus is first placed on the anterior abdominal muscles and maintaining the spine in neutral position, followed by lateral muscle exercises for side support of quadratus lumborum and abdominal wall muscles; finally, an extensor muscle program is added. Repetitions and movement duration should be closely monitored by the therapist.

Core Stabilization

A core stabilization program is based on the principle of coordinated muscle contraction. This contraction is done from a neutral, pain-free position. Finding and maintaining a pain-free position is fundamental to reestablishing isometric muscle control. Flexibility training should not be approached until strength has been regained.

Flexibility

Exercise programs that load the spine throughout ROM have poorer outcomes. Greater mobility is associated with poorer outcomes as well. ROM of the spine has little predictability for future low back pain. Programs emphasizing trunk stabilization with a neutral spine have had the most success.[25–27] These programs emphasize increasing ROM of the hips and knees.

Muscle Performance (Strength Versus Endurance)

The term *strength* is defined as the maximum force that a muscle can produce during a single exertion to create joint torque. The term *endurance* refers to the ability to maintain a force for a period of time. Muscle performance includes strength and endurance. The few studies available suggest that endurance has a much greater prophylactic value than strength.[28] The emphasis should be placed on endurance and should precede strengthening exercises in a gradual, progressive exercise program (i.e., longer duration, lower effort exercises).

Sport-Specific Exercise

The physical therapist, trainer, physician, and coach must collaborate in designing a sport-specific rehabilitation program. New exercises should closely simulate the sport. Progress should be slow enough to develop an awareness of muscle function. The buildup to maximum performance requires time and patience.

Deep Water Running and Swimming

Walking in a swimming pool is a gentle strengthening exercise for the back. Deep water running is excellent for

treating athletes with back pain. The buoyancy of the water helps to unload the spine. Athletes run in the deep end of a swimming pool, normally with the aid of a flotation vest. Water is about 800 times denser than air; thus, resistance met during water running is greater than when running on land. Deep water running can help to maintain aerobic performance for 6 weeks in trained endurance athletes; sedentary individuals can appreciate significantly increased maximal oxygen uptake. During spine rehabilitation programs, deep water running can be used for maintenance training, but deep water running is not a substitute for conventional training.[29–31] Swimming is an excellent exercise for the back, but caution is advised for the novice. The swimming strokes can produce or exacerbate back injury if proper technique is not practiced.

Cycling

Although bicycling is generally considered a healthy form of non–weight-bearing, low-impact exercise, it is important to avoid prolonged flexion in a seated position. A more upright posture is easier on the intervertebral disc; thus, the upright mountain bike posture is preferred to the flexed racing bike posture. Avoiding the vibration of rough terrain is also logical, making stationary cycling a more reasonable option in the early stages of rehabilitation.

Program Guidelines

The following caveats should be considered when prescribing and monitoring any "return to sport" rehabilitation program[32]:

1. Low back exercises are most beneficial when performed daily.[33]
2. The "no pain, no gain" approach when exercising the spine may cause tissue damage associated with certain specific repeated movements.[34]
3. General exercise programs that include cardiovascular training (e.g., walking) have been shown to be effective for rehabilitation of individuals with low back pain and for injury prevention.[35]
4. Intervertebral discs are more hydrated early in the morning after rising from bed; it is unwise to perform full-range spinal motions (bending) shortly after rising.[36]
5. More repetitions of less-demanding exercises assist in the enhancement of endurance and strength. Evidence indicates that endurance has more protective value than strength, and strength gains should not be overemphasized at the expense of endurance.[37]
6. There is no such thing as an ideal set of exercises for all individuals. Although science at present cannot evaluate the optimal exercises for each situation, the combination of science and clinical experience should be used to select an exercise program.
7. Individuals need to be patient and stick with the program. Increased function and pain reduction may not occur for 3 months in some individuals.[37]

Education

Several studies have documented the value of patient education in the treatment of spine problems.[38] Education has been shown to be as valuable to the patient's recovery as physical therapy. In 2004, Frost and colleagues[38] measured the effectiveness of routine physical therapy compared with a single assessment session and advice from a physical therapist for patients with low back pain. They used a multicenter, randomized controlled trial in seven British National Health Service physiotherapy departments. These authors concluded that routine physical therapy was no more effective than a single assessment and advice session from a physiotherapist in treating low back pain.

In the physician's office, handouts are an excellent source of education and can be reference guides for the patient during rehabilitation activities (Table 33.1). Good preprinted handouts are available from multiple sources, such as the Krames (http://www.krames.com/) or the AAOS (http://www.aaos.org/) websites. Personalizing the handouts gives the athlete assurance in his or her provider's interest and commitment to the rehabilitation plan, as well as confidence in the treatment plan on leaving the office. With the availability of digital radiography, it is inexpensive to give the patient a copy of the patient's radiograph to take home. Being educated regarding the nature of the injury and being part of the rehabilitation team, not merely the subject, motivates the athlete, which can bring about speedier and more complete recovery.

Return to Play

For the athlete, returning to play is a central issue and may be measured in terms of games missed as opposed to return of

TABLE 33.1 Ways to Avoid Overuse Injuries

Use good technique.	An overhand pitch produces less strain than a side-arm pitch.
If it hurts, don't do it.	"No pain, no gain" is a poor concept. You feel the fatigue of a good workout, but you must recognize the pain of going beyond fatigue to injury.
Stop when fatigued.	Avoid the temptation of an extra repetition. Sprints are best done after a rest.
Increase duration gradually.	It takes time for the body to respond to increased demand and to strengthen.
Rest for a time after major increases.	It is better to alternate 3 hard days with an easy day, then rest for 2 days.
Quit when you are tired.	When you have exhausted the glycogen stored in your muscles, your technique falters and you are prone to injury.
Do preventive exercises.	Keep your body in balance by stretching to gain full range of motion and loosening contractures.
Remember your old injuries.	When you recall your old injuries, you can work to avoid repeating them.
Warm up slowly.	Use gentle stretching and gradually increasing effort to limber up muscles and deep breathing to stimulate the heart and lungs.

fitness. Generally, the athlete can return to play when there is no pain with sport-specific activities and when full ROM and strength has been recovered. There is no definitive test to measure when that point is reached. Gradual improvement in pain and progression in performing functional activities are predictive of a good prognosis.

Disorders and Treatment

Low Back Pain in Adolescent Athletes

Back pain in the pediatric and adolescent athlete has been well described in several recent articles.[39,40] Etiologies of pediatric back pain include spondylolysis, spondylolisthesis, posterior element overuse syndrome, sacroiliac joint irritation, atypical Scheuermann disease, and disc herniations. When a physician sees a child with back pain, the physician needs to rule out serious disorders, such as infection, tumors, cauda equina syndrome, and inflammatory spondyloarthropathies, then begin acute care, typically involving a rehabilitation program that allows the child to return to normal physical activity. Unlike adults, 90% of whom have no identifiable cause of their back pain, more than 50% of children with back pain were found to have an identifiable cause.[41] More recently, a study of 73 pediatric patients with low back pain resulted in 78% without identifiable cause after exhaustive workup.[42] Careful evaluation is important. An open-ended interview to hear the patient's story and expectations is the most valuable assessment instrument. Obtaining a detailed description of the pain is paramount.

The description of pain needs to include its location, duration, onset, and characteristic. If pain is associated with a particular activity or position, that information is helpful for diagnosis. Even with the most aggressive diagnostic workups and follow-ups, however, an organic cause for back pain in adolescents is found only about half of the time.

Lumbar spine pain or low back pain accounts for 5% to 8% of athletic injuries.[43] Injuries are often due to poor conditioning of the spine, poor biomechanics, or repetitive stresses placed on the spine by the nature of the sport. Overuse injuries from repeated lumbar hyperextension may be common in children participating in sports such as gymnastics, volleyball, and rowing. Evaluation of the sacroiliac joint should be completed, as nonoperative treatments result in significant improvement in 80% of cases.[44]

Historical studies show that the correct diagnosis of acute low back pain is established on the first visit only 2% of the time. After 6 weeks, the diagnostic accuracy increases to 15%, and it increases to 30% at 3 months.[45] The physician's initial visit is best used to rule out serious disorders, such as disc herniation or malignant disease. Although less than 1% of back pain complaints are related to serious spine pathology or require emergent treatment, such as neoplasm or cauda equina syndrome, it is important to exclude these conditions and reassure the patient accordingly.

Aggressive diagnostic workup may be deferred and implemented only for patients who do not improve within 3 or 4 weeks. Often, pain resolves without much treatment, and the athlete continues participation in sports. With severe or prolonged pain that prompts medical consultation, a diagnostic workup is appropriate for guiding the treatment.

Back pain that follows an acute injury is usually attributed to muscle strain. There is little scientific evidence showing muscle strain as a back pain generator, however, probably because pain produced by an injury cannot be differentiated to the various soft tissues of the back.[46] The pain may be localized or diffuse. The patient frequently relates that more stiffness occurred after a night's sleep. This type of back pain attributed to muscle strain tends to improve with time.

Growth is not linear, and as growth spurts occur, an imbalance between new length of bone and old length of muscles occurs. These contractures, whether of the hamstrings or other muscles adjacent to the spine, can produce limited motion and pain with athletic activities.

An adolescent with normal musculoskeletal structure may have back pain from poor standing and sitting posture. The typical profile is of lumbar hyperlordosis, thoracic hyperkyphosis, and contracted hamstrings. Radiographs are unnecessary to make the diagnosis or to institute a program of stretching and postural correction.

Mechanical backache secondary to poor posture is more common in sedentary children. Athletic children are less likely to report nonspecific back pain than their nonathletic counterparts. Children who do not walk to school and have a poor self-image of their health in general report more back pain. Multivariate analysis showed that the incidence of low back pain in adolescents is inversely related to time spent doing physical activity (e.g., regular walking or bicycling) and directly related to television or computer time.[47]

Posture and inactivity contribute to low back pain. The intervertebral discs have the highest fluid content in the morning, which influences the pressure generated on spinal tissues during flexion.[48] Avoidance of flexion after arising in the morning significantly reduces nonspecific back pain.[49]

Plain radiographs are indicated at the time of the first visit if there is a history of severe trauma, loss of neurologic function, or history of unexplained fevers or malignancy. For an adolescent athlete with a high-risk factor because of a repetitive hyperextension maneuver, oblique views are appropriate for evaluation of the pars interarticularis.

Spondylolysis

Spondylolysis is a stress fracture of the pars interarticularis. It is generally considered to be a low-risk fracture that may heal on its own. The fracture occurs most frequently at L5, followed by L4 and L3. Spondylolysis occurs in 5% to 6% of the general population.[1] The lesion is usually asymptomatic and appreciated only incidentally on a radiograph. Generally, no single traumatic event causes spondylolysis; rather, repetitive stress produces fatigue defects, and a single event may complete the fracture. These fractures may not develop bony union but develop fibrous nonunion or heal in an elongated state in a relatively high percentage of patients.[50]

The incidence of pars defects is greater in adolescent athletes than in the general population, and is a particular clinical problem for this population.[51] Sports that require repetitive

hyperextension or extension combined with rotation—such as gymnastics, wrestling, and weightlifting—are more often associated with a stress fracture of the pars interarticularis. White female gymnasts experience a rate of spondylolysis (11%) five times that of the general white female population.[52] Certain participants in sports—such as diving, weightlifting, wrestling, and gymnastics—have disproportionately high rates of spondylolysis. A study of elite Spanish athletes showed the highest rates of spondylolysis in gymnasts and weightlifters followed by throwing athletes and rowers.[53] Other reports suggest that a wide variety of sports increase the risk of spondylolysis, including soccer, volleyball, and baseball.[54]

A major concern for patients with defects in the pars interarticularis is the progressive development of symptomatic spondylolisthesis. The incidence of progressive spondylolisthesis is low (3% to 10%), and mainly occurs during adolescence.[55,56] There is no known correlation between active sports participation and either the occurrence or the progression of spondylolisthesis.

Clinical Presentation

Pain may begin after acute injury, or there may be acute exacerbation of mild symptoms present for weeks or months. Lumbar spinal extension or rotation activities are particularly associated with the generation of symptomatic low back pain. Commonly, affected patients have a hyperlordotic posture and hamstring contractures. The classic test during physical examination is to have the patient stand on one leg and lean backward—the stork test. If the lesion is unilateral, the pain is most often produced by standing on the ipsilateral leg. This test is not definitive, but contributes to the diagnosis.

Spondylolysis is a bone lesion that, in most patients, does not produce a neurologic deficit. Any nerve root signs would suggest an alternative pathology, such as a herniated nucleus pulposus (HNP).

Diagnostic Imaging

Spondylolysis cannot be diagnosed by history and physical examination alone. The key to establishing the diagnosis of spondylolysis is visual confirmation of the pars lesion. The determination of a symptomatic spondylolytic lesion has become more sophisticated with the use of nuclear imaging, CT, and MRI.

A defect in the pars interarticularis is apparent in Fig. 33.3, which shows a three-dimensional CT scan. The classic description of this appearance on the oblique view radiograph is that of a collar on the "Scottie dog." Approximately 20% of the pars interarticularis lesions are seen only on the lateral oblique views, but no difference in sensitivity and specificity between anterior-posterior/lateral and anteroposterior/lateral/two obliques radiographs has been found.[57] Advanced imaging is often required to determine an accurate diagnosis.

MRI is typically used as the primary investigation for adolescents with back pain and suspected stress reactions of the pars interarticularis. MRI has been found to be 92% sensitive for detecting pars injuries, including stress reactions and stress fractures,[58] being especially useful in patients with negative CT who have stress reactions. SPECT use is limited by the high rate of false-positive and false-negative results, and by considerable ionizing radiation exposure.[59]

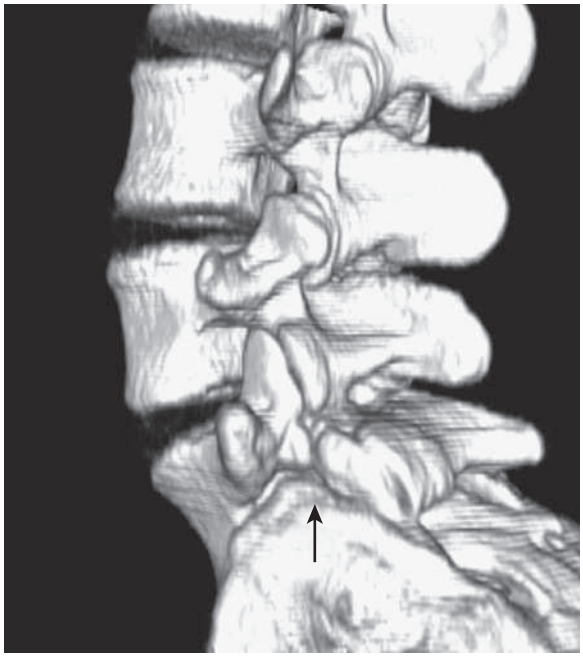

FIG. 33.3 Spondylolysis. Three-dimensional computed tomographic scan shows pars interarticularis defect (*arrow*).

Bone scans have been found to be 94% sensitive and 100% specific for detecting skeletal abnormalities in pediatric patients with back pain.[60] For an adolescent with low back pain, normal radiographs, and a negative bone scan, spondylolysis is ruled out. Other causes should be investigated. MRI may be ordered under these circumstances to rule out disc pathology or other causes for pain in nonosseous tissues. Similarly, adolescents with back pain, positive radiographs, and negative bone scan warrant MRI to investigate further the basis for pain.

Treatment

Most patients with symptomatic spondylolysis do well with conservative treatment short term.[61] The main goals of treatment are amelioration of pain, return to activity, and the attainment of bony healing. Treatment modalities include rest, medication, and bracing, alone or in combination. Some pars interarticularis lesions heal with early care and bracing, particularly early-stage unilateral defects. Osseous healing is unnecessary to achieve an excellent clinical outcome with full return to activities, although attaining bony union, particularly in younger adolescents, should be the goal since the long-term outcome of unhealed spondylolysis is not known.

Activity restriction is important to limit pain. Running, jumping, and sport-specific activities that produced the pain should be eliminated for 4 to 6 weeks. Contact and collision sports are not allowed, and hyperextension activities should specifically be eliminated.

Physical therapy has been proven to be quite effective in the treatment of spondylolysis. Patients with a specific and carefully managed exercise program show significant reduction in pain intensity and functional disability levels.[62,63] Therapy should include exercises to increase hamstring flexibility and to strengthen deep core muscles in the abdomen and the lumbar region.[64]

Transcutaneous elective bone stimulation has received increased attention as an adjunct in promoting healing of spondylolysis in young athletes, though controlled studies have not yet been done.[65]

The role of bracing is controversial. A rigid brace is not uniformly used for the treatment of symptomatic spondylolysis. Many surgeons begin bracing immediately for spondylolysis, whereas others reserve bracing for patients who do not progress with their conservative program or who experience increasing pain. Chronicity of the lesion is important to healing potential. One study reports that 94% of early-stage defects were healed in an average of 3.2 months using a hard brace, whereas only 27% of late-stage defects were healed in 5.7 months.[66] Various studies have determined that only 9% to 15% of cases of symptomatic spondylolysis or grade 1 spondylolisthesis require surgery.[67–69] The indications for surgery are progressive slip, intractable pain, development of neurologic defects, and segmental instability associated with pain. Pain alone can be controlled by activity modification and medication, and is not an indication for surgery. Surgical treatment is directed at repairing the fracture in the pars interarticularis using bone grafting and internal fixation. Various techniques using wires and screws have been advocated. The technique by Chen and Lee,[70] using a pedicle screw and laminar hook, has the advantage of not violating the facet joints, while providing excellent stabilization for healing.

Return to Activity

When follow-up examination reveals no discomfort and pain is well controlled with ordinary daily activities, a low level of sports participation is appropriate. Return to sport can be achieved after 4 to 6 weeks of modified activity. Activity intensity can increase as tolerated. Continued therapy should focus on core strengthening, improvement in posture, and avoidance of hyperextension.

A case report of pediatric cervical spondylolysis showed that over 1.5 million children participate in American football without reported injury due to cervical spondylolysis; therefore, this pathology should not be a restriction to play.[71]

Preventing recurrence is a major goal of treatment. A maintenance fitness program should be included in any workout regimen that is prescribed. Any low back pain that is worsened by extension or twisting should prompt a reduction in activity and increased periods of rest. If these precautions are instituted at the first sign of symptoms, a long course of rest and rehabilitation may be avoided.

Spondylolisthesis

Spondylolisthesis occurs when there is a bilateral defect in the pars interarticularis and one vertebra slips forward relative to the vertebra beneath it. The incidence of spondylolisthesis in athletes is the same as in the general population. No substantiated criteria are available for predicting which cases of spondylolysis will progressively slip, resulting in spondylolisthesis. Patients with dysplastic posterior elements have a higher risk of slip progression. Radiographic studies have shown a strong correlation between slip progression and a more vertical inclination of the superior plate of S1.[72,73] Most cases of spondylolisthesis are mild, unlikely to progress, and cease to progress after growth is complete. With mild spondylolisthesis, there is no increased rate of disability and no reason to restrict participation in sports.

Isthmic spondylolisthesis is the type seen in young athletes, excluding the rare cases of congenital absence of facet joints. Bilateral stress fractures of the pars interarticularis are the distinguishing pathology of spondylolisthesis. The stress fractures are unusual in that they occur in young people and rarely heal spontaneously. The only suspected causative factor, other than familial predisposition, is minor or repetitive hyperextension.

Symptoms associated with spondylolisthesis are dull low back pain exacerbated by activity, particularly hyperextension and rotation. Sports requiring repetitive rotation and extension under load, such as gymnastics, football, wrestling, hockey, pole vaulting, diving, and throwing sports, have been incriminated as causative factors in multiple studies.[74,75] Typical of mechanical-type pain, rest tends to alleviate the pain.

During the examination, the findings of paravertebral muscle spasm, hamstring contractures, and limited flexibility may be dramatic. Kyphosis associated with severe grades of slip flattens the profile of the buttocks and creates a sagittal postural malalignment (Fig. 33.4). A step-off at the lumbosacral level may be palpable.

Weakness, loss of sensation, and a positive straight-leg raise test are usually absent, differentiating spondylolisthesis from a herniated disc. If radiculopathy is present, the L5 root is usually involved. Cauda equina syndrome has been reported in severe cases owing to nerve root stretch over the dome of the sacrum.[76]

The diagnosis is easily confirmed by a lateral radiograph of the lumbar spine. The severity of the slip is graded either by the quartile classification of Meyerding or, more commonly, as a percentage of displacement relative to the top of the sacrum. There is consensus that kyphosis is a more important measure of the deformity than displacement.[77] The slip angle and sacral inclination are used to describe the sagittal plane deformity.

The treatment of a young athlete with spondylolisthesis is based on the same principles as the population at large, but the desire of the individual to continue sports participation must be considered as well. The age of the patient, the severity and duration of pain, and the degree of deformity all must be considered when formulating a treatment plan. A young, minimally symptomatic patient with a less than 25% slip requires little restriction of activity, but should be monitored for progression. Initial flexion-extension lateral radiographs are useful for assessing instability. Serial lateral films at yearly intervals can document any progression of slipping, unless symptoms warrant more frequent follow-up. If the degree of

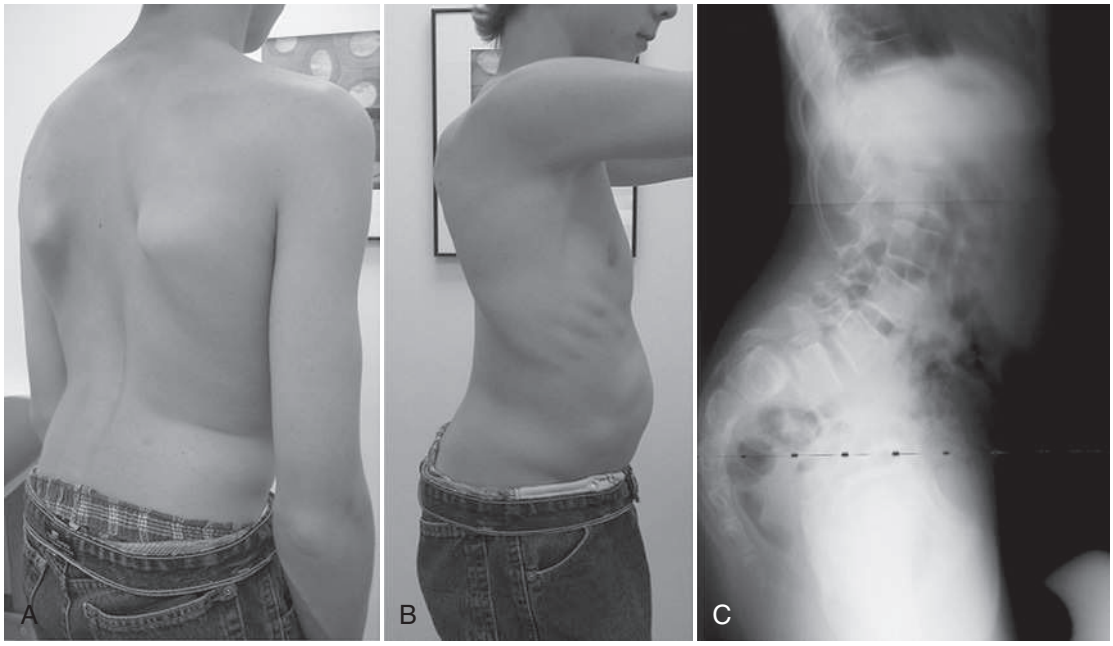

FIG. 33.4 Spondylolisthesis. (A) Paravertebral muscle spasm is striking. (B) Sagittal imbalance produced by severe slip made the clinical diagnosis evident. (C) Lateral radiograph showing the L5–S1 spondylolisthesis.

slip is 25% to 50%, the consensus is that the athlete should be restricted from collision sports, such as gymnastics and football. If the patient is truly asymptomatic, continued participation may be reasonable as a matter of judgment and cooperation.

Surgical stabilization is recommended for an immature patient with documented progression. Stabilization by spinal fusion is also recommended for slips greater than 50%, even if the patient is asymptomatic.

If the patient still has unremitting, disabling pain after a 6-month program of conservative treatment, certain surgical decisions are made: in situ fusion versus reduction, whether to perform decompression, whether to perform anterior and posterior fusion, and plus or minus bed rest. The debate over these issues remains. In situ fusion is the gold standard with well-documented long-term excellent outcomes.[78] Isolated removal of the laminar fragment, or Gill procedure, is contraindicated because further progression is common after that procedure.

Absolute indications for decompression are motor deficit and bowel or bladder dysfunction.[77] Some surgeons do not perform decompression even with motor or sensory signs because these signs tend to improve with a solid fusion.[79] Many surgeons perform a decompression at the time of fusion if weakness, sensory loss, or radicular pain is present, particularly in instances of severe slip. With severe degrees of slip, anterior fusion with or without reduction of the kyphotic deformity can be done using pedicle screw fixation and anterior interbody cages.

Although various methods for reduction of spondylolisthesis are advocated, many are associated with a significant rate of temporary or permanent nerve root damage. Reduction should be done only after wide decompression of the nerve roots, and significant nerve damage may still occur. Return to vigorous athletic participation is not guaranteed after surgery even if the fusion is solid. Most surgeons recommend against any but the least demanding of sports after such a major spine procedure. The decision regarding participation should be delayed until the outcome of surgery is clear.

Lumbar Scheuermann Disease (Juvenile Disc Disease)

The classic radiographic criteria for the diagnosis of Scheuermann disease is kyphosis of the thoracic spine with wedging of 15 or more degrees over three vertebrae.[80] Scheuermann disease is associated with endplate changes, such as irregularity of the apophyseal ring and Schmorl nodes due to defective endplate growth. The causes of Scheuermann disease, which has been attributed to juvenile osteoporosis, are controversial. This condition affects 0.4% to 8.3% of the general population and causes irregularities in ossification and endochondral growth in the thoracic spine in adolescents and young adults.[80] The disease leads to various pathologic changes at the junction of the vertebral body and the intervertebral disc, resulting in pronounced wedging of the vertebral bodies and progressive kyphosis in severe cases. According to various studies, it causes back pain in 20% to 60% of cases, and occasionally causes severe deformity of the spine.[80]

An increased frequency of radiologic abnormalities of the thoracolumbar spine has been reported among young athletes in various sports, such as soccer, gymnastics, water-ski jumping, or wrestling, compared with nonathletes.[81–91] Although the origins of typical Scheuermann disease[91] have been a matter of controversy,[92] atypical Scheuermann disease is considered to be strongly associated with trauma or excessive loading of the spine, especially in the flexed posture and during growth spurts.[93] Axial compression forces apparently

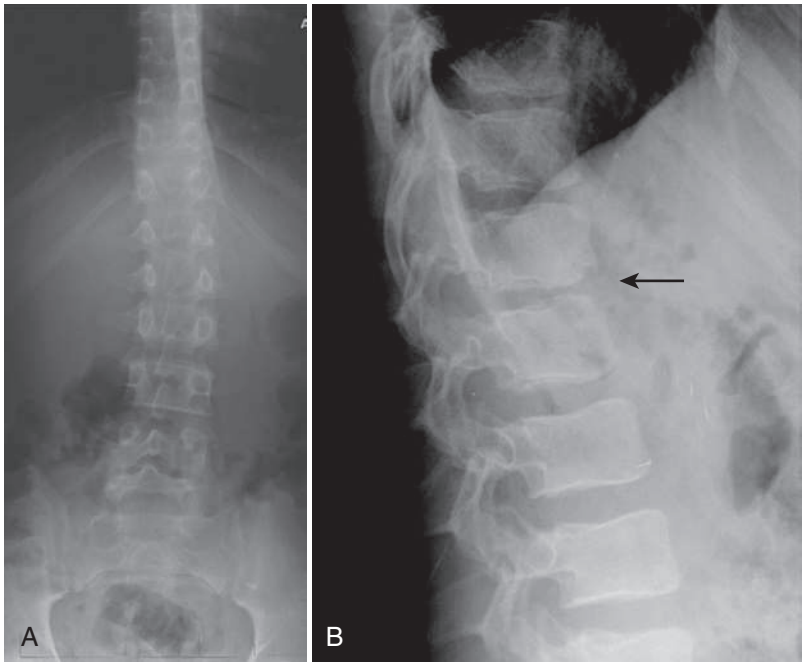

FIG. 33.5 Juvenile disc disease. This 14-year-old baseball player presented with pain localized to the upper lumbar level. (A) Anteroposterior radiograph shows irritative scoliosis. (B) Lateral radiograph shows endplate irregularity and erosion anteriorly at the L1–L2 level.

cause vertebral endplate bulging, whereas compression of the immature spine in flexion is considered to cause anterior intravertebral disc herniation (marginal Schmorl nodes).[92–95] Abnormalities of the vertebral ring apophysis are thought to be the result of failure in tension shear, analogous to Osgood-Schlatter avulsion at the knee (Fig. 33.5).[89]

In 1985, Greene and colleagues[92] described back pain and vertebral changes in the lumbar spine similar to changes seen in Scheuermann disease of the thoracic spine. These changes were accompanied by mechanical low back pain. In 1994, Heithoff and colleagues[96] saw similar changes on MRI and coined the term *juvenile discogenic disease*. Their group detected evidence of thoracolumbar Scheuermann disease and multilevel disc disease of the lower lumbar spine in 9% of the subjects studied. The patients ranged in age from 7 to 66 years, but most were young: slightly less than half of the patients were younger than 30 years; 9% were younger than 21 years. Males outnumbered females 3 : 1. Disc degeneration was found most frequently at the L5–S1 level, followed in order by L4–L5 and L3–L4. Of patients, 80% showed evidence of substantial degeneration at more than one lumbar level, and 53% had disc herniations involving at least one lower lumbar level.

Heithoff and colleagues[96] suspected that a substantial number of young adults have a combination of painful multilevel disc degeneration and lumbar spine changes typical of Scheuermann disease. In their view, both conditions may be caused by an underlying genetic defect in disc structure. It has been estimated that 80% of young patients requiring disc surgery have a genetic predisposition to disc degeneration.[96] Juvenile discogenic disease has been statistically associated with athletic activity and repetitive trauma. Most patients can be treated nonoperatively, but a subset has concurrent spinal stenosis, which may require decompression.[97]

Herniated Nucleus Pulposus

Acute disc herniation, or HNP, is relatively rare in children and adolescents compared with adults. Reports suggest that only 0.5% to 4% of surgically managed HNP occurs in patients younger than 18 years.[98–102] Despite the low incidence, approximately 10% of severe back pain in skeletally immature patients is due to disc herniation.[103,104] High-risk activities include weightlifting and collision sports, such as football.[104] HNP has also been associated with injuries sustained during gymnastics, basketball, baseball, and wrestling.[85] Nearly 95% of herniations occur from L4 to S1 and are fairly evenly distributed between L4–L5 and L5–S1.[105] The L3–L4 level is affected in only 5% of patients.[105]

The presenting symptoms of HNP in children differ from the symptoms seen in adults. The profile of an adolescent with HNP includes the presence of tension signs and sciatic scoliosis, without localizing neurologic signs. Most patients present with low back pain, with or without leg pain.[104,105] Associated leg pain is seen far less often than in adults (<20% of the time).[93] In children, the herniation is thought to be more central and the volume of extruded disc material less than in adults.[99,104] Actual rupture of the disc is rare in children.[106]

Physical examination often reveals an abnormal gait or scoliosis owing to paraspinal muscle spasm.[104,105] Nerve tension signs, such as a positive straight-leg raise test, are present in greater than 80% to 90% of patients, and the crossed-leg raise test is positive in more than 50%.[104,105,107] Objective motor

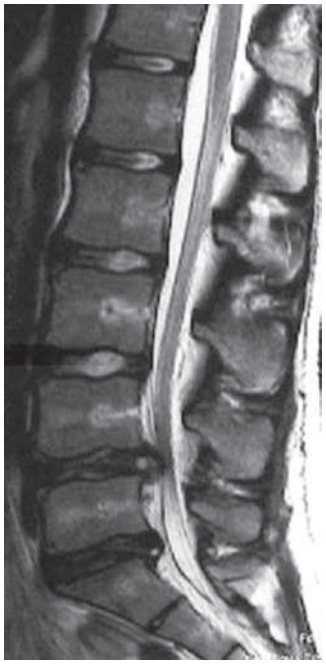

FIG. 33.6 Herniated nucleus pulposus. This 15-year-old wrestler has a black bulging disc at L4–L5 highlighted by a white dot on MRI. (Courtesy Charles Burton, MD.)

weakness may be present in 40%, with the extensor hallucis longus most commonly affected, and deep tendon reflexes at the knee and ankle are decreased in approximately 40% of patients.[105]

MRI is a very effective way to image the disc, spinal cord, and nerve roots. In addition, because of its noninvasive nature, it is a commonly used imaging technique. MRI has been shown to detect 100% of symptomatic herniations (Fig. 33.6).[108] Herniation is associated with endplate changes, with marrow signal intensity changes on MRI, and with increased cartilage in the material removed during surgery. There is a correlation of marrow signal intensity changes on MRI and the biology of the removed material. Avulsion-type disc herniation is common.[109] Occult spina bifida, extralumbar vertebrae, sacralization of the fifth lumbar vertebra, lateral recess stenosis, and spondylolisthesis have been associated with pediatric disc disease.[110]

Conservative treatment is as outlined for nonspecific low back pain. The literature suggests, however, that the overall outcomes of conservative treatment are generally poor. Recommendations suggest a 2- to 4-week trial of conservative management followed by surgical excision of the disc if symptoms have not resolved.[105]

Indications for surgical excision of the disc include persistent symptoms despite conservative management, cauda equina syndrome, progressive neurologic deficits, and reinjury.[104,105] Many authors have reported greater than 90% good to excellent results after surgical excision.[100,102,105,111] After surgical excision, low back pain and leg pain resolved within 3 weeks, and neurologic findings resolved after 3 months.[100] Reactive scoliosis almost always improves with successful treatment.[112] Long-term follow-up studies show excellent outcomes, including absence of pain and no activity limitations.[100,102,111] Satisfactory surgical outcomes may be seen for at least 10 years postoperatively, though may slightly deteriorate with time.[113]

Apophyseal Ring Fracture

Bone fragments at the posterior vertebral endplate have been given numerous names, such as posterior marginal node; limbus fracture; fracture of the vertebral rim, ring, or endplate; epiphyseal dislocation; and apophyseal ring fracture.[114] This condition is unique to adolescents,[104] and was first described by Skobowytsh-Okolot in 1962.[101,115] Endplate fracture was discovered in 20% of patients younger than 21 years and in 33% of patients younger than 17 years who were undergoing lumbar disc surgery.[116] The overall prevalence is only 0.07% of all patients of all ages undergoing disc surgery. There is a strong male predominance, with 85% of cases occurring in boys; 66% of cases are related to a traumatic event, such as weightlifting, heavy work, or sports injury.[101] Associations have also been found with Scheuermann disease[117] and lumbar disc herniations.[118]

Hyperextension of the lumbar spine[119] and rapid flexion together with axial compression to the vertebral column such as occurs with weightlifting are two proposed mechanisms of apophyseal ring injury.[101,104,120] The presenting symptoms of an apophyseal ring fracture are similar to the symptoms seen with HNP—back, buttock, and posterior thigh pain. Symptoms are worse with coughing, sneezing, sports, and prolonged sitting.[104] Pain may radiate down one or both legs. The straight-leg raise test is positive, and contralateral straight-leg raise is frequently positive. Paraspinal muscle spasm, lumbar tenderness, scoliosis, intermittent claudication, paraparesis, and cauda equina syndrome have been reported.[101,104]

Plain radiographs can be useful and show the avulsed fragment in approximately 40% of cases.[101,114] This fragment appears as an arcuate or wedge-shaped bone fragment posterior to the vertebral body or disc space. Alternatively, it can appear as a bony ridge on the posterior surface of the vertebral body. MRI may show a defect in the posterior vertebral rim. The fragment may be seen as a low signal area lying posteriorly, but can be difficult to distinguish from cortical bone and the posterior longitudinal ligament. MRI may be diagnostic in only 22% of cases.[114] CT is an excellent imaging study for these fractures because it can define the bony fragment, any associated disc prolapse, vertebral defect, and severity of any associated stenosis in approximately 75% of cases. CT should be considered if MRI fails to show an expected HNP or ring fracture.[114]

A trial of short-term rest, use of NSAIDs, and physical therapy is indicated. Physical therapy should focus on hamstring stretching, as persistent hamstring tightness has been found following conservative management in adolescent athletes.[121] If symptoms fail to resolve after 2 to 4 weeks or if there is progressive neurologic involvement or cauda equina syndrome, surgical excision of the fragment and any associated disc material should be performed.[104] Intervertebral fusion is controversial at this time due to lack of comparative,

high-level studies.[122] Good to excellent results have been reported after surgical excision in nearly all pediatric cases of avulsed ring fracture.

Cervical Spine Injuries

Traumatic neck injuries in young athletes may be to bone, nerve, or soft tissue. These are increasingly common injuries. Recent data on American football suggests that 0.2/100,000 participants at the high school level and 2/100,000 participants per collegiate level are diagnosed with a cervical cord neurapraxia most commonly due to hyperflexion, during "spear tackling."[123] The order of incidence is as follows[124]:

1. Nerve root or brachial plexus neurapraxia (burners)
2. Cervical strains (muscular injury)
3. Disc injury with neck pain only
4. Cervical sprains (ligament injury)
5. Disc herniation with radicular symptoms
6. Transient spinal cord compression secondary to stenosis
7. Fractures

On-Field Examination

In an on-field examination, if a cervical spine injury is suspected, the physician or trainer should appreciate any spinal pain; altered perception of touch; numbness; and weakness in, or difficulty moving, the extremities. Any player with signs of head trauma, such as disturbed vision, headache, staggering gait, disorientation, or memory loss, should not participate further.

For an ambulatory athlete complaining of pain or spasm in the neck, the physician should localize the tenderness and evaluate for muscle spasm. The physician should evaluate neck ROM and perform a motor and sensory examination of the extremities. On failing the examination, the athlete should be removed from competition and immobilized in a cervical collar. Alarming signs associated with a cervical fracture are acute torticollis, resistance to any motion, and the patient using the hands to support the head. If the player is unconscious, the presumption is that a cervical spine injury exists, and the neck is immobilized. Any facemask should be removed, but the helmet should be left in place. The player should be immobilized before being moved. Players with persistent or severe pain should be given a prompt radiologic evaluation. Return to participation depends on complete resolution of symptoms and normal radiographs.

Field Treatment of Cervical Fractures

Fractures of the cervical spine are relatively rare. The on-field treatment protocol should be well rehearsed and efficient, however. The minimal equipment includes tools or instruments necessary to remove the facemask, a cervical collar, and a backboard. Such an extensive setup may be impractical, but the medical attendant is well advised to know what emergency medical services are available, such as a well-equipped ambulance. A cell phone or other communication capability should be available on the sideline. The key is advance planning.

Lifting an individual high enough to insert a backboard beneath requires a medical team chief who carefully links the head to the chest and six additional people to lift. If a team has not practiced or there are not six individuals immediately trained and available, the athlete should not be moved until there is adequate assistance to immobilize and transport him or her without incurring additional damage. Instructions for the prehospital care of a spinal cord injury on an athletic field are published online by an interdisciplinary task force.[125]

Prevention of Catastrophic Injuries to the Cervical Spine in Football

According to Cantu and Mueller[126] of the National Center for Catastrophic Sport Injury Research, prevention is related to teaching and enforcing good technique in blocking and tackling and the proper use of well-fitted equipment. Cantu and Mueller[126] noted, "The football helmet is not the cause of cervical spine injuries. Poorly executed tackling and blocking technique are the major problems." The neck should be kept upright, avoiding use of the helmet and facemask as the initial and primary contact point in blocking and tackling. Rules against spearing should be strongly enforced, and athletes should strengthen their necks for further protection in the event of a miss-hit. Cantu and Mueller[126–131] stated that being prepared for the treatment and transport of a player with a major spine injury can mean the difference between life and death. That means having a plan and practicing the teamwork necessary for a successful transport.

Return to Play Guidelines

Recent publications have focused on return to play guidelines after cervical spine injury though strong, evidence-based studies are lacking. General guidelines include resolution of symptoms, full ROM and normal or near-normal strength, but these are not unique to the cervical spine.[132] Based on expert opinions, return to sport should be based on radiographic findings as well.[133] Benign injuries, such as spinous process fractures, may be treated with immobilization and return to play once healed. Patients with more than three burners (see later) in a single season or recurrent transient quadriparesis should undergo evaluation and imaging to rule out stenosis or parenchymal injury prior to return to play. Patients who undergo cervical fusion of one or two segments may return to play after successful recovery. More complex injuries that require operative intervention of fusion of three or more levels are contraindicated for return to play.[134]

Cervical Peripheral Nerve Injuries

Burners

"Burners" (also known as "stingers") are common injuries to the neck in collision sports, such as football, hockey, or diving. A high percentage of football players, especially defensive players, experience burners during their playing career. Other sports in which burners occur include wrestling, backpacking,

sledding, skiing, horseback riding, boxing, weightlifting, and climbing.

Burners are caused by either compression or distraction. An asymmetrical axial load on the neck causing compression in the neuroforamen can injure the peripheral nerve root. If the athlete falls directly on the shoulder and the head is distracted away from the shoulder, traction is applied to the nerve root and the brachial plexus. When the cervical spine is hyperextended, hyperflexed, or laterally flexed to the opposite side, the angle between the shoulder and neck is increased beyond the normal range, stretching the brachial plexus.

Symptoms are a severe burning or searing pain in the shoulder and arm associated with loss of sensation and weakness of the arm. The pain may be decreased by abducting the shoulder; this can be achieved by asking the athlete to place a hand on the top of the head. The Spurling maneuver is a provocative maneuver that reproduces the compression mechanism of injury. The patient's neck is extended, laterally flexed to the involved side, and rotated to the involved side with axial loading applied while in that position. The burning or searing pain is reproduced. Extension-compression mechanisms are most common, followed by brachial stretch and direct blow mechanisms.[135]

Burners are best prevented by enforcing the rules on spearing, by strengthening and conditioning the neck, and by proper use of good-quality protective equipment. Shoulder pads are protective equipment for the neck in football. An A-frame design to the shoulder pads brings lateral stability to the base of the neck, preventing lateral tilt while allowing rotation of the head, which occurs at C1–C2 (50%). The base of the shoulder pad needs to extend down well on the chest anteriorly and posteriorly to link the chest to the base of the neck. It is almost impossible to prevent extension of the head. The player needs to learn to block with the shoulder and keep the head down so that the opposing player is not contacted with a facemask or the helmet.

Initial treatment for this injury is removal from participation and rest, followed by strengthening exercises of the neck and, finally, careful stretching and restoration of ROM. Because the pain, paresthesias, and weakness typically last only a few seconds or minutes, these injuries fall into the Seddon classification of neurapraxia. Occasionally, athletes with more severe injuries experience a prolonged recovery period that may last hours to several weeks and may lead to a prolonged loss of time from competition.[136–143] Return to play criteria include full ROM of the neck associated with complete return of arm strength and sensation.

Burners may occur many times during the season, ranging from a transient nerve irritation without residual damage to a complete avulsion of the nerve root from the spinal cord with permanent deficit. Burners are symptoms of injury to either the brachial plexus or a nerve root, and must be evaluated systematically.

Quan and Bird[144] proposed a classification of peripheral nerve injuries that correlates well with electrodiagnostic studies and prognoses, based on earlier classifications by Seddon[145] and Sunderland.[146] This classification scheme is useful for diagnosis and advice in individual cases (Table 33.2).

TABLE 33.2 Quan and Bird Classification of Nerve Injury

Type of Injury	Mode of Recovery	Time to Recovery
Conduction block (neurapraxia)	Remyelination of focal segment involved	2–12 wk
Limited axonal loss	Collateral sprouting from surviving motor axons	2–6 mo
Intermediate axonal loss	Collateral sprouting and axonal regeneration from site of injury	2–6 mo
Severe axonal loss	Axonal regeneration	2–18 mo
Complete nerve discontinuity	No recovery without nerve grafting	2–18 mo

Data from Quan D, Bird SJ. Nerve conduction studies and electromyography in the evaluation of peripheral nerve injuries. *Univ Pa Orthop J.* 1999;12:45–51.

Cervical Stenosis

Congenital cervical stenosis is a risk factor for cervical spine injuries.[147] Two studies have analyzed the relationship of burners to cervical stenosis in college football players at the University of Iowa and Tulane University.[137,148] Burners were more common in players with spinal stenosis as defined by the Torg ratio, especially the occurrence of repeated episodes of neurapraxia. The Torg ratio is defined as the ratio of the spinal canal width to the width of the vertebral body at the same level, and is most narrow at C7. These studies suggest that a Torg ratio of 0.7 to 0.8 or lower is high risk. For players with cervical stenosis, the risk of burners is three times that of players without stenosis (Fig. 33.7).

Transient Spinal Cord Compression

Torg and colleagues[149] described the syndrome of transient quadriplegia, considered to represent a "neuropraxia of the cervical spinal cord." This syndrome includes bilateral upper extremity and lower extremity neurologic involvement with no associated fracture or dislocation. It usually resolves within 36 hours. The transient quadriplegia was associated with developmental spinal stenosis, either as an isolated entity or associated with congenital abnormalities, cervical instability, or intervertebral disc disease. The authors noted statistically significant spinal stenosis in all patients who incurred episodes of transient quadriparesis.[149,150] They also noted that there was "no evidence that the occurrence of neuropraxia of the cervical spinal cord predisposes an individual to permanent neurological injury."[149]

Fracture

Fracture of the Thoracolumbar Spine

Fracture or dislocation of the thoracolumbar spine is unusual. The typical mechanism is an axial load, as from a fall onto the buttocks from a height or at a relatively rapid speed. The injury is usually a relatively benign compression fracture occurring in the lower thoracic spine or at the thoracolumbar junction. Some compression fractures are not easily seen on plain

radiographs (Fig. 33.8). When there is significant pain or tenderness using spot radiographs, CT or MRI can aid in identification and localization of the fracture. Any neurologic findings require special evaluation.

Treatment of spine fractures generally falls into two categories: closed and open. With closed treatment, the fracture is reduced if necessary, and the patient is immobilized in a body cast. Reduction is the primary technique for decompression of the spinal cord. If reduction is not required, the patient is fitted with a brace for comfort.

FIG. 33.7 Cervical stenosis. This young college football lineman has a Torg ratio of 0.4 and is at great risk in continuing the sport because of congenital spinal stenosis.

With open treatment, a surgical procedure is performed to reduce or secure severely displaced or unstable fractures. Open procedures are indicated when two or three of the pillars of the vertebral column are disrupted. Internal fixation is usually required. Pedicle screws and rods are the current devices used for posterior fixation. Anterior fixation with plates and screws is less common. Bone grafting to obtain spinal fusion and biologic long-term stabilization are the final parts of the procedure. Factors to consider when deciding when and if an athlete should return to play after spine fracture are healing, rehabilitation, risk of reinjury, and neurologic status.

Sacral Stress Fracture

Sacral stress fractures, more commonly seen in the intrapartum or postpartum period of pregnancy or elderly osteoporotic patients, also can occur in individuals participating in running sports, typically at an elite level. Large series studies are not available on this condition, and most literature consists of case reports. Pain is often localized to the low back and buttocks.[151] Diagnosis is made using plain radiographs and MRI or CT scan. Treatment includes a brief period of limited weight bearing followed by progressive mobilization, physical therapy, and return to sport in 1 to 2 months, after the pain has resolved. Addressing nutritional status and calcium/vitamin D intake are important in preventing repeat stress fractures.[152] Gait and running analysis can also be performed to assist in recovery and prevention.

Iliac Apophysitis

Apophyseal injuries are a unique injury in adolescent athletes, and are associated with skeletal immaturity and repetitive microtrauma. With iliac apophysis involvement, the patient usually presents with back pain localized to the iliac crest, which facilitates diagnosis. There is local tenderness, which is

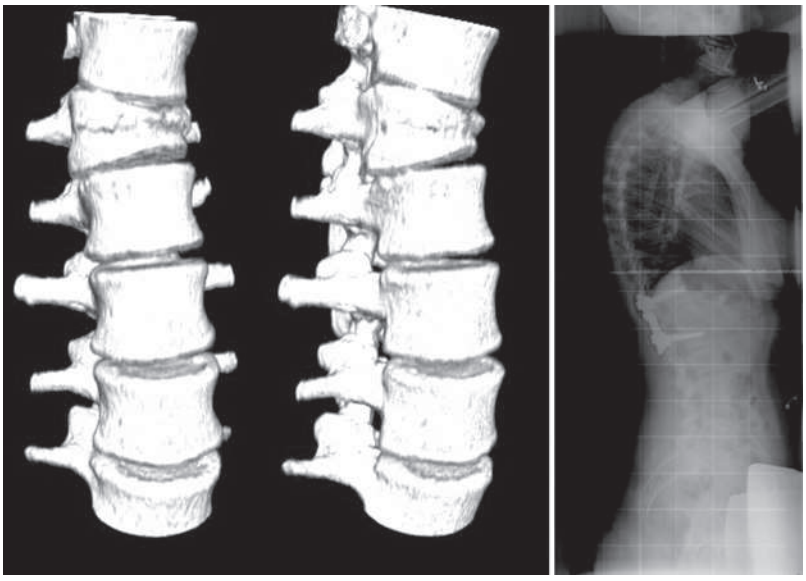

FIG. 33.8 Thoracolumbar fracture in a 16-year-old horsewoman. The fracture was aligned and stabilized by three-level fusion. Anatomic details are clear on this three-dimensional computed tomographic scan.

exacerbated by resisted lateral bending and extension. Radiographs are normal. The treatment is conservative for 3 to 6 weeks, during which time the pain predictably resolves. Bone stimulators have been successfully used in refractory cases.[153] Greater trochanter apophysitis has also been described in an adolescent athlete, whose radiographs showed a widened sclerotic apophysis. The patient had resolution of pain and symptoms after conservative management.[154]

The typical athlete affected is an adolescent runner. Clancy and Foltz[155] described a series of 21 young distance runners, in all of whom pain resolved with alteration of training and rest. As the apophysis closes at the end of growth, even the most recalcitrant cases resolve, similar to Osgood-Schlatter disease of the knee. There are a couple of case reports of avulsion of the apophysis in older teenagers that was surgically repaired, but this is rare.[156,157]

Tumor

Spine cancers in children are rare. Children 7 to 15 years old with spine infection or tumor tend to present with back, pelvic, or abdominal pain.[158] Intradural spinal metastasis pain is a characteristically cramping pain. The physician should take note of back pain that increases with recumbency and keeps the patient awake at night. Progressive pain is characteristic of tumors, not trauma-induced pain. The pain of cancer tends to be constant.

Neoplasia of the spine may originate in either the neural or the osseous elements. Most bony spine tumors of childhood are benign, but they usually cause pain or an irritative scoliosis (Fig. 33.9). Osteoid osteoma is a small, sclerotic, irritative lesion of the posterior spinal elements. The pain is worse at night, and is relieved by aspirin or other antiinflammatory drugs. Although the natural history is for spontaneous resolution of the pain over years, patients do not often tolerate long-term pain well.

Osteoblastoma is a larger version of the same process. Osteoid osteoma and osteoblastoma may manifest as stiffness or scoliosis with or without pain. The lesion may not be apparent on plain radiographs. Bone scan is intensely positive and an excellent first supplemental imaging study in children.

Eosinophilic granuloma in the spine produces a flattening of the vertebra, or *vertebra plana,* rarely with neurologic compromise. Some degree of vertebral regrowth occurs with time in this benign condition. Conservative treatment is indicated if the diagnosis is clear.

Bony malignancies are rare and include leukemia, Ewing sarcoma, and osteosarcoma in bone, and neuroblastoma or astrocytoma in the spinal cord. In the absence of actual bone destruction, these tumors may show subtle signs of pressure owing to their growth, such as separation or thinning of the pedicles or scoliosis.

Spinal cord tumors, such as astrocytoma or ependymoma, are more likely to manifest as extremity weakness, gait disturbance, or scoliosis. Precisely because they are rare, these serious lesions should always be kept in mind. MRI is the study of choice for diagnosis.

PEARLS

1. Back pain in an active adolescent athlete is due to spondylolysis until proven otherwise.
2. An open-ended history taken from the patient is the most cost-effective diagnostic tool and worth the time.

PITFALLS

1. Do not perform a cursory nonfocused history and examination for adolescent back pain.
2. Do not jump to surgery before implementing effective nonoperative treatment for back pain.

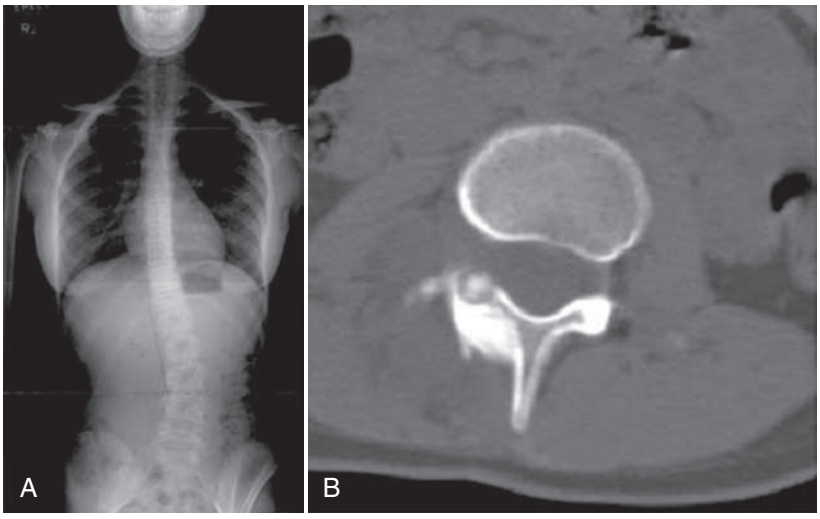

FIG. 33.9 Osteoid osteoma. Tumor did not show on magnetic resonance imaging done for this 14-year-old softball pitcher who presented with back pain and scoliosis. (A) The single-photon emission computed tomographic (CT) scan was hot at L3. (B) This computed tomographic scan clearly delineates pathologic lesion. Irritative scoliosis corrected spontaneously after the tumor was excised.

KEY POINTS

1. Most spine sports injuries in children are chronic injuries resulting from overuse rather than acute injuries secondary to direct trauma.
2. Encouraging the patient to relate his or her history by attentive listening is helpful in determining a differential diagnosis more quickly and accurately.
3. The most common cause of chronic back pain in adolescent athletes is stress fracture or spondylolysis.
4. Sports employing repeated hyperextension maneuvers, such as gymnastics, provide the mechanism for increased stress on the pars interarticularis, which is the site of spondylolysis.
5. Screening radiographs seldom augment a benign history in making a diagnosis. For patients who do not improve in 3 to 4 weeks, CT and MRI can be helpful for diagnosis.
6. Nonoperative treatment is effective for most back pain in children. Spondylolysis, spondylolisthesis, or the rare condition HNP may require operative treatment. Vigorous postoperative rehabilitation may return the athlete to sport.

KEY REFERENCES

1. Bono CM. Low back pain in athletes. *J Bone Joint Surg Am*. 2004;86:382-396.
   This review focuses on spondylolysis and degenerative lumbar disc disease as the major sources of chronic pain in athletes, while pointing out that most low back pain in athletes is due to self-limited sprains or strains. Although these injuries usually respond to nonoperative treatment, the author found direct repair of recalcitrant defects to be the usual course recommended in the literature. Whether the disc changes are worse than changes seen in the general population is debatable. The author advocates anterior interbody fusion for a patient who does not respond to a directed conservative program.
2. Brodke DS, Ritter SM. Nonoperative management of low back pain and lumbar disc degeneration. *J Bone Joint Surg Am*. 2004;86:1810-1818.
   This review article summarizes the treatment options for nonspecific low back pain, including bed rest, medications, physical therapy, manipulation, braces, and injections. The authors acknowledge that a specific pain generator should be sought and that scientific evidence is lacking to support any particular mode of treatment.
3. Ginsburg GM, Bassett GS. Back pain in children and adolescents: evaluation and differential diagnosis. *J Am Acad Orthop Surg*. 1997;5:67-78.
   The authors document the differential diagnosis for back pain in children to include spondylolysis, spondylolisthesis, Scheuermann kyphosis, disc herniations, infections, and tumors. They discuss the appropriate tests for early detection and treatment with a rationale for selecting the most appropriate study.
4. McGill SM. Low back exercises: evidence for improving exercise regimens. *Phys Ther*. 1998;78:754-765.
   This review article documents the biomechanical evidence from the laboratory that can be used to guide the scientific choice of an exercise program for back pain. The author recommends that an exercise program load tissues to strengthen them, while avoiding injury from overexertion. The relative importance of strength, flexibility, and endurance is explored. Specific exercises are described to enhance the stability of the back for rehabilitation and health maintenance.
5. Salminen JJ, Erkintalo MO, Pentti J, et al. Recurrent low back pain and early disc degeneration in the young. *Spine*. 1999;24:1316-1321.
   The authors studied a group of 14-year-old Finnish boys and girls prospectively who had chronic low back pain and compared them with a similar sample of 40 patients who were asymptomatic. The risk of reporting recurrent low back pain up to age 23 years was 16 times as high in the group with early degenerative disc findings. Significant changes included disc protrusion and Scheuermann-type changes on MRI of the lumbar spine.
6. Standaert CJ, Herring SA. Spondylolysis: a critical review. *Br J Sports Med*. 2000;34:415-422.
   The authors based their review on more than 125 articles addressing spondylolysis. They found no controlled clinical trials. Their conclusions were that isthmic spondylolysis is a fatigue fracture of the pars interarticularis, which is more often symptomatic in adolescent athletes. Treatment by activity modification and exercise is usually successful, with symptomatic relief occurring with or without healing of the skeletal defect. Multiple imaging studies have been recommended, and bracing was used in some studies. Rarely, surgery is indicated.

34 CHAPTER Congenital Anomalies of the Cervical Spine

Robert F. Murphy
Daniel J. Hedequist
Michael P. Glotzbecker

Introduction

Congenital anomalies of the cervical spine are an infrequent occurrence; physicians who manage children with these anomalies must be involved in the total care of the patient. Other anomalies are frequently present, including vascular, cardiac, renal, and musculoskeletal manifestations. An accurate diagnosis may be delayed because radiographic evaluation of pediatric patients can be difficult, and these anomalies frequently do not manifest until the patient is older.

This chapter is concerned with the evaluation and treatment of congenital anomalies of the pediatric cervical spine. Special consideration will be given to the role of radiographs and advanced imaging in making an accurate diagnosis, as well as surgical stabilization techniques.

Modern Cervical Instrumentation in Children

In the past, the only internal stabilization option available to surgeons treating children with cervical spine disorders was wiring techniques. These wires were traditionally sublaminar and were found to have acceptable rates of fusion and complications for a variety of cervical spine disorders. With advances in technology, screw options are now available for every segment of the cervical spine. Coupled with rigid rod connections, modern segmental screw instrumentation now affords surgeons a powerful and reliable tool to safely stabilize most pediatric cervical spine anomalies. These advanced constructs offer improved options for treating complex deformities associated with poor bone quality. A thorough understanding of the bony, neurologic, and vascular anatomy is paramount to successful implementation of these techniques.

Occipital Plating

Previous fixation options to the occiput included wiring techniques, such as loop-rod constructs. Modern techniques include the placement of occipital screws (most commonly through a plating system), which are then secured to a rod construct. Recent biomechanical data have demonstrated that occipital screws are superior to loop-rod wiring techniques in all planes of motion.[1] Placement of these screws is most commonly at the external occipital protuberance, and computed tomography (CT) scan–based studies have confirmed this as the thickest area of bone available for fixation with the ability to accept unicortical screws at acceptable pullout strength.[2–4] Studies specifically in children aged 2 to 6 years have confirmed this as the optimal location for screw placement[5] (Fig. 34.1). In a recent review of 70 children treated with occipital plating connected to cervical screws with rods, rates of fusion were high and complications rates were acceptable.[6]

C1 Screws

In congenital anomalies, sublaminar wiring of C1 in children is not always feasible, as the posterior arch of the atlas is not always completely formed. Furthermore, many procedures about the cervical spine require concomitant decompression of C1, which eliminates the ability to obtain wire fixation. Lateral mass screws can be safely placed in patients as young as 2 years old[5,7,8] (Fig. 34.2). CT studies of C1 in children have provided excellent information on the bony anatomy, including appropriate starting point and screw placement trajectory.

Salient principles of techniques for placement of C1 screws in children include a thorough understanding of the relationship of the vertebral artery to the bone (usually obtained by preoperative CT scan). In children, the location of the vertebral artery is usually closer than the traditional 1.5 cm from the midline, as described in adults,[9] and extra care should be assumed in the setting of congenital anomalies. In order to improve exposure of the starting point, some surgeons sacrifice the root of C2[10]; however, we have not consistently found this to be necessary. Hemostasis and control of the venous plexus found in this area are critical in the safe placement of C1 screws.

C1 lateral mass screw placement is successful in a variety of pediatric pathologies, including atlantoaxial instability, with low rates of complications, resulting in predictable fusion.[6,11,12]

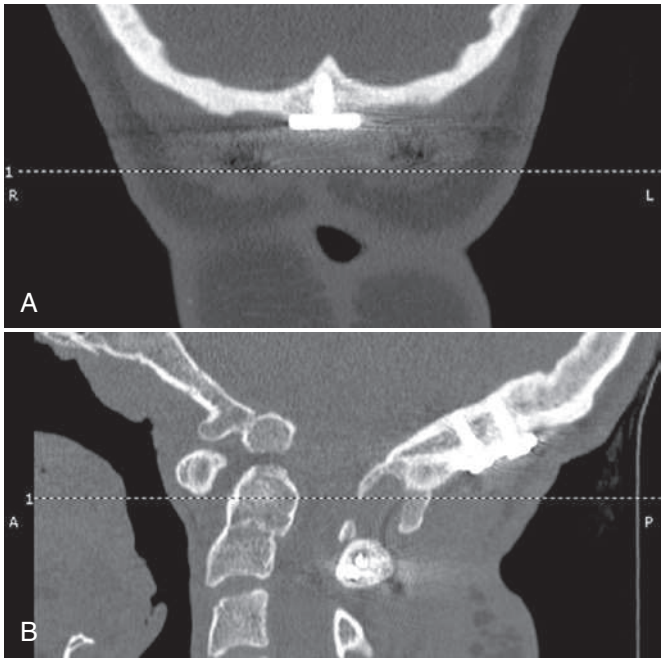

FIG. 34.1 (A) Coronal and (B) sagittal reformatted computed tomographic images showing that the external occipital protuberance is the thickest area of bone available for occipital screw purchase. If concerns of venous sinus penetration are present, unicortical screws may be used with little decrease to the biomechanical strength of the construct.

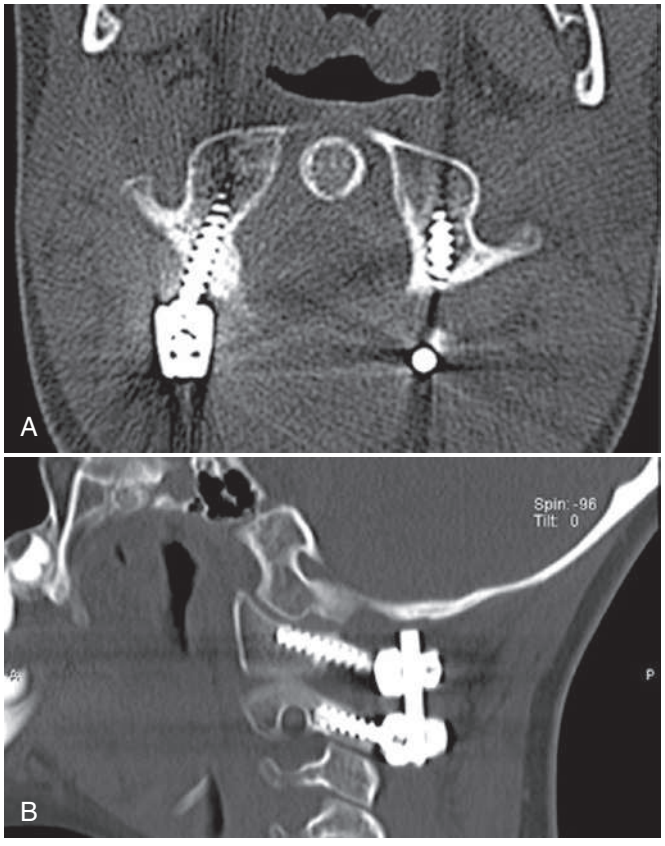

FIG. 34.2 (A) Axial and (B) sagittal reformatted computed tomographic images demonstrating appropriate placement of C1 lateral mass screws.

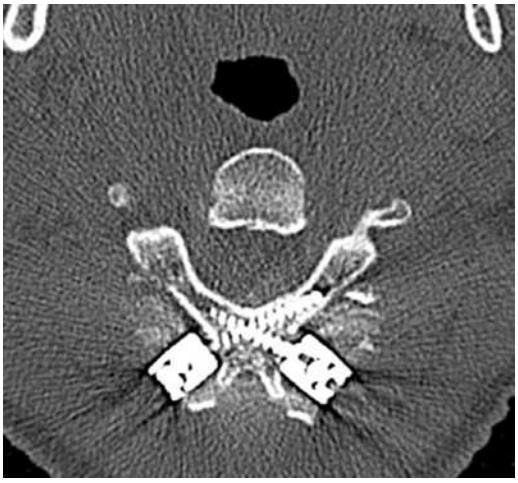

FIG. 34.3 Axial computed tomographic image demonstrating crossed laminar screws at C2.

C2 Screws

C2 is an important segment in pediatric cervical spine fusion constructs, as it can serve as the base of an occipitocervical construct, or the top of a lower cervical construct. Many screw options exist in C2, including laminar screws and pars/pedicle/isthmus screws. With limited space available for the cord at this segment, screw options are an attractive alternative to sublaminar wiring. As in the case of C1, adequate knowledge of the course of the vertebral artery is mandatory for successful implantation.[13]

The spinous process of C2 is the landmark for the entry point for translaminar screws, which are effective for construct rigidity.[14] Clinically, laminar screws are safe and efficacious.[14,15] Canal breach has not been reported in children[11,13] (Fig. 34.3).

Regarding the C2 pars/isthmus/pedicle, there is variability in the terminology. Technically, two separate screw paths exist, but the pars and pedicle are commonly intertwined in a shared mass of bone. Most frequently, surgeons select the course and tract of the screw based on maximum available bony purchase, as well as the location of the vertebral artery and C1–C2 articulation.

Rigid screw fixation, either through pars/pedicle or translaminar screws, is possible in almost all patients. This method serves as an excellent and reliable fixation point in pediatric deformity surgery without injury to the vertebral artery or malposition of screws in the vast majority of patients.[6,11,13]

C1–C2 Transarticular Screws

C1–C2 transarticular screws are a powerful, but challenging, fixation technique. The challenges of screw placement are threefold: dissection of the C2 isthmus must be adequate, dissection of the C1–C2 joint must be complete, and an understanding of the course of the vertebral artery in relation to C1 and C2 must be thorough. Common vertebral artery anomalies that preclude C1–C2 screws include high-riding vessels next to a small isthmus or medially deviated vessels blocking the optimal trajectory. The most common problematic vertebral

FIG. 34.4 Transarticular C1–C2 screws. Note posterior cables securing bone graft. This construct is powerful and stable if the surgeon is aware of the challenges associated with screw placement.

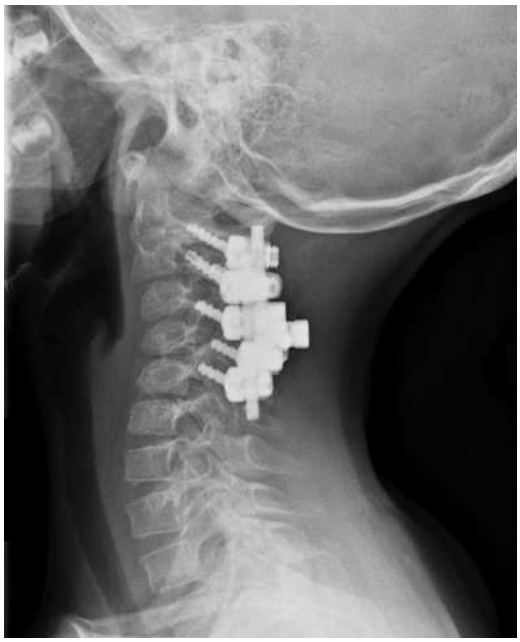

FIG. 34.5 Lateral mass screw placement for cervical instability.

artery course in relation to C2 is a medial deviation.[13] To complicate matters in pediatric patients, few children younger than age 6 years have anatomy suitable for transarticular screws given either the size of the C2 isthmus or the course of the vertebral artery.[5] However, clinical studies have shown that, even in younger patients, screws may be safely placed if the preoperative imaging demonstrates anatomy that allows for safe screw placement[16,17] (Fig. 34.4). Some authors have found success in children younger than age 4 years, as long as safe anatomy on CT scan can be confirmed.[17,18] In cases of severe bony anomalies or aberrant vertebral artery courses, placement of a unilateral C1–C2 transarticular screw is a biomechanically reasonable consideration.[17]

Subaxial Lateral Mass Screws

Several studies have demonstrated that the use of lateral mass screws in children is safe and effective, as long as preoperative planning principles are maintained.[19,20] We use lateral mass screws for a variety of pediatric conditions. Postoperative CT has shown complete screw containment in all cases and there have been no vertebral artery injuries or postoperative nerve deficits.[19,20] (Fig. 34.5) Although subaxial lateral mass screws can be safely placed in children as young as 4 years, the indications are rare. We do not use cervical pedicle screws in pediatric patients given the cadaveric anatomic studies showing the size of the pedicle is not adequate for safe screw placement in the majority of patients.[21]

Halo

The halo orthosis is a powerful tool with a variety of uses in pediatric cervical spine pathology. In patients who present with substantial and significant deformity, the halo can be used to obtain an effective reduction prior to definitive surgical stabilization. Common principles in application of halo rings to pediatric patients include a greater number of pins than traditionally utilized in adult patients, and less torque per pin. Care should be taken to avoid the supraorbital and supratrochlear nerve. The halo should be applied just superior to the equator of the head.[22]

FIG. 34.6 A halo vest orthosis applied intraoperatively can maintain reduction and protect the eyes and face.

Application and use of a halo vest orthosis preoperatively can aid the surgeon in maintaining reduction and protecting the patient during surgery. We commonly apply a halo vest orthosis once the patient has undergone general anesthesia. Once a reduction is obtained, the halo vest is secured. The patient is then turned into the prone position and the posterior leaf of the vest is removed. The reduction is reliably maintained for surgery, and pressure is removed from the face and eyes during the procedure (Fig. 34.6). Given the poor bone quality and pseudarthrosis rates in many pediatric cervical conditions, postoperative use of the halo vest provides additional security to the instrumented spine.

Halo vest orthoses are not benign devices; surgeons must use them judiciously. In a large series of patients, complications occurred in over half of patients. Neurologic changes are not rare when utilizing halo traction for reduction, and pin site infections are frequent.[23] This has led some authors to recommend pinless halo systems, which have been found to be safe in a variety of disorders.[24,25] Halo utilization in toddlers should be used with caution, as these children are prone to falls, which may destabilize the halo vest construct.[26]

Navigation

Improvements in image acquisition and computer-based planning software have afforded surgeons the ability to preoperatively plan and skillfully execute surgery using navigation technology. The feasibility and effectiveness of this technology has already been well explored in the thoracic and lumbar spines in pediatric patients.[27–30] New research is emerging on the utilization of this technology and its applications in pediatric cervical spine surgery.[31]

Specific Cervical Spine Conditions

Basilar Invagination

Basilar invagination (or impression) is a deformity of the base of the skull at the foramen magnum. The relationship between the base of the skull and upper cervical spine is altered, and the tip of the odontoid becomes more cephalad, protruding into the foramen magnum. This deformity may encroach on the brain stem, increasing the risk of neurologic damage.

There are two types of basilar impression. The first is a primary congenital abnormality often associated with other vertebral defects, such as occipitoatlantal fusion, hypoplasia of the atlas, or Klippel-Feil syndrome.[32] Secondary basilar invagination is an acquired developmental condition usually attributed to recurrent microfractures in the region of the foramen magnum from the axial load from the skull, which precipitates softening, flattening, and infolding of the posterior skull base. It is a potential sequela of osteogenesis imperfecta, neurofibromatosis, and other osteochondrodysplasias.[33–35]

Clinical Features

Patients with basilar invagination frequently have a deformity of the skull or neck, and may present with torticollis.[36,37] The symptoms (or lack thereof) are difficult to explain,[36,38] but are generally due to encroachment of the neural structures (particularly the medulla oblongata) at the level of the foramen magnum. The neurologic sequelae are determined by the degree of cranial migration of the dens. In addition to the direct compression of the ventral brain stem, the dens creates a fulcrum for traction on the cervical cord. Cerebellar dysfunction may arise from direct compression or reflect secondary herniation from the posterior fossa.

Basilar invagination is frequently associated with other neurologic conditions, such as Arnold-Chiari malformation[36] and syringomyelia[39–41]; therefore, the clinical picture may be unclear. Patients with pure basilar impression mainly complain of motor and sensory disturbances, such as weakness and paresthesia of the limbs within more severe cases of alteration of gait. In contrast, symptomatic patients with pure Chiari malformation are more likely to complain of cerebellar and vestibular disturbances (gait alteration, dizziness, and nystagmus). However, many patients will present with a combination of these symptoms, as these conditions commonly simultaneously coexist. In both conditions, there may be impingement of the lower cranial nerves as they emerge from the medulla oblongata. There may be pain in the nape of the neck from compression of the greater occipital nerve. Headache may also occur from blockage of the aqueduct of Sylvius, causing increased intracranial pressure.[36,42] Upon physical examination, many of these patients will have findings indicative of cord compression (myelopathy) or upper motor neuron dysfunction, such as a wide-based gait, decreased motor strength, and increased reflexes.

There is a high incidence of vertebral artery anomalies in basilar invagination.[43] The vessels may be compressed passing through the crowded foramen magnum, causing symptoms suggestive of vertebral artery insufficiency, such as dizziness, seizures, and syncope.[36,43,44] Compromise of vertebral arteries in the foramen magnum may lead to degeneration of the spinal cord and medulla, which may be an explanation for the frequent association with syringomyelia or syringobulbia.[45]

Many patients do not develop symptoms until the second or third decade of life[36] due to gradually increasing instability from ligamentous laxity caused by aging. These individuals often develop premature cervical osteoarthritis, and arteriosclerotic changes in the vertebral arteries may make these vessels more susceptible to minor constrictions.

Imaging

Basilar invagination is difficult to assess radiographically. Many measurement schemes have been proposed, such as the Chamberlain,[46] McGregor,[42] and McRae lines on the lateral radiograph (Fig. 34.7) and the Fischgold-Metzger line in the anteroposterior projection. The Chamberlain line[42,46] (a line drawn from the dorsal marginal hard palate to the posterior lip of the foramen magnum) is seldom used because the posterior lip of the foramen magnum (opisthion) is difficult to define on a standard radiograph and is often itself invaginated. The McGregor[42] line (a line drawn from the upper surface of the posterior edge of the hard palate to the most caudal point of the occipital curve of the skull) is easier to identify (Fig. 34.8). The position of the tip of the odontoid is measured in relation to this baseline, and any distance greater than 4.5 mm above the McGregor line is considered abnormal. The McRae line defines the opening of the foramen magnum and is an accurate guide in the clinical assessment of patients with basilar impression because if the tip of the odontoid lies below the opening of the foramen magnum, the patient is likely to be asymptomatic. A criticism of the lateral lines (McGregor and Chamberlain) is that the hard palate is not actually a part of the skull and may be distorted by an abnormal facial configuration or a highly arched palate, independent of a craniovertebral anomaly.[47]

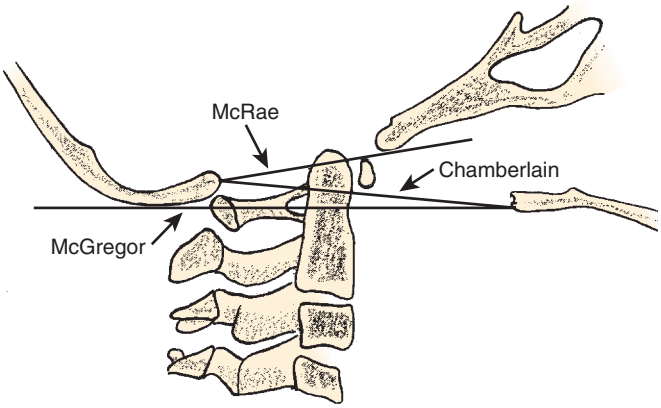

FIG. 34.7 Three lines used to determine basilar impressions. The Chamberlain line (1939) is drawn from the posterior lip of the foramen magnum (opisthion) to the dorsal margin of the hard palate. The McGregor line (1948) is drawn from the upper surface of the posterior edge of the hard palate to the most caudal point of the occipital curve of the skull. The McRae line (1953) defines the opening of the foramen magnum. The McGregor line is the best method for screening because the bony landmark can be clearly defined at all ages on routine lateral radiograph.

FIG. 34.8 A 12-year-old male presented with a history of unusual gait. Routine lateral radiograph suggested that the odontoid was displaced proximally into the opening of the foramen magnum. The McGregor line (*white*) has been drawn from the most caudal portion of the occiput to the hard palate. The tip of the odontoid is more than 4.5 mm above this line, indicating a basilar impression.

Since the advent of CT and magnetic resonance imaging (MRI), the diagnosis of basilar invagination can be made directly rather than based on radiographic lines.[48] MRI also allows direct assessment of neural compression and identifies the presence of associated pathologic processes, such as cord signal change, Chiari malformation, hydrocephalus, syringomyelia, or cerebellar herniation[35] (Fig. 34.9).

FIG. 34.9 Sagittal magnetic resonance image of basilar invagination shows cord signal change.

Treatment

Treatment of basilar invagination depends on the cause of the symptoms and is dictated by the severity of ventral neural compression and reducibility of the deformity. Absolute indications include symptomatic patients with documented impingement with spinal cord signal changes. Relative indications include progressive deformity or significant deformity with cord impingement in asymptomatic patients. Hydrocephalus from aqueductal stenosis, if present, must be addressed first with ventricular shunting before any other surgical interventions.[35]

In symptomatic patients, the cervical spine should initially be realigned using halo traction, which will also help decompress the neural elements. However, careful radiographic evaluation of the occipitocervical junction should precede use of traction,[49] as children with occipitocervical anomalies may be at increased risk of vertebral artery injury.

After application of halo traction, radiographs and MRI may be used to determine the adequacy of reduction and neural decompression. Patients who respond to closed reduction should be treated with posterior decompression via suboccipital craniectomy and upper cervical laminectomy, followed by occipitocervical arthrodesis to maintain stability and promote fusion.[35,37,50,51] The dura should be opened to look at any tight posterior dural bands.[36] In rare cases in which brain stem compression is not relieved by traction, circumferential anterior and posterior decompression, with resection of compressive elements, is recommended, followed by posterior fusion.[35,52–55] Anterior decompression can be performed through an open transoropharyngeal approach[56] or through an endoscopic approach.[57]

FIG. 34.10 A 10-year-old male with basilar invagination following posterior decompression and occiput to C2 instrumented spinal fusion. This is the same patient shown in Fig. 34.8; note the improved relationship of the odontoid to the foramen magnum.

Modern segmental fusion fixation constructs include occipital and cervical screws connected by a rod.[58] Occipitocervical arthrodesis from occiput–C2 can be performed with or without instrumentation at C1[6] (Fig. 34.10). In cases in which primary basilar invagination is diagnosed without neural injury, in situ stabilization without decompression may be beneficial to prevent further progression or neurologic compromise.

Posterior fossa decompression alone for symptomatic secondary basilar invagination typically provides only transient relief of symptoms and is not recommended, as recurrent neurologic deterioration inevitably occurs months to years later. This is because secondary basilar invagination tends to progress even after occipitocervical fusion with infolding of the skull base around the fusion mass and progressive forward bending.[34] Prolonged bracing with an orthotic device and lifelong surveillance may be necessary to halt further recurrence or symptomatic progression.[35,59] Bisphosphonates have shown some promise in being able to delay skull base malformations in some children with osteogenesis imperfecta, but routine surveillance is still required.[60] Some patients with secondary basilar invagination may benefit from surgical stabilization.

Occipitoatlantal Instability

Occipitoatlantal instability is rarely due to a congenital anomaly and is more often caused by trauma. In the past, most patients did not survive this injury; improved resuscitative measures have resulted in more patients surviving this condition. In both traumatic and congenital cases, the clinical and neurologic manifestations are due to trauma near the brain stem, and include motor weakness, pain, vertigo, and vomiting.[61] The most common anomalies of the upper cervical spine associated with this condition include Down syndrome and Klippel-Feil syndrome.[62] Patients who have Down syndrome fail to develop the normal curved architecture in the occipital condyle, resulting in the development of occipitoatlantal instability[63] (Fig. 34.11).

In cases of both congenital and traumatic atlantooccipital instability, surgical stabilization is recommended with arthrodesis from the occiput to C2.[64] Authors have reported successful outcomes using a variety of stabilization techniques.[65] In cases of trauma, neurologic sequelae are common. Any further deterioration should alert the clinician to the possibility of hydrocephalus.[66]

Occipitoatlantal Fusion (Occipitalization, Occipitocervical Synostosis)

Occipitoatlantal fusion is characterized by a partial or complete union between the base of the occiput and C1 (the atlas; Fig. 34.12). It ranges from a fibrous band connecting one or both of the occipital condyles to the atlas to complete osseous union.[67] Both upper and lower cervical anomalies may be associated with this condition, including occipital condyle hypoplasia, basilar impression, or Klippel-Feil syndrome. The incidence of occipitocervical malformations is around 2 per 1000 children, with a male predominance of 80%.[62,68,69]

Clinical Features

Patients with occipitoatlantal fusion have a short neck with limited cervical motion.[70,71] Associated spinal deformities, such as kyphosis and scoliosis, are frequent. Neurologic symptoms do not manifest during childhood, but develop in the third or fourth decades[69] in a slow, unrelenting manner.[72] It is unclear why neurologic problems develop so late and progress so slowly, but they are likely due to the degree of actual or relative basilar impression and the position of the odontoid. When the odontoid lies below the foramen magnum, the patient is usually asymptomatic,[73] but with fusion of the atlas to the occipital condyles, the odontoid may project far into the foramen magnum, producing brain stem pressure[70] (Fig. 34.13).

In this condition, the backward-projecting odontoid compresses the brain stem, causing upper motor neuron findings (spasticity, hyperreflexia, and muscle weakness) and cranial nerve involvement (diplopia, tinnitus, dysphagia, and auditory disturbances). The relative basilar invagination may cause vascular disturbances from vertebral artery involvement and irritation of the greater occipital nerve. Clinical manifestations include syncope, seizures, vertigo, and unsteady gait; dull, aching pain in the posterior occiput; and neck tenderness noted in the area of the posterior scalp. Rarely, acute

respiratory failure secondary to hypoventilation and sleep apnea may occur.[39]

Imaging

In children with occipitoatlantal fusion, radiographs are difficult to interpret, and advanced imaging, such as CT or MRI, may be necessary.[74,75] The condition may range from a bony or fibrous band to total fusion of the atlas into the occipital bone (see Fig. 34.12). Gholve et al.[69] proposed a morphologic classification of this anomaly: zone 1, a fused anterior arch; zone 2, fused lateral masses; zone 3, a fused posterior arch; and a combination of fused zones. Most commonly, the anterior arch of the atlas is fused to the occiput, with a hypoplastic posterior arch. Posterior fusion is not usually evident because this portion of the ring may only consist of a short bony fringe on the edge of the foramen magnum. Although innocuous in appearance, this fringe is frequently directed downward and inward and can compromise the spinal canal.

There is frequently an associated congenital fusion of C2–C3.[73] This results in greater demands being placed on the atlantoaxial articulation, particularly in flexion and extension,[71] resulting in atlantoaxial instability in 50% of patients.[76] Obtaining flexion-extension stress films is imperative. As mentioned earlier, with fusion of the atlas to the occiput, there is a relative loss of height of the atlas, allowing the odontoid to project upward into the foramen magnum and creating a basilar impression (see Fig. 34.13). Finally, a constricting band of dura posteriorly may create a groove in the spinal cord and may be the primary cause of symptoms. The band cannot be visualized on routine radiographs; therefore, MRI should be part of the evaluation.

Treatment

Management of this uncommon problem carries a high risk of morbidity and mortality.[70,77] In patients with persistent complaints of head and neck pain, initial nonoperative methods—such as antiinflammatories, rest, and cervical collars—may be initially attempted. With an unstable atlantoaxial complex and neurologic deficits, we recommend posterior decompression and posterior occipital cervical stabilization and fusion with rigid segmental instrumentation from the occiput to C2.[58] Further stability can be obtained by using a halo fixator in the postoperative period.[78] If reduction is possible and there are no neurologic signs, surgical intervention carries an improved prognosis.[70]

With irreducible ventral compression, transoral resection of the odontoid may be considered,[79] but may risk destabilizing the entire upper cervical spine.[80] We do not recommend isolated cervical laminectomy without instrumentation, as this may increase C1–C2 instability or lead to the late development of a cervical kyphosis, particularly if the laminectomy involves several levels.[81] We also strongly caution against operative reduction (rather than preoperative halo traction), which can result in death.

Anomalies of Ring of C1

In normal development, ossification of the atlas proceeds from paired centers, one for each of the lateral masses, then progresses posteriorly into the neural arches, which are fully ossified at birth except for a gap of 5 to 9 mm posteriorly that closes by the fourth year.[75] The anterior arch of the atlas ossifies from a single center, which appears during the first year of life and fuses to the remainder of the atlas by the third year.[68,75,82] The most common anomalies of C1 are a persistent bifid anterior (Fig. 34.14) and posterior (Fig. 34.15) arch, or a hemiatlas (absence of a C1 facet).

There is about a 3% incidence of failure of closure of either the anterior or posterior arch of the atlas beyond age 4 years.[83] This anomaly can be observed in several conditions, such as skeletal dysplasias, Goldenhar syndrome, Down syndrome, and Conradi syndrome.[51]

Anomalies of the posterior arch can be characterized as median clefts or hypoplasia. A classification scheme for congenital defects of the posterior arch of C1 has been proposed (Fig. 34.16). More than 90% of patients are asymptomatic with a type A median cleft variant, which is incidentally identified

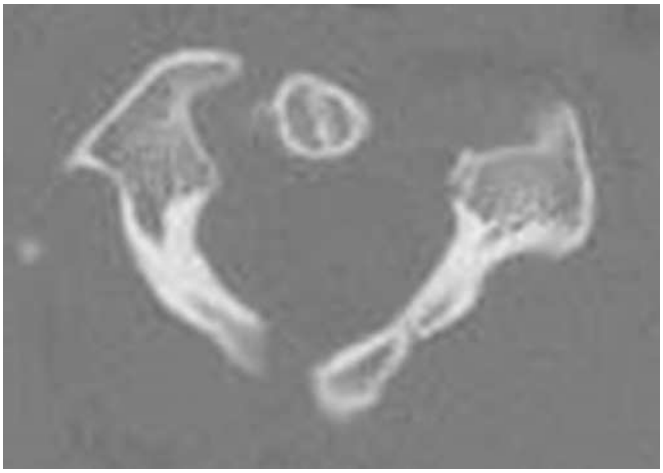

FIG. 34.14 Axial computed tomography scan demonstrating incomplete, or bifid, anterior arch.

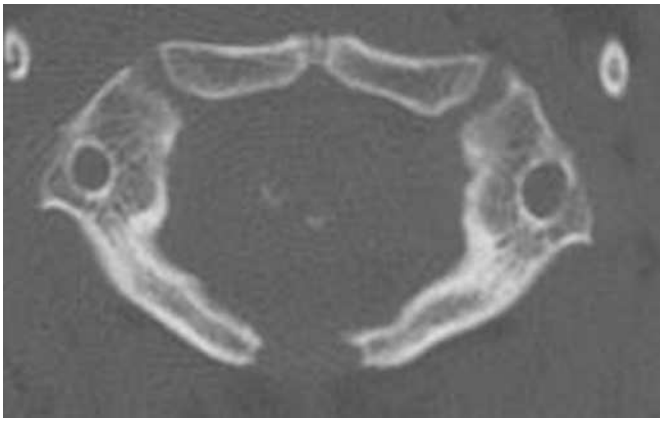

FIG. 34.15 Axial computed tomography scan demonstrating incomplete, or bifid, posterior arch.

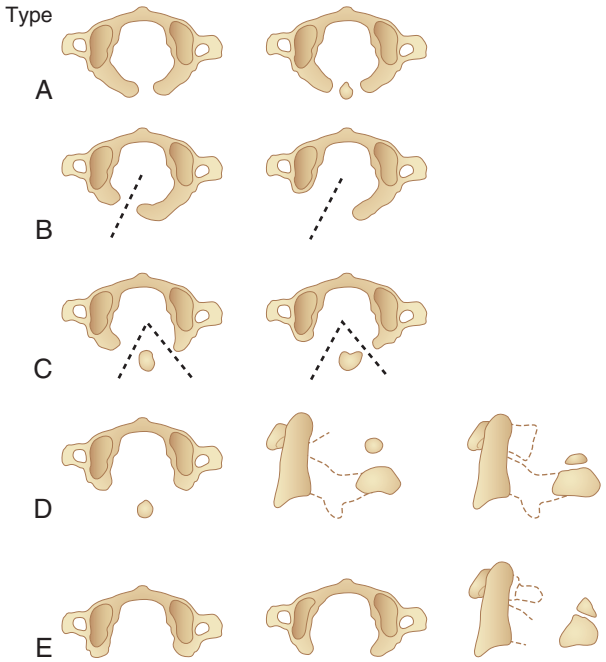

FIG. 34.16 Classification system for posterior C1 ring anomalies. *Type A* is small midline failure of fusion. *Type B* defects are unilateral clefts of variable size, ranging from small gap to complete absence of hemiarch. *Type C* indicates bilateral defects with preservation of most of the dorsal arch. *Type D* is complete absence of posterior arch with a retained, midline tubercle. *Type E* is a complete posterior arch and tubercle deficiency. (Modified from Currarino G, Rollins N, Diehl JT. Congenital defects of the posterior arch of the atlas. *Spine.* 2000;47:267–271.)

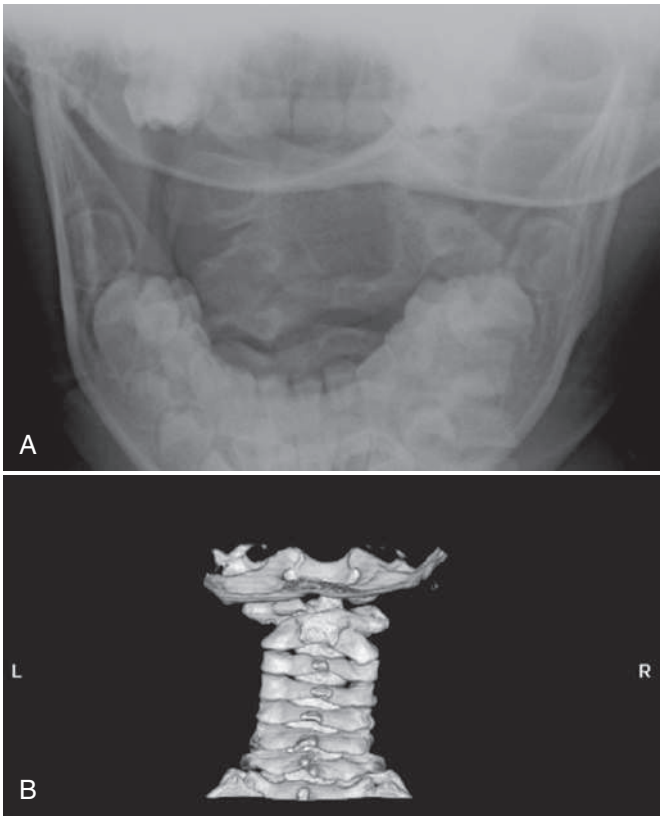

FIG. 34.17 Absence of C1 facet in a 5-year-old child with severe, progressive torticollis. (A) Open-mouth odontoid view shows absence of right C1. (B) Computed tomography scan with three-dimensional reconstructions viewed posteriorly shows absence of right C1. Note how the occipital condyle articulates with C2.

on radiographic studies.[83] Types C and D are accompanied by a free-floating posterior tubercle. These patients may experience neck pain and neurologic symptoms before discovery of the anomaly. The free posterior tubercle has been shown to move with neck extension, and in some cases may migrate anteriorly and traumatize the spinal cord with neck extension. Rarely, hypoplasia of the posterior arch occurs and has been associated with myelopathy.[84]

Dubousset[85] recognized the problem of the hemiatlas of C1, or absence of the facet of C1, which can lead to severe and progressive torticollis in young children (Fig. 34.17). Initially, the deformity is flexible but becomes more severe and eventually fixed as the child ages. CT is necessary to identify this deformity. It can accompany Klippel-Feil syndrome with anomalies of the lower cervical spine as well, and there is an increased incidence of anomalies of the vertebral vessels in these children. Clinicians should utilize arteriographic evaluation before the use of traction or surgical intervention. If the patient is passively correctable, a single posterior fusion, occiput to C2, is recommended.

Atlantoaxial Instability

Atlantoaxial instability can vary from subtle instability to frank fixed C1–C2 dislocation. It is commonly associated with syndromes or other systematic disorders. Specifically in patients with Down syndrome, generalized ligamentous laxity and flat facets predispose to hypermobility and pathologic motion at the craniovertebral and atlantoaxial articulations.[86,87] Up to 40% of these patients have radiologically detectable atlantoaxial instability,[88] although it is symptomatic in only 1% to 2% of cases.[89] Patients with congenital scoliosis, skeletal dysplasia, osteogenesis imperfecta, juvenile rheumatoid arthritis, and neurofibromatosis also can have significant atlantoaxial instability, which may be unrecognized. Other anomalies, such as os odontoideum, can manifest as atlantoaxial instability (see "Anomalies of the Odontoid" later in this chapter).[90]

The significance of anomalies at the atlantoaxial joint are related to the stability of the articulation between the atlas (C1) and the axis (C2), as this is the most mobile section of the vertebral column and consequently has the least stability. Normally, 90 degrees of rotatory motion exists in the cervical spine, and 50% occurs in the C1–C2 joint. Lateral slide is also a component of the rotatory motion. Limited flexion (5 degrees) and extension (10 degrees) are permitted.[91] The freedom of motion is primarily due to the lack of bony constraints, as the odontoid is the only bony buttress to prevent hyperextension. The integrity of the soft tissues (ligaments and capsular structures) provides the majority of stability at this articulation. Therefore, the atlantoaxial joint is extremely mobile but structurally weak. Furthermore, it is located between two relatively fixed points, the atlanto-occipital and C2–C3 joints, which puts C1–C2 at further risk.

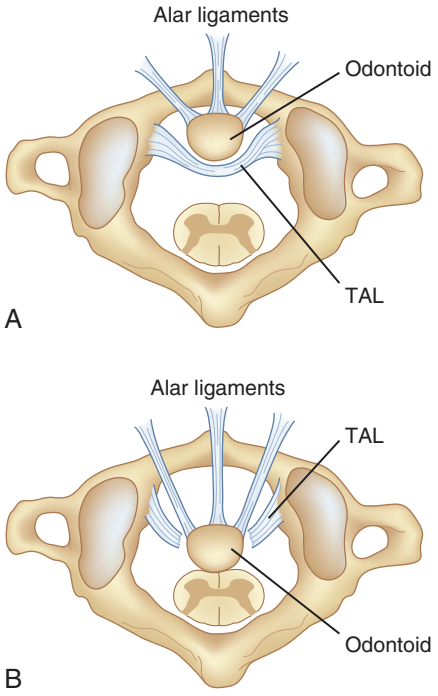

FIG. 34.18 Atlantoaxial joint as viewed from above. (A) Normal. (B) Disruption of transverse atlantal ligament (TAL): Odontoid occupies safe zone of Steel. Intact alar ligaments (second line of defense) prevent spinal cord compression.

The primary ligamentous stabilizer is the transverse atlantal ligament. The alar ligaments form the second line of defense and act as a checkrein after disruption or laxity of the transverse atlantal ligament (Fig. 34.18). Although the alar ligaments appear thick and strong, they stretch with relative ease and permit significant displacement. This secondary stability plays an important role in patients with chronic atlantoaxial instability.

When evaluating this area, Steel defined the "rule of thirds": The area of the vertebral canal at C1 can be divided into one-third odontoid, one-third spinal cord, and one-third "space," which represents a safe zone in which displacement can occur without neurologic impingement and is roughly equivalent to the transverse diameter of the odontoid (usually 1 cm)[92] (see Fig. 34.12). In chronic atlantoaxial instability, the alar ligaments have failed and there is no longer a margin of safety. The patient has exceeded the "safe zone" of Steel and enters the area of impending spinal cord compression. The end result is narrowing of the spinal canal and impingement on the neural elements.[76]

Laxity of the transverse atlantal ligament is common in patients with Down syndrome, with a reported incidence of 15% found in all age groups.[89,93] These patients seem to have rupture or attenuation of the transverse atlantal ligament with encroachment of the safe zone of Steel, but at least initially they are protected by the checkrein action of the alar ligaments from spinal cord compression. In other words, many patients have excessive motion, but relatively few are symptomatic, and most cases are discovered only by radiologic survey.[94,95] MRI can be helpful in assessing the integrity of the transverse atlantal ligament.[96]

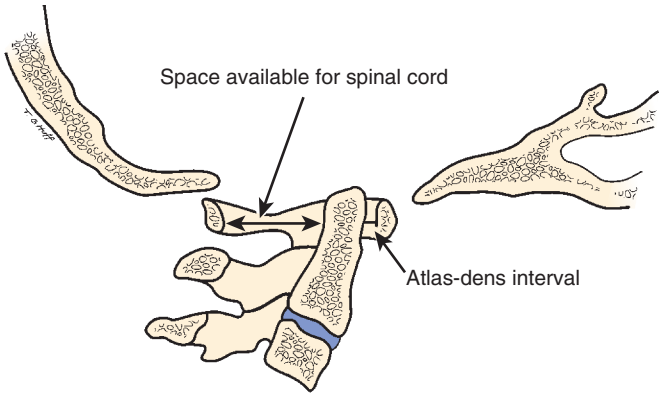

FIG. 34.19 Atlantoaxial joint showing the normal atlas-dens interval (ADI), normal space available for spinal cord (SAC), distance between posterior aspect of the odontoid, and the nearest posterior structure.

Clinical Presentation

In children, the presenting symptoms may be quite subtle and nonspecific. In most patients, the only presenting symptom is generalized weakness, manifested as lack of physical endurance, a history of frequent falling, or the child's asking to be carried.

As patients age, the central nervous system itself becomes less tolerant of intermittent compression, and its ability to recover is diminished. Even with hypermobility at this articulation, it is unusual for patients to become symptomatic before their third decade. When patients do become symptomatic, trauma is immediately suspected, but is often not the case. More likely, the degenerative changes of aging cause the lower cervical articulations to become more rigid. This gradual restriction of caudal motion places an increased demand on the ligaments and capsular structures of the atlantoaxial articulation, and instability develops.

With compression from the odontoid on the spinal cord, the symptoms and signs of upper motor neuron compression are commonly found.[70] If the primary area of impingement is posterior (from the foramen magnum, a dural band, or posterior ring of C1), symptoms are attributed to the posterior columns, with alterations in vibratory responses and proprioception. If there is also an associated cerebellar herniation, nystagmus, ataxia, and incoordination may be observed. Symptoms attributed to vertebral artery compression may occur.

Imaging

The atlas-dens interval (ADI) is the space seen on the lateral radiograph between the anterior aspect of the dens and the posterior aspect of the anterior ring of the atlas (Fig. 34.19). In children, the ADI should be no greater than 4 mm in flexion.[91] In children with ligamentous laxity (such as Down syndrome), instability is present with an ADI of more than 5 mm. Symptoms occur with instability greater than 7 to 10 mm. The ADI does not exceed 3 mm in adults if the transverse ligament is intact.[97]

However, in cases of congenital anomalies, ligamentous laxity, or chronic instability, the ADI is of limited value. In this

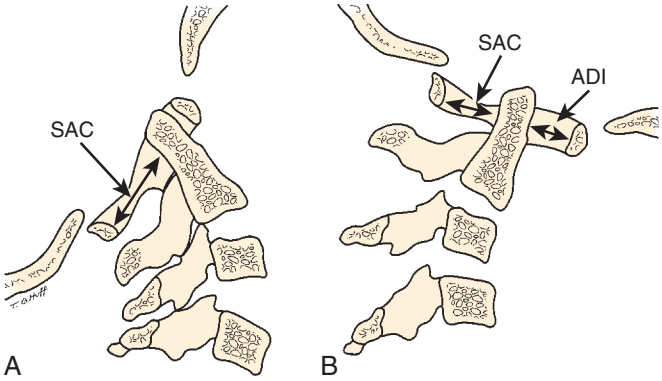

FIG. 34.20 Atlantoaxial instability. (A) Extension: forward sliding of the atlas with increased atlas-dens interval (ADI) and decreased space available for spinal cord (SAC). (B) Flexion: the ADI and SAC return to normal as the intact odontoid provides bony block to subluxation in hyperextension.

situation, attention should be directed to the amount of space available for the spinal cord (SAC). Determining the SAC is accomplished by measuring the distance from the posterior aspect of the odontoid or axis to the nearest posterior structure (foramen magnum or posterior ring of the atlas)[98] (Fig. 34.20). In adults, spinal cord compression does not occur if the SAC is 18 mm or more. While cord compression is possible between 15 and 17 mm, it frequently occurs if SAC is 14 mm or less.

Data on normal variations in sagittal and transverse diameter of the cervical spine have been collected for infants and children. As might be expected, these measurements generally are smaller than in adults and follow a predictable growth curve. Clinical significance is determined via comparison of the absolute diameter with the known norms for that vertebral level and age, and comparison of successive vertebral levels within the same individual. Comparisons between levels in the same patient is more sensitive in determining an abnormality. Jauregui et al.[33] found that Steel's rule of thirds generally applied throughout all of growth, and relative stenosis was defined at 13 mm in children.

Lateral flexion-extension views should be conducted voluntarily by the patient, and no effort should be made by the clinician to assist the patient. Although motion may be limited in certain cases, especially in the setting of pain or noncompliant children/poor effort, avoidance of precipitating a neurologic defect is paramount. Patients who present with a neurologic deficit usually exhibit significant instability (Fig. 34.21).

In patients with multiple anomalies or abnormal bone (such as Morquio syndrome or spondyloepiphyseal dysplasia), the usual radiographic views are not always reliable in confirming the presence or absence of an odontoid.[99] In these situations, dynamic CT scan with reconstruction views is helpful.[74,100] Although much attention has been paid to anterior translation of C1 on C2, extension views should not be ignored, as some patients have significant posterior subluxation.[101]

Dynamic MRI provides direct visualization of the neurologic structures and sites of bony impingement not appreciated on radiography.[74,96] While difficult to perform and time consuming, it is a reliable tool to diagnose instability.[102] MRI can

FIG. 34.21 Significant atlantoaxial instability in a patient with neurologic findings.

evaluate the integrity of the transverse atlantal ligament, as well as other anomalies, such as the Chiari malformation and syringomyelia. Because excessive motion may lead to compression of the vertebral arteries,[75] arteriography is helpful in evaluating patients who exhibit symptoms of transient brain stem ischemia.[103,104]

Current recommendations for radiographic screening for atlantoaxial instability in children with Down syndrome include lateral flexion-extension radiographs taken around age 3 years, and, if these are normal, the child may participate in activities but avoid contact sports.[93,105] Asymptomatic children with evidence of instability on radiographs should undergo MRI to determine if any neural compromise is present (or impending)[106] (Fig. 34.22). The Special Olympics requires repeat radiographs as evidence of ADI of less than 4.5 mm prior to participation in high-risk sports.[89,107,108]

Treatment

Nonoperative care plays a limited role in treatment of symptomatic atlantoaxial instability and is reserved for patients with no symptoms or neurologic findings. Fortunately, many patients remain asymptomatic throughout their life and need only be monitored periodically. Any new-onset pain or abnormalities in motor function should precipitate a thorough workup. In asymptomatic patients, there is currently no agreed upon indication for prophylactic fusion of C1 to C2; however, in cases of progressive instability and/or limited SAC, prophylactic fusion can be considered.

Effective treatment generally can be provided only if the exact cause of symptoms has been determined. Before surgical intervention, reduction of the atlantoaxial articulation should be achieved by either positioning or traction.[55,58,109] The patient

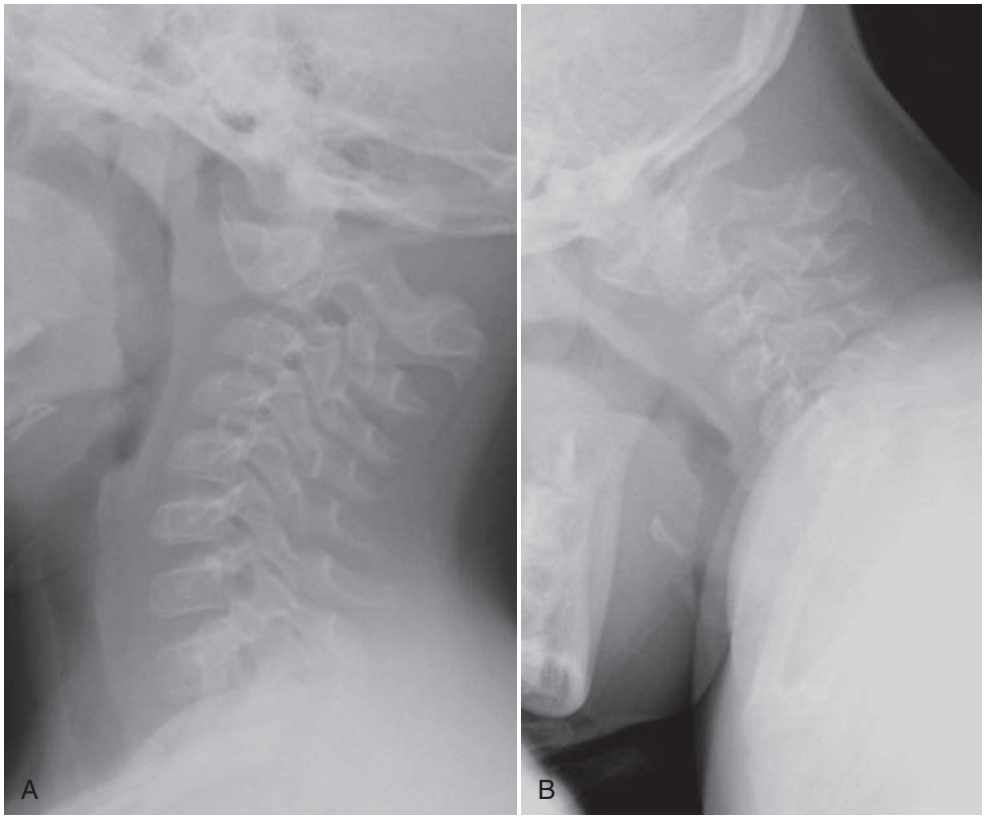

FIG. 34.22 A 5-year-old boy with Down syndrome atlantoaxial instability. (A) Neutral position. (B) In flexion, the atlas-dens interval is substantially increased.

should be maintained in the reduced position preoperatively and monitored for improvement in symptoms and neurologic status.

Prior to modern segmental screw and rod–based instrumentation, results of operative fusion, especially in Down syndrome patients, were disappointing.[110–112] With the advent of rigid internal fixation, such as C1 lateral mass to C2 screws, C1–C2 transarticular screws, and transoral decompression with posterior plating, rates of fusion have increased substantially[113–115] (Fig. 34.23). The improved rigidity afforded by modern segmental spinal instrumentation has substantially reduced the need for postoperative halo immobilization.[116,117] Choice of surgical procedure for stabilization must be individualized based on clinical presentation and surgeon expertise.[58]

Occult respiratory dysfunction in patients with atlantoaxial instability is important to recognize.[118] Many patients have an unrecognized decrease in vital capacity and chronic alveolar hypoventilation as a result of the neurologic injury to the brain stem. Periods of apnea and respiratory distress during surgery or in the immediate postoperative period have frequently resulted in death or have required prolonged respiratory support.[119]

Anomalies of Odontoid (Dens)

Congenital anomalies of the odontoid occur on a spectrum, ranging from aplasia (complete absence) to hypoplasia (partial

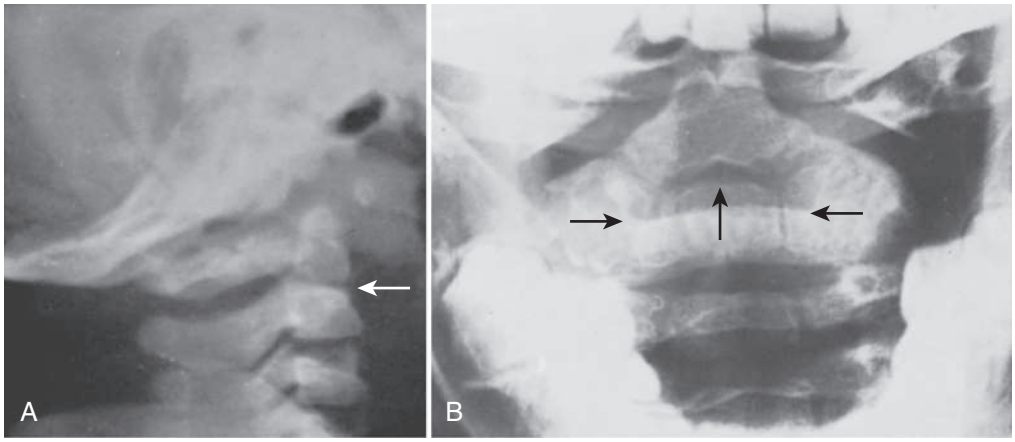

FIG. 34.24 (A) Radiograph of a 6-month-old infant. The odontoid is normally formed and recognizable on routine radiographs at birth, but is separated from the body of the axis by a broad cartilaginous band (*arrow*), similar in appearance to an epiphyseal plate. It represents the vestigial disc space and is referred to as *neurocentral synchondrosis*. (B) Neurocentral synchondrosis is not at anatomic base of the dens, at the level of the superior articular facets of the axis. This open-mouth view shows that the embryologic base of the odontoid is below the articular facets and contributes a substantial portion to the body of the axis. This radiolucent line is present in nearly all children at age 3 years and in 50% by age 4 years; it is absent in most individuals by age 5 years.

absence) to os odontoideum (an anomaly in which a partially or fully formed dens is in bony discontinuity with the body of the axis). Depending on the severity, potential neurologic sequelae may result from an unstable atlantoaxial complex.[120] The frequency of these anomalies is unknown. They are probably more common than typically appreciated, as they are often incidental findings. In the past, malformations of the dens were infrequently reported and considered rare[121–123]; however, improved imaging and awareness have led to an increase in diagnosis.

Ossification of the apex and body of the odontoid proceeds separately. The body is derived from the first cervical sclerotome and is the center of the first cervical vertebra. This center becomes separated from the atlas to fuse with the axis. The apex is derived from the mesenchyme of the most caudal occipital sclerotome.[124]

The body of the dens begins to ossify from two centers between the first and fifth prenatal months. These centers become a single mass by the time of birth.[82] At birth, the apex of the odontoid has not ossified, is V-shaped, and is known as a *dens bicornis*. A separate ossification center within the *dens bicornis* is known as an *ossiculum terminale,* which appears at age 3 years and fuses with the rest of the dens by age 12 years. An ossiculum terminale has been found in a quarter of normal children age 5 to 11 years.

However, an ossiculum terminale may never appear or may occasionally fail to fuse with the dens. In this case, it is considered an *ossiculum terminale persistens*, which is occasionally discernible as either a cyst or an area of increased density. These developmental anomalies are usually firmly bound to the main body of the dens by cartilage. They are of little clinical significance and seldom the source of instability,[125] but reports exist of serious neurologic sequelae.[126]

At birth, the dens is separated from the body of the axis by a cartilaginous band, or neurocentral synchondrosis, that represents the epiphyseal growth plate. It does not cross at the level of the superior articular facets, but lies well caudal to this level within the body of the axis (Fig. 34.24). It is present in almost all children by age 3 years and in 50% of children by age 4 years, but it is absent in most by age 6 years.[127] It rarely persists into adolescence and adult life.

The blood supply to the odontoid is from two sources.[128] The vertebral arteries provide anterior and posterior ascending arteries that originate at C3 and pass ventral and dorsal to the body of the axis and the odontoid. They anastomose in an arcade by the alar ligaments. These arteries supply small penetrating branches to the body of the axis and the odontoid. Lateral to the apex of the odontoid, the anterior ascending arteries and apical arcade receive anastomotic derivatives from the carotids by way of the base of the skull and the alar ligaments. This arrangement of the blood supply is necessary because of the embryologic development and anatomic function of the odontoid. The transient neurocentral synchondrosis between the odontoid and the axis prevents the development of any significant vascular channels between the two structures.[129] The body of the odontoid is surrounded entirely by synovial joint cavities; its fixed position relative to the rotation of the atlas precludes vascularization by direct branches from the vertebral arteries at the C1 segmental level.[124]

Theories on the etiology for os odontoideum are twofold. The first proposes a congenital theory, or failure of fusion of the dens to the body.[130,131] This is supported by a familial form[132] and os odontoideum in identical twins with no history of trauma.[133]

More likely, a traumatic etiology attributes an unrecognized fracture in the region of the base of the odontoid as the cause of os odontoideum.[101,123,134,135] After fracture of the odontoid, contracture of the alar ligaments exerts a distraction force that pulls the fragment away from the base and closer to their origin at the occiput. The delicate blood supply to the odontoid

is easily traumatized and contributes to poor fracture healing or callus formation. Several cases of "os odontoideum" that developed several years after trauma when a normal odontoid was initially present have been reported.[134,136] Infection is a rare cause of dens abnormalities as well.[137]

Clinical Features

Clinical presentation can vary from no symptoms to frank myelopathy secondary to cord compression.[138] Minor trauma is commonly associated with the onset of symptoms. Mechanical symptoms, such as neck pain or headache, may be due to local irritation of the atlantoaxial articulation. Neurologic symptoms are due to spinal cord compression. Because the area of the spinal cord impingement is below the foramen magnum, these patients seldom have cranial nerve symptoms.[139]

If clinical manifestations are limited to mechanical symptoms without neurologic involvement, the prognosis is excellent.[101,139,140] Patients who exhibit only transient weakness of the extremities and paresthesias after minor trauma usually have complete return of function. More concerning are patients in whom there is an insidious onset and slowly progressive neurologic impairment, as they have a greater potential for permanent deficit.[101] Weakness and ataxia are the most common complaints, but sensory loss spasticity, increased deep tendon reflexes, clonus, loss of proprioception, and sphincter disturbances have been described.[98] In few patients, vertebral artery compression at the foramen magnum may lead to symptoms and signs of cerebral and brain stem ischemia, such as seizures, mental deterioration, syncope, vertigo, and visual disturbances.[141]

Radiographic Features

At birth, the normal odontoid can be visualized in the lateral view with an epiphyseal plate. A mistaken impression of hypoplasia may be given by a lateral extension radiograph because the anterior arch of the atlas may slide upward and protrude beyond the ossified tip of the dens, especially in very young patients.[142]

Agenesis or hypoplasia of the odontoid is an extremely rare anomaly that is best seen in the open-mouth view. The diagnostic feature is the absence of the basilar portion of the odontoid, which normally is well below the level of the superior articular facets of the axis. Hypoplasia manifests as a short, stubby peg of odontoid projecting just above the lateral facet articulations (Fig. 34.25). CT scan is necessary to confirm whether an os odontoideum is present in addition to the hypoplasia.

In the os odontoideum, there is a jointlike articulation between the odontoid and the body of the axis that appears radiologically as a wide radiolucent gap (Fig. 34.26). In children younger than 5 years, this gap may be confused with the normal neurocentral synchondrosis. The radiologic appearance of os odontoideum may be similar to a traumatic nonunion, and often they cannot be differentiated.[121] The location of lucency is usually the key to making the diagnosis. In the os odontoideum, the gap is above the level of the superior facets and is wide with a smooth edge. In traumatic nonunion, the gap between the fragments is characteristically narrow and irregular and frequently extends into the body of the axis below the level of the superior facets of the axis.

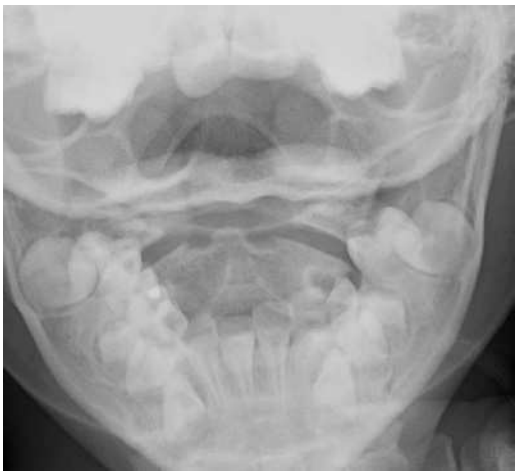

FIG. 34.25 Hypoplasia of the odontoid.

FIG. 34.26 Lateral radiograph of the cervical spine demonstrating wide lucency between the body of the dens and the os odontoideum.

Recommended radiographic views are open-mouth and lateral flexion-extension views. The free ossicle of the os odontoideum usually appears fixed to the anterior arch of the atlas and moves with it in flexion and extension (Fig. 34.27).[98,143] Since the os odontoideum moves with the ring of C1, measurements of its relationship to C1 are of little value. Instability can reduce the SAC but not the ADI.[91] Diminished space available for the cord with neck extension (SAC) significantly correlates with higher risk for myelopathy.[138] While the instability may be in any direction,[98,101] most commonly, the anterior

FIG. 34.28 Lateral radiograph of the cervical spine of a patient with Morquio syndrome; note the difficulty in identifying correct anatomy and potential pathology.

portion of the atlas is usually hypertrophied, and the posterior portion of the ring may be hypoplastic or absent.[144]

In patients with multiple cervical anomalies or those with abnormal bone (such as Morquio syndrome [Fig. 34.28] or skeletal dysplasia), the traditional radiographic views are not always reliable in confirming the presence or absence of an odontoid, as the odontoid may be present but dysplastic, or blend with the surrounding abnormal bone. In these situations, good results have been obtained by using CT scans to ascertain the character of the atlantoaxial articulation.

CT reconstructions are indicated when routine views are unsatisfactory in showing the anomaly. Lateral flexion-extension stress views should be conducted voluntarily by patients, particularly patients with a neurologic deficit. The degree of anteroposterior displacement of the atlas on the axis should be documented (see Fig. 34.20). CT scan can also help to define the anatomy of the craniocervical junction, including the completeness of the atlas ring and the position of the transverse foramina at C1 and C2.[145]

MRI is helpful for evaluating the SAC. MRI studies have shown a direct correlation between cord signal abnormality and the degree of myelopathy measured clinically.[146] Dynamic MRI[147] allows direct visualization of motion of the os odontoideum, atlas, and axis as well as surrounding motion throughout the full range of motion (ROM) of the cervical spine (Fig. 34.29). Open MRI configurations allow analysis of the cervical spine in the physiologic upright position, which may assist in identifying subtle pathology that is not apparent in the nonphysiologic supine position.

Treatment

Patients with congenital anomalies of the odontoid are at increased risk of neurologic injury, as a trivial insult superimposed on an already weakened and compromised structure may be catastrophic. The natural history is variable, and no predictive factors are apparent.[98] While strict indications for surgical stabilization are not apparent, we recommend considering surgery for persistent pain, myelopathy, or frank radiographic instability, as evidenced by instability of 10 mm or more in flexion and extension. Neural decompression must address bony or soft tissue impingement of the spinal cord.

Nonoperative treatment is possible in patients with os odontoideum who have no neurologic deficits or evidence of instability on radiographs. Patients with inflammatory symptoms or even transient myelopathies can expect recovery.[139,148] Cervical traction or immobilization may be helpful in such circumstances.

FIG. 34.29 Sagittal magnetic resonance image of the cervical spine showing cord compression in a patient with os odontoideum.

FIG. 34.30 Posterior cervical arthrodesis from C1–C2 with a wiring technique used to treat a symptomatic patient with os odontoideum.

Considerable controversy exists over the role of prophylactic stabilization in asymptomatic patients with instability. Surgical treatment is not required for every patient in whom an os odontoideum is identified. Patients who have no neurologic symptoms or instability at C1–C2 can be managed with periodic observation. The lack of C1–C2 instability at initial diagnosis does not guarantee that instability will not develop in these patients, however, or that they are not at higher risk for spinal cord injury with trauma.[149] For this reason, longitudinal follow-up with flexion-extension radiographs of these patients is recommended. Klimo and colleagues[98] recommended surgical stabilization for all patients with os odontoideum. The safety of stability and the ability to lead a normal active life may outweigh the possible complications of surgery or the catastrophic dangers of instability. Especially in the pediatric age group, it may be difficult or impossible to limit activity, even in the presence of instability.

When treating symptomatic patients, initial reduction of the atlantoaxial articulation must be accomplished prior to surgery, usually by skull-based halo-gravity traction.[150] Ideally, the patient should be maintained in the reduced position several days before surgery to allow recovery of neurologic function.[139]

Decompression of the neural elements by any offending lesion must be undertaken; the choice of approach depends on the site of compression and the comfort level of the surgeon. Both anterior and posterior decompression strategies can be undertaken with good results. Following any method of decompression, the suggested method of stabilization is posterior cervical arthrodesis and instrumentation of C1–C2. As discussed earlier, wiring techniques with iliac crest bone graft and halo immobilization have been reported with favorable results (Fig. 34.30).[151–155] However, concerns with neurologic injury[151] and incomplete posterior C1 arch formation[112] have made C1 lateral mass screws coupled with C2 screws a safe and reliable option.[8,11,156] In a small or poorly developed spinous process of C2, a threaded Kirschner wire (K-wire) through the spinous process can be helpful in improving the stability of the wiring technique.[157] In a patient with a marginally functioning neurologic status, it may be wiser to perform an occiput-to-C2 arthrodesis and plan to maintain immobilization with a halo vest in extension.

In patients who have a highly mobile but reducible C1–C2 articulation, several authors have reported good results using transarticular screws (see Fig. 34.4).[16,153,155,158,159] Atlantoaxial transarticular screws have been shown to be feasible in pediatric patients; the superior biomechanical stability may eliminate the need for prolonged postoperative halo vest immobilization.[16,160] As discussed earlier, a thorough understanding of the bony and vascular anatomy is paramount prior to attempting an instrumentation around C2.[13,88] When fusion is needed to subaxial levels, lateral mass screws at C3 and below can be used with good results.[11,155,161,162]

With transarticular fixation of C1–C2, the lamina of C1 can be removed without extending the fusion to the occiput. Although this technique is generally reliable and safe, in patients with spinal cord compression, fixed dislocations, or congenital ligamentous laxity, particularly in patients with Down syndrome, extra caution should be employed,[112] and a

postoperative halo-vest orthosis should be considered. Smith and colleagues[163] reported significant problems with C1–C2 stabilization, particularly in patients who are very unstable or have myelopathy. Patients with failed fusions or irreducible dislocations were at high risk for perioperative neurologic complications.

Patients in whom the C1–C2 dislocation is unreducible pose a difficult management problem. Manipulative reduction during surgery is discouraged because it has proved extremely hazardous and may result in respiratory distress, apnea, or death. For patients with no neurologic deficit, a simple in situ posterior fusion is the least hazardous procedure. If neurologic findings are present, posterior decompression by laminectomy has been associated with increased morbidity and mortality[139] and may potentiate C1–C2 instability if performed in isolation. An occiput-to-C2 arthrodesis is recommended in these situations.[164] If reduction of the C1–C2 dislocation is considered necessary or if the clinical situation precludes posterior stabilization, an anterior or lateral retropharyngeal approach can be considered.[165]

Klippel-Feil Syndrome

In 1912, Klippel and Feil[166] published the first report of their eponymous syndrome. They presented a patient with shortening of the neck, a low posterior hairline, and severe restriction of neck motion. After the patient died, postmortem examination revealed complete fusion of the cervical vertebrae. Currently, the term *Klippel-Feil syndrome* (KFS) refers to patients with any congenital fusion of the cervical vertebrae, whether it involves two segments or the entire cervical spine (Fig. 34.31).

The embryologic etiology of KFS likely stems from failure of normal segmentation of the cervical somites during the third to eighth weeks of life. Between 20 and 30 days' gestational age, the paraxial mesoderm undergoes segmentation into spherical, discrete somites. As somites mature, they subdivide into sclerotomes, myotomes, and dermatomes. The sclerotomes, precursors of the adult vertebral bodies, undergo resegmentation such that the caudal section of one somite fuses with the cephalad segment of the adjacent one to form a vertebral body[167] (Fig. 34.32).

The precise reasons behind this failure of segmentation are yet to be elucidated, as only a few patients have inherited this condition.[168,169] Pedigree analysis and molecular studies have defined specific genetic abnormalities that may account for these anomalies. The gene *SGM1* has been identified as the first human Klippel-Feil locus (*SGM1*) in a large affected family. Experimental animal models have identified genes in segmentation and somitogenesis pathways, such as in the HOX, PAX, and Notch signaling pathways.[124]

As these embryologic abnormalities occur early in development, the pathology may not be limited to the cervical spine. Patients with KFS commonly have other defects in the genitourinary,[170,171] nervous,[172] cardiopulmonary,[173,174] and auditory systems.[175,176] Actually, many of these other abnormalities are more detrimental to the patient's general well-being than the cervical fusions. Because the incidence of related congenital

FIG. 34.31 Lateral cervical radiograph of a patient with Klippel-Feil syndrome. Note the multiple congenital cervical fusions.

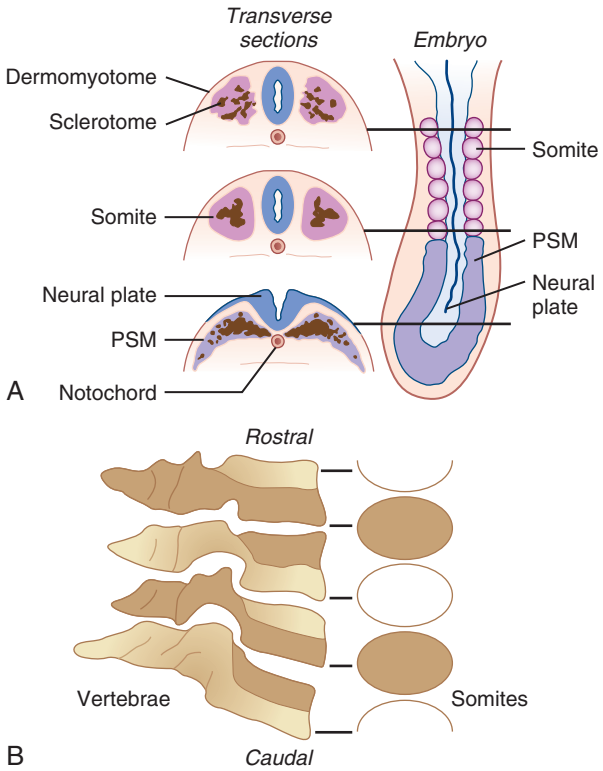

FIG. 34.32 (A) Embryologic differentiation of the mesoderm into pairs of somites on either side of the spinal cord. Somites divide further to form the ventral sclerotome and dorsal dermomyotome. (B) Cells from the rostral and caudal half of adjacent somites fuse to form future vertebral bodies and arches. Defects in this process have been theorized in Klippel-Feil syndrome. PSM, paraspinal muscles. (Modified from Tracy MR, Dormans JP, Kusumi K. Klippel-Feil syndrome. *Clin Orthop* 2004;424:183–190.)

anomalies is fairly high, all patients with KFS should have the aforementioned organ systems thoroughly investigated[171] (Box 34.1).

Clinical Features

The classic description of KFS is a triad of low posterior hairline, short neck, and limitation of neck motion. However, fewer than half of patients have all three signs (Fig. 34.33).[171]

BOX 34.1 Abnormalities Associated With Klippel-Feil Syndrome

Common

Scoliosis: 60%
Renal abnormalities: 35%
Sprengel deformity: 30%
Deafness: 30%
Synkinesis: 20%
Congenital heart disease: 14%

Less Common

Ptosis
Duane contracture
Lateral rectus palsy
Facial nerve palsy
Syndactyly
Hypoplastic thumb
Upper extremity hypoplasia
Neurenteric cyst

Clinically, the most consistent finding is limitation of neck motion, which is directly related to the degree of cervical spine involvement. Generally, flexion-extension is better preserved than rotation or lateral bending. If fewer than three vertebrae are fused or if only the lower cervical segments are fused, the patient generally has no detectable limitation.[177] In addition, many patients with marked cervical involvement are able to compensate with hypermobility at the unfused joints and to maintain a deceptively good range of motion. Some patients may have 90 degrees of flexion-extension, only occurring at a single open interspace. Rarely, patients have fixed hyperextension of the neck; this is usually associated with iniencephaly (absence of the posterior cervical laminae and an enlarged foramen magnum[178]; Fig. 34.34).

Shortening of the neck is a rare finding, and a low posterior hairline is uncommon. Other head and neck manifestations—such as facial asymmetry, torticollis, or neck webbing—occur in fewer than 20% of patients.[171,177] In KFS, concomitant Sprengel deformity occurs in up to 35% of cases, either unilaterally or bilaterally[171,179] (Fig. 34.35). Since the scapula develops from mesodermal tissue high in the neck, it is thought to be due to the same interruption in the normal embryologic development pathway of the cervical somites.[177]

FIG. 34.33 A 9-year-old child with Klippel-Feil syndrome. Note short neck with tendency toward webbing, mild torticollis, and asymmetry of eye level. The patient clinically has marked restriction of neck motion, impaired hearing, and mirror motions (synkinesia) of upper extremities.

FIG. 34.34 A 12-year-old girl presented with Klippel-Feil syndrome and iniencephaly—enlarged foramen magnum and absent posterior laminae. Note fixed hyperextension and long segment of cervical fusion (C2–C6) and abnormal occipitocervical articulation. This pattern could be viewed as a more elaborate variation of the C2–C3 pattern of McRae. Flexion-extension and rotational forces are concentrated in the area of the abnormal occipitocervical junction. These patients may be at risk of developing instability with aging.

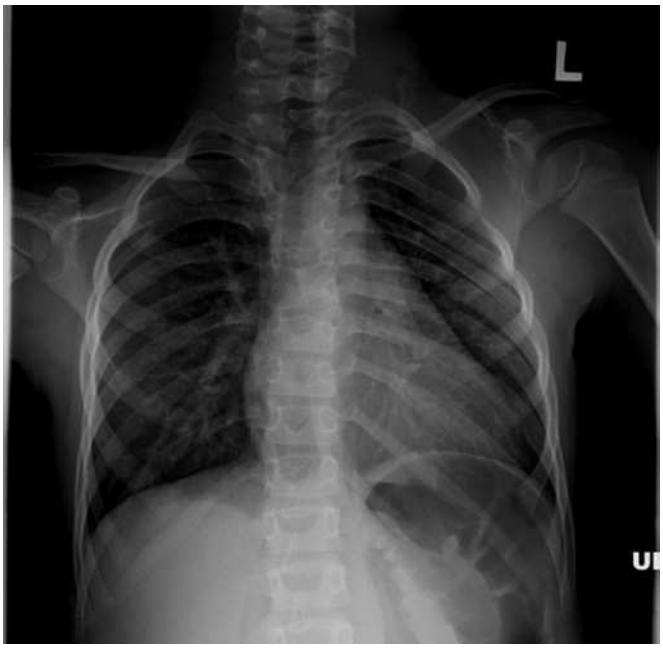

FIG. 34.35 A patient with concomitant Klippel-Feil syndrome and Sprengel deformity of the left scapula.

FIG. 34.36 Scoliosis below cervical deformity in a patient with Klippel-Feil syndrome. Note the previous Sprengel deformity correction.

Many patients are asymptomatic, but if they develop symptoms, they are generally localized to the head, neck, and upper extremities. The symptoms result from direct irritation or impingement of the cervical nerve roots, with radicular symptoms in the upper extremities.[45] Most patients who develop symptoms are in the second or third decade of life. Sources of the symptoms are either mechanical in nature due to inflammation of a cervical articulation, or neurologic in nature, owing to root irritation or spinal cord compression. Most symptoms originate at the open segments, where the remaining free articulations are hypermobile,[180] which can lead to instability or early arthritis. There may be constriction and narrowing of the nerve root at the foramen from osteophytic spurring.[181]

If joint instability is progressive or if there is appropriate trauma, myelopathy may occur, ranging from mild spasticity, hyperreflexia, and muscular weakness to sudden complete quadriplegia after minor trauma.[182,183] Syncope and neurologic compromise may be associated with mechanical compromise of the vertebral arteries secondary to hypermobility, with ischemic episodes.[184]

Associated Conditions

Scoliosis

Scoliosis is the most frequent anomaly found in association with KFS.[185,186] Up to 60% of patients have a significant degree of scoliosis, most of whom require treatment and should be followed through the growth years. Two types of scoliosis can be identified: congenital scoliosis, owing to vertebral anomalies and differential growth patterns (Fig. 34.36), and compensatory scoliosis, below the area of vertebral involvement. Congenital scoliosis is more frequent[171]; in fact, up to 5% of patients with congenital scoliosis have been found to have concomitant KFS.[187]

Radiographic examinations should include posteroanterior and lateral views of the spine to assess both coronal and sagittal plane deformities. If recognized early, many spinal deformities can be successfully managed with standard orthoses. Progressive curves are more likely associated with children who have extensive fusions,[186] and frequently occur in the normal-appearing vertebrae below the primary curve. Documented progression demands appropriate treatment to prevent serious additional deformity. Thoracic scoliosis may seriously compromise pulmonary function.[173] At present, many of these patients require posterior spinal stabilization.

Renal, Cardiac, Auditory Abnormalities

More than one-third of children with KFS can be expected to have a significant urinary tract anomaly, which is often asymptomatic. Ultrasonography is a noninvasive way to screen adequately for the anomalies associated with this syndrome.[188] Abnormalities include unilateral absence of a kidney, a double collecting system, renal ectopia, horseshoe kidney, and hydronephrosis from ureteropelvic obstruction. KFS is also associated with congenital heart disease (4.2–14%). The most common lesion reported has been an interventricular septal defect occurring alone or in combination with other defects, such as patent ductus arteriosus and abnormal position of the heart and aorta. The association of hearing impairment and deafness in KFS (>30%) is seldom mentioned in orthopaedic reports. There is no characteristic audiologic anomaly, and all types of hearing loss (conductive, sensorineural, and mixed) have been described. These patients should undergo a complete audiometric evaluation when defects are discovered.[130–136]

Mirror Motions (Synkinesis)

Mirror motion, or synkinesis, is involuntary paired movements of the hands in which the patient is unable to move one hand without similar reciprocal motion of the opposite hand. This phenomenon appears to occur in approximately 20% of patients with KFS[171]; thus, some authors have suggested that synkinesis should be included as part of the syndrome.[172] The etiology of synkinesis is unknown, but it appears to be a separate neurologic defect not caused by cervical vertebral fusions.[189] Autopsy specimens suggest that the clinical findings are due to inadequate or incomplete decussation of the pyramidal tracts in conjunction with a dysraphic cervical spinal cord.

Imaging

Adequate radiographic evaluation of the child with KFS can be difficult, especially if involvement is severe. Fixed bony deformities can prevent proper positioning, and the mandible, occiput, or foramen magnum may overlap the upper cervical vertebrae. Flexion-extension radiographs or CT scans may be necessary to provide information to assess stability.[181] With MRI, the relationship between the bony elements and neurologic structures (both the spinal cord and cervical nerve roots) can be assessed directly to show any potential sites of neural compression.[190,191]

The radiographic hallmark of KFS is fusion of any cervical vertebrae, whether a simple synostosis of two bodies (congenital block vertebrae; Fig. 34.37) or massive fusion of the entire cervical spine[166] (see Fig. 34.31). Other anomalies may be present, including flattening and widening of the involved vertebral bodies or an increase in the space available for the spinal cord.[192,193] Absent disc spaces or hypoplasia of the disc space can often be seen (Fig. 34.38). In a young child, narrowing of the cervical disc space cannot always be appreciated because the ossification of the vertebral body is incomplete, and the unossified endplates may give the false impression of a normal disc space. With continued growth, the ossification of the vertebral bodies is completed, however, and the fusion becomes obvious.[193]

Hemivertebrae are common (Fig. 34.39) occurring in up to 74% of patients. The incidence increases with the number of segments fused. Fusion of posterior elements usually parallels fusion of the vertebral bodies. In a young child, particular attention should be paid to the laminae because fusion posteriorly is often more apparent earlier.[171]

Knowledge of the normal variations in cervical spine mobility, particularly in children, is important in evaluating patients with KFS.[194] Pseudosubluxation of C2 on C3 with flexion can be observed in 45% of normal children younger than 8 years of age (Fig. 34.40).[127] Marked angulation at a single interspace during flexion, rather than a uniform arc of vertebral motion, can be observed in normal children (16%) and may be misinterpreted as vertebral fusion below. Advanced imaging with CT scan can aid surgeons in understanding bony abnormalities and also serve as an aid for preoperative planning.[195]

FIG. 34.37. Congenital block vertebrae at C6–C7. Symptoms are directly related to the number and level of involved vertebrae; this represents the most benign form of Klippel-Feil syndrome.

FIG. 34.38 Absent disc spaces in a patient with Klippel-Feil syndrome.

In KFS, the diameter of the spinal canal is usually normal. Narrowing occurs in adult life and is due to degenerative changes or hypermobility.[191,196,197] Enlargement of the canal is uncommon and may indicate conditions such as syringomyelia, hydromyelia, or Arnold-Chiari malformation. The intervertebral foramina are usually smooth in contour, but are frequently smaller than normal and oval rather than circular (Fig. 34.41). Posterior spina bifida is common (45%), but anterior spina bifida is rare. Rarely, there is complete absence of the posterior elements. This condition is usually accompanied by enlargement of the foramen magnum and fixed hyperextension of the neck, referred to as iniencephaly[178] (see Fig. 34.34).

Any KFS anomaly may extend into the thoracic spine. An anomaly of the thoracic spine on a routine chest radiograph may be the first clue to an unrecognized cervical synostosis. With a high thoracic congenital scoliosis, the radiographic evaluation should routinely include lateral views of the cervical spine.

Patterns of Cervical Motion

There are three patterns of cervical motion in KFS, described by Pizzutillo et al.[180]

FIG. 34.39 Cervical hemivertebra in Klippel-Feil syndrome.

FIG. 34.41 Enlarged neural foramina in Klippel-Feil syndrome.

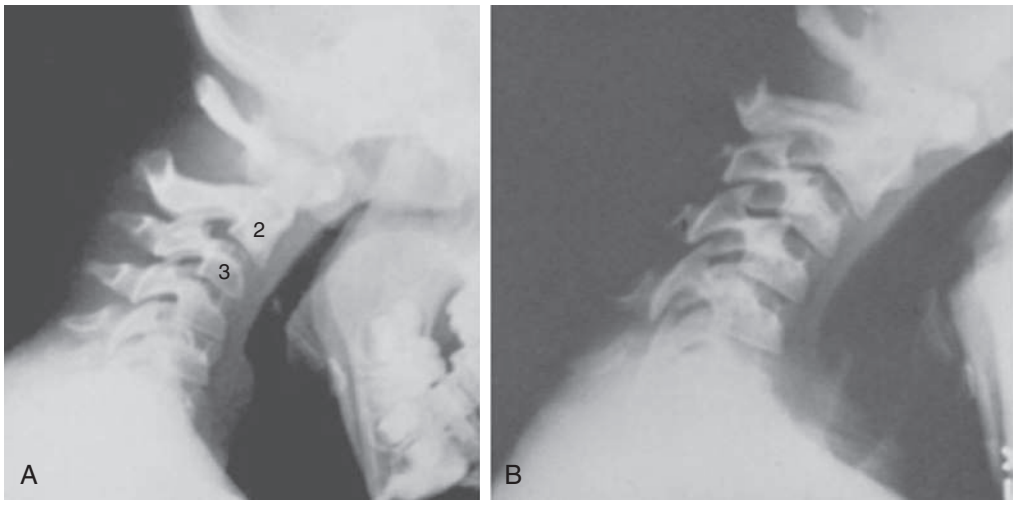

FIG. 34.40 (A) Pseudosubluxation of C2 on C3 in a child at age 5 years. (B) At age 10 years, flexion view of the cervical spine shows normal motion without pseudosubluxation. This normal variation can be found in more than half of children younger than 8 years.

Type 1 is fusion of C2 and C3 with occipitalization of the atlas. Flexion-extension is concentrated in the area of C1 and C2, and the odontoid can become hypermobile, narrowing the spinal canal and compromising the spinal cord and brain stem.

Type 2 is a long fusion with an abnormal occipitocervical junction. The center of flexion-extension and rotation is concentrated in the area of the abnormal odontoid or poorly developed ring of C1, which cannot withstand the wear and tear of aging.[197–199] It is important to differentiate this pattern from the pattern in a patient with a long fusion and a normal C1–C2 articulation (Fig. 34.42), which is usually compatible with a normal life expectancy.

Type 3 is a single open interspace between two fused segments (Fig. 34.43). As the cervical spine motion is concentrated at the single open articulation, this hypermobility may lead to frank instability or degenerative osteoarthritis.[180,200] This pattern can be easily recognized because the cervical spine appears to angle or hinge at the open segment.

Similarly, Samartzis et al.[198] studied cervical fusion patterns in patients with KFS. Their classification system encompassed three types: type I, single fusion; type II, multiple, noncontiguous fusions; and type III, multiple, contiguous fusions. Type I is associated with axial neck symptoms; types II and III were associated with radiculopathy and myelopathy.

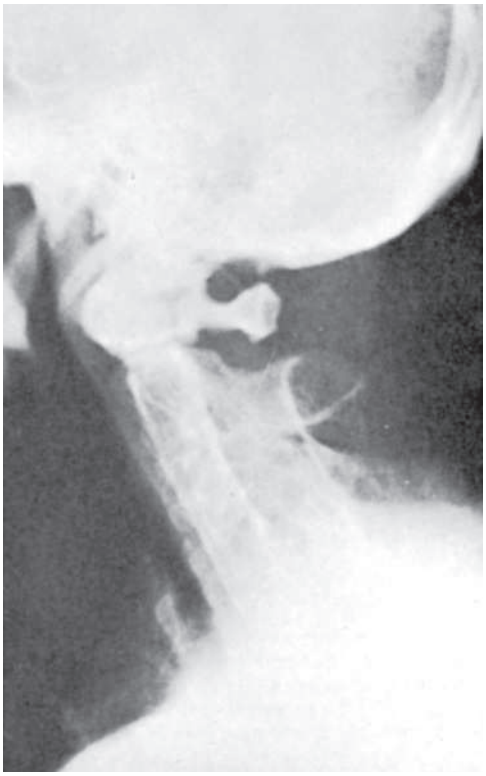

FIG. 34.42 Radiograph of a 45-year-old man with Klippel-Feil syndrome. The patient has complete fusion of C2–C7. Flexion-extension occurs only at atlantoaxial articulation. There are no symptoms referable to the neck despite two previous serious falls. This pattern seems to be relatively safe because a normal occipitocervical junction serves as protection from late instability.

Treatment

A patient with KFS with minimal involvement can be expected to lead a normal active life with no or only minor restrictions

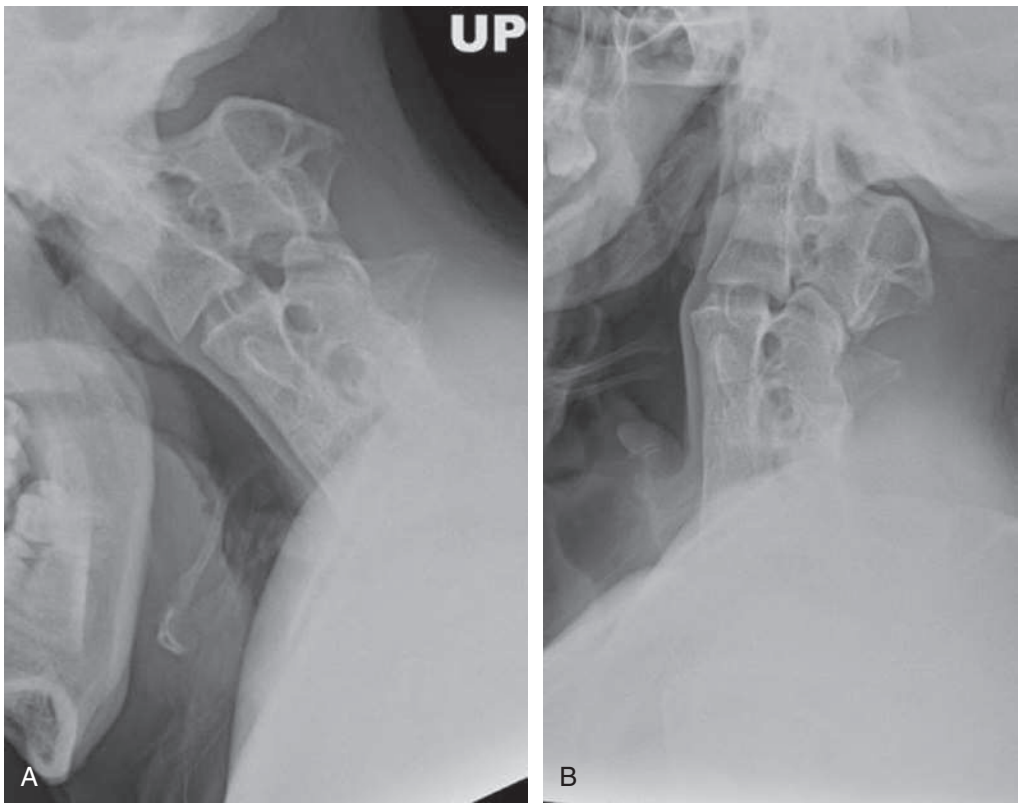

FIG. 34.43 (A) Flexion and (B) extension lateral radiographs show a single open interspace in Klippel-Feil syndrome.

or symptoms. In fact, the actual treatment of KFS is confined mostly to the area of associated conditions. Even patients with severe cervical involvement can have a good prognosis if early and appropriate treatment is instituted, especially regarding associated scoliosis and renal abnormalities.

Treatment options center on prophylaxis, mechanical treatment, and cosmetic treatment. Regarding prophylaxis, patients with long segments of cervical fusion or high-risk patterns of cervical spinal motion should avoid activities that might risk the cervical spine. In these patients, the mobile articulations are under greater mechanical demands and are less capable of protecting them against traumatic insults. Additionally, although neurologic compromise or death after minor trauma has been reported in patients with KFS,[182] the role of prophylactic surgical stabilization in asymptomatic patients has not yet been defined. There is no satisfactory definition of when the risk of instability warrants further reduction of neck motion.

For symptomatic patients with mechanical symptoms, conservative treatment measures are reasonable and may include antiinflammatories or a cervical collar. Symptoms that suggest neurologic compromise require consideration and thorough physical examination and radiologic evaluation. The area of neural compression must be determined before surgical intervention. Attempts should be made preoperatively to obtain reduction of the spinal column in advance of surgical stabilization. Also, the anesthesiologist may need to plan for airway management and be prepared for difficult intubation.[201]

Treatment of the cosmetic aspects of this deformity has found limited success. Occasionally, children's abnormal neck posture may be improved with bracing. Bracing requires long-term application, however, and excellent patient cooperation. Correction of the bony deformity by direct means, such as wedge osteotomy or hemivertebrae excision, has been done on a limited basis. Ruf et al.[202] reported hemivertebrae resection for correction of head tilt. Occasionally, carefully selected patients who have cervical congenital scoliosis may obtain some correction and improvement of appearance by use of the halo vest combined with posterior cervical fusion. Bonola[203] described a method of rib resection to attain apparent increase in neck length and motion. This procedure is an extensive surgical experience, however, and is a great risk to the patient. No subsequent reports have appeared in the literature.

Soft tissue procedures, Z-plasty, and muscle resection may achieve cosmetic improvement in properly selected patients. These procedures can restore a more natural contour to the shoulders and neck and an apparent increase in neck length. Neck motion is generally not increased, and the scars may be extensive, particularly in a patient with a large skin web. If an omovertebral bone is present or an abnormal connection to the clavicle,[204] its removal may permit an increase in neck and shoulder motion. The risk of brachial plexus injury from traction is higher in patients with KFS because there are likely to be anomalous origins of the cervical nerve roots in these patients.

Congenital Muscular Torticollis

Congenital muscular torticollis is a common condition caused by contracture of the sternocleidomastoid (SCM) muscle, usually discovered in the first 6 to 8 weeks of life. The head is tilted toward the involved side and the chin rotated toward the contralateral shoulder (Fig. 34.44). A palpable mass may be, but usually is not, detected within the first 4 weeks of life (Fig. 34.45).[205] It is a nontender, mobile enlargement beneath the skin, attached to or located within the body of the SCM. Ultrasonography may be helpful in assessing the mass.[206] After 4 to 6 months of age, the mass is usually absent, and the contracture of the SCM muscle and head posture are the only clinical findings (Fig. 34.46).

With progression of the condition, deformities of the face and skull can result.[207] Flattening of the face and skull (termed *plagiocephaly*) on the side of the contracted SCM muscle is due to the position of the child when sleeping. In the past, many children slept prone,[208] and the face remodeled to conform to the bed. The "Safe to Sleep" movement (formerly known as "Back to Sleep") has substantially decreased the percentage of children who sleep in the prone position.[209] In children who sleep supine, reverse modeling of the contralateral aspect of the skull is evident.

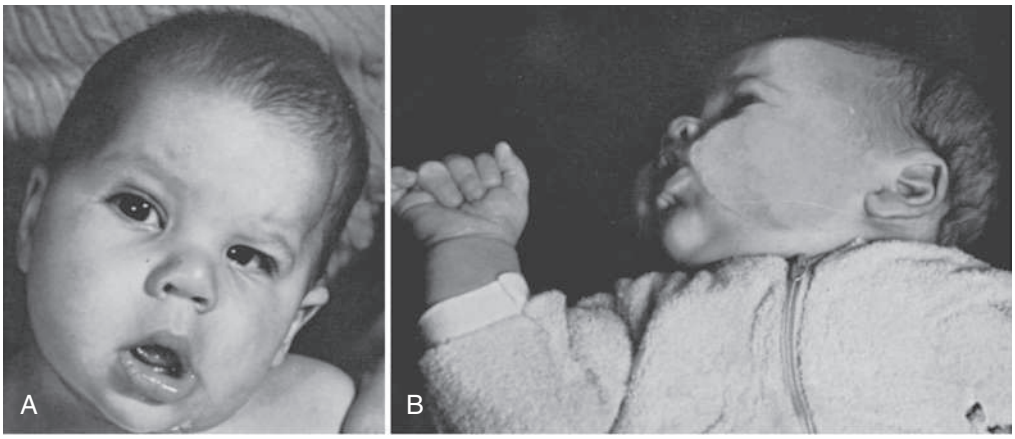

FIG. 34.44 A 6-month-old infant presented with right-sided congenital muscular torticollis. Note rotation of the skull and asymmetry and flattening of the face on the side of the contracted sternocleidomastoid.

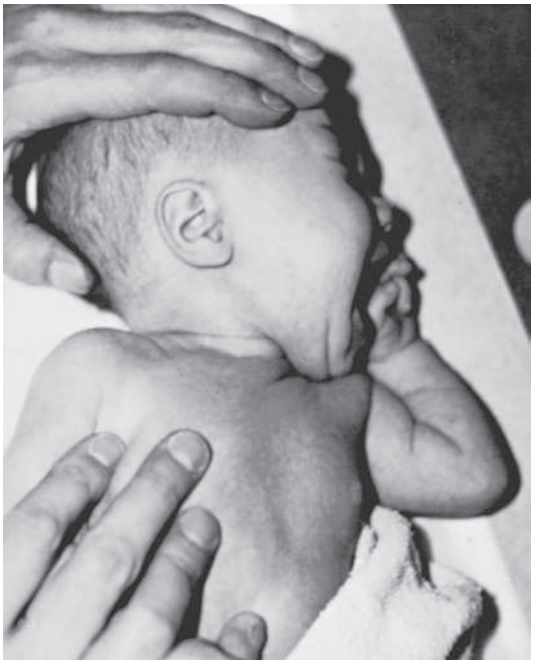

FIG. 34.45 A 6-week-old infant presented with swelling in the region of the sternocleidomastoid. The mass is usually soft, nontender, and mobile beneath the skin, but is attached to the muscle.

FIG. 34.46 This 18-month-old child had torticollis that was resistant to stretching exercises and required surgical release.

Clinical Presentation

Currently, the etiology of congenital muscular torticollis is thought to be due to compression of the SCM during delivery.[210] While most commonly unilateral, bilateral torticollis has been reported.[211] Although commonly associated with breech or difficult deliveries, it may occur after otherwise normal deliveries or in cesarean sections.[205]

In MRI studies of infants with congenital muscular torticollis, Davids et al.[210] found signal changes in the SCM muscle similar to changes observed in the forearm and leg after compartment syndrome. In cadaveric dissections, the fascia covers the entire SCM, strongly suggesting that congenital muscular torticollis represents a compartment syndrome. Experimental work with dogs suggests that the lesion is due to occlusion of the venous outflow of the SCM muscle. As in the sequelae of compartment syndrome in other locations of the body, the occlusion results in edema, degeneration of muscle fibers, and eventual fibrosis of the muscle body.

The clinical deformity is related to the ratio of fibrosis to remaining functional muscle.[207] With sufficient normal muscle, the SCM stretches with growth, and the child will not likely develop the torticollis posture. If fibrosis predominates, there is very little elastic potential, and deformity ensues. With time, the fibrosis of the sternal head may entrap and compromise the branch of the accessory nerve to the clavicular head of the muscle, leading to a late increase in the deformity due to progressive denervation.[212]

Congenital muscular torticollis is associated with uterine crowding, or "packaging syndrome," due to restriction of infant movement in the tight maternal space. In many children, the lesion is on the right side,[210,213] and up to 20% of children will have concomitant developmental dysplasia of the hip.[214,215] In one series, all patients with concomitant hip disease required treatment for their dysplasia. Some authors recommend screening hip ultrasounds for all patients with congenital muscular torticollis.[216]

Differential Diagnosis

Head and neck postural deformities are a common complaint in children. While congenital muscular torticollis is the most common cause of wry neck posture in infants and young children, the differential diagnosis is diverse, and many other problems may lead to this unusual posture (Tables 34.1 and 34.2), including bony deformities, soft tissue lesions, inflammatory conditions, and neurologic conditions.

In fact, coexisting bony anomalies are common in the setting of congenital muscular torticollis. In 20 cases of muscular torticollis, Gyorgyi[217] found congenital cervical fusions, asymmetrical facet joints, basilar impression, atlantoaxial dislocation, assimilation of the atlas, and deformities of the odontoid process. Occipitocervical malformations, basilar invagination, KFS, and asymmetrical development of the occipital condyles may manifest as torticollis.[36,68,171]

The posture of the head and neck, as well as the stiffness of the deformity, may provide clues as to the etiology. In the presence of both head tilt and rotatory deformity, the pathology is more likely at C1–C2, whereas head tilt alone indicates a more generalized problem in the cervical spine. Rigid deformity, especially without contracture of the SCM muscle, points to a bony anomaly of the cervical spine (particularly C1–C2) as a cause of torticollis.

Soft tissue problems are less frequent and may include excessive skin webs (pterygium colli), which maintain the neck posture. SCM muscle tumors, cystic hygroma, branchial cleft cyst, and thyroid teratoma are rare but possible. Inflammatory conditions include cervical lymphadenitis or retropharyngeal

TABLE 34.1 Differential Diagnosis of Torticollis

Congenital	Acquired
Occipitocervical anomalies	Neurogenic
Basilar impressions	Spinal cord tumors
Atlantooccipital fusion	Cerebellar tumors (posterior fossa)
Odontoid anomalies	Syringomyelia
Hemiatlas	Ocular dysfunction
Pterygium colli (skin web)	Bulbar palsies
Congenital muscular torticollis	Traumatic (particularly C1–C2)
Klippel-Feil syndrome	Subluxations Dislocations Fractures Inflammatory Cervical adenitis Spontaneous hyperemic atlantoaxial rotatory subluxation Tuberculosis Typhoid Rheumatoid arthritis Acute calcification of disc Miscellaneous Sandifer syndrome (hiatal hernia with esophageal reflux)

TABLE 34.2 Torticollis Caused by Bony Anomalies

Congenital Anomalies of Craniocervical Junction	Acquired Anomalies of Craniocervical Junction
Klippel-Feil syndrome	Traumatic
Atlantooccipital synostosis (unilateral)	Subluxations
Odontoid anomalies	Dislocations
Aplasia	Fractures
Hypoplasia	Inflammatory
Os odontoideum	Rheumatoid arthritis
Occipital vertebra	Idiopathic
Asymmetry of occipital condyles (hypoplasia)	Atlantoaxial rotatory displacement Subluxation Fixation

abscess.[218] Polyarticular juvenile rheumatoid arthritis may involve the cervical spine, and torticollis may be the only clinical sign. Following pharyngitis, spontaneous atlantoaxial rotatory subluxation may occur,[219,220] resulting in torticollis.

Traumatic causes should be considered also, as torticollis commonly follows injury to the C1–C2 articulation. Children with conditions with known C1–C2 instability (Morquio syndrome, spondyloepiphyseal dysplasia, and Down syndrome) should be evaluated thoroughly. Intermittent torticollis can occur, as in the case of a seizurelike disorder termed *benign paroxysmal torticollis of infancy*. Similarly, Sandifer syndrome, involving gastroesophageal reflux with sudden posturing of the trunk and neck, is a known etiology of torticollis in children with cerebral palsy.[221] Neurologic disorders, particularly space-occupying lesions of the central nervous system, are often accompanied by torticollis. Other neurologic

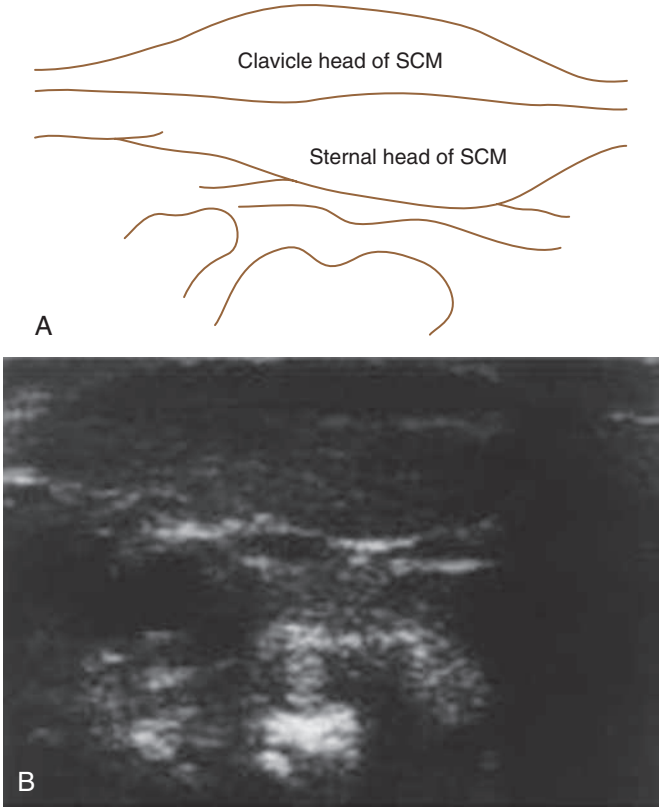

FIG. 34.47 (A) Abnormal appearance of sternocleidomastoid (SCM) in congenital muscular torticollis. (B) Ultrasonography shows homogeneous, hyperechoic mass on the SCM. (Modified from Tien YC, Su JY, Lin GT, et al. Ultrasonographic study of the coexistence of muscular torticollis and dysplasia of the hip. *J Pediatr Orthop* 2001;21:343–347.)

causes include dystonia musculorum deformans and disorders of hearing and vision that can result in head tilt.[222]

In the setting of acute-onset torticollis, atlantoaxial rotatory subluxation must be part of the differential diagnosis. Early treatment is paramount, as acute treatment for this condition can often be nonoperative. Chronic or missed rotatory subluxation often will require more aggressive treatment.

Imaging

While the diagnosis of congenital muscular torticollis is most commonly made on clinical grounds, sometimes imaging modalities are needed for confirmation. Ultrasonography is now considered the most sensitive test for confirming the diagnosis of congenital muscular torticollis. A homogeneous, hyperechoic mass within the SCM muscle is diagnostic of congenital muscular torticollis.[223] Ultrasound has proven to be a very sensitive and specific modality in making the diagnosis[224] (Fig. 34.47).

Children with torticollis who fail to improve with routine conservative treatment should be evaluated with radiography to exclude an osseous abnormality or fracture. However, adequate radiographic interpretation (especially at the occipitocervical junction) may be difficult because of the abnormal head position. It is helpful to remember that the atlas moves with the occiput: a radiograph directed 90 degrees to the

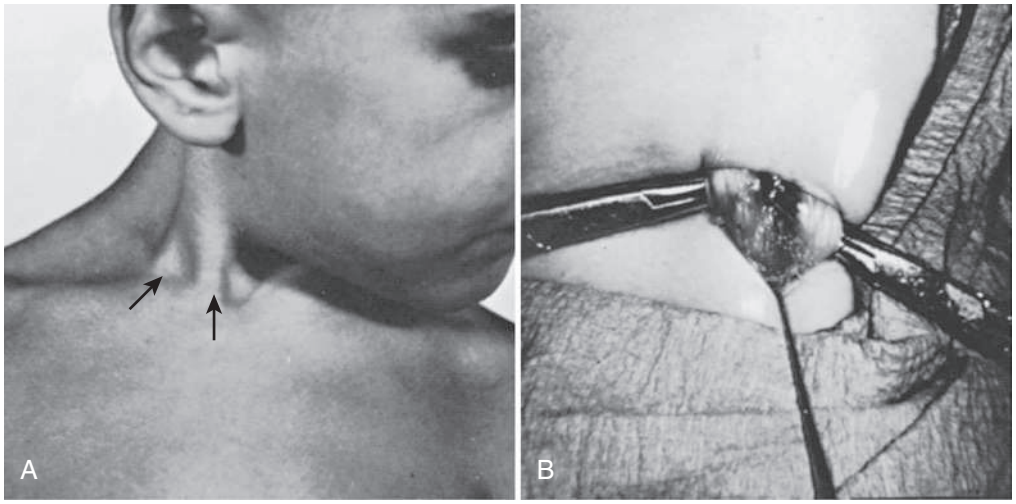

FIG. 34.48 (A) Clinical appearance of a 6-year-old child with congenital muscular torticollis. Note appearance of two heads of sternocleidomastoid (*arrows*). (B) Operative exposure of the same patient shows complete replacement with fibrous tissue of the two heads of the sternocleidomastoid..

lateral skull usually results in a satisfactory view of the occipitocervical junction. Flexion-extension films may also be necessary to reveal cervical instability.

CT scans may be beneficial, especially in the cases of discerning torticollis from atlantoaxial instability, or C1–C2 rotatory subluxation. This is because plain radiographs cannot differentiate the position of C1 and C2 during subluxation from that in a normal child whose head is rotated, as the images are identical. Using dynamic CT scans by rotating the head to the right and left, the clinician can determine the position of the facets.[220]

Nonoperative Treatment

Excellent results can be obtained with conservative measures in most patients,[205,213,225] which includes physical therapy and stretching exercises. Controlled manual stretching is safe and effective in greater than 95% of patients with congenital muscular torticollis when seen before the age of 1 year.[226] The most important prognostic factors for success are minimal rotational deficit, age less than 1 year, and absence of a palpable tight band or tumor in the affected SCM muscle.

Standard maneuvers include stretching the SCM muscle by positioning of the ear opposite the contracted muscle to the shoulder and touching the chin to the shoulder on the affected side.[227] Utilization of a physical therapist in performing exercises may be more beneficial than teaching parents on their own.[228] When adequate stretching has been obtained in the neutral position, these maneuvers are repeated with the head hyperextended to achieve maximal stretching. When plagiocephaly is present, the use of a sleeping helmet may reduce the deformity.

Surgery

There are no clear indications for surgery. In situations with persistent significant deformity persisting beyond 1 year of age with an obviously tight SCM, release of the muscle can be considered. In patients without functional deficit, indications for treatment are not clear. Early aggressive treatment of acute torticollis is important, as progression to chronic rotatory subluxation becomes a more significant problem requiring more aggressive treatment. Established facial asymmetry and motion limitations usually preclude a good result[225]; asymmetry of the skull and face improves as long as adequate growth potential remains after the deforming pull of the SCM is removed.[207] Although it has been traditionally thought that age greater than 1 year precluded good results, good cosmetic results can be obtained in children 5 to 7 years of age (Fig. 34.48).[229] Even patients older than 8 years can benefit from unipolar or bipolar release of the SCM and postoperative physical therapy.[230] Even if neglected, delayed release of the SCM has been found to be successful in improving both neck ROM and head and facial deformities.[231]

Surgery consists of resection of a portion of the distal SCM muscle. At least a 1-cm segment should be removed to guard against recurrence of the deformity. A transverse incision is made low in the neck to coincide with a normal skin fold.[232] The two heads of the SCM are identified, and both are sectioned. The investing fascia around the SCM must also be released.[205] Rotation of the chin and head at this point generally reveals the adequacy of the surgery, and palpation of the neck shows any extraneous tight bands that could lead to partial recurrence of incomplete correction. In an older child, an accessory incision (bipolar) is often required to section the muscle at its origin on the mastoid process. The whole muscle should not be excised because this may lead to reverse torticollis or asymmetry in the contour of the neck.[213] It is important not to place the incision near or very near the clavicle because scars in this area tend to spread and are cosmetically unacceptable.

The postoperative regimen includes passive stretching exercises of the SCM muscle, which should begin as soon as the patient can tolerate them. Occasionally, head traction at night is helpful, particularly in an older child. Bracing or cast correction may be necessary if the deformity has been of long

duration or if the torticollis posture has become a habit for the child. In the right cohort of patients, results of surgery are uniformly good, with a low incidence of complications or recurrence. Slight restriction of the neck motion and anomalous reattachment can occur but are generally unnoticed by the patient, and recurrence is rare. Residual fascial bands may be an etiology for persistent neck posturing. The most common postoperative complaint is disfiguring scarring.[213,232]

Acknowledgment

We are deeply indebted to Dr. R. Hensinger, author of prior versions of this chapter. Much of the current work was built upon his previous efforts.

35 CHAPTER Congenital Anomalies of the Spinal Cord

Muhammad M. Abd-El-Barr
Kevin T. Huang
R. Michael Scott
Mark R. Proctor

Introduction

Congenital anomalies of the dorsal midline structures—including neural tissue, muscle, skin, and bones—fall into the broad category referred to as *neural tube defects* (NTDs). When referring to NTDs, there are several different types. They range from common entities that are not clinically important to major anomalies that have significant implications throughout the nervous system. *Spinal dysraphism* refers to a group of anomalies involving the bony or nervous components of the spine and, more specifically, the failure of fusion of these midline structures. *Spina bifida* refers to bony posterior structures that do not completely fuse in the midline. Although uncomplicated, bony spina bifida is a common asymptomatic radiographic finding. When it is associated with complex anomalies of the nerve roots, dura, and even organs outside the nervous system (such as those within the genitourinary or gastrointestinal systems), it can be a source of major disability. The embryologic defects related to spinal dysrhaphism can occur either due to failure of primary neurulation and closure of the neural tube, which should occur in the third or fourth fetal week of life, or later failures of secondary neurulation. The incidence of spinal dysraphism is estimated to be 0.05 to 0.25 per 1000 live births.[1]

Spinal dysraphism has been recognized since the earliest of times and in all cultures. The most severe of these defects can result in permanent disability to patients, depriving them of "those qualities held in high esteem by our society—independence, physical powers and intelligence."[2] Aristotle (384–322 BCE) recommended infanticide for these children, leading to an ongoing debate about the diagnosis and management of these difficult defects, including the current trend toward antenatal treatment.

Spinal dysraphism is divided into two main categories: (1) *Spina bifida aperta* is characterized by herniation of the spinal cord and nerves through a defect in the skin, apparent at birth and/or on prenatal imaging. *Myelomeningocele* (MMC) is the most common of these defects. (2) *Spina bifida occulta* involves less obvious defects, as the neural structures are covered by full-thickness skin. Although each can be associated with significant spinal cord pathology, the associated anomalies of the nervous system are far greater when the lesion is associated with a loss of spinal fluid (see discussion of "unified theory" in the myelomeningocele section later in the chapter). Management of spinal dysraphism involves three main stages: (1) accurate diagnosis; (2) surgical intervention, if warranted; and (3) postoperative care, which often includes lifelong management of neurologic deficits that can worsen over time. This chapter reviews the major types of congenital anomalies of the spinal cord, including the exciting but controversial subject of prenatal diagnosis and surgical intervention for open MMC defects.

Embryology

Many of these congenital anomalies are associated with presumed problems in embryogenesis; a review of relevant embryogenesis will be helpful for the practitioner to understand these anomalies.

The development of the spine occurs between the second and sixth week of gestation and progresses in the following stages: gastrulation, primary neurulation, secondary neurulation, and retrogressive differentiation. Gastrulation (day 16) occurs when the mesoblast (future mesoderm) converts the bilaminar embryonic disc to a trilaminar structure. By 18 days of development, all three germ layers are present. The neural groove, which is a longitudinal depression, is destined to be the brain and spinal cord.

Neurulation (beginning at day 22) is the process by which the neural groove deepens to become a hollow neural tube, and includes two phases. The rostral opening closes first in humans (day 24), while the caudal opening closes at 28 days of gestation. Primary neurulation is completed by the fourth week of gestation. Errors in this phase lead to open neural tube defects, such as MMC or encephalocele, when affecting the brain.

Secondary neurulation refers to the canalization of secondary tubules and the formation of a secondary neural tube

caudal to the lower lumbar levels. This secondary neural tube will fuse with the primary neural tube. Errors during this process of secondary neurulation can lead to a terminal MMC or lipomyelomeningocele. The caudal cell mass, which is responsible for secondary neurulation, is also responsible for the formation of other organ systems, and accounts for the frequent association of anomalies of the distal spinal cord with those of the anorectal or genitourinary system.

At approximately 45 days of gestation, the caudal end of the neural tube (i.e., immature spinal cord) extends to the coccygeal spinal level. At this point, retrogressive differentiation is partly responsible for the cranial ascent of the neural tube as compared to the bony structures, although the differential growth of the spinal cord and spine is the major reason that, in a majority of adults, the conus medullaris corresponds to the level of the L1–L2 disc.[3]

Spina Bifida Aperta

The term *spina bifida* was first proposed by Nicolaas Tulp, a Dutch physician and surgeon who was pictured in Rembrandt's famous painting "Anatomy Lesson" for his description of MMC in 1651.[4] Originally, it was used to describe a duplication of the spinous process, but is currently still used for any malformation of the lumbar spine.[5]

Myelomeningocele

Embryology

MMC is the most common significant birth defect affecting the spine. It is characterized by herniation of a malformed spinal cord and its related meninges through a defect in the bony spinal canal and skin. MMC refers to herniation of the meninges through such a defect, without associated spinal cord tissue.

MMC most likely occurs when the posterior neuropore fails to close during primary neurulation, or if it reopens due to distention of the central canal by cerebrospinal fluid (CSF). This spinal abnormality is only one of the constitutive abnormalities seen in this disorder, which can also include Chiari II malformation, hydrocephalus, and multiple brain abnormalities, including partial agenesis of the corpus callosum, thalamic adhesions, and gyral malformations.

McLone and Naidich attempted to explain this constellation of findings with their "unified theory."[6] This theory hypothesizes that the open spinal defect and associated drainage of CSF leads to a loss of backpressure within the developing ventricular system of the brain, causing the collapse of the rhomboencephalic vesicle, which results in a small posterior fossa. This resultant small posterior fossa in effect forces the growing cerebellum and hindbrain to herniate downward into the cervical spinal canal, which is the hallmark finding of the Chiari II malformation. This downward herniation causes an obstruction of the fourth ventricle outlet, which causes hydrocephalus in the fetus or, in the newborn after closing the MMC, eliminates the spinal defect as a CSF drainage pathway.

Epidemiology

The incidence of MMC ranges from less than 1 case per 1000 live births to almost 9 cases per 1000 live births.[7] It is unclear what accounts for this regional variability. Ethnicity also appears to be involved in the epidemiology, with Hispanics having a higher rate of neural tube defects compared with African Americans and Asians in the United States, even after taking into account other factors.[8,9]

In the 1970s, it was noted that the red cell folate levels of women of lower socioeconomic status in the United Kingdom were lower than those of higher socioeconomic status, and that these women had a higher rate of pregnancies complicated by neural tube defects.[10] A double-blind randomized trial commissioned by the Medical Research Council Vitamin Study Group (UK) showed that periconceptional folic acid supplementation (4 mg/day in mothers with a previous history of NTDs) was associated with a substantial risk reduction of 72%.[11] The result of this study was the impetus of the US Centers for Disease Control and Prevention (CDC) recommending 4 mg/day folic acid supplementation for those mothers with a high risk of MMC due to a previously affected pregnancy.[12] A randomized study of more than 4000 low-risk Hungarian women found a statistically significant reduction of NTDs with folic acid supplementation (800 mg/day). This led to the further recommendation by the CDC that all women of reproductive age should take 400 mg folic acid daily in addition to consuming a folate-rich diet.[13]

Prenatal Diagnosis

Historically, the rates of prenatal diagnosis of MMC were relatively low, but this has changed in recent years, especially in developed countries. Serum screening of α-fetoprotein and acetylcholinesterase and the use of ultrasound yield current detection rates close to 80%.[14]

Ultrasound can be particularly effective in diagnosing MMC; as a result, rates of detection have increased dramatically over the last 2 decades. Both direct and indirect signs of MMC and other neural tube defects can be seen on ultrasonography. These indirect signs include the "lemon sign" (frontal bossing), the "banana sign" (deformation of the cerebellum), and obliteration of the cisterna magna (Fig. 35.1).[1] The diagnosis can be made as early as the tenth week of gestation in some cases, but the majority of cases are diagnosed between weeks 18 and 24.[15]

There is evidence, including sequential imaging studies, to suggest that the neurologic deficits in MMC may be progressive, with movement in the lower limbs decreasing with gestational age, and worsening of the hydrocephalus and hindbrain herniation.[16] Conversely, animal models of spina bifida showed preserved neurologic function and improved hindbrain herniation when there was prenatal coverage of the spinal defect.[17] This suggested that many of the final phenotypes of MMC may be due to a "two-hit" process, in which the spinal defect may initiate lower limb dysfunction, but the continued egress of CSF through the defect may cause some of the hindbrain defects, and further damage may

ensure exposure of the neural elements to the intrauterine environment.[18]

As can be imagined, once the diagnosis has been made, the parents and health care team are faced with an ethical dilemma. Termination of pregnancy is one option that is often pursued, with rates of termination around 20% in the United States and around 80% in Europe.[19] However, many countries have made termination of pregnancies illegal, even in the face of the most severe malformations. In addition, other families would not consider this a viable choice if it were permissible. Therefore, regardless of the choice made by the parents, a spina bifida center should include a multidisciplinary team consisting of neurosurgeons, orthopedists, neonatologists, urologists, and social workers.

Initial Management

A detailed physical examination is necessary when assessing an infant with an MMC. The physical examination evaluates the general well-being of the infant and the deficits associated with the MMC, and seeks to find associated anomalies. The physical examination should include an assessment of the actual MMC defect, with an eye toward surgical closure, and a complete neurologic examination with an emphasis on attempting to localize the functional level of the MMC. An assessment of any orthopedic deformity and urologic function is also important. It is critical to assess the patient clinically and radiographically for concomitant findings of hydrocephalus, as many of these infants will require treatment for the condition by either placement of a shunt or endoscopy. This can be assessed by head circumference, bulging of the fontanelle, and splaying of the cranial bones at the sutures. Hindbrain dysfunction or the concomitant finding of a Chiari II malformation can be suggested by the findings of stridor or apnea.

The condition of the MMC will determine the rapidity of surgical intervention. One should not rupture the sac if it is not ruptured, although this is uncommon. If the sac has ruptured, the neural placode should be readily visible and prophylactic antibiotics should be started. The lesion should be kept moist with a nonadherent dressing.

The neurologic examination should include cranial nerve examination, as Chiari II malformations can present with lower cranial nerve dysfunction, such as stridor from vocal cord paralysis or swallowing difficulty. Eye motion abnormalities and nystagmus are also common. Examination of the lower extremities is of paramount importance, as it allows one to assess the functional level of the MMC. Particular attention should be paid to the position of the legs at rest, as well as fixed contractures and wasting of particular muscles, as they suggest paralysis of the nerves innervating these muscles. One should also pay attention to the lowest level of reactivity to painful stimuli. Table 35.1 lists the segmental innervation of the lower extremities and can be used to assign a functional level to the defect.[20]

In addition to the neurologic assessment, a general orthopedic assessment of the lower extremities is also important, as many of these patients have clubfeet (equinovarus defects) and/or dislocated hips. Spine radiographs can be used to assess the associated scoliosis, although this can usually be done later. If a major gibbus is seen clinically, then the radiographs should be taken before closure of the MMC, as resection of the gibbus might be necessary.[21,22] Many patients with MMC have associated urologic problems; as such, clean intermittent catheterization should be initiated immediately to avoid urinary tract infections.

Postnatal Surgery for MMC Closure

Closure of the MMC defect should occur within 24 to 48 hours after birth to decrease the risk of meningitis and ventriculitis. It is important to note to the parents that the procedure is lifesaving and can prevent deterioration of function, but it does not improve neurologic function. If there is no evidence of hydrocephalus, then closure of the MMC can be done as an isolated procedure. If significant hydrocephalus is present, closure of the MMC should be accompanied by CSF diversion (discussed later).

The goals of the closure of the MMC are twofold. Primarily, it is to seal the spine and spinal cord and guard against the entry of bacteria. Second, it is to preserve neurologic function and to prevent tethering of the spinal cord, although it must be stressed that the rate of retethering is very high.

Surgically, the infant is put in the prone position after intubation under general anesthesia with gentle gel rolls so that the abdomen is free and to minimize epidural bleeding. An elliptical incision is made outside the normal skin and the zona epithelioserosa, which is a thin, pearly layer that surrounds the placode. It is important to excise this tissue, as leaving it may lead to the development of epidermoid inclusion cysts. For most MMC defects, the defect is oriented in the superior/posterior axis, making a vertical closure easier, but there are times when a horizontal closure may be easier[23] (Fig. 35.2).

Next, radial excision of the skin surrounding the placode is done, with care not to damage the placode. For MMCs with complete lack of distal neurologic function, some authors have advocated complete excision of the placode, which may prevent future tethering. However, most surgeons endeavor to preserve the placode. In fact, it may be beneficial to reconstruct the placode into a tubular form so that it fits into the dural sac and is less likely to tether.

Once this is done, the surgeon attempts to free the dura from the underlying fascia. The two edges of dura are then approximated and sewn together in a water-tight fashion.

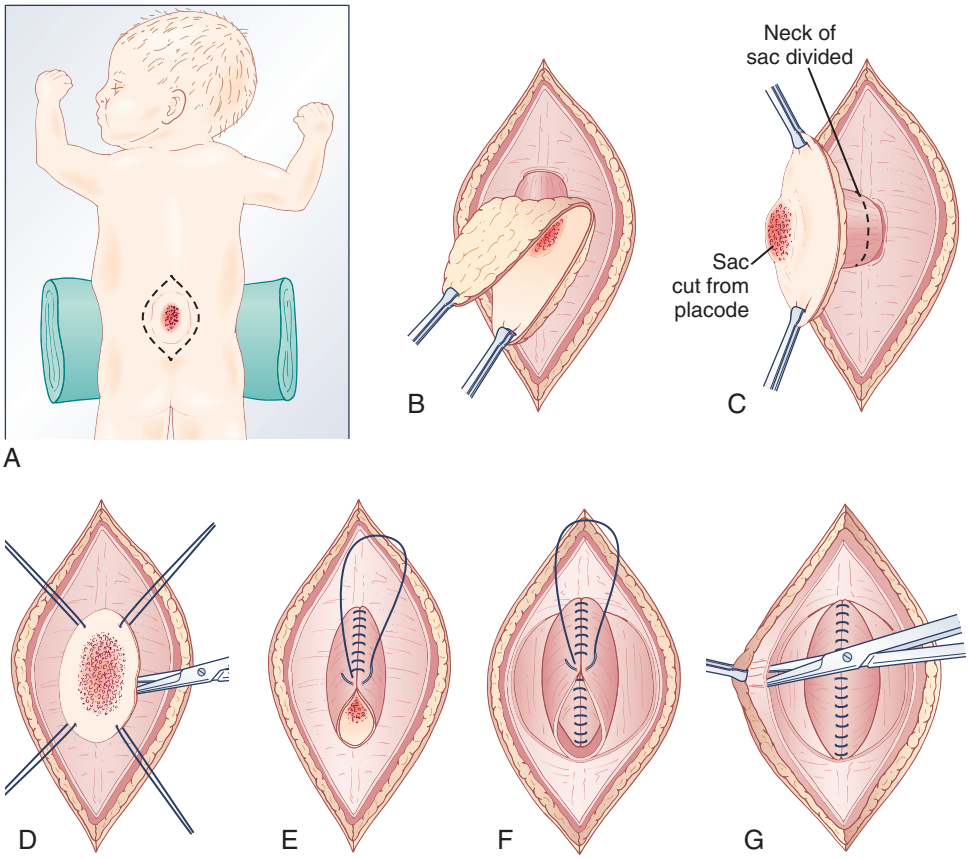

FIG. 35.2 Myelomeningocele closure. Technique for closure of myelomeningocele (see text). (A) The infant is placed in the prone position with towel rolls under the hips. An elliptic incision is outlined just outside the zona epithelioserosa, which may be oriented on the vertical or horizontal axis. (B) The incision is to the level of the lumbodorsal fascia. The apices of the island of skin within the incision are grasped with clamps, and the skin is undermined medially until the dural sac is seen to funnel through the fascial defect. (C) The dural sac is first incised at its base. The skin is excised from the placode and discarded, allowing the placode to fall into the spinal canal. (D) The everted dura is undermined and reflected medially to envelop the placode. The placode itself may be folded medially and sewn into a tube at this point. (E) The dural layer is closed with nonabsorbable suture, using a running stitch. (F) The fascia is incised to the muscle, undermined, and reflected medially to create second layer of closure. G, Skin is undermined using blunt techniques to permit closure.

Because the dura is often weak and the closure tenuous, it is a good idea to close the fascia in a separate layer. This is done by radially releasing the fascia from the overlying muscle and bringing the two edges of fascia together, over the closed dura. Next, to close the skin, undermining using blunt dissection is often necessary around to the abdomen. A two-layer closure is preferred, with interrupted nonabsorbable suture for large defects.

Larger defects require more complicated closure techniques; a close collaboration with plastic and reconstructive surgery is an important adjunct. The goal of closure is to minimize tension between individual tissue planes and to maximize tissue healing. One method to ensure this is to use an S-shaped skin opening, allowing for the use of local rotational flaps.[24] Rhomboid flaps and latissimus dorsi flaps can be used. We have also described using (1) local fascial turnover flaps with or without paraspinous muscle flaps for deep coverage of the dural repair followed by (2) linear, midline skin closure with good results[25] (Figs. 35.3 and 35.4).

Postoperatively, infants should be placed prone to avoid pressure on the incision. It is important to use a barrier dressing to avoid soiling with urine or stool. To monitor for the potential for hydrocephalus, daily head circumferences are measured and weekly head ultrasounds are obtained. It is important to have both orthopedic and urologic consultations to plan appropriate timing for repair of other associated anomalies and establish baseline urologic function. Routine catheterization is also important.

In Utero Closure

The first prenatal MMC repair was done in 1997. Early results suggested that this prenatal surgery had improved outcome for the infant in terms of decreased rates of hindbrain herniation, but also showed an increase in maternal risk, namely, the risk of preterm labor and uterine dehiscence.[26] These promising results were the impetus for the management of the Myelomeningocele Study (MOMS), which was a randomized trial at three tertiary centers that compared prenatal MMC closure to traditional postnatal closure.[18]

For this trial, the uterus was exposed via a low transverse laparotomy incision and exteriorized. The fetus and placenta were then located by ultrasound and hysterotomy. The MMC was closed in a standardized manner under magnification, generally using an allograft as a patch.

The primary outcome was the need for CSF shunting at 12 months. The prenatal group had a statistically significant lower rate compared with infants randomized to postnatal

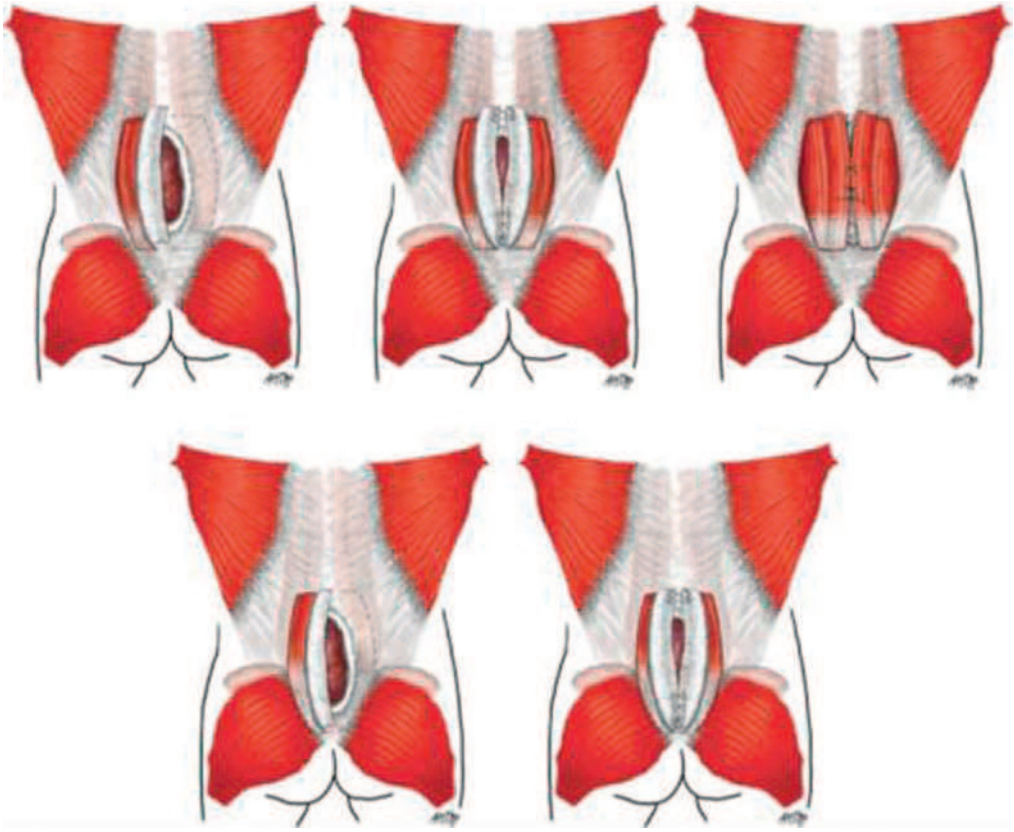

FIG. 35.3 Extradural myelomeningocele reconstruction. *Top,* Paraspinal muscle fascia is incised laterally and elevated medially over the underlying muscle. After the turnover fascial flaps are sutured together in the midline, the paraspinous muscles are then advanced medially. *Bottom,* If the majority of the defect is caudal to the paraspinous musculature, the paraspinous muscle fascia is turned over in continuity with the gluteal muscle fascia without additional muscle coverage. (From Patel KB, Taghinia AH, Proctor MR, Warf BC, Greene AK. Extradural myelomeningocele reconstruction using local turnover fascial flaps and midline linear skin closure. *J Plast Reconstr Aesthet Surg.* 2012;65[11]:1569-572.)

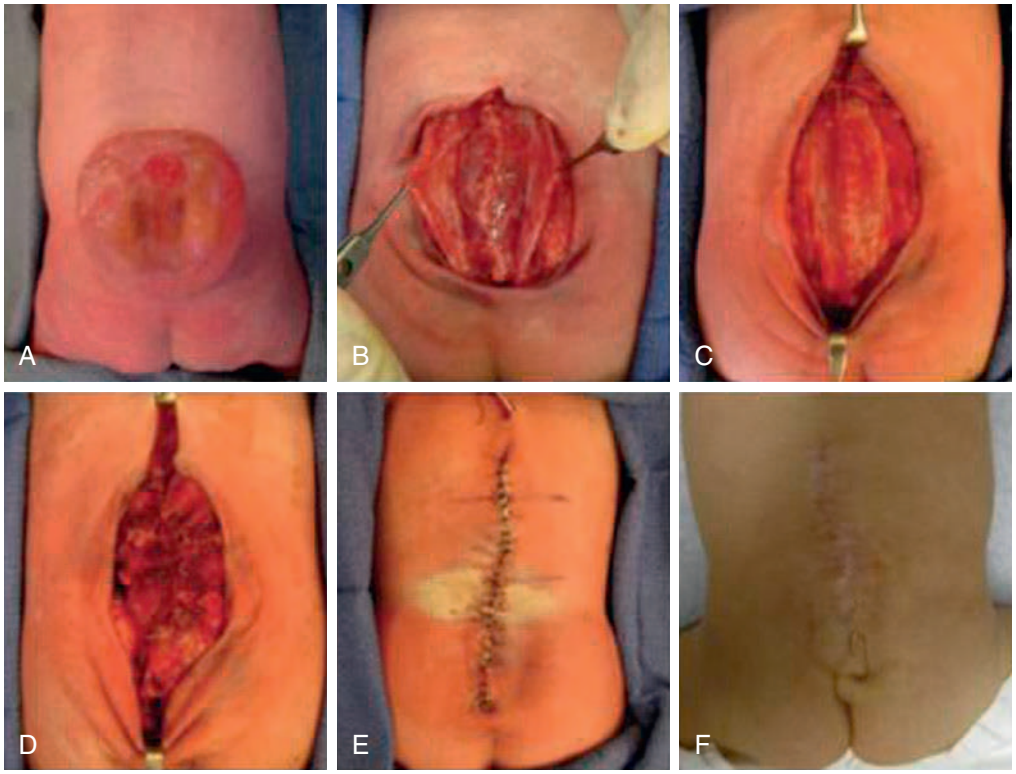

FIG. 35.4 (A) Two-day-old male with an 8.5 × 8.0 cm lumbosacral myelomeningocele. (B) Elevation of paraspinous turnover fascial flaps. (C) Closure of fascial flaps over the dural repair. (D) Additional soft tissue coverage using bilateral paraspinous muscle advancement flaps. (E) Widely undermined skin flaps advanced medially for midline linear closure. (F) Healed incision 4 months postoperatively. (From Patel KB, Taghinia AH, Proctor MR, Warf BC, Greene AK. Extradural myelomeningocele reconstruction using local turnover fascial flaps and midline linear skin closure. *J Plast Reconstr Aesthet Surg.* 2012;65[11]:1569-1572.)

closure (68% to 98%). The prenatal group also had lower rates of hindbrain herniation, brain stem kinking, abnormal fourth-ventricular location, and syringomyelia. Although the ability to walk is dependent on the level of the lesion, infants in the prenatal group were also more likely to walk without orthotics or devices. Interestingly, infants in the prenatal group underwent more delayed procedures for spinal cord tethering, likely because the initial closure was a less technical operation, aimed more at sealing the defect than releasing the spinal cord. Furthermore, the rates of maternal and pregnancy complications were higher with prenatal surgery. A later publication suggested that modification of the surgical technique, including not using a trochar and minimizing the separation of the amniotic membrane, resulted in lower rates of premature rupture of membranes and chorioamnion separation, and most infants were able to be delivered at a later gestational age.[27] A recent phase I study of an endoscopic approach to prenatal closure appears promising.[28] Larger ventricular size may be a prognostic sign for the requirement of a CSF diversion procedure.[29] More long-term follow-up is needed to ensure that these results hold up.

Ventriculoperitoneal Shunts

It is estimated that close to 80% of MMC patients will develop hydrocephalus, with 5% to 10% requiring CSF diversion at birth.[1] Most children who develop hydrocephalus will do so within the first 6 months of life. Interestingly, some patients develop hydrocephalus after MMC repair, as the egress of CSF from the defect is sealed off. The indications for CSF diversion are increasing head circumference, CSF leak from the MMC closure site, or signs of increased intracranial pressure, such as bradycardia or apnea. Some children may also develop a syrinx as a result of excess fluid buildup. If a CSF diversion is thought to be needed at the time of MMC repair, it can be done under the same anesthetic.[30] In a study comparing a wait-and-see approach for the placement of a ventriculoperitoneal shunt and automatic placement of the shunt, patients who had their shunts placed later had a significantly higher risk of developing a shunt infection.[31] However, by waiting to be certain that it is necessary, it is likely that some patients who would have been shunted can avoid this procedure.

Endoscopic Third Ventriculostomy

Endoscopic third ventriculostomy (ETV) is a procedure that was first proposed by W. Jason Mixter, founding chairman of neurosurgery at Massachusetts General Hospital, in 1923.[32] He used a urethroscope to puncture a hole in the floor of the third ventricle of a patient with noncommunicating hydrocephalus. Mixter's instrumentation and visualization were poor and cumbersome and did not have much appeal

to his colleagues. As technology improved, specifically the development of charged-couple devices, which convert optical data to electrical impulses, better visualization, magnification, and lighting could be delivered to an endoscope and the size of the endoscopes could be reduced.[33] Recently, there has been a resurgence in interest in treating many types of hydrocephalus using ETV with and without choroid plexus cauterization (CPC), which is reducing the need for patients to have an implanted device (shunt). This can be of great value to patients if the efficacy and longevity of the ETV procedures are borne out over time, as implanted shunts are at permanent risk of mechanical failure, infection, and other complications. Interestingly, the efficacy of ETV with and without CPC was established, out of necessity, in Africa, where there was less access to implanted shunts and where it is often very difficult for these children to receive shunt revision surgery if the shunt fails.[34] This modality is now being introduced to first-world countries with widely accessible modern shunts, a rare transfer of medical innovation from less-developed to more-developed countries. In a large series of over 100 patients, Warf and Campbell showed that using ETV and CPC as a primary treatment of hydrocephalus in patients with MMC was successful in 76% of patients, with a predicted lifetime success rate of 76% if reopening of a closed ETV was performed.[34] Importantly, close to 10% of patients could not undergo ETV and CPC, most commonly due to postinflammatory distortion of intraventricular anatomy. Preliminary evidence in North American studies supports these results.[35] A recent meta-analysis of ETV of approximately 500 patients, 53% of whom presented with MMC, revealed a success rate of 55%.[36] Due to the high morbidity of shunt failures and infection in MMC, it may be reasonable to attempt an ETV with CPC in patients requiring CSF diversion; thus, we are likely to see reductions in the number of shunted patients in the future. There are caveats in that, for some patients, the intraventricular anatomy may not be ideal for the ETV procedures. When failures of ETV do occur, they are commonly within 6 months of treatment,[34,37] a time when the skull bones remain open. This means that, although some infants might be converted to an implanted shunt, ETV failure should not lead to increased intracranial pressure and a poor outcome, as the baby will generally present with a more benign acceleration of head growth. To date, there have been no studies looking at ETV for hydrocephalus that occurs after prenatal treatment of MMC.

Surgical Complications

Latex Allergy

There has been an observation of a definite increase in allergy to latex, as found in surgical gloves and urinary catheters, in patients with spinal dysraphism.[38] Health care providers must be vigilant in this regard, as the allergy is type I, an immediate immunoglobulin E (IgE) reaction that can result in anaphylaxis and death. This sensitization is thought to arise from repeated exposure to latex products, although there is evidence that patients with spinal dysraphism have higher levels of total and latex-specific IgE compared with normal patients.[39] For this reason, all surgical procedures on spina bifida patients are recommended to be done in a latex-free environment. At most pediatric centers, this latex-free precaution is established immediately, before any evidence of allergy is present, to prevent this reaction.

Late Deterioration

Although MMC is a congenital birth defect and most of the neurologic sequelae are present at birth, there is risk for progressive loss of function from several causes. Signs of worsening in a patient should be investigated, as early treatment affords the best outcome. Reasons for neurologic deterioration in an MMC patient include hydrocephalus, Chiari malformation, hydromyelia, tethered cord, and progressive spinal deformity. Many of these conditions can coexist; thus, it might not be easy to determine the exact reason for neurologic deterioration in an MMC patient. Therefore, it is generally best to consider a top-down approach.

Hydrocephalus can be the source of dysfunction for many reasons, including the primary effects of the progressive ventricle size, and the secondary effects this can have on the Chiari II malformation and the hydromyelia. Therefore, workup for MMC patients who present with neurologic deterioration should start with a brain scan. If this shows worsening ventriculomegaly, the treatment might be obvious. If the ventricles are not enlarging, paradoxically, the hydrocephalus can still cause worsening Chiari or syrinx symptoms; thus, the spine should be imaged. If the symptoms appear to be Chiari related (i.e., cranial nerve dysfunction) or syrinx related (i.e., upper extremity weakness) the treatment might still be for hydrocephalus, which will often improve these other conditions. If the findings are purely in the lower extremities or bowel/bladder, the tethered cord might be the source, in which case the treatment is directed there. The presence of findings is not always a mandate for surgery; rather, these findings should be placed in context to previous imaging and clinical presentation of the patient. It is therefore important that these patients are followed longitudinally by a highly specialized multidisciplinary clinic, including neurosurgeons, orthopedic surgeons, urologists, pediatricians, and physical therapists.

Shunt Malfunction/Increased Intracranial Pressure

Any neurologic deterioration in a patient with MMC should invoke a thorough investigation for increased intracranial pressure. If a shunt is present, it can malfunction, and even the ETV can fail. This is often confusing to first-line responders, who may not think of the possibility of hydrocephalus since no shunt is present. Studies have shown sudden death from hydrocephalus in patients treated with ETV alone.[40,41] It is important to note that many MMC patients have baseline ventriculomegaly, or "arrested" hydrocephalus. There is some evidence that some of these patients may benefit from an insertion of a new shunt or shunt revision,[42] which is a decision made carefully by the neurosurgeon. Eye examinations can be vitally important in looking for papilledema in these

patients, and occasionally direct monitoring of intracranial pressure is needed. For patients who have undergone ETV, reopening of the ETV site has been shown to be effective, even if it is performed later.[43]

Tethered Cord

Tethered cord syndrome (TCS), in which the spinal cord is attached to the surrounding tissues and limited in its movements, can cause neural structures to stretch and lead to multiple neurologic, urologic, and orthopedic defects. It is important to note that by radiographic criteria, such as a low-lying conus or attachment of the spinal cord to overlying tissue, all MMC patients will have the picture of a "tethered cord," but it is only approximately 20% to 30% that will have symptomatic TCS.[44,45] Interestingly, fetal repair does not seem to change the incidence of this phenomenon, as 30% of patients that underwent a fetal repair subsequently presented with TCS, with 63% of these patients having a cutaneously derived intradural inclusion cyst. In fact, it may paradoxically increase this risk because the prenatal closure, despite its overall complexity, is a less technically exacting operation regarding the spinal cord.

Signs and symptoms of TCS are more likely to appear early in life, when growth is rapid. We often see spikes of presentation between 4 to 6 and 12 to 14 years of age, which coincide with growth spurts. Symptoms can include back and leg pain, urinary incontinence, gait abnormalities, progressive foot deformities, and kyphoscoliosis. In children whose function is already compromised, such as with gait abnormalities from low-lying lesions, loss of more function can significantly alter quality of life; thus, early diagnosis and treatment are essential.[46]

Surgery to detether a tethered cord is similar to that for a lipomyelomeningocele. It is important to identify the most cephalad normal lamina above the spina bifida defect. This most cephalad lamina is removed, and the underlying normal spinal cord is identified. Working in a caudal fashion, the dorsal and lateral attachments are detached using sharp dissection. This should continue until the cord is noted to fall into anterior spinal canal. There is some evidence that using electrophysiology—namely, electromyography (EMG)—and compound muscle action potentials can be helpful in making these dissections safer and perhaps decrease the rates of subsequent tethering.[47]

Although the aim of surgery is to halt neurologic deterioration, there is some evidence that detethering operations may actually improve neurologic function, including gait and motor difficulties and urinary incontinence.[48,49] It is for this reason that early detection and surgery are important.

Chiari Malformations

Chiari malformations refer to abnormalities of the hindbrain originally described by the Austrian pathologist Hans Christian in the early 1890s.[50] There are four main types described, but the most relevant to the topic of spinal dysraphism is the Chiari type II (CMII) malformation. CMII is almost always (>95%) associated with myelomeningocele or, rarely, other forms of spinal dysraphism.[51,52] In this malformation, there is downward displacement of the cerebellar vermis and brain stem through the foramen magnum (Fig. 35.5). Hydrocephalus is also present about 90% of the time.

Infants with CMII requiring treatment are in a fairly severe category and can present with inspiratory stridor due to vocal cord paralysis, bradycardia, or apnea.[53,54] Older children will

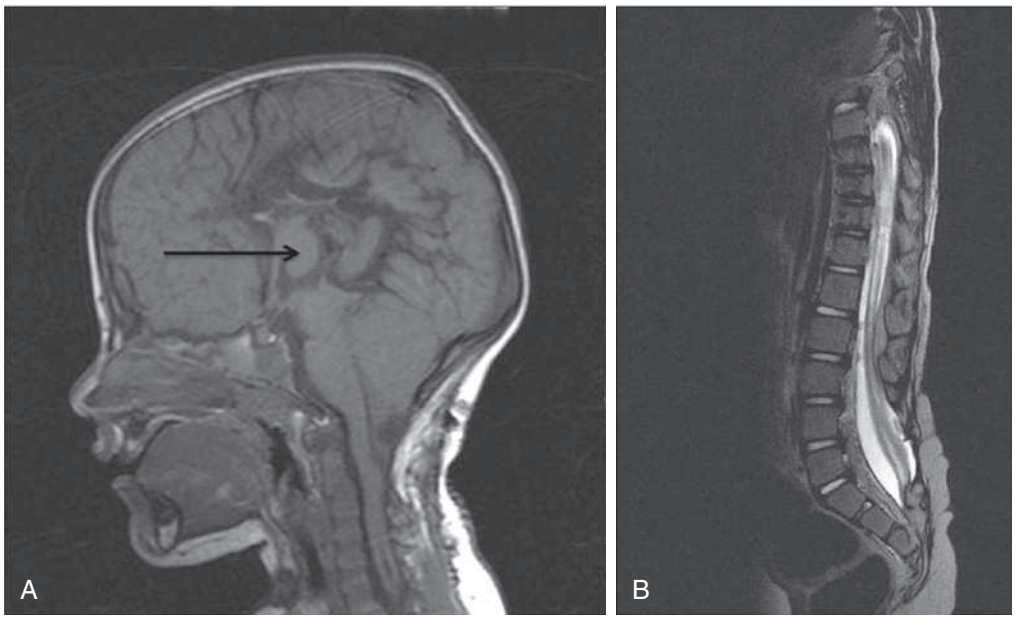

FIG. 35.5 Magnetic resonance imaging findings of Chiari II malformation. (A) Sagittal T1-weighted MRI reveals many of the associated findings in Chiari II malformations, including lack of corpus callosum, large massa intermedia (*arrow*), descent of the cerebellar tonsils, as well as descent of the brain stem. (B) Sagittal T2-weighted MRI reveals low-lying conus and myelomeningocele.

generally present with more mild symptoms, including lower cranial nerve palsies, ataxia, and tussive headaches.

The indications for surgical intervention for CMII lesions in myelomeningoceles are difficult, as many of these patients will have the radiographic findings of Chiari II but not require treatment. Generally, if patients present with these symptoms, treatment of the hydrocephalus can be effective in treating these Chiari symptoms, presumably by reducing the pressure from above that is putting downward pressure on the brain. However, some children do require Chiari decompression if the hydrocephalus treatment was not effective in relieving the symptoms.

The goal of surgery for Chiari malformations is to equilibrate CSF pressure dynamics between the intracranial and intraspinal subarachnoid spaces. This involves a posterior fossa decompression through a suboccipital craniotomy. Some centers do only bony decompression, while others advocate for at least a partial duraplasty, which involves thinning of the dura. The third option involves opening the dura at the craniocervical junction. A meta-analysis suggests that patients who undergo duraplasty have higher levels of symptom control and syrinx resolution, but also higher rates of CSF-related complications, such as CSF leaks or the development of a pseudomeningocele.[55]

Hydromyelia

Hydromyelia, or the abnormal widening of the central canal of the spinal cord due to the presence of CSF, is recognized with increasing frequency in association with MMC. The true incidence of hydromyelia in MMC patients may be close to 70%.[44] Some have posited that the presence of hydromyelia may be due to persistent hydrocephalus that transmits increased CSF pressure down the central canal.[56] Others have hypothesized that the hydromyelia is due to a transmission of a systolic pressure wave in the intracranial compartment to the cerebellar tonsils, which, in turn, is transmitted to the central canal.[57,58] This is why treatment of the hydrocephalus can be effective for treating the hydromyelia.

Whereas classic syringomyelia usually presents with dissociated sensory loss (presumably due to damage to the decussating anterior white commissure), hydromyelia associated with spina bifida can present with preserved sensation, but progressive bladder dysfunction and quadriparesis. Scoliosis also might be related to hydromyelia, but it can also be related to primary bone abnormalities, or spinal tethering.[59]

Spina Bifida Occulta

Spina bifida occulta represents the other major subcategory of spinal dysraphism. As opposed to spina bifida aperta, spina bifida occulta is a condition in which there is a congenital defect in the dorsal elements of the spinal canal, but the overlying skin is left intact, and the diagnosis is often not detected at birth. This is a distinct condition that may be associated with TCS and the risk for deterioration over time, which has different implications for both prognosis and treatment.

Embryology

In contrast to MMC, spina bifida occulta arises from defects at a later point in embryologic development. At 27 days of gestation, the neural tube has completely closed, finishing the process of primary neurulation.[60,61] This closure is the result of complex interactions between numerous intercellular signaling factors. By definition, this closure occurs successfully in all spina bifida occulta patients. The neural tube then separates from the overlying ectoderm in a process thought to be highly dependent on *cadherin* expression.[62,63] Following neural tube closure, canalization occurs from days 27 to 48. During this process, cells from the primitive streak distal to the caudal neuropore form a caudal cell mass, which, in turn, form vacuoles that go on to become the conus medullaris, cauda equina, and filum terminale.[64] These eventually fuse with the distal neuropore, forming the distal spinal cord.

The formation of the bony and muscular distal spinal elements occurs simultaneously. By the end of primary neurulation, paired mesoderm-derived somites have given rise to paired sclerotomes, flanking either side of the notochord ventral to the neural tube.[65] These sclerotomes migrate medially, meeting one another in the midline to eventually form the basis of the bony vertebral column. Sclerotomal cells then subsequently migrate dorsally to envelop the neural tube, forming the dorsal vertebral arch structures. The overlying back musculature and deep dermal tissues are simultaneously derived from the remaining somite cells left over after the sclerotomal cells have separated.

In spina bifida occulta, any number of these subsequent embryologic steps may be disrupted, leading to occult dysraphism. For example, failure of proper separation of elements during neural canalization can lead to either a fatty or fibrofatty filum terminale. Similarly, failure in the migration or fusion of dorsal sclerotomal cells may lead to malformation of the bony and muscular elements of the dorsal spine. Though these malformations may not become obvious or symptomatic until much later in development, many can be clearly traced to anomalies during early gestation.

Epidemiology

The true prevalence of occult spinal dysraphism is currently unclear, as many mild anomalies, such as a fibrofatty filum terminale, have an uncertain natural history.[66] As many of these abnormalities are detected either incidentally or as part of the workup of an overlying suspicious cutaneous sign, it is unclear how many of these anomalies become symptomatic, and, in turn, how many cases remain undiagnosed in the pediatric and adult populations. As a corollary, the measured incidence of occult spinal dysraphism has grown over time as imaging technology has become more widely available and awareness of screening for cutaneous manifestations has increased.

Estimates for lipomyelomeningocele and lipomeningocele have ranged from 0.3 to 1.6 per 10,000 live births with a higher incidence in Hispanic populations and a lower incidence in black populations.[67,68] The estimated prevalence of isolated

filum terminale abnormalities are significantly higher. Cadaveric studies have yielded a presence of 4% to 6% for filum terminale lipomas.[69] Imaging prevalence studies have reported a slightly lower incidence: 0.2% to 4.0%.[70–72] Reports of the incidence of congenital dermal sinus tracts are somewhat more varied. Earlier studies, based on clinical examination of children, report a significantly higher incidence (1–4%) compared with later studies that supplement clinical investigation with imaging technology (~0.04%).[73–76] This is not surprising, as the vast majority of patients with suspicious cutaneous stigmata, even in prescreened populations, will not have underlying evidence of spinal dysraphism.[77] Other congenital malformations, such as spinal neurenteric cysts, diastematomyelia, and sacral agenesis, are rarer still, with data limited to case reports or small case series.

Of note, as opposed to the case of MMC, there have not been demonstrated associations of occult spinal dysraphism with folic acid deficiency. This has been most carefully studied in the specific case of lipomyelomeningocele. Repeated efforts have failed to find any reduced incidence of lipomyelomeningocele with dietary folic acid supplementation.[68,78] These data reinforce the idea that occult spinal dysraphism represents a pathologic entity distinct from MMC, with roots in developmental errors that occur after the complete neural tube closure.

Clinical Presentation

Occult spinal dysraphism should be suspected when there is the presence of suspicious cutaneous stigmata, syndromic or midline congenital malformations associated with spinal dysraphism, or symptoms suggestive of lower spinal cord pathology.

In terms of cutaneous stigmata, common suspicious lesions include the presence of a midline or paraspinal mass, a capillary hemangioma (port wine stain), a distinct lumbrosacral tuft of hair, a polypoid lesion or caudal appendage, hyper- or hypopigmented nodules or macules, an atretic meningocele, a sacral dimple, a sinus tract, or a significantly deviated gluteal cleft.[79,80] (Fig. 35.6). Due to the wide variety of possible manifestations, the incidence of some form of cutaneous stigmata is high, but only a fraction of those children have radiologic evidence of underlying spinal dysraphism on further investigation. There are reports that as many as 5% of all neonates bear some form of cutaneous stigmata, the most common of which is a sacral dimple, but only 7% of those bearing the stigmata go on to have signs of dysraphism on radiologic studies.[81] Nevertheless, due to the serious potential consequences of leaving an underlying malformation unrecognized, most children with suspicious cutaneous lesions should typically undergo further investigation.

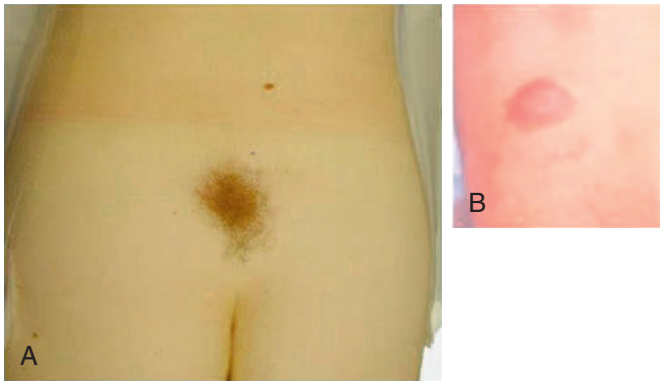

FIG. 35.6 Cutaneous stigmata of occult spinal dysraphism. (A) Hypertrichosis in a young woman, indicating underlying tethered cord. (B) Lumbosacral hemangioma.

Several congenital syndromes and associations are also known to be associated with occult spinal malformations; their presence typically warrants screening for spinal dysraphism. One of the more common is VACTERL, an association of co-occurrences involving the following, which comprise the acronym: vertebral anomalies, anal atresia, cardiac defects, tracheoesophageal fistula, esophageal atresia, renal and radial anomalies, and possibly limb defects. Though not linked through a common pathogenic pathway, these anomalies are known to be associated with one another. Tethered cord is a common occurrence in children with any type of anal and/or sacral anomaly, due to the common embryology of the caudal cell bud, VACTERL included. An estimated 8% to 45% of children with anorectal malformations have associated pathologic spinal abnormalities.[82–85] Other known syndromic associations include SACRAL syndrome (spinal dysraphism, anogenital, cutaneous, renal, and urologic anomalies) and the more recently coined PELVIS syndrome (perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag).[86,87] It should be noted that in all of these, there is a common thread of association between anorectal abnormalities and underlying spinal abnormalities.

Finally, if neither cutaneous manifestations nor nearby congenital abnormalities are present, progressive symptoms localized to the lower spinal cord and cauda equina should also raise suspicion for possible occult dysraphism. These symptoms include progressive lower extremity weakness, urinary incontinence and/or retention, bowel incontinence, high-arched feet, leg asymmetry, and/or scoliosis. It is important to recognize that these deficits may be present at birth, but more commonly present in a delayed fashion. As such, a detailed history and physical are, as always, critical to making a diagnosis. Lower extremity weakness may be particularly challenging, as younger children may be limited in their ability to give a clear history and/or participate in bedside examination. Thus, other associated signs—such as progressive inward toeing of the feet, refusal to walk or stand independently, or increased long-tract signs on examination—should also raise concern for underlying spinal cord issues. This suspicion should be particularly heightened in children who achieve a given developmental level and then experience unexplained regression.

Investigation

When an underlying occult spinal congenital malformation is suspected, the next step in workup is typically radiologic

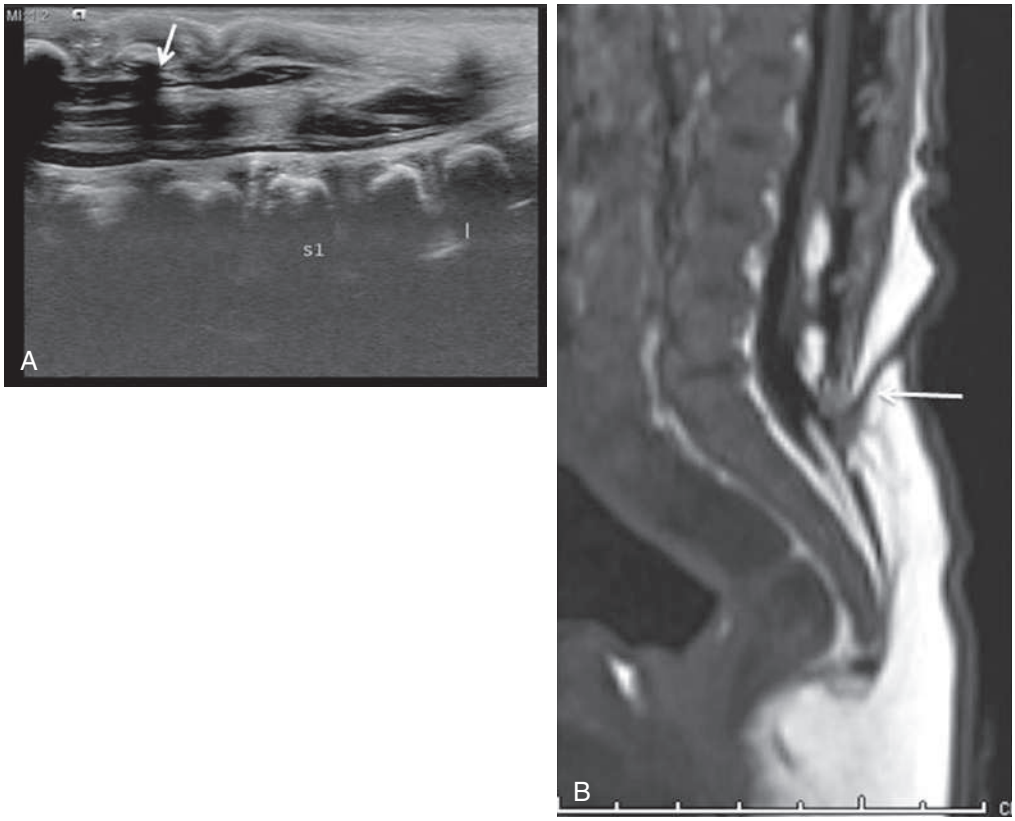

FIG. 35.7 Ultrasound findings of occult dysraphism. (A) Midsagittal ultrasound shows dermal sinus tract (*arrow*). (B) Midsagittal magnetic resonance image reveals dermal sinus tract in better resolution (*arrow*).

investigation. This can take the form of either a focused ultrasonography or magnetic resonance imaging (MRI), each with their distinct advantages and disadvantages.

Ultrasound studies are quick, cost effective, and generally give a good impression of the underlying structural composition of underlying structures if done before the ossification of the bones excludes effective imaging. Structures are contrasted based on their echogenicity; as such, bone, spinal fluid, and the spinal cord are well differentiated from one another. In addition, gross structural abnormalities, such as the presence of an MMC, a low-lying conus, or large lipoma, can also be examined, and even subtler details, such as a thickened filum terminale, can be identified[88] (Fig. 35.7**).** Moreover, this information can be obtained with some degree of motion tolerance, avoiding the need to sedate a child to obtain the study. Finally, cine views actually can show movement of the spinal cord, which can be limited in tethering conditions.

Ultrasonography has its limitations, however. Obtaining an adequate study can be dependent much more on technician experience and skill than in other imaging modalities. Furthermore, shadow effects created by highly echogenic structures, such as bone, can obscure the view of underlying structures; thus, these studies are only effective up to 3 to 4 months of age. Perhaps most important, tissues of similar echogenic properties are often poorly contrasted, leading to inadequate resolution of soft tissue structures. As such, while ultrasound is often an excellent initial study to evaluate the spine, and is useful for screening purposes, MRI studies may be needed to make a final diagnosis. In our practice, if the clinical suspicion is low to moderate and a high-quality ultrasound performed by an experienced radiologist is normal, no further workup is pursued.

MRI has the advantage of excellent soft tissue contrast, therefore being able to easily discern fat, fluid, fibrous, and neuronal content from one another. As such, it serves as the basis for the diagnosis of most forms of spinal dysraphism, both as a means to better characterize the suspected anomaly, and to help evaluate for any other associated lesions or changes to normal anatomy.[61] The main disadvantage of MRI in the pediatric population is the need to remain near motionless while images are being captured. For many children younger than 6 to 7 years of age, this requires sedation, rarely even general anesthesia, and all of the associated risks that these bring. As such, while MRI is often necessary for treatment planning and to confirm the final diagnosis in occult spinal dysraphism, it should only be pursued once clinical suspicion is high enough to justify the potential risks.

In addition to radiologic examination, other adjuvant tests may be helpful to determine if TCS exists. Urodynamic studies are a very objective way of determining any degree of urologic impairment, and whether it is neurogenic in origin. Patients whose primary complaint is urologic, such as enuresis or failure to potty train, often can have a broad differential diagnosis for their issues. A collection of urodynamic tests,

including cystometry, uroflowmetry, abdominal leak point pressure, urethral pressure profile, stress testing, and postvoid residual volume determination, can often help isolate the extent and nature of urologic complaints. Patients with spina bifida have been known to exhibit detrusor hyperreflexia and dyssynergia, detrusor hypocompliance, impaired bladder sensation, and absence of a bulbocavernosus reflex.[89,90] Moreover, urodynamic studies can not only help in the diagnosis of a patient's urologic complaints, but are also valuable to track any decrease in function over time or potential improvement with surgical correction.[90–95]

Specific Spina Bifida Occulta

Lipomyelomeningocele

Lipomyelomeningocele is one of the most common forms of occult spinal bifida. As the name implies, a lipomyelomeningocele refers to the presence of a subcutaneous lumbrosacral lipoma that is contiguous with the neural and meningeal elements that have extended through a congenital defect in the dorsal bony spinal elements. These neural elements are often not well formed; instead, they form a neural placode, similar to that found in spina bifida aperta.[96] This arises from premature disjunction of the neural and epithelial ectodermal layers. When this step occurs before the neural tube is completely closed, mesenchymal elements insert themselves into the closing neural placode, eventually becoming a mass of fat that prevents complete neural tube closure.[97]

As previously mentioned, lipomyelomeningocele is among the most common of spina bifida occulta lesions, although this might be because it is easily diagnosed on physical examination and does not actually represent a higher prevelance.[67,68] Unlike some other forms of occult deformities, the fatty mass is typically visible at birth; thus, the diagnosis often can be made before neurologic sequelae arise.[64]

Since most children with the defect will go on to present with gradually worsening neurologic deficits, surgical correction is advisable in most cases.[98] Timing can be somewhat controversial; however, some authors advocate correction early in life before symptoms develop, while others recommend delaying treatment until signs of deficit present. Since the risks of surgery are not trivial, and not all children will progress to have a neurologic deficit with this lesion, it is certainly justifiable to delay surgery until deficits are apparent. Treatment involves the resection of the lipoma and release of any tethered neural elements, with the ultimate goal of preventing any traction on the spinal cord as the child grows. Since the lipoma is intimately related to the neural placode, residual fat almost always must be left in place in order to minimize any deficits to the patient. Moreover, since there is a dural defect as well, repair involves either primary dural closure or a duraplasty, depending on the size of the defect (Fig. 35.8). Due to the complex nature of the lesion and the need to leave fatty elements on the neural placode, the rate of symptomatic retethering is high, with as many as 20% of patients presenting with retethering issues in a 10-year period.[99]

Filum Terminale Syndrome

Filum terminale syndrome refers to the scenario of progressive TCS in the setting of a thickened filum terminale. The pathogenesis is thought to arise from either excessive fibrous tissue in the filum or a filum lipoma, causing reduced inelasticity. As the bony spine grows and elongates, this inelastic filum is thought to "tether" the spinal cord, causing chronic traction, tension, and eventual ischemia-related oxidative stress on the lower spinal cord.[100] Classic radiologic evidence involves the presence of an abnormally thick (>2 mm) or fat-containing filum and a low-lying conus medularis, frequently defined as below the mid-vertebral level of L2.[72,101] However, it has become clear that the conus can be in a normal position even in symptomatic patients. Treatment typically involves a microsurgical exploration with sectioning of the filum, and often the procedure can be done with minimal to no bony removal (Fig. 35.9). It is important to stimulate the thickened filum to ensure that there are no important motor roots involved. Timing for treatment is somewhat controversial, with some authors arguing for early intervention while others advocate observation until the development of symptoms.[97,102] Risks of surgery are quite low.

Occult filum terminale syndrome, defined as the presence of symptoms of tethered cord in the setting of normal radiologic findings, has recently been a topic of ongoing interest. Surgical intervention in patients without radiographic abnormalities is a notion that has been met with significant controversy, and requires very thoughtful consideration and careful patient selection. However, case series–level data of tethered cord release have reported an 87% rate of improvement in urologic dysfunction in such patients.[103] Patients who appear to have more classic sequelae of TCS, such as presence of multiple concurrent orthopedic, urologic, neurologic, and/or cutaneous sequelae, as well as those with documented urodynamic dysfunction, tend to have higher success rates with detethering.[104,105]

Sacral Agenesis and Caudal Regression

Congenital absence of any part of the sacrum is, by definition, indicative of sacral agenesis. When combined with other congenital malformations of the caudal spine, lower limbs, urogenital system, and anus/rectum, it is known as caudal regression syndrome. In one particular subform, there is complete agenesis of the lower half of the sacrum associated with an anterior presacral mass and anorectal stenosis, in a hereditary, autosomal dominant condition known as the Currarino syndrome (also known as Currarino triad).[106,107] Sacral agenesis has multifactorial origins, with known strong associations with maternal diabetes.[108]

When detected, treatment of sacral agenesis is often conservative. Sacral anomalies often require no treatment, and surgical intervention is required only in cases of symptomatic spinal tethering or when the presacral mass is symptomatic (Fig. 35.10).[109] It is important to recognize that when the distal spine fails to form, often the distal spinal cord fails to form. Therefore, the neurologic deficit is not from tethering, but

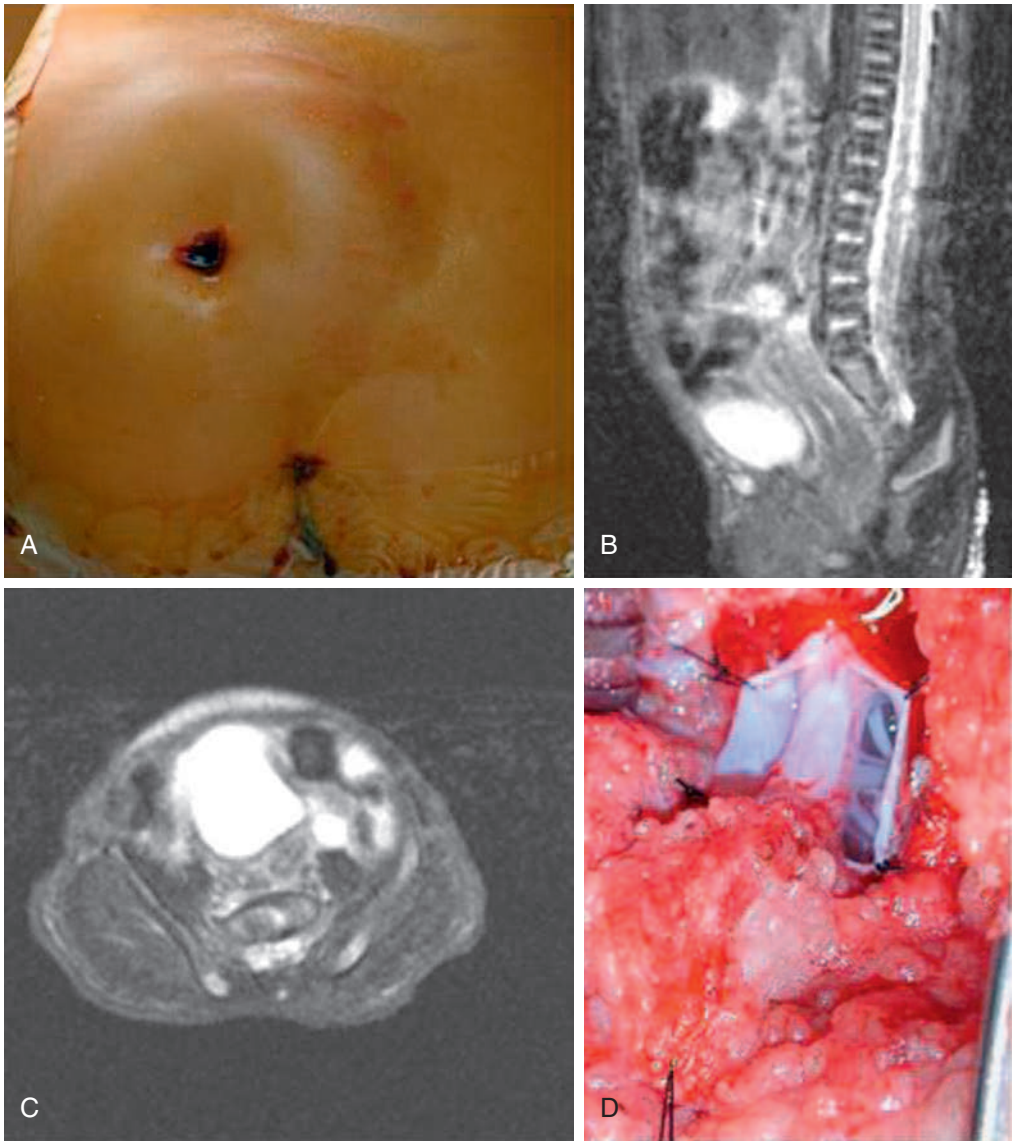

FIG. 35.8 Lipomeningocele. (A) The patient was noted to have a large mass in the back with an associated dimple at birth. (B) Sagittal fat-saturated T2-weighted magnetic resonance image showed evidence of low-lying conus. (C) Axial images showed evidence of fat past the conus. (D) At 6 months of age, after the dura was opened, a dorsal lipoma was found. A YAG laser was used to debulk the mass. Seven years later, the patient presented with symptoms of tethered cord and had to be detethered.

actually from absence of normal neural elements that cannot be fixed. Symptomatic dural stenosis can also be a feature in rare cases, with decompressive duraplasty being a necessary part of the repair.[110]

Congenital Dermal Sinus

Congenital dermal sinuses are abnormal tracts that communicate the overlying skin and the underlying intraspinal contents. As discussed previously, these are thought to arise from a focal failure of ectodermal separation.[75] The majority arise in the lumbrosacral region, though abnormal sinus tracts can develop all along the dorsal neuraaxis.[75] Though typically diagnosed based on observation of the tract on examination of the patient's skin, these lesions can also present with intraspinal infections, intradural dermoid or epidermoid cysts, focal neurologic deficits, and/or pain.[75,111,112] When encountered, surgical correction with intradural exploration and obliteration of the sinus tract is advised. This should be performed rapidly, as the complication of infection can turn a simple problem into a very complex one (Fig. 35.11).

Split Cord Anomalies

Congenital sagittal splitting of the spinal cord, known as split spinal cord malformation (SSCM) as well as diastematomyelia, are uncommon lesions with unclear embryologic origins. Two different subtypes exist, with SSCM type I lesions characterized as two hemicords with separate dural and arachnoid coverings separated by a bony cartilaginous septum, and SSCM type II lesions defined as those with a single dural and arachnoid sheath and fibrous septum dividing the two

hemicords.[113,114] (Fig. 35.12). Though the exact pathogenesis has yet to be determined, it is hypothesized that the condition arises from an accessory neurenteric canal that splits the neural plate. This canal may allow for the connection of endodermal and ectodermal elements, which can later be populated by mesenchymal cells that go on to form the dividing septum.[114,115]

Data on the natural history and treatment of these lesions are more limited, given their rarity. However, when encountered, prophylactic surgical treatment is generally considered, given the observation that children who present at older ages tend to have more significant deficits.[116] Surgical correction typically involves laminectomy, surgical removal of the intervening septum, and possibly reconstructive duraplasty, depending on the type of split cord abnormality. The association with other tethering lesions is very high; efforts should be made at the time of surgery to release concurrent tethering elements, such as fibrous bands, paramedian dorsal roots, and/or a thickened filum terminale.[117] Removal of the intervening septum before detethering is recommended if present because of the hypothetical risk of neurologic injury to the detethered cord if it recoils onto the septum.

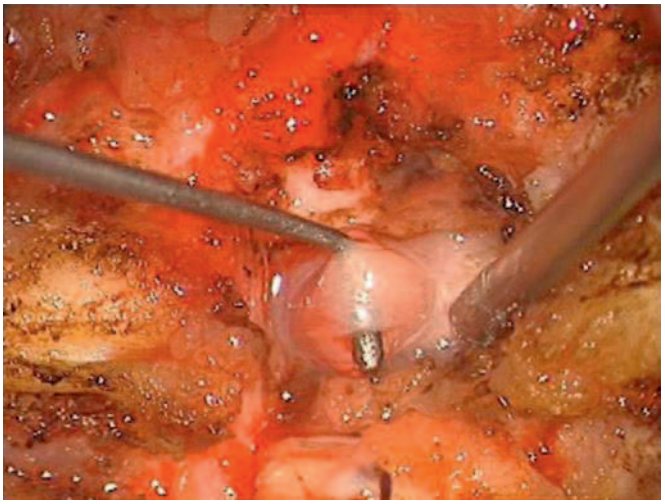

FIG. 35.9 Intraoperative findings in filum terminale syndrome. In this syndrome, a thickened filum terminale is found (elevated by a nerve hook). This is sectioned sharply after stimulating and ensuring that there are no involved motor roots.

Neurenteric Cyst

Neurenteric cysts are abnormalities that arise from focal persistence of parts of the neurenteric canal, which temporarily connects the amniotic sac and the yolk sac during the third week of gestation. Persistence of this canal can split the notochord and eventually lead to either abnormal attachments between ectodermal and endodermal elements, or a persistent

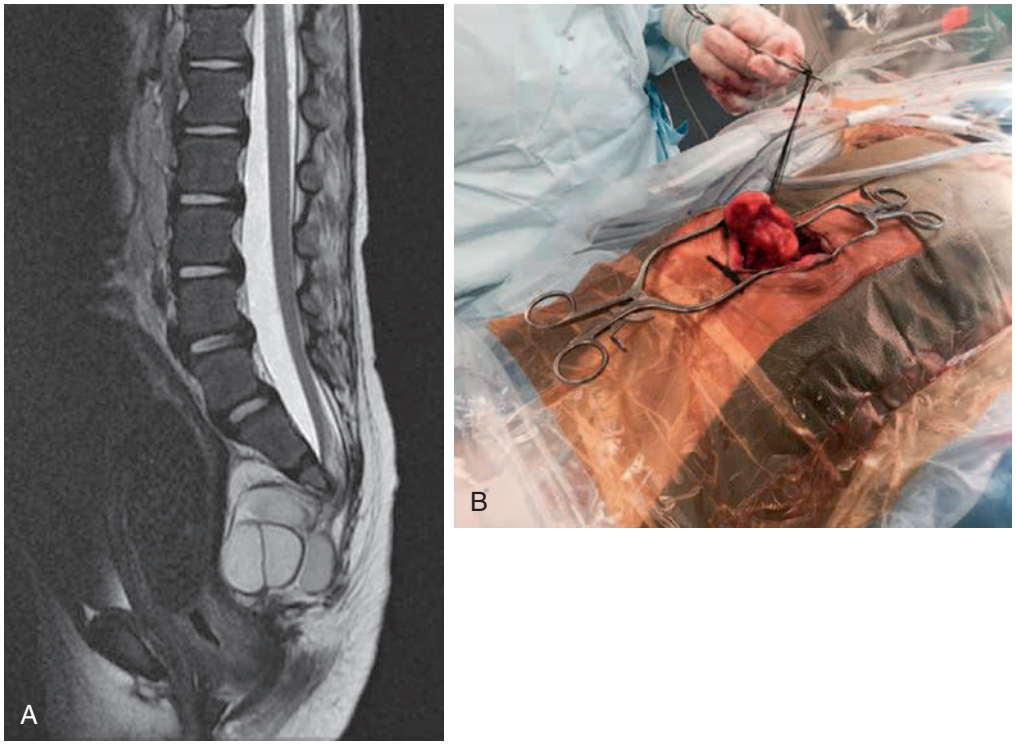

FIG. 35.10 Currarino syndrome in a 3-year-old female with chromosome 7 deletion with global developmental delay and microcephaly. She was found to have a sacral dimple. (A) T2-weighted sagittal magnetic resonance image showed a complex spinal dysraphism with a low conus ending in the sacral region attached to an intradural lipomatous mass, which was connected ventrally to a large presacral mass suggestive of a sacrococcygeal teratoma. The patient had chronic constipation. She was able to stand but not ambulate. Urodynamic studies were unremarkable. The patient underwent detethering of the conus and resection of the intradural fatty mass, which was found to contain hair and sebaceous material. (B) This mass was resected and disconnected from the ventral presacral mass. This mass was removed en bloc.

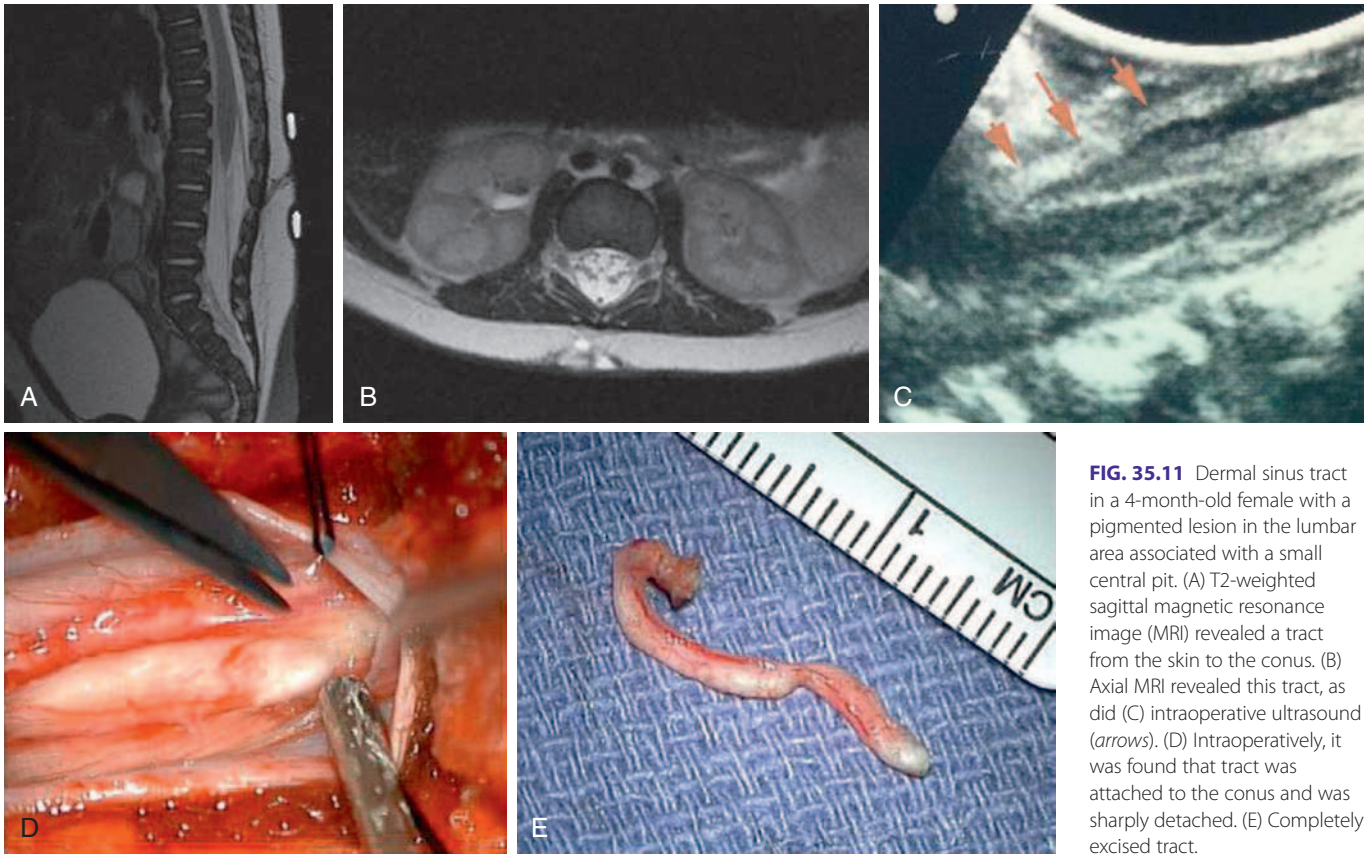

FIG. 35.11 Dermal sinus tract in a 4-month-old female with a pigmented lesion in the lumbar area associated with a small central pit. (A) T2-weighted sagittal magnetic resonance image (MRI) revealed a tract from the skin to the conus. (B) Axial MRI revealed this tract, as did (C) intraoperative ultrasound (*arrows*). (D) Intraoperatively, it was found that tract was attached to the conus and was sharply detached. (E) Completely excised tract.

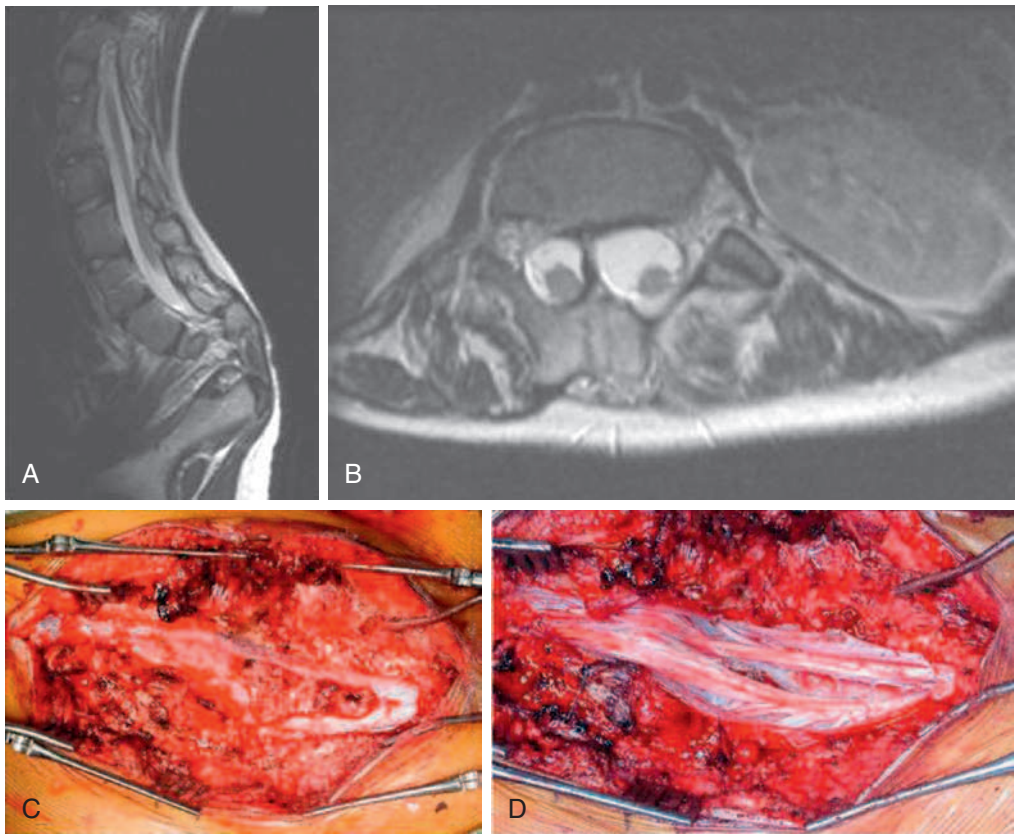

FIG. 35.12 Split cord syndrome in an 11-year-old girl with progressive scoliosis. She had severe distal lower extremity weakness, more marked on the left side than the right, with atrophy of both calves, more dramatic on the left, and weakness of both feet, more dramatic on the left. The patient also had a probable dermal sinus tract near the tip of the coccyx associated with a hair that entered the dermal sinus tract. (A) T2-weighted sagittal magnetic resonance imaging (MRI) revealed low conus, and (B) T2-weighted axial MRI revealed the presence of two dural tubes separated by a thick intervening bone. This separation appeared to extend into the thoracic spine. (C) Intraoperatively, a thick bony septum was found to separate the two dural tubes. (D) This was drilled off. The dura was closed primarily in the cephalad and rostral directions, but an allograft had to be placed where the bone was most prominent.

FIG. 35.13 Magnetic resonance imaging of cervical spine shows anteriorly placed neurenteric cyst compressing the spinal cord and causing myelopathy.

ventral cyst that goes on to be known as a neurenteric cyst[118] (Fig. 35.13). Neurenteric cysts are rare, with only case report and case series data available, but they have been known to occur throughout the neural axis.[119] The available data suggest that the natural history of these cysts is characterized by recurrent ruptures, gradual enlargement, and progressive motor weakness. As such, surgical excision is recommended.[120] Extramedullary lesions can often be excised completely, but intramedullary lesions may lack a clear cyst wall; thus, subtotal resection may be the best achievable result in certain cases.[120]

Conclusion

Spinal dysraphism represents a wide spectrum of abnormalities that may affect the spinal cord, and should be considered when assessing a spine patient—especially when they are "unknowns," such as onset scoliosis or lower extremity deformity. The spectrum of types of abnormality and complicated presentations makes these challenging diagnoses. The best treatment, with respect to both timing and type of intervention, is not always evident. The clinician must understand surgical and medical nuances of treatment, and these patients need long-term follow-up due to the risk of recurrence, as well as a strong support system due to the associated dysfunction of the bowel/bladder, lower extremity, and urogenital systems. Associated brain anomalies are often present as well. A multidisciplinary team—including a neurosurgeon, orthopedic surgeon, urologist, and specialized primary care physician—is necessary to ensure that the best care is delivered.

More work on uncovering genetic and environmental factors for the development of these defects will hopefully lead to measures to decrease their incidence. Prenatal surgery might offer hope as an alternate treatment option for spina bifida aperta, though it is clear that there are increased risks to the mother and more long-term follow-up is needed. ETV is reducing the need for shunts to treat hydrocephalus in these individuals, which is an exciting new development. Most important, as more of these children enter adulthood, for a disease that previously had a significantly reduced life expectancy, adult practitioners need to be more familiar with the condition.

36 CHAPTER Cervical Spinal Disorders Associated With Skeletal Dysplasias and Metabolic Diseases

Bruce V. Darden II
Christopher O'Boynick
Jose Manuel Casamitjana

The sheer number of skeletal dysplasias and metabolic diseases associated with spinal disorders makes the topic quite daunting. This number is constantly growing and the boundaries are being redefined as modern medicine works to understand these complex entities. The limited literature on these topics does little to cover their wide gamut of pathologies. Notwithstanding the rarity of their presentation, it is vital that practitioners have a grasp on some of the key features of these diseases to accurately diagnose and select an appropriate treatment plan. Examination of these individuals with an awareness of the more commonplace cervical abnormalities is the safest option.

Skeletal Dysplasias and Metabolic Diseases

Skeletal dysplasias are typically identified at birth secondary to physical findings, family history, and imaging studies. The archetypal physical findings are body length and body proportions. Workup is indicated for any infant born to average-sized parents with a height below the fifth percentile and is also warranted if the child should ever move below the fifth percentile as he or she grows. These dysplasias typically come in one of two forms. The first is short limbs with a relatively normal trunk; the other is a short trunk with relatively normal limbs. It is important, but beyond the scope of this chapter, to identify the site of limb shortening. This can be in the proximal or distal aspect of the limb. Radiographs can be helpful to identify the affected region, whether it be the metaphysis or the epiphysis.

Mucopolysaccharidoses (MPS) are a group of several syndromes resulting from an abnormal metabolism of mucopolysaccharides. Many of these conditions are associated with short stature, thoracolumbar kyphosis, and cervical spine abnormalities. Diagnosis typically requires serum and urine markers. Accuracy of diagnosis is paramount, as there is significant variability in prognosis and treatment options between the syndromes.

Patient Evaluation

As with any pediatric condition, examination can be difficult, but it is paramount to a successful diagnosis. A meticulous history from the parent—including activity level, milestones, and bowel and bladder dysfunction—is very important. Children afflicted with these conditions rarely complain of pain.

A complete neurologic examination must be performed. Serial evaluations can be helpful to gauge progression of any condition. Distracting conditions related to the underlying disease, such as lower extremity deformities, can make examination more difficult and must be taken into account.

Imaging

Plain radiographs of the cervical spine are recommended as part of any evaluation. These should include sitting or standing anteroposterior and lateral views. Radiographs allow evaluation of the osseous structures of the cervical spine. Some of these conditions result in delayed ossification of the cervical elements and limit the usefulness of radiographs. Table 36.1 outlines imaging techniques and the abnormalities best visualized with each technique.

Flexion-extension lateral films focused on the occipitocervical junction are very useful for diagnosing instability (Fig. 36.1). Communication with the patient, family, and radiology staff about the goals of this procedure is necessary to obtain quality images. These images allow a measurement of key parameters related to upper cervical instability and upper cervical stenosis. It is important to know the normal values of cervical radiographic parameters when assessing patients with cervical deformities. These measurements include the anterior atlantodens interval (AADI) and the space available for the cord (SAC). The AADI measures the distance from the dens to the posterior border of the anterior arch of the atlas, and should be less than 5 mm in a normal child during flexion.[1] The SAC is a measurement of the distance from the

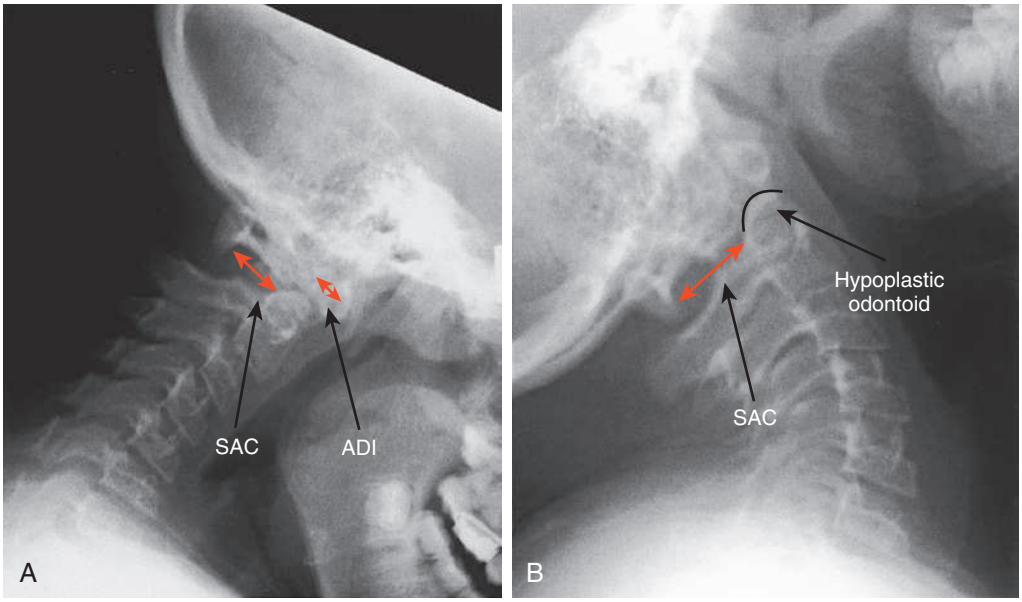

FIG. 36.1 (A) Extension and (B) flexion films focused on the occipitocervical junction can be very helpful in diagnosing instability. These images of a child with spondyloepiphyseal dysplasia congenita demonstrate instability in extension with the front of C1 riding over the hypoplastic odontoid. ADI, atlantodens interval; SAC, space available for the cord.

TABLE 36.2 Upper Cervical Spine Radiographic Parameters

Radiographic Parameters	Normal Values
Anterior atlantodens interval	Adult normal: <3.5 mm in flexion Child normal: <4.5 mm in flexion Abnormal: >5 mm
Space available for the cord at C2	Infant: 13 mm 3–6 y: 18 mm 7–10 y: 19 mm 11–14 y: 19.4 mm

dens to the anterior edge of the posterior ring of the atlas; the range of normal values can be found in Table 36.2.[2] An increasing AADI or a decreasing SAC can be indicative of instability and/or stenosis.

Computed tomography (CT) allows a more detailed examination of the bony anatomy, and is particularly useful in assessing the upper cervical spine. The quality of the images and the ability to create three-dimensional reconstructions based on CT data can be helpful tools for preoperative planning (Fig. 36.2). CT scans expose the pediatric patient to a significant amount of radiation, however, and thus should be used sparingly and only when absolutely necessary.

Magnetic resonance imaging (MRI) is another very useful tool for evaluating the cervical spine in patients with cervical deformity. MR images take more time to acquire than CT images and often require sedation to obtain satisfactory images. MRI is a very sensitive tool for detecting stenosis, cord compression, cord signal changes, and other cord abnormalities (Fig. 36.3). With the advent of flow-sensitive MRI techniques and magnetic resonance angiography (MRA) protocols, a complete picture of cerebrospinal fluid (CSF) dynamics and cerebral blood flow can also be assessed.

As with lateral C-spine radiographs, flexion-extension MRI can be performed to identify dynamic cord compression versus a fixed stenosis. Positioning is critical in these patients. A forced flexion position in a sedated child with undiagnosed atlantoaxial instability can have dire consequences. The child should be placed on a bolster, allowing the neck to fall into a neutral or extended position. The flexion position should be avoided until confirmation of a patent spinal canal.

Ultrasound has a limited role early in development and can be used to evaluate the spine and spinal cord in patients up to 6 months of age.[3,4]

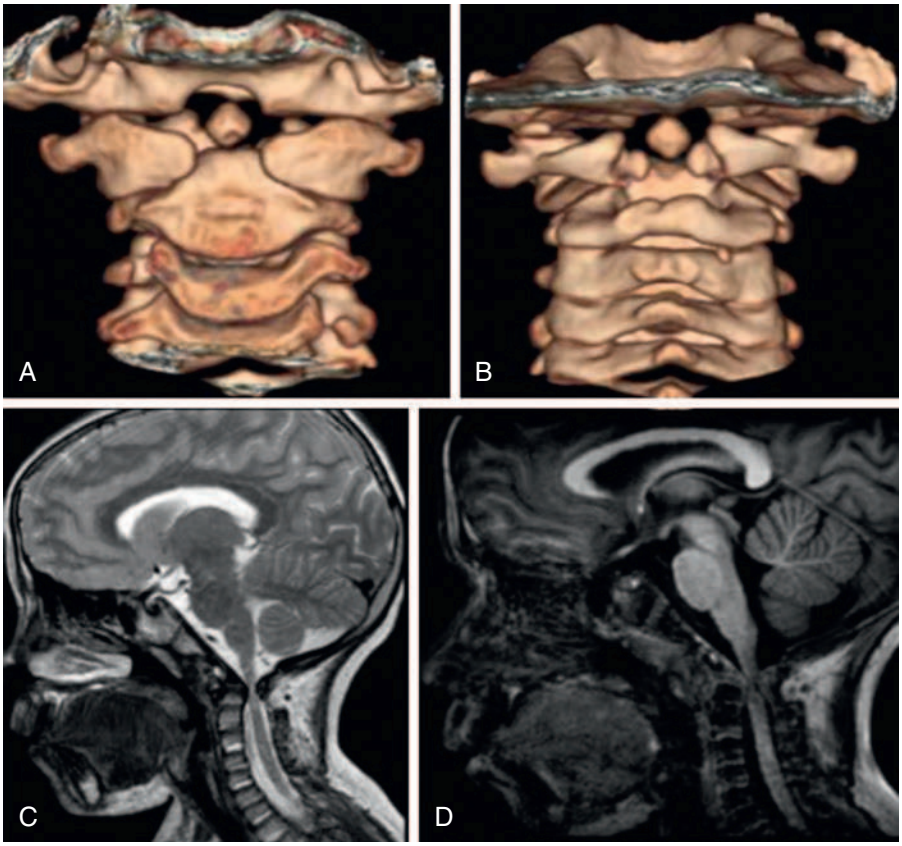

FIG. 36.2 (A–B) Three dimensional reconstructions of the upper cervical spine can aid in visualization of the complex deformities associated with these conditions and are helpful for preoperative planning. Computed tomography allows visualization of an os odontoideum in a child with Morquio syndrome. (C–D) Magnetic resonance imaging demonstrates the hypertrophied ventral soft tissue associated with Morquio syndrome that leads to craniocervical stenosis.

Treatment

These complex patients require a multidisciplinary approach. They are best served at high-volume centers with the training and facilities necessary to accommodate them. This would include a pediatric anesthesia team practiced in the intubation, positioning, and anesthetic requirements unique to these patients and procedures. Postoperatively, they will require care in the pediatric intensive care unit (ICU) and will need a treatment team familiar with the features of these conditions.

Children with skeletal dysplasias and metabolic syndromes typically fall into one of four categories when it comes to management. These include observation, observation with restrictions, relative indications for surgery, and absolute indications for surgery. The following section highlights the general principles of treatment. Specific treatment options are discussed later in the chapter as they apply to each condition.

Patients with skeletal dysplasia without evidence of neurocompromise or instability can be followed serially with observation. At a minimum, neurologic examination and cervical radiographs should be completed at each visit. Any change in neurologic examination would warrant an MRI.

A subset of patients will have radiographic evidence of mild, nonprogressive instability. These patients are best managed with a restriction from high-risk activities that would put their upper cervical spine at risk. Sports such as football, diving, and gymnastics should be included on this list. Communication about the risk associated with their condition is necessary when limiting activities.

A normal neurologic examination with radiographic evidence of significant stable kyphosis, with an AADI of 5 to 8 mm, or decreased SAC on MRI demonstrates relative indications for surgical intervention.

Absolute indications are reserved for patients with neurologic compromise, cord lesions, AADI greater than 8 mm, progressive kyphosis, and/or a dynamic instability resulting in severe reduction of the SAC.

The surgical procedure of choice is dependent on the underlying disease and surgical lesion. Treatment options include decompression, fusion, and decompression with fusion. Decompression should be reserved for patients with stenosis but without instability in a neutral or lordotic cervical spine. The concern with decompression alone is postlaminectomy kyphosis. Fusion alone is performed in patients demonstrating a dynamic instability that results in neurologic compromise without a fixed stenosis.[5–7] Decompression and fusion should be used to treat stenosis and instability and should also be used in those conditions associated with a postlaminectomy kyphosis.[8,9] Ventral procedures, including corpectomies and

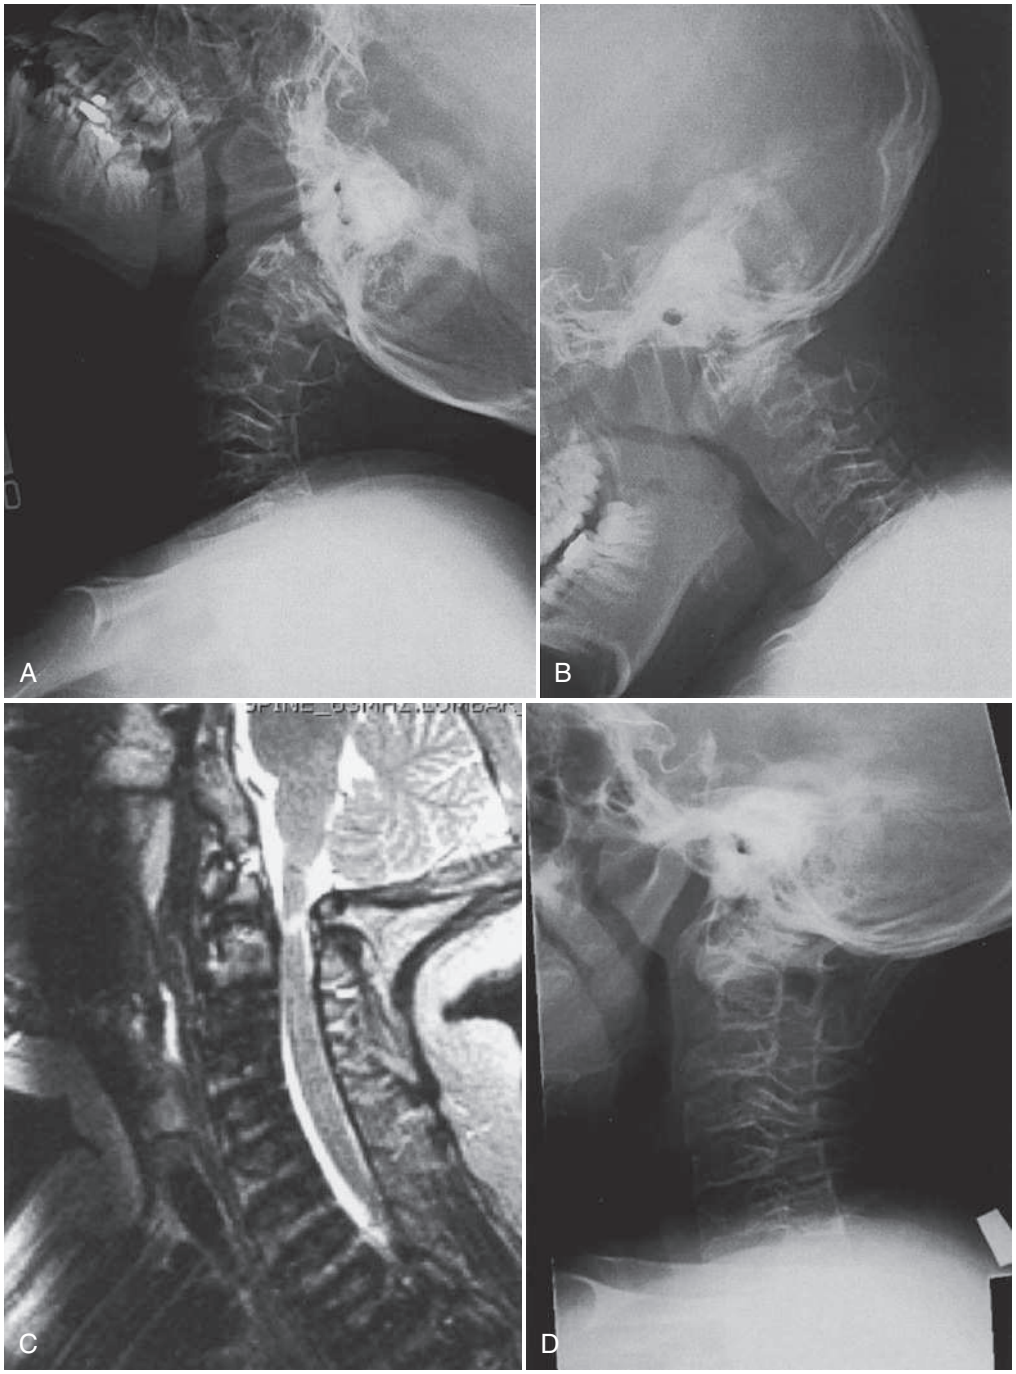

FIG. 36.3 (A–B) Flexion and extension radiographs demonstrating hypermobility at the C1–C2 joint. (C) Magnetic resonance imaging revealing signal changes within the cord secondary to compression. (D) Radiograph of the upper cervical spine after a noninstrumented occiput to C2 fusion.

strut grafting, should be reserved for conditions that result in a progressive kyphosis.[10]

Specific techniques of arthrodesis are beyond the scope of this chapter and have been previously described by multiple authors.[6,11,12] Close adherence to their described techniques should result in favorable outcomes. These procedures can be performed with or without internal fixation; the dysplastic anatomy is often the deciding factor regarding its implementation.[13,14] Preoperative CT scans with reconstructions and intraoperative navigation systems are excellent tools to aid in successfully instrumenting a deformed spine.[15]

In the setting of these procedures, diligent communication about the indications, anticipated outcomes, and possible complications is very important.

Postoperative immobilization is usually achieved by a halo or a brace. This will depend on the age and size of the child being treated. At a minimum, the halo should be MRI compatible. Pediatric patients require six to eight pins and have a lower torque allowance due to cranial size, skull thickness, and incomplete ossification. Regardless of the device, immobilization is maintained until radiographic evidence of solid fusion mass is identified.

Complications

Postoperative complications can be divided into early and delayed categories. Early complications include respiratory difficulty, wound drainage, and neurologic injury. Delayed complications include pseudarthrosis, infection, juxtafusional breakdown, and complications related to halo traction.

Respiratory difficulty is often multifactorial. These patients often have underlying lung and/or chest wall abnormalities that prevent normal lung function. Halo cast application and prolonged intubation superimposed on these preexisting conditions can lead to complications. Supportive ventilation techniques can be employed. As with all surgical patients, aggressive pulmonary toilet and rapid mobilization still remain the best options to prevent these complications.

Durotomy rates are increased in some forms of skeletal dysplasia. Shunting and duraplasty techniques at the time of index procedure can help to reduce this complication. CSF leaks can lead to wound compromise and breakdown.[12,16]

Neurologic injury typically results from a direct trauma to the spinal cord. In patients with preoperative neurologic compromise, the cord is already in a traumatized state and may be prone to added insult. In achondroplasia, it is recommended that no instruments be placed into the spinal canal secondary to the already reduced canal size. Neurologic injury can occur with or without instrumentation being placed in the spinal canal.[12,17] Somatosensory and motor evoked potentials should be considered in all cases to help reduce positional and instrument-related neurologic injury.[18]

Successful fusion has been linked to the use of autograft bone, meticulous surgical technique, and the use of internal fixation.[5,6,11,12] Numerous studies have outlined increased pseudarthrosis rates when allograft bone was utilized.[19,20] C1–C2 fusion rates were doubled with use of the transarticular screw technique over the sublaminar wiring technique in a study by Farey et al.[15]

Skeletal Dysplasias

Achondroplasia

Achondroplasia is by far the most common skeletal dysplasia routinely evaluated in the spine surgeon's office. This genetic defect of fibroblast growth factor receptor 3 function results in highly specific characteristics that make it recognizable at birth. These findings include rhizomelic extremities along with frontal bossing and nasal bridge depression. Head-to-body ratio can also be larger in patients with achondroplasia. Infants with this condition typically present with hypotonia in the trunk and extremities.

Stenosis of the craniocervical joint and upper cervical spine is present in nearly 60% of individuals.[21] However, all patients with achondroplasia have some component of foramen magnum stenosis. CT-based measurements have demonstrated a foramen magnum size three deviations below the mean in more than 90% of patients.[16] It is smaller than normal in all age-matched controls and has no association with head circumference.[22] This compression has two etiologies. The first is direct impingement of the spinal cord on the posterior rim of the foramen; the second is due to an invagination process of the foramen into the ring of C1.[23] Hecht et al.[22] reports that nearly one-third of these patients demonstrate symptoms of spinal cord compression, including sleep apnea, hypotonia, and quadriparesis. These factors all contribute to an increased risk of death in the first year of life.[24] Infants affected with this condition require careful neurologic examination, sleep laboratory studies, CT, and MRI evaluations during infancy. In addition to these tests, somatosensory evoked potentials have demonstrated excellent efficacy in diagnosing cervical myelopathy.[25,26]

Despite the plethora of diagnostic modalities, there still remains no consensus on patient selection or timing for operative intervention. Wang et al.[23] did correlate measurements of the foramen magnum with those who required decompression. The cross-sectional area of 239 mm^2 was found to be half that of normal controls.[23] Nelson et al.[25] found that cervicomedullary decompression was successful in reducing sleep apnea and improving sleep study results in affected patients. The abnormal CSF dynamics associated with achondroplasia result in a high rate of CSF leaks postoperatively and often benefit from the use of external ventricular drainage systems at the time of decompression.[16,27] Cervicomedullary decompression has been used successfully to treat a number of symptoms secondary to upper cervical stenosis; some authors go as far as to suggest that asymptomatic individuals with signal changes within the cord should also be treated.[28,29] Wassman et al.[30] prefer nonoperative management with continued sleep apnea monitoring while awaiting the natural enlargement of the foramen as the child matures.

Cervical stenosis in the subaxial cervical spine can also occur in patients with achondroplasia. While congenitally stenotic, subaxial cervical stenosis typically does not present until adulthood and is the result of the typical degenerative processes associated with normal individuals.[26,31] If symptoms of pain and/or weakness are present and are recalcitrant to nonoperative modalities, cervical decompression is the treatment of choice.[32,33] This can be done with laminectomy or laminoplasty per surgeon preference, along with selective foraminotomies, as indicated by imaging. Fusion is typically not necessary.

Cervical instability is relatively common in most skeletal dysplasias but is very rare in achondroplasia.[34,35]

Pseudoachondroplasia

Pseudoachondroplasia is a short-limbed form of dwarfism resulting from a defect in the cartilage oligomeric matrix protein. This results in a similar disruption to body proportions akin to that of achondroplasia, but that is where the similarities end.

Pseudoachondroplasia is associated with a generalized ligamentous laxity that results in atlantoaxial instability that increases with age.[36] It can also result from an os odontoideum and to a lesser extent odontoid hyperplasia or any combination of these factors.[5,36] Regardless of the cause, patients with this condition require lateral flexion and extension radiographs

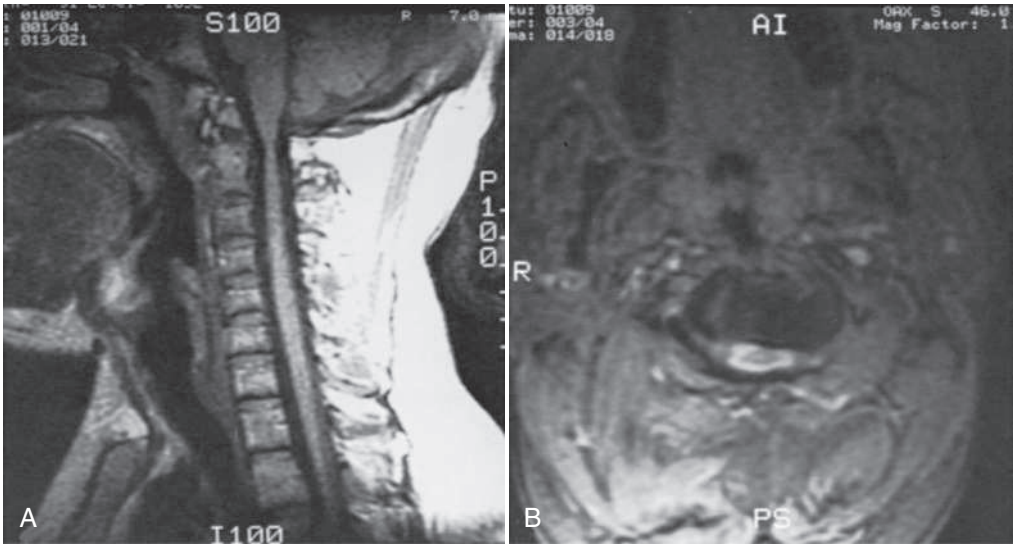

FIG. 36.4 (A) Sagittal and (B) axial magnetic resonance images of a patient with pseudoachondroplasia demonstrating marked stenosis at C1–C2. Note that the subaxial cervical spine demonstrates a normal spinal canal diameter without congenital stenosis.

prior to undergoing any procedure requiring intubation. Any instability that results in neurologic symptoms requires surgical fixation.

While achondroplasia results in severe congenital spinal stenosis, pseudoachondroplasia patients have a normal spinal canal diameter and relatively normal-sized bony anatomy; thus they can tolerate standard instrumentation (Fig. 36.4).

Spondyloepiphyseal Dysplasia

Spondyloepiphyseal dysplasia comes in two forms. The tarda type has a minimal effect on the cervical spine and is not discussed here. The congenital type is strongly associated with atlantoaxial instability secondary to ligamentous laxity, odontoid hypoplasia, or os odontoideum.[5,37–39] This condition results from a defect in type II collagen. Diagnosis is based on imaging findings of delayed ossification centers in the setting of a shortened trunk.[40]

Atlantoaxial instability presents in up to 50% of children with this condition.[41,42] Diagnosis can be made as early as in the first year of life and is usually associated with delayed motor milestones. This instability can occur in flexion or extension. Radiographic diagnosis can be difficult due to the delayed ossification of the posterior elements in this condition as well as the generalized flexibility of the juvenile cervical spine. Flexion-extension sagittal MRI is useful in this situation to quantify the amount of motion at this segment and to identify any stenosis or signal change within the cord. A patient with a normal MRI and less than 5 mm of translation on lateral C-spine films can be treated conservatively. If more than 5 mm of translation is visible on radiographs or there is evidence of spinal cord compression or cord signal change, then fusion without decompression is indicated. Decompression is reserved for patients with severe stenosis and myelopathy.[43]

The decision on the number of fusion levels is up to the discretion of the treating surgeon and may depend on the amount of ossification posteriorly in addition to the direction of instability. Fixation can be performed with or without halo application (Fig. 36.5). It is recommended that evoked potentials be monitored during the initial positioning as well as during the procedure. Ain et al.[44] demonstrated a better than 90% fusion rate with a similar rate of neurologic improvement in patients with atlantoaxial instability in the setting of skeletal dysplasia.

Kniest Dysplasia

Kniest dysplasia is another condition resulting from a defect in type II collagen production. From a cervical spine standpoint, this condition is very similar to spondyloepiphyseal dysplasia and results in atlantoaxial and occipitoatlantal instability.[44–47] Again, serial radiographs and sagittal flexion-extension MRIs can be used to determine any need for stabilization. The indications for surgical fixation are similar to those for spondyloepiphyseal dysplasia.

Metaphyseal Chondrodysplasia

The McKusick type, or cartilage-hair dysplasia, results in ligamentous laxity and atlantoaxial instability.[48,49] This condition has multiple physical abnormalities and is often associated with immunodeficiency.[48,49]

Metatropic Dysplasia

This condition arises from an uncoupling of endochondral and perichondral growth and results in short stature and dumbbell-shaped long bones.[50] Similar to most of the other dysplasias, atlantoaxial subluxation is a concern secondary to odontoid hypoplasia.[51] This condition has been associated with rotatory subluxation following failed fusion as well as C2–C3 instability due to anatomic abnormalities of the C2 lateral mass.[6] Leet et al.[52] has associated this condition with cervical spinal stenosis and identified patients

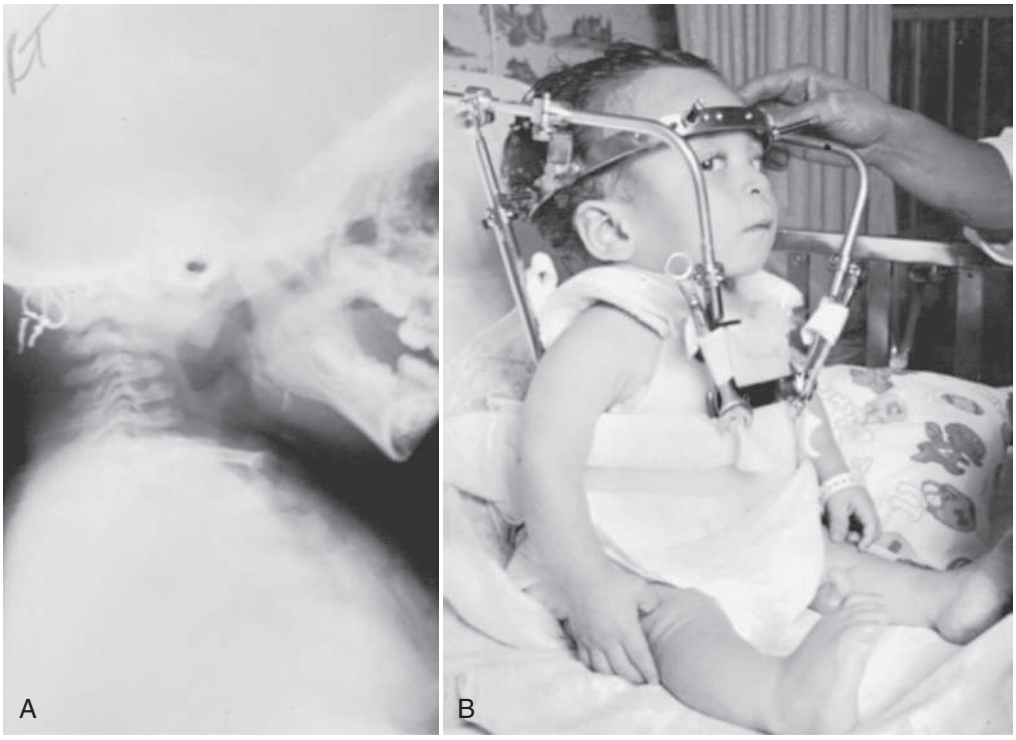

FIG. 36.5 (A) Radiograph of occipitoaxial wiring of an 18-month-old child with instability secondary to spondyloepiphyseal dysplasia. (B) Halo bracing can be used preoperatively, intraoperatively, and postoperatively to aid in reduction and to maintain stability when attempting fusion.

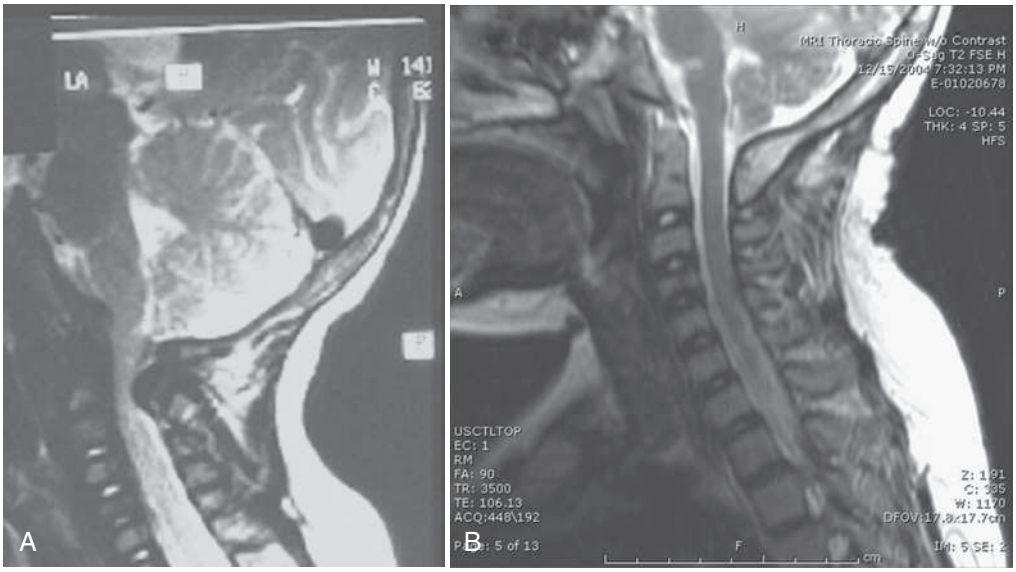

FIG. 36.6 (A) Preoperative and (B) postoperative images of a child with chondrodysplasia punctata treated with C1 laminectomy with occipitocervical fusion for cord compression. Postoperative magnetic resonance image shows a patent craniocervical junction without cord signal changes.

who may need decompression along with atlantoaxial fusion procedures.

Chondrodysplasia Punctata

This condition is characterized by short limbs, ichthyosis, and flat facial features. It has been associated with cervical cord compression from atlantoaxial instability (Fig. 36.6) as well as congenital cervical stenosis.[53] These patients can have subaxial kyphosis along with subluxation in the cervical spine, requiring radiographic and MRI evaluation.[54–57] Due to the dysplastic nature of the vertebral bodies and their association with kyphosis, a 360-degree fusion is recommended.[58]

Diastrophic Dysplasia

Diastrophic dysplasia arises from a defect in diastrophic dysplasia sulfate transportase. This condition has several key features associated with its diagnosis, including "hitchhikers thumb," "cauliflower ear," micromelia, and short stature.

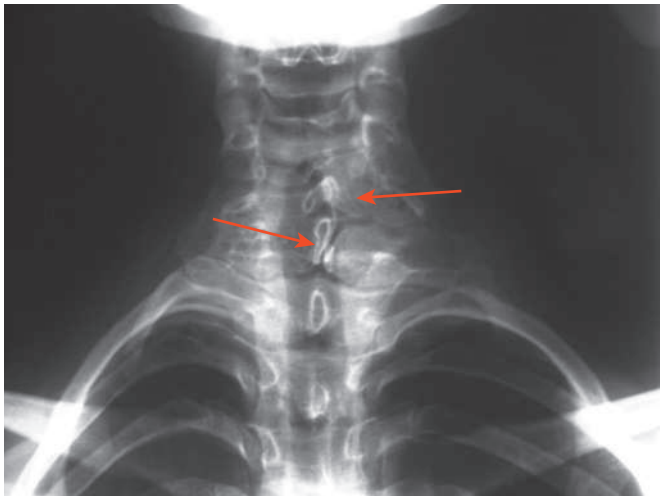

FIG. 36.7 Anteroposterior radiograph of the cervical spine demonstrating multilevel spina bifida common to diastrophic dysplasia.

FIG. 36.8 Progressive cervical kyphosis typically requires 360-degree fusion procedures, as illustrated in this radiograph of a child with diastrophic dysplasia.

These patients all demonstrate spina bifida of the cervical spine (Fig. 36.7).[59,60] Upper cervical instability and upper cervical stenosis is not as common in diastrophic dysplasia as it is in some of the previously mentioned conditions, but it has been reported.[61,62] Perhaps the hallmark cervical abnormality associated with this condition is midcervical kyphosis (Fig. 36.8).[63,64] This may result from a combination of vertebral body wedging, ligamentous laxity, and the aforementioned cervical spina bifida.[10,60,65] This condition tends to resolve as the patients age.[59,65] In some cases, the kyphosis does not resolve and fusion becomes necessary. Kyphosis of greater than 60 degrees at initial evaluation has been linked to progression and can ultimately result in dire consequences.[59,65] Postmortem examinations of the spinal cord demonstrate changes in the anterior columns consistent with anterior cord compression. Kyphotic progression without neurologic compromise can be treated with posterior fusion alone. This posterior tethering allows for a gradual correction of the kyphosis as the anterior column continues to grow. In those instances in which neurocompromise is suspected, a 360-degree fusion should be considered. Decompression must occur anteriorly and kyphosis correction must be done carefully. Caution must also be used posteriorly during the exposure secondary to the high incidence of spina bifida.

These patients also develop cervical spondylosis as early as the second decade of life, which requires long-term follow-up.[61]

Camptomelic Dysplasia

Camptomelic dysplasia arises from a defect on the *SOX9* gene. Similar to diastrophic dysplasia, this condition results in cervical kyphosis, with an incidence of about 40%.[66–68] Treatment options are similar to those mentioned previously. However, the deformity and neurologic compromise in these patients often do not respond as favorably to fusion as they do in diastrophic dysplasia.[66–68]

Larsen Syndrome

This is a rare genetic condition of variable inheritance resulting from a mutation in the *filamin B* gene. This disrupts the normal skeletal development. Patients with Larsen syndrome often develop a progressive cervical kyphosis and should be managed similarly to patients with diastrophic dysplasia.[69]

22q11.2 Deletion Syndrome

This microdeletion has been linked to numerous syndromes, including velocardiofacial syndrome, DiGeorge syndrome, and conotruncal face anomaly syndrome. This syndrome is associated with multilevel hypermobility in addition to several bony abnormalities of the upper and subaxial cervical spine. All of these abnormalities can lead to significant instability and cervical stenosis.[69] Surgical treatment is specific to each individual and dependent on the deformities present.

Mucopolysaccharidoses

Hurler Syndrome: Mucopolysaccharidosis Type 1

This condition is associated with atlantoaxial instability and is typically a result of odontoid dysplasia.[70,71] Myelopathy can develop in these patients secondary to abnormal soft tissue formation on the tip of the dens. With the advent of bone marrow transplantation and enzyme replacement, there have been documented cases of resorption of this mass and resolution of symptoms.[72,73] These masses resolved slowly over the course of nearly 9 years.[73]

Hunter Syndrome: Mucopolysaccharidosis Type 2

Hunter syndrome is a lysosomal storage disease secondary to a defect in iduronate-2-sulfatase. The mucopolysaccharide is

deposited posterior to the dens and can result in spinal stenosis.[74] Cervicomedullary decompression, along with laminectomy down to the subaxial cervical spine, is the recommended treatment for this condition.[75]

Morquio Syndrome: Mucopolysaccharidosis Type 4

Morquio syndrome comes in two varieties depending on the genetic defect and the resultant mucopolysaccharide that ultimately accumulates. This condition is perhaps the most severe of the metabolic syndromes as it relates to the craniocervical junction. Odontoid hypoplasia results in atlantoaxial instability, while ventral extradural soft tissues continue to hypertrophy and ultimately narrow the craniocervical junction.[76–78] This instability in the setting of severe stenosis has been linked to progressive myelopathy, quadriplegia, and sudden death.[79] The amount of hypertrophied tissue appears to correlate more with neurologic symptoms than does the odontoid dysplasia or direction of subluxation. As previously mentioned, workup typically includes flexion-extension radiographs and a flexion-extension MRI (Fig. 36.9). Criteria for fusion are similar to those mentioned for skeletal dysplasia, and fusion is recommended secondary to the high incidence of neurologic injury and poor recovery of myelopathic patients.[17,79] The hypertrophic craniocervical tissues tend to resolve after fusion, but direct anterior decompression can be performed transorally for significant compression (Fig. 36.10).[80,81]

Summary

The topic of cervical spine abnormalities associated with skeletal dysplasias and metabolic disease can be daunting.

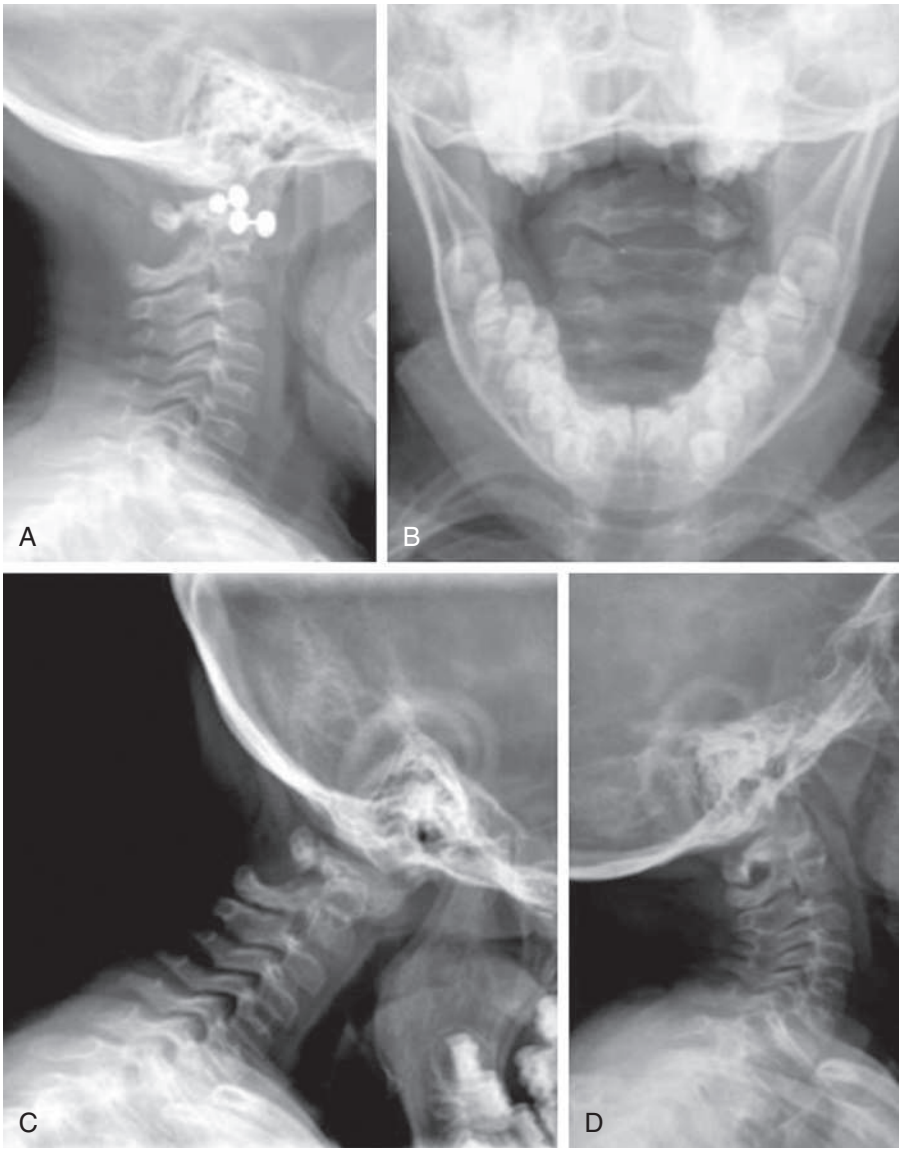

FIG. 36.9 (A–D) Plain radiographs of a child with Morquio syndrome. (B) The open-mouth view demonstrates hypoplasia of the odontoid. (C) Flexion and (D) extension views reveal a flexion instability with greater than 5 mm of motion. This is most easily visualized based on the relationship of the posterior ring of C1 to that of C2.

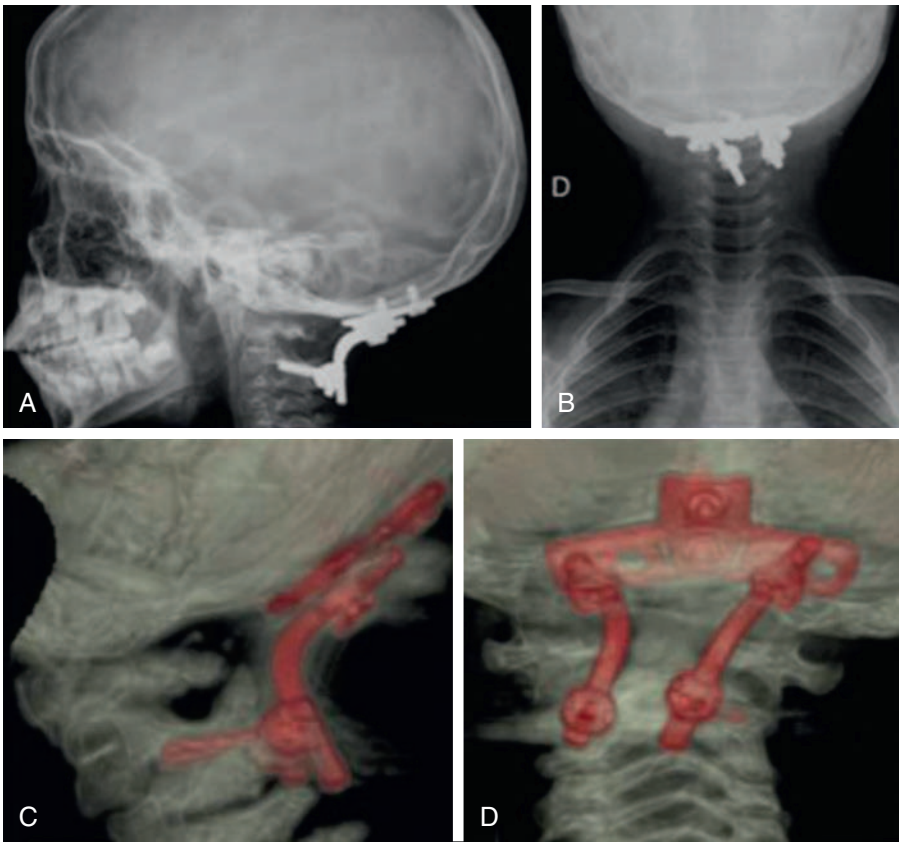

FIG. 36.10 Postoperative images of a child with Morquio syndrome following occiput to C2 fusion for a flexion instability.

Modified from Mackenzie WG, Shah SA, Takemitsu M. The cervical spine and skeletal dysplasia. In: Benzel EC, et al, eds. *The Cervical Spine,* ed 5. Philadelphia: Lippincott Williams & Wilkins; 2012:408–428.

While advances are made every day in diagnosis and medical management, surgical treatment of these patients evolving pathology remains the only option. Early recognition and accurate diagnosis of the underlying condition is vital. Table 36.3 serves as a quick reference guide for the syndromes discussed and their associated abnormalities.[82] A knowledge of the typical manifestations associated with each syndrome and an understanding of their workup will help to quickly and safely treat these patients.

37 CHAPTER Pathophysiology, Natural History, and Clinical Syndromes of Cervical Disc Disease

Sreeharsha V. Nandyala
A. Jay Khanna
Hamid Hassanzadeh

Cervical disc disease refers to a cascade of degenerative changes that results in spondylosis, which is the most common disorder in the aging adult cervical spine.[1] Spondylosis is often clinically benign and is ubiquitous within the population.[2,3] Radiographic evidence of cervical spondylosis is purported to be present in 25% of adults younger than 40 years of age, 50% of adults older than 40 years, and 85% of adults older than 60 years.[3,4] By age 65 years, 95% of individuals have radiographic findings suggestive of cervical spondylosis.[1]

The etiology of cervical spondylosis and stenosis can be classified into static and dynamic factors.[5,6] Static factors include congenital spinal stenosis, herniation of disc material, osteophytosis, and ligamentous hypertrophy and infolding (Fig. 37.1).[7] Conversely, the dynamic factors are characterized by motion aberrations (translation and angulation) that act on the spinal column during movement.[5] The combined effect of both the static and dynamic factors can decrease the sagittal diameter of the spinal canal and potentiate central and neuroforaminal compression.[8,9]

A multitude of biochemical and biomechanical abnormalities are associated with disc desiccation. Alterations—including a relative increase in the ratio of keratin sulfate to chondroitin sulfate, dehydration, and the loss of protein and mucopolysaccharides—have been described.[10,11] These changes decrease the viscoelasticity of the intervertebral disc, thereby promoting fibrosis and loss of disc height. The disc height loss occurs at a relatively greater magnitude in the ventral portion of the disc and results in a diminution of the normal cervical lordosis.[12] This facilitates the elongation of the ventral moment arm and causes ventral vertebral body compression and, eventually, kyphosis of the cervical spine.[12] In addition, the loss of disc height will cause hypertrophy and infolding of the ligamentum flavum and the facet joint capsule, further diminishing the dimensions of the spinal canal and the neuroforamina.

The greater loading forces that act on the ventral aspect of the cervical spine owing to disc height loss are transmitted to the uncovertebral and facet joints. In addition to promoting joint hypertrophy, the greater loads facilitate osteophyte formation at these joints and at the bare edges of the vertebral bodies. Furthermore, the shear biomechanical forces will separate Sharpey fibers and the peripheral fibers of the anulus fibrosus from the edges of the vertebral body, which can enable the nucleus pulposus to protrude or herniate into the spinal canal or the neuroforamen.[5] Additionally, the posterior longitudinal ligament will proceed to buckle when subjected to the greater loading forces. The C5–C6 interspace is the most commonly involved level, followed by the C6–C7 level and then the C4–C5 level.[4]

The conglomerate effect of cervical spondylosis can manifest as three distinct clinical syndromes: axial neck pain, cervical radiculopathy, and cervical spondylotic myelopathy. Axial neck pain denotes pain along the cervical spinal column and is related to facet arthrosis and the paraspinal musculoligamentous structures.[13] Cervical radiculopathy designates dermatomal findings in the arm that are characterized by sensory and/or motor disturbances owing to nerve root compression. Last, cervical spondylotic myelopathy is typically insidious and is associated with the hallmark long-tract signs. This chapter will elucidate the pathophysiology, natural history, and clinical findings associated with axial neck pain, cervical radiculopathy, and cervical spondylotic myelopathy.

Axial Neck Pain

Pathophysiology

Axial neck pain is defined as pain emanating from the region of the neck bounded superiorly by the superior nuchal line, laterally by the neck margins, and inferiorly by an imaginary transverse line through the T1 spinous process.[14,15] Anterior neck pain stems from strain of the sternocleidomastoid, the strap muscles, and their attachments. Posterior neck pain is thought to result from poor posture, faulty ergonomics, or muscle fatigue.[16] Frequently, subaxial neck pain can be associated with a postural adaptation relating to pain at the shoulder, craniovertebral junction, or at the temporomandibular joint.[16]

The pathophysiology of axial neck pain remains elusive and is subject to considerable scrutiny. However, numerous theories have been suggested. Disc desiccation is associated with inflammation, changes in disc innervation, and biomechanical hypermobility.[17,18] The plexus of the sinuvertebral nerve

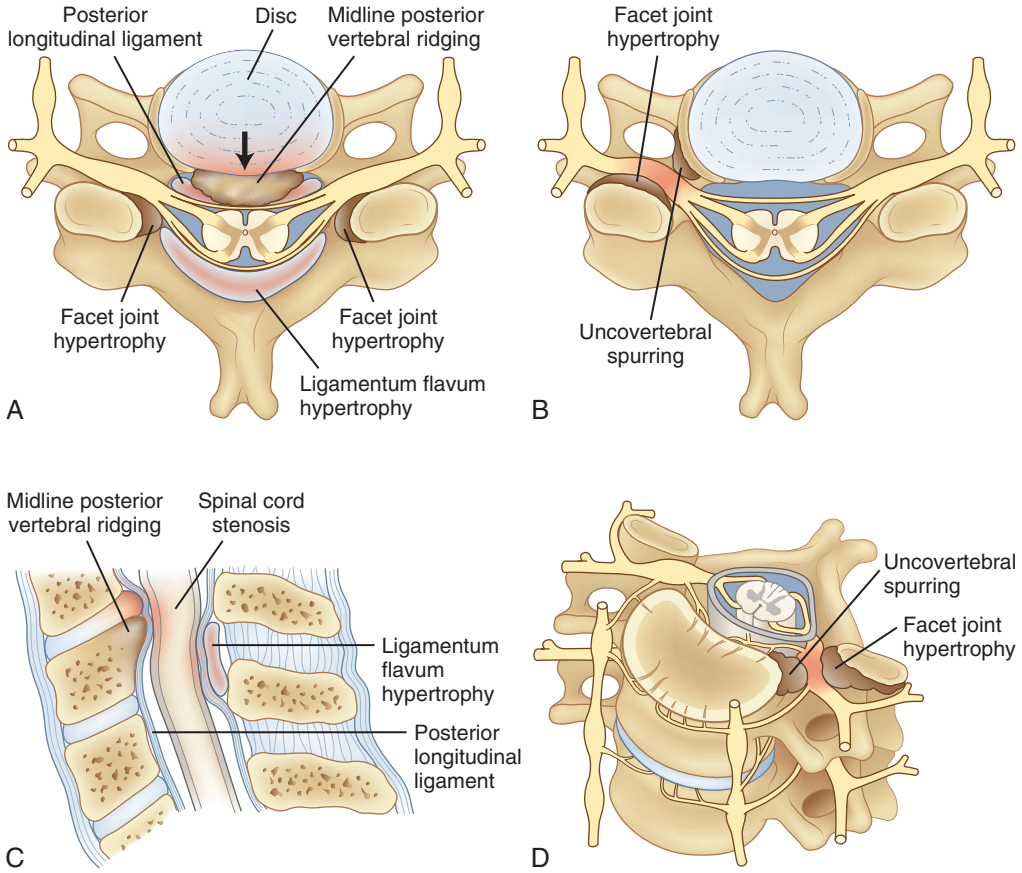

FIG. 37.1 Structural elements that can contribute to cervical spinal stenosis. (A, C) Central stenosis and (B, D) foraminal stenosis are shown. (Modified from Zebala LP, Buchowski JM, Daftary AR, O'Brien JR, Carrino JA, Khanna AJ. The cervical spine. In: Khanna AJ, ed. *MRI Essentials for the Spine Specialist.* New York: Thieme; 2014:111–154.)

innervates the dorsal portion of the cervical disc while the plexus of the cervical sympathetic trunk innervates the ventral portion.[19] With disc inflammation, biochemical mediators—including prostaglandin E_2, bradykinin, histamine, serotonin, and potassium—can sensitize the nociceptors present in these nerves.[17] In addition, elevated tissue levels of tumor necrosis factor-α (TNF-α) have downstream effects that can also sensitize nociceptors and stimulate cytokine production by promoting the formation of the nerve growth factor/TrkA receptor complex.[17,20] Recent studies have demonstrated the expression of the TrkA receptor in the mast cells of degenerative intervertebral discs and in chondrocytes.[20,21] These inflammatory mediators can also facilitate the degradation of the disc matrix, which can enhance hypermobility. Notably, the interleukin-1 (IL-1) and TNF-α–induced cascades—such as the mitogen-activated protein kinase, nuclear factor kappa B (NF-κB), and prostaglandin signal transduction pathways—have been implicated.[22] These inflammatory changes and biomechanical hypermobility are thought to contribute to the development of discogenic axial neck pain.

Some evidence suggests that the degeneration of the posterior facets can also contribute to axial neck pain. The facet joints from C3–C4 to C8–T1 receive innervation from the medial branches of the cervical dorsal rami above and below each joint, whereas the third occipital nerve innervates the C2–C3 facet joints.[16,19] The biomechanical hypermobility and greater loading forces that result from cervical spondylosis can increase motion about the posterior facets and generate pain.[23] Several studies have demonstrated that controlled diagnostic blocks of the cervical facet joints can relieve axial neck pain.[14,23-28] However, these studies are marred by mixed results.

Degenerative arthritis of the suboccipital spine can manifest as headache and can radiate caudally or to the back of the ear. In addition, suboccipital headaches can result from the irritation of the greater occipital nerve, which stems from the posterior rami of C2, C3, and C4.[16,29] Furthermore, the sinuvertebral nerves from C2–C3 can also contribute to suboccipital headache and neck pain, as they innervate the atlantoaxial ligament, tectorial membrane, and the dura mater of the upper cervical cord and posterior cranial fossa.[16,19]

Epidemiology and Natural History

Axial neck pain does not seem to carry a gender predisposition and is thought to be more prevalent in individuals with a history of injury, headaches, low back pain, or multiple medical comorbidities.[30] Some evidence suggests that nearly 66% of adults have experienced neck pain during their lifetime, 5% of whom are disabled by it.[31] Axial neck pain is often associated with injury to the cervical musculoligamentous

complex and typically resolves within 6 weeks of onset with conservative treatment alone. However, chronic neck pain persists in 10% to 34% of adults.[32–34] Furthermore, of those with chronic neck pain, 50% will also report suboccipital headaches.

Few studies have characterized the natural history of axial neck pain. In general, nonoperative treatment is often the mainstay in the majority of patients with axial neck pain. Judicious utilization of analgesics, antiinflammatories, and physical therapy is warranted and has been demonstrated to relieve neck pain in 70% to 80% of cases.[35] DePalma et al. reported that 29% of patients had complete relief of neck symptoms, while 49% demonstrated improvement following 3 months of conservative treatment.[36] Similarly, Rothman and Rashbaum reported on the 5-year outcomes of patients with "predominantly" axial neck pain who were treated conservatively.[37] The authors demonstrated that 23% of patients remained disabled. In addition, there was no difference in outcomes between the operative and nonoperative cohorts at the 5-year follow-up period. As such, nonoperative management is advocated for nonneurogenic axial neck pain.[37]

Clinical Syndromes of Axial Neck Pain

Patients with axial neck pain from cervical degenerative disc disease will often report symptoms that have persisted for longer than 12 weeks. The pain is typically along the posterior neck and trapezius muscles with occasional radiation toward the head or into the periscapular region.[16] Localized pain suggests muscle sprain or a soft tissue injury.

Axial neck pain is worsened with flexion, which increases the loading forces on the discs. In addition, axial compression may also exacerbate the pain.[33,38] Prior to designating cervical spondylosis as the causative factor, signs and symptoms suggestive of a neoplastic or infectious process must be evaluated, including inquiry into nighttime pain, weight loss, or fevers and chills. Often, axial neck pain is encountered concomitantly with radicular or myelopathic symptoms, which warrants a full neurologic examination. Severe neck pain may overshadow radicular symptoms in the arm.[38] As such, provocative maneuvers that provide compression on the nerve roots, including the Spurling and L'Hermitte signs, should be elicited.

The determination of the point of maximal discomfort can also be of diagnostic value. Anterior neck pain stemming from muscular strain of the sternocleidomastoid or the strap muscles can be elicited by rotation of the neck to the contralateral side. Posterior neck pain that worsens with head extension and rotation is suggestive of discogenic pain. In addition, limited head rotation to one side is associated with dysfunction of the ipsilateral atlantoaxial articulation.[16] Pain with axial loading of the neck can be suggestive of facet-mediated pain.

Often, patients with shoulder and rotator cuff disease may present with neck pain. In addition, the patient may develop postural adaptations in the neck that result in overuse of the normal tissue, which may exacerbate the neck pain. Rotator cuff disease can be evaluated with the Neer and Hawkins tests for impingement as well as with abduction testing. The resolution of symptoms following a joint injection into the subacromial space may also aid in the diagnosis of rotator cuff pathology.[38]

Care must be taken to determine if C4 radiculopathy is the source of neck pain, as the C4 dermatome includes the proximal trapezial and posterior scapular regions.[13,38] Unilateral neck or scapular pain should raise suspicion of C4 radiculopathy.[38] To further investigate for potential radiculopathy, the patient should be asked about paresthesias within the C4 dermatome.[38]

In addition to organic musculoskeletal processes in the neck and shoulder, pathologic referred pain from the viscera can also elicit neck pain. Furthermore, inflammatory arthritis must be assessed with particular inquiry regarding morning stiffness, rigidity, or polyarticular symptoms.

Cervical Radiculopathy

Pathophysiology

Cervical radiculopathy is characterized by pain, loss of strength and/or sensation, or diminished reflexes in the upper extremity that follows a predictable dermatomal pattern. Radicular findings result from compression of the cervical nerve roots at a location between their origins from the spinal canal to their egress from the neural foramen.[16] Cervical spondylosis—characterized by the loss of disc height and disc herniation, infolding of the facet joint capsule and the ligamentum flavum, and osteophytosis—results in foraminal stenosis. In addition, osteophytes may compress the vascular supply to the nerve root, thereby causing spasm of the radicular arteries.[16] Furthermore, venous outflow may also be compromised, resulting in edema of the nerve roots.[39]

An inflammatory component is believed to be associated with radicular pain generated from nerve root compression.[40] Initially, neural compression results in edema that can eventually lead to fibrosis. This may lower the pain threshold of the nerve root.[40] Furthermore, the inflammation is perpetuated by the neuropeptides and other chemical mediators released by the compressed sensory nerve and by the desiccated disc material.[41] Some evidence suggests an increased concentration of neurogenic chemical mediators of pain, including substance P, in the dorsal root ganglion after 1 to 4 weeks of symptom onset.[41]

Biomechanical hypermobility may also contribute to dynamic compression of the nerve roots, thereby resulting in radicular symptoms when the patient moves the neck. Flexion of the cervical spine lengthens the neural foramen up to 31%, while extension shortens the foramina up to 22%.[42] Ipsilateral rotation narrows the foramen, while contralateral rotation widens it. With extension, the ligamentum flavum can become redundant and will taper the foraminal space. Flexion or extension can translate or angulate the vertebrae and can stretch the nerve root, resulting in radicular symptoms.[16] This dynamic compression can explain why some affected patients may not have radicular symptoms with the neck in a neutral static position.

The importance of nerve root tensioning is demonstrated by the relief of radicular findings with shoulder abduction, which is characterized by resting the hand on top of the head.[16,43] Some evidence suggests that shoulder abduction will decrease nerve root tension and can also lift the dorsal root ganglion cephalad, which distances it from the compressive lesion.[43] In addition, venous blood flow is also facilitated with shoulder abduction with the decompression of the epidural veins.

Epidemiology and Natural History

Incidence of cervical radiculopathy peaks in the sixth decade of life and has a point prevalence of 3.5 per 1000 persons.[44,45] Radiculopathy can be acute, subacute, or chronic.[45] Patients younger than 55 years of age often present with radiculopathy secondary to herniated disc material; older individuals often have osteophytosis causing the neuroforaminal stenosis.[46]

The natural history of radiculopathy has not been clearly elucidated, as treatment is typically provided to the patient. Favorable outcomes are often reported with nonoperative management. Radhakrishnan et al. demonstrated that 90% of patients with cervical radiculopathy remained asymptomatic or minimally affected at 5.9 years of follow-up.[44] As with axial neck pain, nonoperative management is primarily advocated. Nearly half of the patients with cervical radiculopathy report symptom resolution within 6 weeks of onset with nonoperative treatment.[46]

Clinical Syndromes of Cervical Radiculopathy

Radicular symptoms follow a predictable dermatomal distribution in the upper extremity. In addition to sensory and motor dysfunction, patients may report tingling and burning sensations across the affected dermatome.[16] It must be noted, however, that due to potential redundancies in neural innervation, clinical findings may overlap dermatomes. As such, a careful physical examination must be performed to delineate compressed nerve roots and to identify any potential neural redundancies.

Arm and neck pain that is associated with cervical radiculopathy is frequently unilateral. Patients may present with a head positional preference to the contralateral side of the arm pain.[16] The pain is exacerbated with extension and lateral rotation of the head to the side of the pain, termed the Spurling maneuver. This technique minimizes the dimensions of the foraminal space and specifically stresses the foraminal structures, including the nerve root and the vasculature. The Spurling maneuver enables the physician to distinguish cervical radiculopathy from other causes of neck and arm pain, including peripheral nerve compression.[16]

C3 radiculopathy results from pathology at the C2–C3 neuroforamina. C2–C3 has the largest foramen and contains the smallest cervical nerve root.[47] As such, C3 radiculopathy is relatively uncommon. Clinical symptoms that are associated with C3 nerve root compression include headache and sensory disturbance over the upper neck and occiput. No clear myotome has been identified for the C3 nerve root. As such, patients with C3 radiculopathy present similar to those with axial neck pain.[16,46]

The C4 nerve roots exit through the C3–C4 neuroforamina. Similar to C3 radiculopathy, pure C4 nerve root compression is unusual.[46] However, it must be noted that C4 radiculopathy can cause axial neck and shoulder pain.[48] It is associated with sensory disturbances in the lower neck extending to the trapezius region and to the anterior chest. In addition, because the C3–C5 nerve roots innervate the diaphragm via the phrenic nerve, patients with C4 radiculopathy may manifest paradoxical respiration, as evidenced with fluoroscopic evaluation.[49,50] The "sniff test" is performed under fluoroscopy and is characterized by rapid, repeated inspiration, which results in unilateral diaphragmatic paralysis in patients with C4 radiculopathy.[16,49,50]

C5 radiculopathy stems from compression of the C5 nerve root in the C4–C5 neuroforamen (Fig. 37.2).[51] It is characterized by pain that radiates from the neck, over the shoulder, and to the proximal lateral arm. Deltoid weakness often manifests and patients have difficulties with shoulder abduction. Often, patients report weakness with hair brushing or during dressing. In addition, the pectoralis, biceps, or the brachioradialis reflex can be diminished. Sensory deficit is localized to the lateral aspect of the arm, below the shoulder.[52] C5 radiculopathy must be distinguished from primary shoulder joint and rotator cuff dysfunction.[16,46]

C6 nerve root compression within the C5–C6 disc interspace will result in C6 radiculopathy, which is characterized by pain radiating from the base of the neck to the lateral aspect of the elbow and into the radial forearm and radial two digits[52] (Fig. 37.3).[51] This C5–C6 level pathology is the most common radiculopathy because the greatest amount of cervical spondylotic degeneration occurs at this disc interspace.[53,54] The increase in degenerative disease is due to greater angular mobility at this level, a higher mechanical load, and a smaller baseline canal diameter. A majority of flexion and extension of the subaxial spine occurs at segment C5–C6 in the anatomically normal cervical spine, causing this intervertebral level to be more subject to wear-and-tear forces. Additionally, C5–C6 also carries a large mechanical load in the normal cervical spine, also increasing risk of stenosis and degeneration.[55–57] Patients will present with weakness of the biceps muscle along with the extensor carpi radialis, which is solely innervated by the C6 nerve root. In addition, C6 radiculopathy is associated with diminished biceps and brachioradialis reflexes. The sensory changes are similar to that of carpel tunnel syndrome.[16,46]

C7 radiculopathy is associated with cervical spondylosis at the C6–C7 disc interspace (Fig. 37.4).[51] The C7 nerve root supplies the triceps muscle. Patients will present with weakness with arm extension about the elbow joint. In addition, it is associated with diminished triceps reflex. Of note, C7 radiculopathy may occur concurrently with Horner syndrome owing to sympathetic dysfunction, although some studies have suggested that this can be a variable finding.[52,58] Sensory dysfunction can be isolated to the middle and index finger, while pain can radiate from the interscapular area, through the midarm,

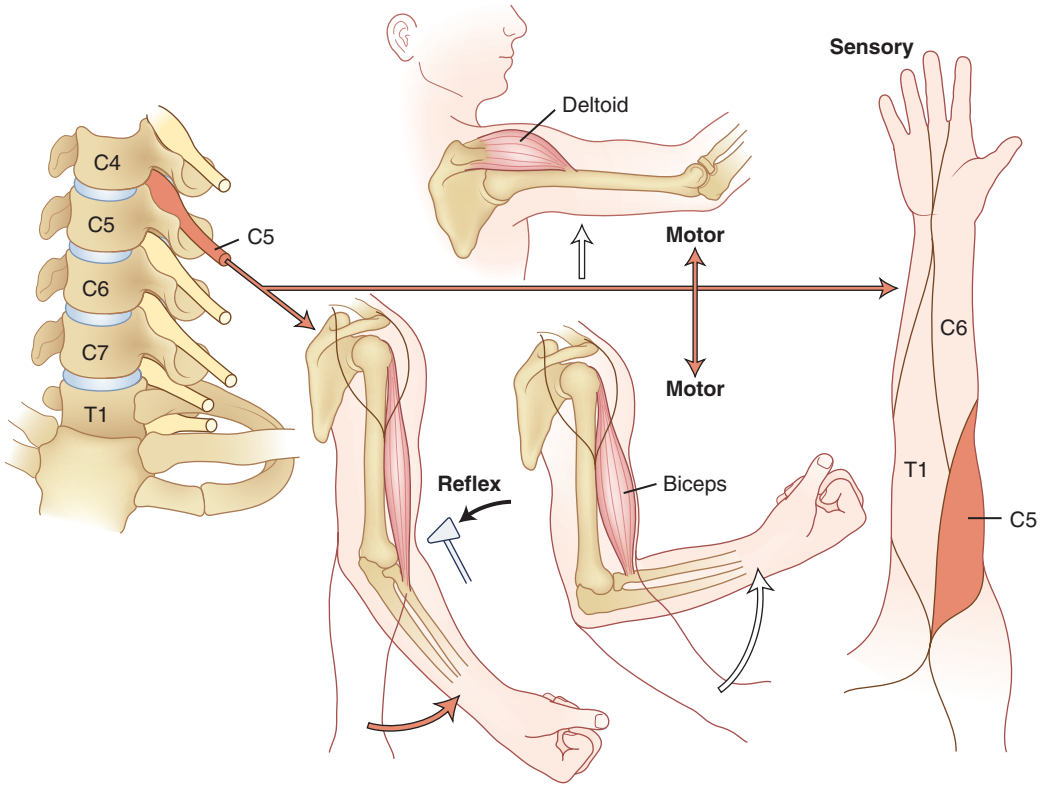

FIG. 37.2 C5 nerve root anatomy, dermatome, and myotome. (Modified from Paterno JM, Silverberg CM, Khanna AJ, Singla AK. and down the middle three fingers. In addition, chronic breast pain has been reported with C7 radiculopathy.[16,46,59]

Last, C8 radiculopathy is characterized by pathologic changes at the C7–C8 disc interspace (Fig. 37.5).[51] The C8 nerve root innervates the intrinsic hand muscles and finger flexors. The "benediction sign" is often present in patients with C8 radiculopathy and is characterized as weakness with extension of the fourth and fifth digits. Similar to C7 radiculopathy, sympathetic dysfunction may be present and can present with Horner syndrome.[52,58] Sensory changes can be localized to

FIG. 37.6 Sagittal T2-weighted magnetic resonance image depicts C5–C6 disc herniation resulting in increased cord signal intensity (*arrow*) and elevation of the posterior longitudinal ligament (*arrowhead*). (From Zebala LP, Buchowski JM, Daftary AR, O'Brien JR, Carrino JA, Khanna AJ. The cervical spine. In: Khanna AJ, ed. *MRI Essentials for the Spine Specialist*. New York: Thieme; 2014:111–154.)

the medial aspect of the arm and forearm, and the ulnar two fingers. The patient can present with weakness of the wrist extensors, flexors, and intrinsics with the exception of the extensor carpi radialis and flexor carpi radialis. C8 radiculopathy can be distinguished from ulnar nerve entrapment as ulnar nerve pathology spares all of the short thenar muscles except the adductor pollicis.[16,45]

Cervical Myelopathy

Pathophysiology

Myelopathy is defined as the presence of long-tract signs secondary to mechanical compression of the afferent or efferent nerve tracts of the spinal cord.[46,60] Compression of the spinal cord is the result of both static (such as degenerative stenosis and disc protrusion) and dynamic (such as instability due to trauma) risk factors (Fig. 37.6).[7]

The normal anteroposterior diameter of the cervical spine is 17 to 18 mm in adults; the cervical cord itself measures 10 mm in diameter from anterior to posterior.[61–63] Congenital cervical stenosis is defined as a spinal canal that measures less than 13 mm.[61,62] While congenital stenosis may not be clinically symptomatic by itself, it is associated with a lower threshold for the magnitude of degenerative spondylotic changes that are required to compress the spinal cord to cause myelopathy.[16] In addition, the shape of the spinal cord in degenerative settings has been correlated with the development of cervical myelopathy.[63] If the cross-sectional area of the cord is reduced by the critical amount of 30% and the remaining transverse area is less than 60 mm^2, signs and symptoms of cervical cord compression can manifest.[63] Furthermore, a lower anteroposterior compression ratio of less than 0.4 correlates histologically with severe cord injury.[64–66] The Pavlov ratio, which is the anteroposterior diameter of the spinal canal divided by the anteroposterior diameter of the vertebral body at the same location, indicates developmental cervical narrowing if the value is less than 0.8.[16,64,65]

Dynamic factors are also correlated with the development of cervical myelopathy. Hyperextension of the neck is associated with buckling of the ligamentum flavum ventrally into the canal.[16] In addition, during extension, a retrolisthesed vertebral body can squeeze the cord between the inferoposterior edge of the vertebral body and the superior edge of the lamina caudal to it. Similarly, anterolisthesis during flexion can also compress the spinal cord.[16] Breig et al. demonstrated that the spinal cord thickens and shortens with extension, which potentiates compression from the redundant ligamentum flavum or the lamina[67] (Fig. 37.7). With flexion, the pressure within the cord can increase if a compressive lesion is pressing against the cord.[16]

Mechanical compression and ischemia can be concomitant in the development of cervical myelopathy. Breig et al. demonstrated that flow through the anterior spinal artery and the radicular arteries can diminish when the vessels are tented over a disc or vertebral body.[67] In particular, the transverse intramedullary arterioles are considered most vulnerable to vascular compression and they perfuse the gray matter and the adjacent lateral columns.[68] However, the blood flow through the posterior spinal arteries remains unaffected.[16]

Chronic cervical myelopathy is associated with demyelination and irreversible neurologic deficit likely due to ischemic death (apoptosis) of the oligodendrocytes (Fig. 37.8).[7] This cell lineage is the most susceptible to ischemic injury.[69,70]

Natural History

Cervical myelopathy develops in a small proportion of patients with spondylosis and is often encountered beyond the fifth decade.[71,72] Some evidence suggests that myelopathy is more common in men and in those with labor-intense occupations.[71,72] The development of cervical myelopathy is often insidious in its early stages. By the time a patient presents with overt clinical signs and symptoms, surgical management is often warranted. Numerous studies have demonstrated that cervical myelopathy is associated with a progressive deterioration of motor and sensory function, with 95% of patients who report gradual intervening periods of disease progression and stability.[73]

Some studies have demonstrated that the progression of cervical myelopathy is highly variable, with many patients

(A) Flexion image demonstrating no stenosis. (B) Extension image of C6–C7 stenosis due to ligamentum flavum impingement (*arrow*) and continued disc bulge. (From Zebala LP, Buchowski JM, Daftary AR, O'Brien JR, Carrino JA, Khanna AJ. The cervical spine. In: Khanna AJ, ed. *MRI Essentials for the Spine Specialist.* New York: Thieme; 2014:111–154.)

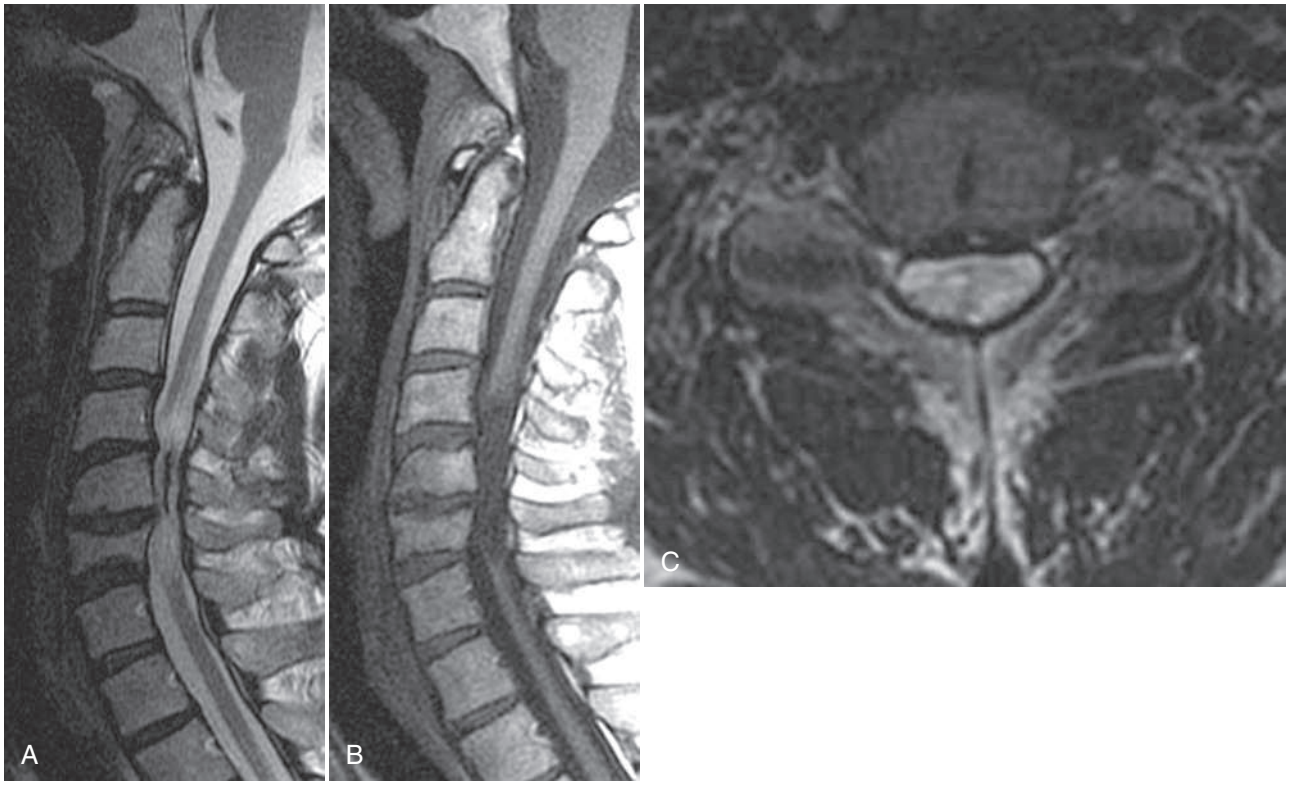

FIG. 37.8 Spinal cord atrophy as a result of persistent central canal stenosis. (A) Sagittal T2-weighted image showing C4–C6 stenosis and C5 spinal cord atrophy with surrounding edema. (B) Sagittal T1-weighted image demonstrates low cord signal intensity from C4–C5 to C6–C7. (C) Axial T2-weighted image at C4–C5 shows spinal cord atrophy. (From Zebala LP, Buchowski JM, Daftary AR, O'Brien JR, Carrino JA, Khanna AJ. The cervical spine. In: Khanna AJ, ed: *MRI Essentials for the Spine Specialist.* New York: Thieme, 2014: 111–154.)

who report a relatively benign form of the disease.[73–75] Epstein et al. reported that 38% of patients remained stable and 26% of patients deteriorated, with older patients most likely to experience worsening of symptoms.[74] However, the majority of patients who present with neurologic dysfunction do not have spontaneous improvement.[73]

Clinical Syndromes of Cervical Myelopathy

The anatomic site of compression dictates the clinical findings seen with cervical myelopathy. Sensory symptoms are related to three distinct sites of compression on the cervical cord: (1) the spinothalamic tract, which affects contralateral pain and temperature; (2) posterior columns, which involves ipsilateral position and vibration sense disturbances, leading to gait disturbances; and (3) dorsal root compression, which facilitates dermatomal findings.[16] At the level of the cervical lesions, lower motor neuron findings predominate and are characterized by hyporeflexia and weakness in the upper extremities. Conversely, caudal to the level of the cervical cord lesion, upper motor neuron signs are present, with hyperreflexia and spasticity in the lower extremities.

Patients can often present with difficulties with fine motor movements in the hands, characterized by difficulty with handwriting or typing.[76] This becomes progressively worse with gross motor dysfunction, characterized by gait abnormalities and falls. Gait may become spastic and patients may report weakness and wasting of the lower extremities. Severe chronic myelopathy can result in loss of proprioception, broad-based gait, and, eventually, quadriplegia.[16,77] Nurick et al. proposed a disability grading system based on these gait abnormalities[75] (Table 37.1).

Various physical examination findings are associated with cervical myelopathy. Often, patients can present with hyperreflexia of the deep tendon reflexes, changes in muscle tone or clonus, and the presence of long-tract signs, including the Babinski sign in the lower extremities and/or the Hoffman sign in the upper extremities.

In the upper extremity, the Hoffman sign (stimulation of the extensor tendon of the third digit with forcible flexion and sudden release of the distal phalanx, which prompts the thumb to flex and adduct along with concurrent flexion of the index finger) is often appreciated.[46,78,79] In addition, the inverted radial reflex is elicited by stimulating the distal brachioradialis tendon with gentle percussion, which yields hyperdynamic finger flexion.[80] The inverted radial reflex is associated with cord compression at C6.[16] Furthermore, poor ability to grip and release is often indicative of myelopathy in the hand.[81] Superficial reflexes, including the abdominal or cremasteric reflexes, are also compromised with cervical myelopathy.

In the lower extremity, the Babinski sign is elicited by rubbing the lateral aspect of the plantar surface of the foot from the heel to the metatarsal pads with a blunt object, which prompts the great toe to dorsiflex and the other toes to fan out if an upper motor neuron lesion is present.[46] It should be noted that numerous variations of the Babinski sign can be present in the patient, including the Oppenheim sign (apply heavy pressure with the thumb and index finger over the tibia and stroke down to the ankle), Gordon sign (apply pressure on the calf muscles), Schaefer sign (apply pressure on the calcaneal tendon), Bing sign (stimulate the great toe with a pin prick), Chaddock sign (stimulate the lateral foot with a blunt object), and the Gonda and Allen signs (provide forceful downward stretching of the distal phalanx of the second or fourth toe).[46,82] Any of these variations can be present in the patient.

Sensory deficits must also be evaluated in patients with cervical myelopathy. Crandall et al. reported on the various clinical findings associated with afferent nerve tract compression in patients with myelopathy.[53] Neck pain was present in 50% of patients, radicular pain in 38%, Lhermitte sign (shocklike sensation that radiates down the spine following flexion of the neck) in 27%, and sphincter tone changes in 44%.[53] In addition to these findings, changes in pain, temperature, proprioception, and dermatomal sensation may be present.

Signs and symptoms in the hands can often characterize the primary reason for why the patient seeks medical attention. Ono et al.[81] demonstrated two signs that are specific to "myelopathy hand": the finger-escapee sign (patient tries to extend digits fully with the palm facing down and the ulnar two or three digits drift into abduction and flexion after 30 seconds) and the grip and release test (suboptimal performance in the ability to open and close the fist rapidly).[16,81] Patients may also report diffuse numbness in the hands, which must be distinguished from carpal tunnel syndrome and peripheral neuropathy. In addition, wasting of the intrinsic hand muscles is often present.[16]

Myelopathy can often be accompanied by radicular findings in some patients. Myeloradiculopathy is associated with spinal stenosis with concurrent compression of the neuroforaminal contents. This can be reproduced with the Spurling maneuver, as described earlier.[46,53] Myeloradiculopathy produces lower motor neuron signs at the level of the cervical cord lesion and upper motor neuron signs caudal to the level of compression. In addition, Edwards et al. demonstrated that 13% of patients with spondylotic myelopathy present with both cervical and lumbar involvement.[83] These patients present with both upper and lower motor neuron findings in the lower extremities, which often complicates the clinical picture.

TABLE 37.1 Cervical Spondylosis Disability Grade

Grade	Signs
0	Signs or symptoms of root involvement without spinal cord disease
1	Signs of spinal cord disease without gait difficulty
2	Slight difficulty in gait that does not prevent full-time employment
3	Difficulty in walking that prevents full-time employment or housework but does not require assistance
4	Able to walk only with assistance or with aid of a frame
5	Chairbound or bedridden

Modified from Nurick S. The pathogenesis of the spinal cord disorder associated with cervical spondylosis. *Brain.* 1972;95:87-100.

Summary

Cervical disc disease describes a series of degenerative changes that can result in clinically significant radiculopathy and/or myelopathy. Numerous static and dynamic biomechanical and physiologic forces contribute to cervical spine degeneration. It becomes incumbent upon the spine surgeon to recognize clinical signs and symptoms consistent with clinically significant radiculopathy and/or myelopathy, as cervical spondylosis is ubiquitous among the aging general population.

38 CHAPTER Medical Myelopathies

Brandon L. Raudenbush
Olga Selioutski
Lawrence Samkoff
A. Jay Khanna
Addisu Mesfin

Medical myelopathies encompass a wide spectrum of conditions ranging from nutritional deficiencies to intrinsic spinal cord disorders and manifestations of systemic infections. Spine surgeons should maintain these conditions in their differential diagnosis for patients with myelopathy. Depending on the cause of the medical myelopathy, the spine surgeon should either manage it directly or refer it to appropriate providers.

Spinal Cord Anatomy

Longitudinal Orientation

The spinal cord starts at the foramen magnum and extends through the entire length of the vertebral canal in the embryonic phase. The spinal cord grows slower than the vertebral canal; in infancy, it extends to the L2 and L3, but may terminate anywhere between L1 and the second sacral (S2) vertebra.[1] In adults, the tip of the spinal cord (conus medullaris) ends at L1–L2.[2] The dissimilarity in growth between the cord and its canal leads to the lumbar nerve roots needing to descend within the subarachnoid space to reach the corresponding vertebral levels prior to exiting the spinal column, creating a group of roots called the cauda equina. The spinal cord has two enlargements (cervical and lumbar) at C3–T2 and L1–S3.[3] There are 31 segments in the spinal cord (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal).

Transverse Orientation

The spinal cord consists of white and gray matter strategically organized for rapid communication between peripheral structures and the brain. The structure has two identical semiovals separated by the deep ventral median fissure anteriorly and dorsal median sulcus posteriorly and joined only at the midline.[4]

The gray matter is an H-shaped, mirror-imaged structure, with each half subdivided into dorsal (containing sensory neurons) and ventral (containing lower motor neurons) horns and an intermediate column (containing autonomic neurons). The white matter is subdivided into anterior, lateral, and posterior columns containing either ascending or descending tracts. Three major tracts will be reviewed here.

Ascending Lateral Spinothalamic Tracts

The *ascending lateral spinothalamic tracts* relay pain, temperature, and crude touch sensation. The pain is transmitted to the dorsal root ganglia (DRG) neurons (first-order primary sensory neurons), which synapse ipsilaterally in the dorsal horn of the gray matter with the second-order neurons. The axons of the second-order neurons cross to the *contralateral side* via the anterior commissure two levels higher than the associated dermatome and ascend in the contralateral lateral column.

Ascending Dorsal Column–Medial Lemniscus Tracts

The *ascending dorsal column–medial lemniscus* tracts relay vibratory sensation, proprioception, and fine-touch discrimination. These sensory modalities are transmitted to the DRG neurons, axons of which enter the posterior columns forming fasciculi gracilis and cuneatus, remaining ipsilateral to the side of entry without crossing until the level of medulla, where they synapse with the second-order neurons. The axons of the second-order neurons decussate in the lower medulla and ascend as medial lemnisci to the level of the thalamus.[5] This pathway serves the basis for somatosensory-evoked potentials recording during intraoperative monitoring.

Descending Lateral Corticospinal (Pyramidal) Tracts

The fibers from the primary motor cortex descend via pyramidal tracts to synapse on the lower motor neurons of the anterior horns. The vast majority of these fibers decussate at the level of medulla (top of C1 level) prior to entering the lateral columns of the contralateral side.[6] This pathway serves

as the basis for transcranial motor-evoked potentials recording during intraoperative monitoring.

Vascular Diseases of the Spinal Cord

Infarctions of the Spinal Cord

Arterial Spinal Cord Infarctions

Isolated spinal cord infarction is much less frequent than cerebral infarction, accounting for only 1% of all strokes.[7] Based on the pathogenesis, there are two main types of spinal cord ischemia: (1) mechanical disruption of the blood supply, resulting in anterior or posterior spinal artery infarcts, and (2) infarcts occurring after prolonged global hypotension or hypoperfusion, resulting in central and transverse infarcts.[8,9] Compromise of the spinal vascular supply results in a constellation of deficits specific to that vessel's territory.

Since the anterior spinal artery supplies the anterior two-thirds of the cord, its occlusion leads to abrupt flaccid paralysis (quadriplegia or paraplegia, depending on the level of ischemia) due to involvement of the bilateral descending corticospinal tracts, loss of superficial pain, and loss of temperature discrimination (bilateral ascending spinothalamic tracts) below the level of the vascular compromise, with preservation of vibration and position sense carried by the unaffected ascending posterior columns supplied by the posterior arteries. In addition, there is autonomic dysfunction with loss of sphincter control, bladder atonia, and paralytic ileus. Spasticity eventually ensues, with exaggerated deep tendon reflexes, positive Babinski responses, and ankle clonus.[9]

The occlusion of one of the posterior spinal arteries results in the infarction of the ipsilateral posterior third of the hemicord as well as alteration in specialized and complex discriminative sensory functions.[10]

In the context of surgical procedures, the most frequent mechanism of infarction is manipulation of the aorta or its branches. Nonsurgical etiologies include severe hypotension or hypovolemia from significant blood loss, aortic thrombosis, embolization, and aortic dissection, all resulting in global spinal hypoperfusion.[11]

Distinct from cerebral infarction, most (>80%) spinal infarcts are painful. Causes of ischemic spinal cord injury are listed in Box 38.1.

Spinal venous infarctions are rare, typically involving the thoracic cord and causing paraparesis and sensory disturbance of the lower extremities. Venous infarctions are subdivided into hemorrhagic or ischemic. Hemorrhagic and embolic venous infarctions have sudden onset and rapid progression and are painful. The clinical onset of a nonhemorrhagic infarction is protracted, with gradual evolution of the symptoms.[13]

Evaluation of Suspected Stroke of the Spinal Cord

Imaging

Computed tomography has little application to the diagnosis of spinal ischemia. It lacks the sensitivity, especially in the cervical region, to be adequate for reliable exclusion of ischemia, but may identify compressive causes of myelopathy (epidural hematoma, tumors). Spinal angiography (arteriography) is indicated occasionally, usually for diagnosis and treatment of a spinal arteriovenous malformation. Spinal magnetic resonance imaging (MRI) is a diagnostic test of choice for diagnosis of infarction.[14]

Treatment is guided by the underlying etiology. There are limited reports on use of recombinant tissue plasminogen activator in patients with spinal cord ischemia.[15] The goal is to improve spinal cord perfusion with permissive hypertension and maintenance of euvolemia, which may be supplemented by lumbar cerebrospinal fluid (CSF) draining to reduce intrathecal pressure and augment perfusion. Corticosteroids have no role in the treatment of spinal cord infarction unless noninfectious inflammation is established.[14]

The prognosis for functional recovery is guarded. Few patients improve; rarely (<10%), patients achieve a remarkable recovery of function, particularly of motor control and ability to walk. The short-term mortality rate is 20% to 25% over the first month following onset of symptoms. Overall life expectancy is diminished because of vascular, infectious, and other medical complications.

Spinal Cord Vascular Lesions

The vascular lesions are subdivided into neoplastic vascular lesions (hemangioblastoma, cavernous malformation), aneurysms, arteriovenous fistulas, and arteriovenous malformations (AVMs) (Box 38.2).[16]

BOX 38.1 Causes of Ischemic Spinal Cord Injury

Nonsurgical Vascular Pathology

Ischemic infarction due to arterial atherosclerosis/embolism
Ischemic infarction due to aortic dissection or thrombosis
Ischemic infarction due to fibrocartilaginous embolism[12]
Venous infarctions
Arteriovascular malformation (vascular steal)
Vasculitis
Decompression sickness
Vascular constriction (triptans, illicit substances)

Surgery Related

Hypoperfusion due to:
- Hypotension/cardiac arrest
- Hypovolemia (blood or volume loss)
- Clamping of the radicular feeding artery
- Clamping of the aorta

BOX 38.2 Classification of Vascular Malformations

Arteriovenous Malformations

Extradural-intradural
Intradural
- Intramedullary
- Conus

Arteriovenous Fistulas

Intradural
Extradural

Cavernous Hemangioma (Cavernomas)

Cavernomas are slow-growing, raspberry-shaped vascular malformations that become symptomatic in the case of bleeding or from direct cord compression. Symptoms depend on lesion location. Diagnosis is made with a characteristic spinal MRI appearance with evidence of blood degradation products at different stages. The lesions are well demarcated, with mixed signal intensity and popcorn appearance. The core is surrounded by a rim of low intensity that corresponds to hemosiderin. Hemosiderin-sensitive sequences (gradient echo or susceptibility-weighted imaging) are beneficial in the diagnosis of cavernous hemangiomas. Treatment of symptomatic patients requires surgical resection.[17]

Hemangioblastomas

These vascular lesions of the spinal cord can be sporadic or familial, as in case of von Hippel–Lindau syndrome. MRI is needed for diagnosis, and treatment entails surgical resection if the lesion is symptomatic.

Arteriovenous Malformations and Arteriovenous Fistulas

Spinal dural arteriovenous fistulas are the most common type of spinal cord vascular malformation.[18] These lesions are defined by abnormal connections between a radicular feeding artery and the coronal venous plexus of the spine without an intervening capillary bed. The actual fistula site is at the dural sleeve of the nerve root. The arterial blood flow is shunted directly into the venous plexus, leading to venous congestion, venous hypertension, and potential venous infarctions.[18] Clinical presentation is characterized by the insidious progression of weakness and sensory deficits in the lower extremities. MRI findings include presence of cord edema and dilated and tortuous perimedullary dural vessels. The gold standard for diagnosis is a catheter spinal angiography. Treatment is surgical disconnection or endovascular occlusion.[15]

Intramedullary (or glomus) AVMs are characterized by the presence of tightly compacted groups of arterial and venous vessels (nidus) inside the spinal cord. The AVM is supplied by multiple feeding arteries from the spinal arteries. This is a high-flow system shunting blood from the vital tissue and is often associated with aneurysms. The most common presentation is related to a hemorrhage, direct compression, or ischemia. Diagnosis is made by spinal MRI by demonstrating intramedullary flow voids and subsequent spinal catheter angiography.[15]

Inflammatory Spinal Cord Disorders

Transverse Myelitis

Transverse myelitis (TM) is an immune-mediated, inflammatory acute or subacute spinal cord disorder that causes a combination of motor, sensory, pain, and autonomic-sphincteric dysfunction that evolves over hours to days, but sometimes up to a few weeks. TM can be primary or idiopathic, or, more often, secondary to other systemic or neurologic disorders.[19] Although TM may result in complete disruption of all tracts across the spinal cord cross-section, more commonly there is variability in the severity of functional impairment. Thus, patients may present with variable degrees of sensory loss, weakness, neck or back pain, and bladder and bowel dysfunction. The pattern of weakness is usually level dependent, with quadriparesis with cervical cord TM and paraparesis with thoracolumbar TM; however, cervical cord disease often spares the upper extremities. Acutely, limbs may have flaccid weakness, with loss of deep tendon reflexes, although the presence of extensor plantar responses, urinary and bowel retention, and a protopathic (pain and temperature) sensory level localizes to the spinal cord. Some patients can present with a purely dorsal column syndrome, with loss of vibration and proprioception, resulting in a sensory ataxia. Patients with hemicord involvement may present with dissociated motor and sensory symptoms, ipsilateral weakness and loss of vibration and proprioception, and contralateral loss of ability to feel pain and temperature. This constellation of symptoms and signs is characteristic of Brown-Séquard syndrome, invariably localizing to the spinal cord. Pathology is usually 2 to 3 segments above the clinical sensory level but may be higher.[20]

The etiology of idiopathic TM is not established. It can occur following a nonspecific virus or vaccination.[19] TM secondary to a systemic or neurologic disorder is important to identify, as treatment of the underlying condition decreases the risk of relapse. Systemic diseases associated with TM include systemic lupus erythematosus (SLE), Sjögren syndrome, Behçet disease (BD), and sarcoidosis.[1,4] Both multiple sclerosis (MS) and neuromyelitis optica (NMO) very commonly present with TM and need to be considered in the differential diagnosis. These conditions are discussed later in this chapter.

MRI of the spine is the diagnostic test of choice in evaluating TM, often demonstrating a contrast-enhancing and expansile intrinsic cord lesion of variable length (Fig. 38.1).[2] It is important to note that clinical features of TM cannot be differentiated from spinal cord compression, necessitating emergent imaging to allow for expeditious surgery if necessary. Other diagnostic testing includes complete blood count, serum chemistries, rheumatologic screening (antinuclear antibody, anti-Ro/La antibodies), and serum angiotensin-converting enzyme. Lumbar puncture and brain MRI are helpful in the diagnosis of MS. Serum aquaporin-4 antibody is both highly specific and sensitive for NMO.[21]

The first line of treatment for idiopathic TM is pulse intravenous (IV) steroids, most often with methylprednisolone 1000 mg daily for 3 to 7 days, followed by a prednisone taper. Plasma exchange (5 to 6 treatments every other day) for steroid-refractory TM has demonstrated efficacy in patients with idiopathic TM, MS, and NMO, resulting in complete or near-complete recovery in the majority of patients.[19,22] Patients with TM secondary to another disorder will require long-term treatment for their underlying condition to prevent recurrence.

(B) Sagittal MRI with contrast enhancement of subacute longitudinally extensive transverse myelitis (*arrow*) in a patient with NMO.

Multiple Sclerosis

MS is a chronic immune-mediated disease of the central nervous system (CNS) that is a leading cause of neurologic disability in young adults. It is pathologically characterized by inflammation, demyelination (in both white and gray matter), and axonal degeneration. Although the etiology of MS is unknown, it is widely thought to be initiated by an aberrant immunologic response to an environmental agent in genetically predisposed individuals. While an infectious cause is suspected, no single virus or bacteria has been isolated. MS predominantly affects women by a 2:1 ratio and is more common in white individuals of Northern European descent and in those living in increasing latitudes away from the Equator. However, the disease tends to be more aggressive in those with African American ethnicity.

MS is classically described as a white matter disease disseminated in time and space. In 85% of patients, the disease presents with relapses and remissions (RRMS), with attacks of neurologic symptoms that resolve completely or nearly completely over weeks to months, followed by periods of clinical stability. Within 10 years, 50% of patients with RRMS will enter a secondary progressive phase (SPMS), with slowly accumulating disability, in large part due to myelopathy.[23,24] Approximately 15% of patients with MS present with progressive neurologic dysfunction at disease onset, usually due to myelopathy, classified as primary progressive MS (PPMS). A subset of patients with both SPMS and PPMS continue to have both clinical relapses and inflammatory radiologic disease and are categorized as having progressive MS with activity.

MS relapses are defined as new or worsening symptoms lasting at least 24 hours, not associated with a systemic illness, and separated by at least 30 days.[25] MS flares are associated with neurologic disability, functional impairment, and psychosocial disruption, all of which affect quality of life.[26] With increasing disease duration, patients tend to have less recovery from exacerbations, leading to accrual of disability. Clinical features of MS are varied and depend on regions of involvement. Most patients present with optic neuritis, brain stem–cerebellar syndrome, hemispheric disease, or spinal cord impairment.

Spinal cord disease in MS usually presents with upper motor deficits (facial-sparing hemiparesis, quadriparesis, paraparesis, with hyperreflexia, Babinski sign, and spasticity, due to corticospinal tract dysfunction); paresthesias and numbness of the limbs and trunk (often with a sensory level to pinprick due to spinothalamic involvement and/or proprioceptive and vibratory deficit, and Romberg sign due to posterior column dysfunction); Lhermitte phenomenon, a paroxysmal electrical sensation radiating from the neck down the midline spine and into all four limbs, triggered by neck flexion; and bladder and bowel dysfunction, including urinary urgency, urinary retention, urinary and fecal incontinence, and constipation. Optic neuritis is typically unilateral, with rapidly progressive monocular visual loss and pain with eye movement over several days, with an afferent pupillary defect on exam. Funduscopy is usually normal, since there is only retrobulbar optic nerve inflammation. Brain stem–cerebellar symptoms include diplopia with internuclear ophthalmoplegia or sixth nerve palsy, dysarthria, vertigo, facial numbness, unilateral trigeminal neuralgia or facial palsy, and truncal or limb ataxia. Hemispheric manifestations include contralateral hemiparesis, hemisensory loss, and cognitive impairment. In addition, many patients with MS complain of late-day fatigue, paroxysmal tonic limb spasms, and dysesthetic limb and trunk pain.

PPMS and SPMS most often present as an insidiously worsening myelopathy. Patients often complain of asymmetric leg weakness, eventually with involvement of the contralateral leg, and, later, the upper extremities. This is accompanied by neurogenic bladder and bowel, epicritic sensory loss, and limb spasticity. Less frequently, patients may develop progressive spastic hemiparesis or pancerebellar ataxia. Finally, cognitive

dysfunction can affect from 40% to 70% of patients with MS, in both the relapsing and progressive stages of the disease, with impairment of short-term memory, attention and concentration, executive function, verbal fluency, and visuospatial processing, not uncommonly leading to a subcortical dementia. More rarely, PPMS may present as an isolated dementia.

The diagnosis of MS relies primarily on the clinical history and examination, with demonstration of events and neurologic signs disseminated in time and space.[25] The McDonald criteria for MS can be fulfilled without ancillary support on the basis of an appropriate history and neurologic exam, with the caveat that MS is the best explanation of the disorder. However, in the majority of individuals diagnostic testing is critical.

MRI is the most sensitive tool for both MS diagnosis and disease monitoring. The former is centered on demonstrating lesions that are both temporally and spatially disseminated. MS lesions are classically seen in the periventricular, juxtacortical (including the corpus callosum), and infratentorial regions and in the spinal cord. Brain lesions are typically ovoid in shape and configured perpendicularly to the ventricles. However, MS can also present with large, tumefactive hemispheric lesions, mimicking a mass. Spinal cord lesions are typically short segmented (one to two vertebral spaces) with a dorsal predilection. Both active and old lesions are hyperintense on T2 and fluid attenuation inversion recovery (FLAIR) sequences; gliotic lesions that correspond with axonal loss are hypointense on T1 sequences (Fig. 38.2). Active, inflammatory lesions are gadolinium enhancing, often with an open-ring configuration in the brain. The McDonald criteria define MRI dissemination in space (DIS) as 2 or more lesions in at least 2 of the periventricular, juxtacortical, infratentorial, or spinal cord regions. MRI dissemination in time can be established with either the presence of both asymptomatic gadolinium-enhancing and -nonenhancing lesions on a single scan or by the development of new T2/FLAIR or new gadolinium-enhancing lesions on sequential studies performed after the index study.[25]

FIG. 38.2 Sagittal T2-weighted magnetic resonance image of a patient with multiple sclerosis and short-segment cervical myelitis at C4–C5 (*arrow*).

MRI is also useful in patients with PPMS whose history reveals a progressive neurologic impairment, usually referable to the spinal cord, that has evolved for at least 1 year. MRI criteria for DIS in PPMS relies on demonstration of two or more spinal cord lesions and at least one lesion in one of the aforementioned periventricular, juxtacortical, or infratentorial zones.[25]

CSF is often useful in confirming the diagnosis of MS when the clinical history and MRI findings are either nondiagnostic or atypical. The presence of CSF oligoclonal bands and/or elevated immunoglobulin (Ig) G index on isoelectric focusing is seen in more than 95% of patients with MS. Mild to moderate CSF lymphocytosis (≤50/μL) and protein elevation (≤100 mg/dL) may also be seen.

Because of the sensitivity of MRI, visual, brain stem auditory, and somatosensory evoked potentials are less commonly used in the diagnosis of MS. Of these, delayed latency of visual evoked responses are the most useful in establishing DIS in selected patients.

Differential diagnosis of MS is broad and includes systemic inflammatory disorders (sarcoidosis, vasculitis, connective tissue disease), CNS infection (Lyme disease, neurosyphilis, HIV related), neoplasm (CNS lymphoma, gliomatosis cerebri), nutritional deficiencies (B12, copper), and structural/compressive disorders (Chiari malformation, cervical spondylotic myelopathy). These diseases can usually be excluded by the clinical history, laboratory findings, and appropriate imaging.

Acute MS relapses are usually treated with short courses of steroids, most frequently with a 3- to 5-day course of high-dose IV methylprednisolone, followed by tapering prednisone for 2 weeks. Patients with severe neurologic deficits that are refractory to steroids may achieve enhanced recovery with plasma exchange.

The treatment of MS has been revolutionized with the development of disease-modifying therapies (DMT) in the early 1990s. There are now 11 Food and Drug Administration–approved injectable, parenteral, and oral agents for RRMS, including four formulations of interferon beta-1a or -1b, glatiramer acetate, mitoxantrone, natalizumab, fingolimod, teriflunomide, dimethyl fumarate, and alemtuzumab. However, the use of mitoxantrone has diminished due to complications of leukemia and cardiomyopathy.[27] Each of these DMTs have demonstrated efficacies in reducing annualized relapse rate and the development of new and contrast-enhancing lesions on brain MRI; the latter is an important component in monitoring patients on treatment.[28] Although there is no established therapy for PPMS, both rituximab and ocrelizumab, monoclonal antibodies that target CD20 B lymphocytes, have demonstrated efficacy in patients with PPMS with activity.[28–30] There are no approved medications for SPMS, although DMTs for RRMS are commonly used in patients with SPMS who have ongoing relapses.[27] The choice

of therapy in a particular patient depends in large part on the severity of inflammatory disease activity, based both clinically and radiologically, with more potent but riskier agents (e.g., natalizumab, fingolimod, alemtuzumab) reserved for patients with aggressive disease.[31] Last, symptomatic treatment directed at MS-associated spasticity, neurogenic bladder and bowel, pain, fatigue, and mood dysfunction is an important facet of patient care.[31]

Neuromyelitis Optica

NMO is an autoimmune, relapsing disease of the CNS that is also characterized pathologically by inflammation and demyelination. NMO was historically portrayed as a monophasic illness related to MS that caused simultaneous optic neuritis and transverse myelitis, sparing the brain. However, with relatively recent advances in neuroimmunology, NMO is now known to be an autoantibody-mediated disorder that is usually distinguishable from MS, with uniquely characteristic involvement of not only the optic nerves and spinal cord, but also the cerebral hemispheres and brain stem. Unlike MS, relapses in NMO often cause severe neurologic disability that requires prompt evaluation and treatment. NMO affects women at a rate of 8:1, a higher ratio than MS. Its incidence in African Americans is also greater than that seen in MS.[32]

Optic nerve involvement in NMO may be unilateral or bilateral, resulting in severe visual loss, not infrequently associated with a long-segment optic neuritis on MRI. Spinal cord attacks are associated with severe quadriparesis or paraparesis, with associated spinothalamic and dorsal column deficits below the level of the lesion as well as urinary or bowel retention. MRI typically reveals a longitudinally extensive central intramedullary hyperintense lesion, spanning three or more vertebral levels, resulting in spinal cord expansion. Other less common manifestations of NMO include refractory hiccoughs or vomiting due to medullary disease, hypersomnolence and syndrome of inappropriate antidiuretic hormone with hypothalamic lesions, and encephalopathy with multifocal tumefactive subcortical inflammatory disease.[32]

Serum antibody to aquaporin-4 (also known as NMO-Ab), a CNS water channel that is expressed on foot processes on CNS astrocytes, is now established as pathogenic in NMO. The serum antibody is found in up to 85% of patients with a cell-based assay.[33] The presence of this antibody in patients presenting with syndromes associated with NMO is highly predictive of future relapse.[22,32]

NMO relapses are treated with high-dose IV steroids followed by a prolonged steroid taper, although plasma exchange is also frequently necessary to achieve satisfactory recovery. Long-term therapy with immunosuppressive agents is mandatory to prevent exacerbations. Although prednisone alone can be used, most clinicians use steroid-sparing agents, including azathioprine, mycophenolate, and rituximab, to reduce complications of chronic corticosteroids.[21] Novel monoclonal antibodies directed against downstream mechanisms of antibody-mediated, inflammatory cytotoxicity, including eculizumab and tocilizumab, are also under study for use in NMO.[34,35]

Myelopathy Due to Connective Tissue Conditions and Diseases

Rheumatoid Arthritis

There have been medical advancements over the last 20 years in the pharmacologic treatments for autoimmune diseases such as rheumatoid arthritis (RA). These treatments include the development of the biologic class of disease-modifying antirheumatic drugs (DMARDs), tissue necrosis factor-α (TNF-α) inhibitors, and traditional DMARDs such as methotrexate.[36] Due to the increased efficacy of these treatments, the true prevalence of cervical spine abnormalities in RA and other inflammatory arthropathies is not known.

RA most commonly affects the occiput–C1 articulation, a saddle joint, and the C1–C2 joint, a pivot joint. These are true synovial joints that RA and other inflammatory arthritides have a predilection to, including 65% of cases involving C1–C2 instability and 20% involving basilar invagination.[37–39] Radiographic findings include vertebral body and spinous process bony erosion and cystic changes, C2 pseudotumor and pannus formation, discitis, as well as ligamentous inflammation, laxity, and calcification.[38,39] RA can be a cause of spinal cord compression due to this degenerative cascade and resultant instability. Subaxial spine degeneration, especially after previous upper cervical spine fusion, should be followed clinically with dynamic radiographs and an MRI scan if upper motor neuron signs are present.[37,40,41] Further fusion and decompression surgery may be indicated depending on the patient's degree of cervical instability and spinal cord compression.

Systemic Lupus Erythematosus and Antiphospholipid Antibody Syndrome

SLE is a chronic and relapsing autoimmune connective tissue disease that affects multiple organ systems. SLE affects the skin, joints, kidneys, lungs, heart, blood, as well as the nervous system, primarily by activating the immune system with formation of immune complexes.[42] The CNS also can be affected by SLE. Patients can present with a headache or mild confusion all the way to seizure or frank myelopathy with or without optic neuritis.[43] There were 19 neuropsychiatric syndromes associated with SLE described by the American College of Rheumatology Research Committee in 1999.[44]

Patients with SLE myelopathy often have CSF abnormalities, including increased protein, pleocytosis, and decreased glucose. The term "longitudinal myelitis" has been given to the characteristic increased MRI signal seen on T2-weighted sequences over several continuous segments.[45]

Antiphospholipid antibody syndrome is characterized by a hypercoagulability and is associated with antiphospholipid antibodies. It is thought to be a possible variant of SLE. These antibodies include lupus anticoagulant, anticardiolipin, and antibodies against β_2-glycoprotein 1. As in SLE, there are wide ranges of neurologic disorders that can be associated with this condition, including myelopathy.

Therapies for these conditions include high-dose IV steroids for acute symptoms, IV immunoglobulin, cyclophosphamide, and plasmapheresis.[43,46]

Sjögren Disease

Sjögren disease is characterized by dry eyes (xerophthalmia), dry mouth (xerostomia), and a noninflammatory arthritis.[47] The disease is about 10 times more common in women than in men and can also have neurologic manifestations, including myelopathy, transverse myelitis, optic neuropathy, and necrotizing myelitis.[47–49] Treatment includes corticosteroids and, in some cases, plasma exchange.[47,49,50]

Behçet Disease

BD is a chronic inflammatory disorder of the blood vessels that can also involve inflammation of the parenchymal CNS (neuro-Behçet). The exact cause of this disease is unknown but thought to be autoimmune related.[51,52] Symptoms can include inflammation with sores or thrombosis in the mouth, eyes, skin, joints, digestive system, brain, and genital regions.

Neuro-Behçet affects approximately 5% to 49% of patients with this disease and can cause symptoms from confusion, psychosis, and mild weakness to complete paralysis.[51–56] Treatment includes high-dose IV steroids and/or TNF-α inhibitors such as infliximab and etanercept; adalimumab has shown variable results.[54,56]

Neurosarcoidosis

Sarcoidosis is a noncaseating granulomatous disease involving multiple organ systems and tissues. Its cause is believed to be autoimmune in nature, but the exact pathogenesis is not known.[57,58] The disease most commonly presents with bilateral hilar lymphadenopathy (>90%), pulmonary infiltrates, skin and eye lesions, and arthralgias. Granulomatous infiltrates can appear in any tissue, including the spine, and can cause arachnoiditis, cauda equina syndrome, intradural or extradural granulomas, and intramedullary spinal masses.

A small percentage of patients (5–10%) can develop CNS involvement, and a definitive diagnosis is difficult to obtain. The mean age of onset of neurologic symptoms is typically in the fourth decade of life.[59] Definitive diagnosis requires a biopsy that will demonstrate noncaseating epithelioid granulomas, and a biopsy sample of the spinal cord is not desirable. Biopsy of lung tissue is a less morbid procedure. MRI scan of the neural axis can be normal in some cases, but contrast-enhanced MRI may show a diffuse increased signal in parenchymal cord tissue or masses.[59–62]

Little is known about the natural history of patients with CNS involvement in sarcoidosis. Recovery over months or years occurs in 60% to 80% of patients with pulmonary disease, however. Treatment is similar to other autoimmune and connective tissue causes of myelopathy, and includes aggressive IV steroids, DMARDs, and TNF-α inhibitors.

Infectious Myelopathies

Several infections can lead to myelopathy in patients due to a variety of disease processes. Most commonly, a direct invasion of neural cells causing edema and permanent neurologic tissue scarring is the mechanism. There is a predilection for these processes to occur in the immunocompromised patients; however, it can occur in those in good health as well. A thorough history, physical examination, radiologic studies, and possibly invasive testing (e.g., CSF analysis) are necessary to make the diagnosis.

Viral Myelitis

Human Immunodeficiency Virus Infection

Human immunodeficiency virus (HIV) is the cause of acquired immunodeficiency syndrome (AIDS) in an estimated 30 million people worldwide.[63] HIV infection has been associated with immunodeficiency, neoplasia, and neurologic disease.[64] High rates of neurologic complications (up to 40–50%) have been reported.[65–67]

In patients with AIDS, vacuolar myelopathy (VM) is the most common spinal cord disease, found in up to 30% of patients prior to the antiretroviral therapy.[68] This most common form of myelopathy in HIV infection was first described by Petito and colleagues,[69] observing spinal cord degeneration. Autopsy revealed a high rate of spinal cord disease that was clinically not as prevalent and likely underrecognized.

Symptoms of VM can overlap with other myelopathies associated with HIV-1 infection; however, the pathologic appearance is distinct. There is a loss of myelin and spongy degeneration found on histologic examination, and the lateral and posterior columns are more affected. The microvacuolization of the white matter of the spinal cord resembles that of subacute combined degeneration. The vacuolization appears to result from intramyelin swelling, with axons being preserved, for the large part. Microglial nodules may be detected in the spinal cord gray matter.[69]

Symptoms of VM include a slowly progressive lower extremity weakness, lack of balance with gait instability and ataxia, dorsal column sensory changes in vibration and position, urinary frequency, urinary urgency, and erectile dysfunction. Spastic paraparesis is present, with weakness being greater than spasticity; prominent hyperreflexia and extensor plantar responses of the lower extremities are also usually present.

MRI findings in patients with AIDS-associated myelopathy can occur in up to 86% of patients. The most common finding is spinal cord atrophy followed by diffuse intrinsic cord signal abnormality.[70] Enhancement with gadolinium is not common. If the MRI of the spinal cord is lacking any findings, CSF can be examined for infection of other pathogens or for the presence of HIV.

Vacuolar myelopathy is a diagnosis of exclusion, as other opportunistic infections and conditions in HIV can be the cause of myelopathy in AIDS patients.

Human T-Cell Lymphotropic Virus Type 1

The human T-cell lymphotropic virus type 1 (HTLV-1) was the first oncogenic human retrovirus to be discovered in 1980.[71] It has since been implicated as the cause of cancer (adult T-cell leukemia/lymphoma) and several other spectrum inflammatory diseases.[72,73] It is believed to infect around 10 to 20 million people worldwide, and the clinical course is usually progressive without remission.[71–75] Infection can occur through a variety of methods, including mother to child, sexual activities, through the sharing of needles and syringes, and by the transfusion of infected blood products in countries that do not screen for HTLV-1 infection.[73,75,76]

The myelopathy that can develop in those infected with HTLV-1 is referred to as *tropical spastic paraparesis* or *HTLV-1 associated myelopathy* (TSP/HAM). It is characterized by chronic involvement of the pyramidal tracts, mainly at the thoracic level, causing lower extremity spasticity and weakness, urinary disturbances, pain, paresthesias, and sensory disturbances.[71,76,77] In a recent longitudinal cohort study by Tanajura and colleagues,[78] the development of neurologic signs and symptoms of HTLV-1 infection occurred in up to 30% of patients. The most common subjective findings were hand and feet numbness, nocturia, and urinary urgency. Lower extremity hyperreflexia and weakness with a positive Babinski sign were the most common objective findings.[78]

Infection of HTLV-1 shares a similar route of transmission as HIV, and dual infection is common.[79] The incidence of myelopathy among patients coinfected with both HIV and HTLV-1 is likely higher, especially in areas where HTLV-1 infection is endemic.[80] Treatment outcomes for TSP/HAM are disappointing; thus it remains as symptomatic therapy only.

Herpesviruses

Varicella-zoster virus (VZV) is a human neurotropic double-stranded DNA alpha-herpesvirus. VZV is the cause of chickenpox (varicella); after active infection, it remains latent for decades in the dorsal root and autonomic ganglia of the autonomic nervous system. As individuals age or become immunocompromised, a decrease in the VZV-specific cell-mediated immunity can occur, resulting in VZV reactivation, causing severely painful and blistering dermatomal eruptions called shingles (herpes zoster).[81–84]

Myelopathy associated with VZV can present as soon as days or weeks after acute varicella, and can present without the typical vesicular eruption and rash associated with herpes zoster.[82,85] Symptoms include a monophasic spastic paraparesis, with or without sensory features, and with or without sphincter problems.[81,82,85] The myelopathy can be insidious, progressive, and sometimes even fatal in immunocompromised patients, such as those with AIDS.[85] MRI can reveal serpiginous enhancing lesions and, in cases of VZV vasculopathy, can cause spinal cord infarcts seen on diffusion-weighted MRI.[85,86]

Diagnosis of VZV myelopathy can be confirmed with CSF analysis for virology. In myelopathy patients, the CSF usually contains a mild mononuclear pleocytosis with normal or slightly elevated protein. The CSF should be analyzed for DNA by polymerase chain reaction and for anti-VZV IgG and IgM.[81] Treatment for VZV myelopathy includes urgent IV acyclovir (10–15 mg/kg three times daily for 14 days) and possibly steroids, especially in those with VZV vasculopathy.[82,87,88]

Myelopathies Resulting From Bacterial Diseases

Syphilis

Sexually transmitted infections (STIs) take a huge toll on patients and society, both medically and economically. There are 20 million new STIs estimated to occur yearly in the United States, with direct and indirect medical costs estimated to exceed $16 billion.[89] Syphilis is an STI that accounts for 20% of these infections and occurs due to an infection by the bacterium *Treponema pallidum*.[89] In 2013, primary and secondary syphilis infection in the United States was estimated to occur in 5.3 cases per 100,000, more than double the lowest-ever rate of 2.1 in the year 2000.[90] The highest rates were found in men who have sex with men, with men accounting for more than 90% of syphilis cases in 2013.[89–91]

The *primary stage* of syphilis infection is marked by a single sore, or chancre, that occurs at the site where the bacterium entered the body. The chancre is firm, round, small, and painless. The time between infection and the first symptom can range from 10 to 90 days, and the chancre lasts 3 to 6 weeks before healing without treatment.[91] If no antibiotic treatment is sought, the infection progresses to the secondary stage.

The *secondary stage* of syphilis infection is characterized by a skin rash or rashes, typically nonpruritic in nature, and rough red to reddish brown spots located on the palms and the bottoms of the feet. Without antibiotic treatment, individuals will progress to tertiary or latent syphilis after the primary and secondary symptoms disappear. *Tertiary syphilis* can occur 10 to 20 years after the infection was acquired and affects up to 15% of those that were not treated at the primary or secondary stages.[91]

Invasion of the CNS by the *Treponema pallidum* bacterium usually occurs within 1 year of the primary infection. Headache and meningismus symptoms can be seen during the secondary syphilis stage, with up to 2% of patients having acute meningitis. Patients that are not treated with penicillin can develop neurosyphilis.

Tabes Dorsalis and Syphilitic Meningomyelitis

The spinal cord can be heavily affected by syphilis. Prior to the discovery of antibiotics, syphilis was believed to be the most common cause of spinal cord disease.[67,92] Tabes dorsalis is the prototypic spinal cord disease associated with syphilis and can be divided into three phases: the *preataxic phase*, the *ataxic phase*, and the *terminal* or *paralytic phase*. Currently, tabes dorsalis is thought to account for only 5% of neurosyphilis

cases, but it is still a diagnostic and treatment dilemma in the developing world.[93,94] Testing for neurosyphilis includes algorithms for those with and those without HIV infection and may not catch all cases of chronic syphilis.[95,96] Tests include CSF VDRL (Venereal Disease Research Laboratory), CSF FTA-ABS (fluorescent treponemal antibody absorbed), CSF TPPA (*Treponema pallidum* particle agglutination assay), CSF T pallidum PCR (polymerase chain reaction), and CSF INNO-LIA (line blot immunoassay).[96]

Pathology of the spinal cord reveals overall atrophy in the posterior columns and spinal roots, with dorsal column demyelination of the fasciculus gracilis, root entry zone, and Lissauer tract. There is also thickening of the medium and small blood vessel walls. MRI findings include spinal cord atrophy and intramedullary hyperintensities, similar to findings seen in subacute combined degeneration; however, they can be normal in some cases.[94,97]

The *preataxic phase,* or period of "lightning pain," is the first phase occurring 10 to 15 years after primary infection and can last as long as 3 years. The majority of patients present with severe and lancinating pain. Other findings include a loss of muscle stretch reflexes, sensory losses, Romberg sign, and Argyll Robertson pupils (intact visual acuity but decreased pupillary light reflex and irregular pupils). Pain sensation is disturbed, with a delay in pain perception of approximately 15 seconds and an aftersensation lasting 30 seconds. Superficial pain sensation may be normal, but deep pain sensation is typically abnormal. Loss of deep pain sensation is reported with the application of pressure to the ulnar nerve (Biernacki sign), the Achilles tendon (Abadie sign), and the testicle (Pitres sign). Neuropathic pain is difficult to treat but can be attempted with gabapentin or other neuromodulatory agents.[98]

The *ataxic phase* is characterized by severe ataxia in the legs and has a variable duration of 2 to 10 years. Patients continue to lose deep pain sensation as well as proprioception and vibratory sense, which leads to a slapping and uncoordinated gait. These neurologic losses can lead to neuropathic joints and arthritic changes in the ankles, knees, hips, and spine.[99–102]

The final phase is known as the *terminal* or *paralytic phase*. The average duration of this final phase is between 2 and 10 years and is characterized by cachexia and paralysis, with severe constipation and urinary incontinence being prominent as well. Fatality is typically related to urosepsis or sepsis from decubitus ulcers.

Syphilitic meningomyelitis is seen most commonly in male patients between 25 and 40 years old and within 6 years of primary infection.[103,104] A slow and gradual leg weakness is noted and has similar symptoms as those with myelopathy due to cervical spondylosis. Muscle stretch reflexes are exaggerated with positive Babinski signs but muscle bulk is preserved. Autonomic dysfunction with urinary frequency, hesitancy, and impotence are common. On pathologic exam, the meninges are thickened and inflamed, with symmetrical involvement of the lateral columns. Granulomatous invasion with inflammation and vascular changes are noted in the medium and small vessels.

FIG. 38.3 Sagittal T2-weighted magnetic resonance image demonstrating a kyphotic deformity at the thoracolumbar junction arising from granulomatous disease (Pott disease).

Tuberculosis

Tuberculosis (TB) is caused by *Mycobacterium tuberculosis* and is a common source of neurologic complications in less-developed parts of the world. Skeletal manifestation of tuberculosis most commonly affects the spinal column in nearly 50% of cases.[105] Myelopathy occurring from spinal tuberculosis (Pott disease) is typically a compressive myelopathy due to a collapsing anterior spinal column from spinal instability as well as compression on the spinal cord from granulation tissue (Fig. 38.3).

Neurologic symptoms are present in more than 90% of patients with spinal TB and include sensory deficits, pain, paraplegia, and incontinence.[106] Thoracic spine involvement is most common (57%), followed by the cervical spine (29%).[106] The mainstay of treatment is medical, with long-term antibiotic therapy for at least 1 year, although 6 months may be adequate in some clinical situations.[107,108] Surgery has been noted to improve both pain and neurologic function in patients with progressive neurologic symptoms, but its usefulness is still debated.[109,110] Long-term sequelae and adverse outcomes can still be noted in those treated surgically, including chronic pain, deformity, and permanent neurologic injury.[105,106,109,110]

Spinal Epidural Abscesses

Spinal epidural abscesses (SEAs) are potentially devastating infections that can have a high mortality rate (Fig. 38.4). There are few high-quality studies to guide treatment of this potentially devastating condition.[111–113] Despite advances in early detection, diagnosis, and treatment, mortality rates can still

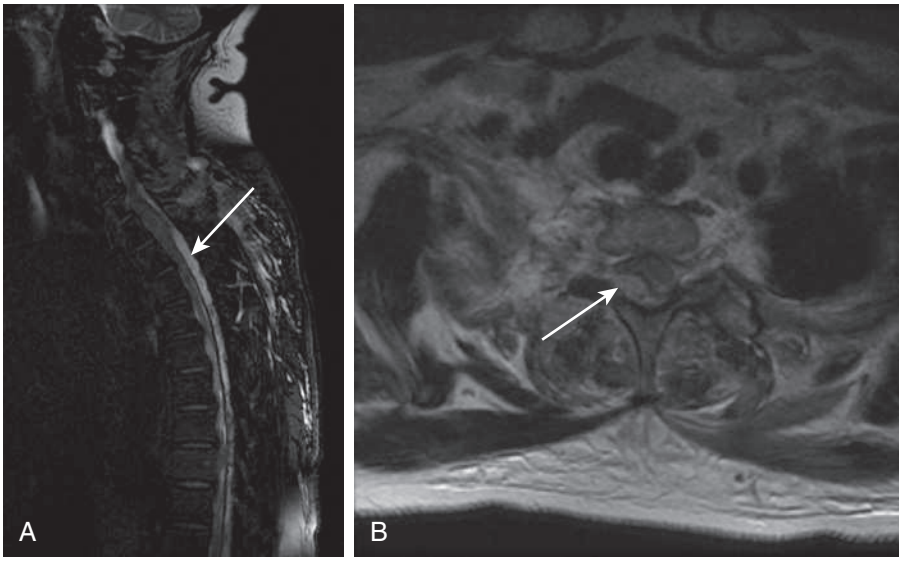

FIG. 38.4 (A) Sagittal T2-weighted short tau inversion recovery magnetic resonance image (MRI) of a patient with cervicothoracic epidural abscess compressing the spinal cord (*arrow*). (B) Axial T2-weighted MRI of the thoracic spine from the same patient demonstrating right-sided epidural spinal cord compression with cord deviation to the left (*arrow*).

approach 20%, and failure of medical treatment alone is as high as 75% to 99%.[111,113–115]

The incidence of SEAs is thought to be approximately 1.8 per 100,000 persons per year, with *Staphylococcus aureus* as the most common organism.[116] Several risk factors have been associated with SEAs, including HIV infection, IV drug use, diabetes mellitus, obesity, prior spinal surgery, advanced age, alcoholism, and liver disease.[108,111–115,117,118] Upper cervical epidural abscess, although rare, is associated with high rates of mortality and permanent neurologic deficits.[119]

In a recent database study by Schoenfeld et al., advanced age and liver disease were found to increase in-hospital mortality significantly; diabetes and chronic lung disease were the most frequently encountered comorbidity.[118] In the same study, hospital charges averaged nearly $160,000, with a range of $4000 to $3.3 million in charges. In addition to recalcitrant back pain, neurologic symptoms are present in a large portion of this population, with permanent paralysis as a known complication.

Practitioners should have a high index of suspicion for infection in patients presenting with back pain, subjective fevers, and weakness.[120] Other findings can include an increased white blood cell count, elevated C-reactive protein, and elevated erythrocyte sedimentation rate. Patients with multiple medical comorbidities and chronic immunosuppression may not have as prominent features compared with immunocompetent patients.

Noncontiguous SEAs have been reported by Ju et al., with risks being a delay in diagnosis (>7 days), a concomitant area of infection outside of the spine, and an erythrocyte sedimentation rate of greater than 95 mm/h.[112] Vertebral osteomyelitis is a common associated finding seen in approximately 86% of SEA cases.[108] In a recent retrospective review of electronic medical records in 355 patients over an 18-year period, Kim et al. determined patient characteristics that were prone to medical treatment failure. Factors associated with medical treatment failure included infection caused by methicillin-resistant *Staphylococcus aureus* (MRSA), patients older than 65 years, those with diabetes, and patients with major neurologic deficits.[115] Current treatment recommendations remain controversial, but there is a push for early surgical debridement in addition to long-term antibiotic treatment.

Nutritional Myelopathies

Vitamin B12 Deficiency

Vitamin B12 (cobalamin) deficiency is the most common nutritional cause of myelopathy.[121] Vitamin B12 is absorbed in the gastrointestinal tract via the intrinsic factor. Gastric parietal cells make intrinsic factor. Autoimmune-associated loss of parietal cells leads to lack of production of intrinsic factor. This is called pernicious anemia, and is the most common cause of vitamin B12 deficiency.[121] Myelopathy occurs in the setting of vitamin B12 deficiency because it is responsible for the myelination and maintenance of the CNS. Other causes of vitamin B12 deficiency include a history of gastric bypass surgery, a strict vegan diet, and nitrous oxide abuse.[122,123] Since vitamin B12 is found in meat and dairy, a vegan diet leads to inadequate intake. Nitrous oxide is a recreational inhaled drug that causes depletion of vitamin B12.

Clinically, patients will present with myelopathic signs and paresthesias of the upper and/or lower extremities. MRI of the spine in the setting of vitamin B12 deficiency will have a pathognomonic sign called the "inverted V sign" (Fig. 38.5).[124]

Lab work to determine serum vitamin B12 levels is the first step in evaluating for vitamin B12 deficiency.[121] If a low serum level is reported, additional testing of serum methylmalonic

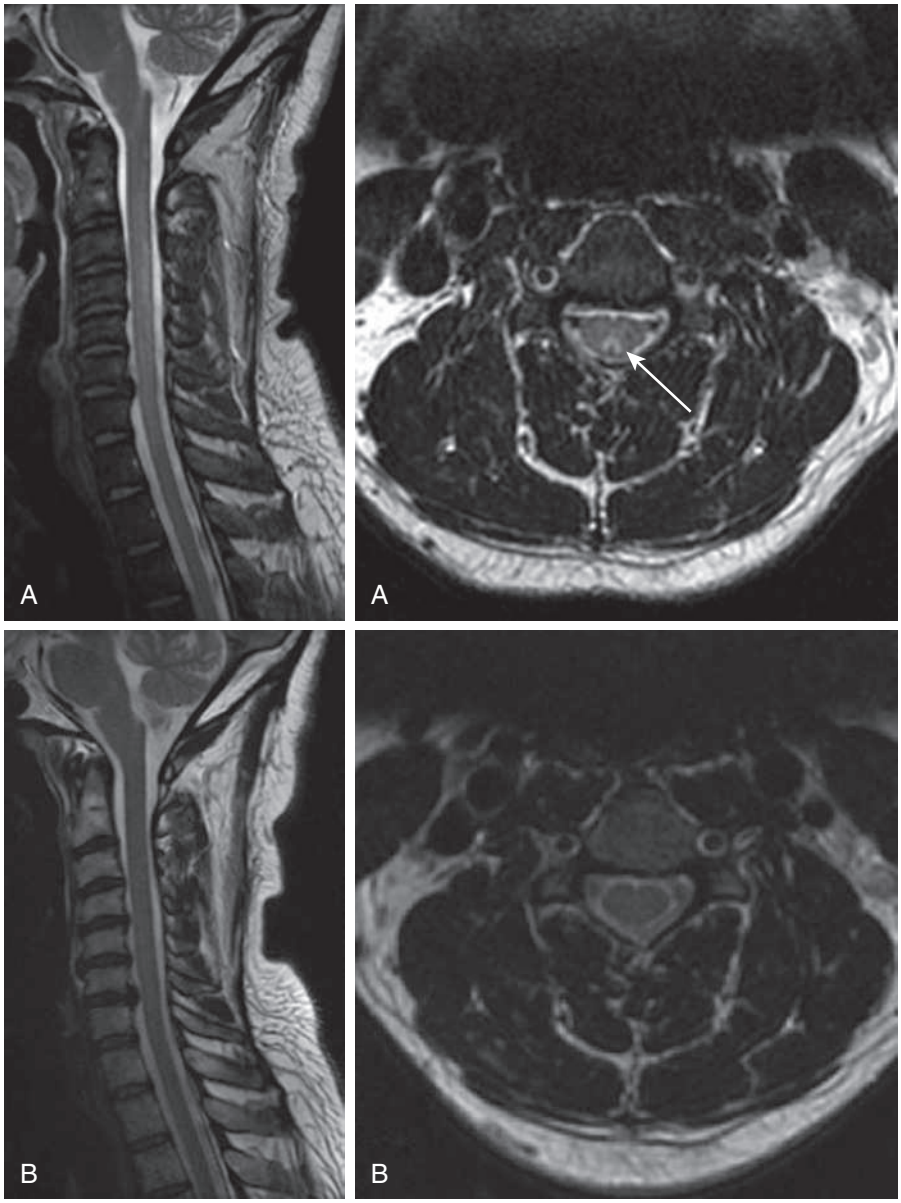

FIG. 38.5 (A) Sagittal and axial T2-weighted magnetic resonance imaging (MRI) of the cervical spine in patient with vitamin B12 deficiency. Note the "inverted V sign" on the axial MRI (*arrow*). (B) Sagittal and axial T2-weighted MRIs taken 6 months after the initiation of vitamin B12 injections demonstrating resolution of the nverted V sign.

acid and total homocysteine should be performed. In the presence of vitamin B12 deficiency, the serum level of these two proteins is highly elevated. If there are no dietary or other risk factors for vitamin B12 deficiency, then testing for pernicious anemia is recommended. Anti-intrinsic factor antibody and/or antiparietal cell antibody can be tested; a positive result is usually diagnostic of pernicious anemia.

Treatment of vitamin B12 deficiency consists of vitamin B12 injections (cyanocobalamin). Injections may consist of 1000 µg several times a week for up to 2 weeks, followed by monthly injections and clinical evaluation for resolution of symptoms alongside laboratory testing.[121] There are also options for oral vitamin B12 treatment. If the inverted V sign was present on spinal MRI on repeat imaging following vitamin B12 treatment, the sign will no longer be present. Pernicious anemia often requires lifelong treatment.

Copper Deficiency

Copper deficiency is a less common form of myelopathy and clinically presents in a manner similar to vitamin B12 deficiency.[125,126] Copper is important in the function of key enzymes, and deficiency can affect the CNS. Risk factors for inadequate gastrointestinal copper absorption and subsequent deficiency include gastric bypass surgery, increased zinc intake, and malabsorption syndromes. Diagnosis is via serum copper and ceruloplasmin levels and treatment is with supplementation of oral copper and elimination of risk factors if possible.

39 CHAPTER Nonoperative Management of Disc and Degenerative Disorders

Daniel Park
Jad G. Khalil
Michael P. Planalp

Introduction

Axial neck pain is a significant and highly prevalent cause of disability. Cross-sectional, population-based surveys have demonstrated that acute and chronic neck pain permeates the population at large.[1–3] In population registries from Norway, and later corroborated in Finland,[3] Bovim and colleagues[1] showed an overall prevalence of neck pain of 34.4%, with 13.8% of these individuals reporting chronic neck pain of greater than 6 months' duration. In their evaluation of 1131 patients, Cote and colleagues[2] found that 54% of subjects had experienced significant neck pain, 5% of which was reported as highly disabling. In the acute setting, the majority of neck pain can be thought of as resulting from soft tissue sprains and muscle strain. Chronic pain, on the other hand, is more likely to be caused by a degenerative etiology.

Degeneration, or spondylosis, of the cervical spine is a descriptor applied to a wide range of cervical disorders. Pain etiology can be discogenic, radiculopathic, and myelopathic in nature, all of which usually originate with degenerative changes of the cervical disc space. Degeneration of the healthy disc can lead to subsequent bulge or herniation, leading to impingement of the neural structures adjacent to the disc. In addition to neuropathic pain, disc degeneration can lead to loss of the normal cervical alignment and collapse into kyphosis due to loss of disc height. This degenerative cascade can also lead to instability of the cervical motion segments and compensatory osteophytosis, providing another vehicle for compressive potential. Posterior neural impingement can also occur through hypertrophy of the facet joints and ligamenta flava.

These conditions can happen independently or together and may lead to axial neck pain, causing patients to seek medical attention for relief of neck pain, arm pain, weakness, or numbness. Many of these problems are self-limited; for this reason, the vast majority of patients are successfully treated nonoperatively, using a combination of established methods. Surgery is typically reserved for patients with myelopathy or severe, progressive weakness. This chapter will discuss the various nonoperative modalities focusing on the degenerative causes, particularly axial neck pain and cervical radiculopathy. We will not address the impact of myelopathy due to the surgical nature of this disorder.

General Treatment Approach

Once the diagnosis is made, a discussion must take place between the physician and patient regarding the direction of treatment. Initial treatment decisions are based upon the disease course. Fortunately, the natural history of nonmyelopathic spondylotic cervical disorders is statistically favorable. In their long-term study of 205 patients with axial neck pain, Gore et al. showed 79% improved with nonoperative care.[4] In this study, only one-third of patients reported persistent moderate to severe pain, with initial symptom severity and specific injury being the only predictors of refractory disease.

With regard to radiculopathy, results of conservative management are similar. In their 1965 study, DePalma and Subin[5] found that 75% to 90% of patients will have symptomatic improvement of radicular pain with nonoperative therapy. These data are corroborated in the classic study by Lees and Turner,[6] who found the natural history of cervical radiculopathy to be generally favorable, with only 25% of patients having persistent or worsening symptoms and no patients with radiculopathy progressing to myelopathy. It is important to note the distinction in treating cervical myelopathy, which is generally considered a surgical disorder because of the progressive nature of disease.[7] Surgery has been shown to improve prognosis in myelopathy, with better functional and neurologic outcomes versus nonoperative care.[8]

In the clinical setting, it is difficult to predict which patients suffering from axial neck pain or radiculopathy are likely to improve and which are likely to fail nonoperative measures. Because of this and because research has shown that an overwhelming proportion of patients are likely to improve with conservative management alone, nonoperative treatment is the initial approach of choice for patients with axial neck pain or radiculopathy. Surgery is reserved for patients with neurologic deficits, progressive dysfunction, or failure to improve after an appropriate course of nonoperative treatment. The

definition of what constitutes an appropriate course of nonoperative treatment (in terms of duration and actual regimen) has not been standardized, however.

The rationale for initially avoiding surgery is clear, but it is more difficult to identify if nonoperative measures can actually improve the natural history. No controlled trials have compared the various nonoperative regimens (e.g., physical therapy modalities, traction, medications, manipulation, and immobilization) versus the natural history (i.e., no treatment at all). Several studies have looked at various treatment regimens and algorithms but are limited by lack of sufficient control groups to definitively compare outcomes to natural history. As a baseline, the nonoperative progression consisting of immobilization, ice, rest, nonsteroidal antiinflammatory drugs (NSAIDs), traction, postural education and strengthening, oral steroid tapers, acupuncture, and transcutaneous electrical nerve stimulation can be used. This regimen was analyzed by Lees and Turner[6] and resulted in 77% of patients having good to excellent results. Based on comparison with previously published surgical series, the authors suggested that their nonoperative outcomes were comparable to surgical outcomes and superior to the natural history of cervical radiculopathy. This interpretation is limited, however, by the absence of true controls in the surgical or natural history categories, as previously mentioned.

There are also no studies adequately assessing outcomes of surgical versus nonsurgical treatment. Saal et al. studied a group of patients divided into surgical and nonsurgical arms and concluded there were more favorable outcomes in the nonsurgical group.[9] However, valid conclusions are difficult to make from this study due to more disease severity at initial presentation in the surgical group. This study and others[4–6,9,10] have shown correlation between higher disease severity at initial presentation and failure of nonsurgical treatment; these patients may be better suited to operative intervention. There remains an unknown dividing line between patients who could benefit from conservative management and those who should be offered immediate surgery at the outset to avoid delays in delivering the ultimately needed treatment.

Regardless of whether surgical or nonsurgical treatment is selected, there are certain modifiable risks of which every patient should be made aware. Smoking is a well-documented risk factor for neck pain[11–13] and has been shown to advance degeneration of the intervertebral disc and connective tissues. Occupations requiring excessive cervical motion and overhead work may accelerate the process of disc degeneration, as can vibration caused by heavy equipment.[11,13–15] Lifestyle and occupation changes may be a necessary first step in the treatment process to prevent and alleviate symptoms.

Mechanical Treatment Modalities

From cited literature, the natural history of cervical spondylosis trends toward resolution. Therefore, the immediate goals of the physician are to control the patient's pain, minimize the disruption of the patient's life and work, and educate the patient about the problem and prognosis.

When tailoring treatment for each patient, the initial approach should be directed at pain control and the restoration of movement. Pain is usually the first complaint; patients will frequently limit their activities or even immobilize themselves in order to prevent pain exacerbation. Immobility can quickly lead to deconditioning, leading to further decreases in activity, further deconditioning, and chronic pain. It is therefore crucial to encourage participation in physical therapy to regain strength and retrain proper alignment. Table 39.1 summarizes available nonoperative treatments for cervical degenerative disorders.

Immobilization

Activity can often lead to pain exacerbation, causing a patient to decrease participation. A short course of cervical spine immobilization can be used initially to decrease local inflammation of painful joints and soft tissues around nerve roots. Immobilization may also diminish muscle spasm, and the warmth provided by wearing the collar may be therapeutic.[16] While the use of collars has theoretical benefits, there is no evidence to suggest their efficacy. Their use has neither limited the duration or severity of radiculopathy[17] nor decreased the degree or duration of neck pain after whiplash injury.[18]

Since their use has not been statistically delineated, we believe that the use of collars should be reserved to the short term, not to exceed 2 weeks. Prolonged immobilization should be avoided to prevent deconditioning and atrophy of the cervical musculature. Nighttime collar wear may be helpful by maintaining proper cervical alignment during the entire night and protecting the discs from abnormal loads associated with poor posture while the patient is not in control.

Temperature Therapy

As mentioned, heat from a cervical collar has been shown to provide subjective therapeutic benefits, but cold therapy can also relieve discomfort due to pain and spasm. In the acute period, inflammatory changes may be exacerbated by external heat sources and should be avoided in favor of cryotherapy. After the acute pain period has started to wane and motion has started to return, heat may see added benefit. These measures can generally be tried by the patient at home and do not require the attention of a physician unless they are used directly to facilitate an active rehabilitation program.

Passive Modalities

Massage, ultrasound, and iontophoresis all have failed to be of proven long-term efficacy.[19] Other passive modalities that require no effort on the part of the patient may also be of limited value because the patient is not an active participant in his or her own recovery.

Traction

In the literature, traction has not proven to show any long-term benefit.[20–23] However, patient reports suggest it continues to be a

TABLE 39.1 Nonoperative Modalities for Treatment of Cervical Disc and Degenerative Disorders

Modality	Pros	Cons
Cervical collars	Immobilization may decrease inflammation and muscle spasm.	Muscle atrophy from prolonged use.
Ice or heat	Ice may relieve acute pain and spasm; heat beneficial when regaining motion.	Heat may exacerbate pain in acute period.
Traction	With neck in flexion, may relieve foraminal compression.	Avoid in myelopathic patients; if neck extended, may worsen compression of narrowed foramen.
NSAIDs	Safe, cost-effective method to decrease inflammation.	Gastrointestinal side effects, cardiovascular risks with COX-2 inhibitors.
Narcotics	Rapid pain relief in acute period.	Constipation, sedation, depression, and potential for abuse.
Corticosteroids	May decrease radicular pain acutely.	Avascular necrosis, increased blood glucose, unproven long-term benefits.
Muscle relaxants	Acute relief of muscle spasms.	Sedation, fatigue, abuse potential, limits participation in rehabilitation.
Exercise and physical therapy	Well tolerated, aerobic conditioning.	No long-term pain benefits shown, forceful passive range of motion may lead to further injury and increased pain.
Cervical manipulation	Some anecdotal reports of relief.	No objective evidence of improvement in pain; rare potential complications, including myelopathy, spinal cord injury, vascular injury.
Cervical steroid injections	Antiinflammatory effect, interruption of nociceptive input/sympathetic blockade, mechanical disruption of adhesions.	Rare complications include dural puncture, meningitis, epidural abscess, intraocular hemorrhage, epidural hematoma, adrenocortical suppression, paralysis.

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal antiinflammatory drugs.

home therapy and is said to provide intermittent symptom relief for patients with axial neck pain or radiculopathy. The presence of myelopathy is a contraindication to traction, as it can put the spinal cord under stretch and cause further damage. If traction is to be employed at home, care should be taken to explain the need for a flexion-type moment to expand the available space for the nervous structures. Extension can increase the stenosis in an already compromised neural foramen.

Pharmacotherapy

The following medications are among the most frequently used drugs to combat cervical disc disease.[24]

Nonsteroidal Antiinflammatory Drugs

NSAIDs are the most common intervention prescribed for nonmalignant chronic pain in the United States[25] and they should be considered first-line pharmacotherapy for the patient who presents with cervical spondylosis and radiculopathy. In a retrospective review of patients with neck pain and other disorders from 2000 to 2014, Wong[26] found evidence to suggest that NSAID use is more effective than placebo, despite finding no increased benefit in treating low back pain. The mechanism of action aims to decrease prostaglandin synthesis, thereby decreasing the inflammatory response. It also has analgesic properties.

There are many drugs currently on the market that are over the counter and possess safe side effect profiles, but there are risks associated with long-term use, including liver, cardiac, kidney, and gastrointestinal problems. The low cost and relative effectiveness of these drugs make them an ideal first-line agent. Most over-the-counter NSAIDs inhibit cyclooxygenase-1 (COX-1) and COX-2. There are now a range of selective COX-2 inhibitors that avoid the side effects associated with inhibiting the COX-1 enzyme, including gastrointestinal problems and platelet dysfunction. However, selective COX-2 inhibitors have not proven to be any more effective than their nonselective relatives in controlled trials of osteoarthritis.[27–29] Selective inhibitors are also associated with higher cost and potential cardiovascular complications.[30]

Oral Corticosteroids

Much like NSAIDs, corticosteroids are utilized for their antiinflammatory properties. Unlike NSAIDs, however, corticosteroids possess no analgesic properties. Used systemically, corticosteroids are often administered to patients with acute neck or arm pain.[24] Oral tapers are most commonly used with good anecdotal results but little clinical data. Theoretically, their antiinflammatory properties should decrease any swelling surrounding impinged nerve roots, and may diminish radicular pain. It is thought they are more effective at treating radicular arm pain than axial pain, but no long-term benefit in altering the natural history has been shown. The side effect profile can include immunocompromise, metabolic derangement, and avascular necrosis of the femoral and humeral head. Because of these rare but significant complications, corticosteroids should be used judiciously. They may be contraindicated in patients with severe diabetes because of effects on blood glucose, and patients being administered steroids need to be counseled appropriately.

Opioids

Opioid analgesics should be used with care in the patient with axial neck pain. There is a role for their use in the acute setting of pain exacerbation, but due to their addictive and

tolerance-building properties they should not be used by the spine surgeon to manage chronic neck pain. Opioids are best reserved for the acute setting as breakthrough treatment to supplement NSAIDs or in patients who cannot tolerate NSAIDs. Once an acute exacerbation of pain is controlled, weaning should immediately commence.

Opioid medications are one of the most studied drug classes, and their side effects are well established. Constipation, sedation, depressant qualities, abuse potential, and the tendency to develop tolerance all limit their effective use. As patients develop more tolerance to their current opioid level, the dosage will need to increase in order to continue effectiveness. Extended-release opioids provide a more even blood level for longer periods, but the use of these medications should be judicious. In practice, the spine surgeon should work closely with a pain management specialist to manage patients requiring such regimens. A multidisciplinary pain program should also include a psychological evaluation and emotional support, while seeking to decrease the patient's pain level and teaching the patient to deal with unresolved pain.

Neuropathic Pain

Amitriptyline is an antidepressant commonly used for patients with cervical disc disease.[24] Its benefit is multifactorial in that it is able to treat depression, sleeplessness, and pain, all of which can be associated with chronic neck pain. While the mechanism is currently not fully understood, amitriptyline has shown some analgesic benefit in a placebo-controlled trial of lower back pain and lumbar radiculopathy.[31] There is currently no replicative study in the cervical spine, but extrapolation may be possible.

Gabapentin is an anticonvulsant medication frequently used to treat radicular pain. While the mechanism has not been fully described, it is an analog of the γ-aminobutyric acid (GABA) neurotransmitter and is currently Food and Drug Administration (FDA) approved to treat neuropathic pain. Robertson et al. found gabapentin to have greater efficacy in pain reduction compared to placebo in patients with neuropathic pain due to sciatica.[32] Reported side effects were minimal and included dizziness, somnolence, chest pain, dry mouth, constipation, headache, and peripheral edema.

Both gabapentin and amitriptyline have a time lag of several weeks before they show therapeutic benefit. There are clear uses elsewhere in the body, but limited research related to the cervical spine to clearly identify their role in treatment.

Muscle Relaxants

Muscular spasm can be a significant component associated with degenerative cervical disease, and antispasmodic medications are commonly prescribed. Similar to opioids, muscle relaxants tend to cause sedation and fatigue, and they are increasingly being recognized for their abuse potential. Their depressive effect may be more pronounced when administered simultaneously with opioids. Muscle relaxants should only be used as short-term treatment because they may impair the patient's ability to participate in rehabilitation.

Exercise and Physical Therapy

Over the long-term course of disease, there is inadequate data to show if physical therapy can alter the natural history of cervical radiculopathy.[33,34] Several short-term studies have shown good results, however, when compared to surgical groups. Enqquist et al.[35] conducted a prospective randomized trial looking at patients with cervical radiculopathy treated with anterior cervical decompression and fusion with physiotherapy compared to physiotherapy alone. The surgical group resulted in more rapid pain improvement in the first postoperative year, but by the conclusion of the study at 2-year follow-up, the differences between groups decreased. Peolsson et al.[36] found similar results while evaluating physical function after 2-year follow up. The conclusion from these studies is that a structured physiotherapy program should be tried on all patients and those who fail should be counseled regarding surgery.

In the acute pain period, patients may have difficulty participating in aggressive therapy regimens. A graduated program of physical therapy is commonly prescribed for these patients, starting with initial passive modalities and progressing to active modalities in order to regain strength lost during any immobilization. There has not been any proven benefit from passive modalities in the long term,[37] but they are well tolerated short term when patients are too symptomatic to participate in an active therapy regimen. Eventually, when the acute pain resolves, a program of isometric exercises is started allowing strengthening without potentially painful cervical motion. This program can help regain strength lost due to intentional or unintentional immobilization, and also teach proper posture and biomechanics to prevent further harm. Concern does exist that isometric contraction of the cervical musculature can cause increased intervertebral disc loading force, exacerbating pain, but often the benefit outweighs this theoretical disadvantage. In general, passive modalities pose greater risk than active exercises and should be limited in their use. At the extremes of motion, patients are not able to protect themselves and forcible motion can result in worsening pain and loss of motion.

After the initial passive and isometric phase, active range of motion and resistance exercises are typically added as tolerated by the patient. An expanded program addressing weaknesses of the entire body, but focusing on the neck and shoulder girdle,[34] may be instituted to improve biomechanics and posture. For a patient with cervical disc disease, special attention should be given to the scapular stabilization muscles, including the trapezius, deltoids, latissimus dorsi, and rhomboids. Aerobic conditioning may also be helpful in relieving symptoms but is ideally limited to low-impact activities, such as walking, cycling, swimming, and use of elliptical trainers.

Once the patient has gained familiarity with the exercises, the program will shift from recovery to prevention in a long-term home exercise regimen. This will include simple exercises that can be performed easily on a daily basis with inexpensive equipment found at home.

Manipulation

There are no quality data to suggest clinical effectiveness of manipulative therapy on the cervical spine[38] and its efficacy for the treatment of cervical radiculopathy has not been established.[39–42] Further, although there are many theories, the mechanisms of action for manipulation are poorly understood.[43] There is some evidence that cervical manipulation can provide some short-term relief from cervicogenic headaches and neck pain[39] but no data to suggest long-term effectiveness.

There are, however, several rare and potentially catastrophic complications of cervical manipulation, including radiculopathy, myelopathy, spinal cord injury, and vascular injury.[41] The complication rate is admittedly small, at 5 to 10 per 10 million manipulations.[39] Thomas[44] showed the risk of carotid artery dissection and vertebral artery dissection with manipulative therapy to be less than the risk in the general population. Nevertheless, in the absence of objective evidence showing any proven benefit and given the known risks (albeit low probability), cervical manipulation is not routinely recommended for patients with cervical radiculopathy and should be strongly avoided in patients with known myelopathy.

As with all therapeutic interventions, the patient should be made aware of any potential complications associated with intervention. If manipulation is employed, the clinician should be able to identify patients at risk for injury and be able to recognize any suspicious symptoms. Absolute contraindications for spinal manipulation include vertebral fracture or dislocation, infection, malignancy, spondylolisthesis, myelopathy, vertebral hypermobility, Marfan and Ehlers-Danlos syndromes, osteoporosis, spondyloarthropathies, severe diabetes mellitus, anticoagulation therapy, and objective signs of spinal nerve root compromise.[38] A radiographic screen for cervical instability should be performed prior to manipulative therapy.

Injections

According to current literature, steroid injections into the cervical spine can be expected to yield 50% to 80% good to excellent results in patients with cervical radiculopathy. However, unlike the lumbar spine, there is a paucity of studies to adequately evaluate the true efficacy of cervical injections. With current research, it is unclear how to compare with either the natural history of radiculopathy or surgical management. A possible reason for the lack of data for cervical injections is the increased risk of performing them relative to lumbar injections. Nonetheless, the theoretical benefits are the same, and since disease pathophysiology of disc degeneration and radiculopathy is similar in the lumbar and cervical spine, benefit should likewise be found in the cervical spine. The effects of steroids are multifactorial: an antiinflammatory effect, with inhibition of prostaglandin synthesis; interruption of nociceptive input from somatic nerves; a direct membrane-stabilizing effect; blockade of neuropeptide synthesis; sympathetic blockade; the mechanical effect of the injectant breaking up epidural adhesions; and blockade of C fiber activity in the dorsal root ganglion.

Epidural Injections

Injections of steroid into the epidural space are a mainstay of management for lumbar degenerative disease. In the cervical spine, however, there is little well-designed literature to adequately judge clinical effectiveness. In their prospective analysis of 42 patients, Stav et al.[45] injected methylprednisolone into either the epidural space or the posterior cervical musculature. There was a statistically significant difference in outcomes at 1 week, with the epidural group reporting 76% good to excellent results using the visual analog scale versus 36% in the musculature group. The difference in groups continued to the 1-year follow-up (68% good to excellent results for epidural injections vs. 12% for muscle injections).

In a retrospective analysis, Cicala and colleagues[46] found 56% to 80% good to excellent results at 6 months after C7–T1 epidural steroid injections; but their patient population was mostly a multitude of neck pain instead of radiculopathy. They also had no control group, making it virtually impossible to find a difference between the injection group and the natural history of disease in these patients. A separate investigation by Rowlingson and Kirschenbaum[47] looked at 25 patients with a clinical diagnosis of radiculopathy. Their analysis showed 64% good to excellent results at 15 months after C6–C7 or C7–T1 epidural steroid injections—but, again, without a control group. Finally, Ferrante and colleagues[48] reviewed 100 patient charts in search of predictors of good outcomes with cervical epidural steroid injection. Age greater than 50 years with radicular pain had better outcomes at 13.5 months unless radiculopathy was due to disc herniation.

Selective Nerve Root Blocks

A variant of epidural steroid injections, selective nerve root blocks instead bathe a specific nerve root in steroid injectant. These injections can be considered more localized, as they can direct a higher concentration of steroid solely at the inciting nerve rather than the entire cord. From a safety standpoint, they also decrease the risk of direct cord injury, as they are targeting a root instead. Retrospectively, Slipman and colleagues[49] found 60% good to excellent results at 21 months after injection. Vallee and colleagues[50] found 50% good to excellent results at 12 months in their prospective evaluation.

Complications and Efficacy

Like surgery, cervical injection therapies are an invasive measure and there are well-documented complications that can result, including infection (1–2%), neurologic deterioration, intravascular injections (7.9–11.6%), cerebrospinal fluid fistulas (0.4–6%), persistent positional headaches (28%), arachnoiditis (6–16%), hydrocephalus, air embolism, urinary retention, allergic reactions, stroke, blindness, hematomas, seizures, and death.[51]

There is insufficient literature to date to definitively establish a long-term benefit of cervical injections when compared to the natural history of disease. Successful treatment by injections is often defined by transient pain relief, but it is difficult to differentiate between treatment success and the normal self-limited course of disease. Recent evidence has suggested there may be little long-term difference between injection of steroid versus saline.[52,53] In addition, multiple studies have followed patients over 1- to 2-year intervals after treatment with epidural methylprednisolone and determined the treatment did not result in functional benefit or decrease the need for eventual surgery.[54,55] Epstein[51] concluded in a 2013 review that although cervical injections may offer transient pain relief in this patient population, the plethora of risks outweighs the benefits. In practice, the risks of injection should not be taken lightly; thus, a discussion of the risks and benefits needs to take place with the patient.

If injection therapy is pursued, there are several strategies to help minimize the incidence of complications. Utilizing an interlaminar approach at C6–C7 or C7–T1 can be safer, because the epidural space is typically larger there. Epidural injections should also be avoided at the level of a large herniated disc, where the cord may be displaced more posteriorly into the epidural space and preclude safe needle entry. If a dural puncture does occur during the procedure, the injection should be aborted because of a conduit that now connects the spinal and epidural spaces. There is potential neurotoxicity with certain injection preparations (e.g., Depo-Medrol formulation of methylprednisolone acetate, which contains ethylene glycol, a substance associated with arachnoiditis). Finally, injection can be performed with only light sedation so that the patient can report pain and neuropathic symptoms during the procedure. Selective root blocks are theoretically safer than epidural injections, although both have relatively few reported complications.

Diagnostic Injections

Theoretically, if injection of local anesthetic with or without steroid gets rid of a patient's pain, this finding can confirm the anatomic location of the patient's symptoms. The targeted use of selective root blocks should therefore provide confirmatory diagnostic information for preoperative planning. Unfortunately, there is only limited evidence suggesting validity of this notion. Sasso et al.[56] found they could accurately identify radiculopathy by performing selective nerve root injections. They looked at 101 patients in which MRI findings were equivocal, multilevel, or do not agree with the patient's symptoms and found that a negative diagnostic injection was superior in predicting the absence of an offending lesion.

Biotechnology and Future Treatment Strategies

Over the last 20 years, the largest area of progress has been with regard to disc biology and potential targets of pharmaceutical therapy. But while we have seen a veritable explosion of literature, there is still a relative paucity of data to begin implementing these theoretical treatments into clinical practice.

Many inflammatory cytokines and growth factors have been shown to be relevant to the biology of intervertebral disc degeneration, including interleukin (IL)1-β, IL-6, IL-8, transforming growth factor β, bone morphogenetic protein 7/osteogenic protein 1, bone morphogenetic protein 2, prostaglandin E_2, nitric oxide, platelet-derived growth factor, and insulin growth factor 1. These molecules will be the targets of future research. By increasing the action of anabolic factors and decreasing the action of catabolic factors, we can achieve a net healing vector to the intervertebral disc space. How we deliver the message will come in several forms.

Medications

Antiinflammatory medications are designed to decrease production or action of some of these molecules. Several NSAIDs can inhibit the prostaglandin family, but research into the specific roles of these other proinflammatory molecules is in its relative infancy and directed medications acting on growth factors are yet to be trialed.

Direct Injection

Whether a single growth factor is injected or a combination of many, the goal will be to change the balance of catabolism to anabolism. Goni and collegues[57] ran a pilot study comparing the epidural perineural injection of methylprednisolone against autologous conditioned serum. Autologous conditioned serum is known to have high quantities of IL-1 receptor antagonist, and since IL-1 is thought to play a part in pain generation of radiculopathy, they hypothesized that injection of a local antagonist might reduce the symptoms of cervical radiculopathy. Their trial was small, with only 40 randomized patients, but showed similar effectiveness to epidural perineural injection of steroid, while effecting longer symptom relief.

Platelet-rich plasma is another preparation containing many growth factors in a high concentration after it is spun down from a patient's blood. Currently, it is used to stimulate wound healing, and is being evaluated in other areas of orthopaedics as well to stimulate cell proliferation and prostaglandin and collagen synthesis.[58] A limitation to direct injection of growth factors is the relatively short-term effectiveness of the drug. Degradation and diffusion can limit the therapeutic effect. Also, given that the intervertebral disc is the largest avascular tissue in the body, results of local injection may be short-lived without a method of increased nutrient delivery.[59]

Gene Therapy

As the disc tissue degenerates, growth factors may need to be present for an extended exposure to net a positive effect. Direct injection may last in the short term of weeks to months, but definitive change may need a constant replenishment of growth factors to the desired tissue. In this application, gene therapy can be used to transfer the genetic material to encode

and produce a protein into a target cell that can then be implanted or injected in the local disc environment. There are already several ongoing human studies that are trying to replicate previous data built with animal models.[60,61]

Cell-Based Therapies

Growth factors work at the level of the microenvironment, stimulating their effect on individual cells. With significant degeneration, the entire disc macroenvironment can be altered. The tissue architecture is such that nutrient supply is diminished, and a positive feedback loop exists whereby degeneration leads to more degeneration. Cell-based therapies aim to resupply cells and extracellular matrix to the disc space. At the time of this publication, there are several stem cell–based studies currently ongoing.[62,63] Cellular senescence is thought to play a pivotal role in age-related degenerative changes of the intervertebral disc.[64,65] In the lumbar spine, several studies looking at reimplantation of disc tissue have been done, leading to excitement regarding the future prospects of cellular therapy. Multipotent stem cells[66–68] and platelet-rich plasma[69] are gaining research support in other areas of orthopaedics, and now are an active area of research for regenerating cellularity and engendering repair within the degenerated nucleus pulposus. Human studies are still needed to better clarify usefulness of treatments like these.

Summary

The natural history of cervical disc and degenerative disorders is statistically a favorable one. For this reason, nonoperative treatment is the initial recommendation for patients without neurologic deficit. While there is no standardized algorithm by which clinicians may progress, several modalities have shown short-term benefit in reducing pain. However, due to a lack of quality literature, none of the commonly used nonoperative therapies has been proven to alter the long-term course of disease. In a retrospective literature review of conservative treatment of radiculopathy and myelopathy between 1953 and 2013, Alentado and colleagues[70] found limited evidence supporting an optimal period of nonsurgical management prior to operative intervention. Their analysis of outcomes and cost-effectiveness supported operative intervention between 4 and 8 weeks of symptom onset, but evidence-based conclusions could not be made, and further research must be done. Similarly, there are no high-level studies comparing operative to nonoperative treatment, but there are smaller studies that have shown benefit to surgical intervention for radicular and myelopathic symptoms within 3 months of symptom onset. Alvin[71] reviewed all published economic data through January 2014 evaluating cost-effectiveness of surgical interventions for degenerative cervical diseases. There is currently no consensus as to the cost-effectiveness of nonoperative versus operative intervention for mild cervical myelopathy and radiculopathy; further research is needed to elucidate the optimal treatment algorithm. Until such studies are available, empirical and anecdotal evidence must be used.

In the absence of proven benefit, treatments should be used only if they are associated with a reasonably low level of risk. A program of gradual, progressive nonoperative treatment seems most reasonable, adding therapies in a stepwise fashion as failure of symptoms to resolve dictates. Short-term bracing and rest, NSAIDs, oral corticosteroid taper, short-term narcotics, physical therapy, and corticosteroid injections can be used judiciously by the treating physician. In patients with myelopathy, progressive or severe neurologic dysfunction, or failure to improve despite time and nonoperative treatment, surgical management should be discussed.

40 CHAPTER Surgical Management of Axial Neck Pain

Raj Rao
Satyajit Marawar

Axial neck pain refers to posterior neck pain without radicular symptoms in upper extremities. The patient's description of the neck pain can vary and is frequently poorly defined. The pain may be dominant on one side or bilateral, and may be associated with headaches or neck stiffness. The pain is often associated with referral to the trapezius muscles, shoulder blades, or interscapular region.

Most people experience neck pain at some point in their lifetime. A 2010 study on the global burden of disease estimates that 332 million people are afflicted with neck pain worldwide. Among all musculoskeletal conditions, neck pain is the second highest contributor to years lived with disability (33.6 million years lived with disability), ranking only behind low back pain, the leading cause of musculoskeletal disability worldwide.[1] The United States Bone and Joint Initiative task force on neck pain reported a 12-month prevalence of neck pain ranging as high as 30% to 50%, although the prevalence of activity-limiting pain was between 1.7% and 11.5 %.[2] Neck pain also impacts the workforce, with 11% to 14% of workers reporting neck pain that limited activity in the past year.[3] A study of work absenteeism in a cohort of claimants at the Ontario Workplace Safety and Insurance Board showed that an estimated 11.3% of claimants who lost time from work listed neck pain as the reason.[4] Prevalence of neck pain increases with older age, peaking in middle years and declining in later years of life.[3]

Only a small proportion of subjects with neck pain are disabled enough to seek medical attention, and only a fraction of the population with chronic neck pain will ever see a surgeon. The role of surgical fusion has traditionally been limited in the treatment of patients with only axial neck pain. At the same time, the number of surgical procedures done for cervical degenerative pathology in general has been exponentially increasing in the last 2 decades. Marawar et al.[5] analyzed data collected in the National Hospital Discharge Survey from 1990 to 2004 and reported that from 2000 to 2004, a total of 451,166 anterior cervical discectomy and fusion (ACDF) surgeries were performed in United States. The authors found an overall 8-fold increase in the total number of ACDFs performed over the three 5-year time periods between 1990 and 2004. The greatest proportion (49%) of surgeries was in the group of patients aged 46 to 64 years. Over the same time period, utilization rates for ACDF dramatically increased (28-fold) in the group of patients aged 65 years and older. Interestingly, the number of ACDFs done in patients younger than 45 years also rose significantly, from 27,278 from 1990 to 1994 to 151,407 from 2000 to 2004.[5] The reasons behind this enormous increase in the number of ACDFs performed are likely multifactorial. Aging of the population, a greater access to diagnostic imaging, patient demand for pain relief, and an increased number of fellowship-trained spine surgeons may all play a role.

The proportion of procedures that were carried out for axial neck pain, as opposed to neurologic findings, is not clear from the databases mentioned earlier. There are, however, other outcome studies that shed some light on the prevalence of surgery for the subgroup of patients with axial neck pain. Palit et al. noted that 38 (22%) out of 175 ACDF procedures done in their medical group from 1989 to 1994 were for patients with nonradicular neck pain.[6] Eck et al., while comparing outcome of ACDF in patients with and without radicular symptoms, reported that 41 (21%) of 202 patients who underwent ACDF by two surgeons had axial neck pain alone.[7] On the other hand, Lied et al. from Norway reported that 20 (5.1%) of 390 patients who underwent ACDF for cervical disc degeneration had neck pain only without radicular or myelopathic symptoms.[8] Reasonable conclusions from these datasets are that (1) global variations exist in the utilization of surgery to treat axial neck pain, and (2) with the large increases in the overall number of ACDF procedures being done in the United States, there is likely a proportional increase in the utilization of surgery to treat patients with purely axial neck pain. It is therefore critical to continually evaluate the available evidence to define the role of surgery in treating axial neck pain.

Etiology and Pathophysiology of Axial Neck Pain

Smith and Robinson described "cervical disc syndrome" in patients with cervical disc degeneration as a constellation of symptoms that included chronic pain in the posterior part of

the neck, shoulder, occiput, and arm; paresthesias in the arm; limitation of movement of the neck; and roentgenographic evidence of cervical disc degeneration.[9] Although the clinical approach to neck pain has focused on the degenerated cervical disc as the primary pain generator, neck pain is most certainly multifactorial in nature. The cervical motion segment is a five-joint complex comprised of a disc, and paired uncovertebral joints anteriorly, and paired facet joints posteriorly. Stabilizing soft tissue structures include the ligamentum nuchae, which attaches to the spinous processes in the midline and surrounding musculature, including the trapezius and deeper paraspinal muscles (semispinalis capitis, splenius capitis, longissimus and interspinalis). All of these structures could potentially play a role in pain generation.

Disc degeneration is thought to begin with loss of proteoglycans and consequent desiccation of the disc nucleus. This results in changes in the mechanical properties of the disc, with increasing stresses on the outer anulus and the facet joint. This can cause annular disruption, resulting in increased motion and abnormal stresses at the facet and uncovertebral joints, even under physiologic loading conditions. Eventually, the collective result of these changes can cause central canal and foraminal narrowing, with impingement of the neurologic structures.

Although the anatomic process of degeneration is reasonably well defined, the correlation of axial neck pain to the degenerative process is poorly understood. The sinuvertebral nerve, a branch of the dorsal ramus that supplies the posterior anulus, can get irritated by an annular tear and lead to neck pain.[10] Chemonociceptors and altered stresses at the facet joint capsule can contribute to neck pain. Myofascial trigger points are also commonly found in patients with neck pain. Han et al. reported that the incidence of myofascial pain syndrome with associated trigger points varied between 30% and 85% in people presenting to pain clinics with persistent pain in the head, neck, shoulders, or low back.[11]

There is little evidence in the literature to support disc degeneration as a primary etiology of neck pain. Multiple studies have found cervical disc degeneration on MRI scans in asymptomatic volunteers.[12–17] Further, disc degeneration seen on MRI in asymptomatic subjects is often accompanied by other common degenerative findings, such as disc bulging,[12,16] annular tears, narrowing of the disc space, and foraminal stenosis.[12–14] The Bone and Joint Decade 2000–2010 Task Force on Neck Pain and its Associated Disorders in fact concluded that there was no evidence to suggest that common degenerative changes seen on imaging studies were strongly correlated with neck pain symptoms.[12–14]

The role of prior soft tissue trauma in causation of neck pain is even more controversial. Whiplash-associated disorders (WAD) is a term assigned to the symptom complex that patients present with after a rear-end mechanism vehicular collision. Neck pain and headaches are the major symptoms. A Quebec task force on whiplash injury reported that WAD is almost always self-limited and rarely results in permanent harm.[18] On the other hand, Freeman and colleagues[19] reviewed the literature refuting the role of whiplash syndrome and determined: "There is no epidemiologic or scientific basis in the literature for the following statement: whiplash injuries do not lead to chronic pain, rear impact collisions that do not result in vehicle damage are unlikely to cause injury, and whiplash trauma is biomechanically comparable to common movements of daily living." Macnab[20] reported that 45% of the patients with whiplash injuries had continued symptoms 2 years after a court settlement action. He suggested that, in his experience, "10% to 20% are left with discomfort of sufficient severity to interfere with their ability to do work or enjoy themselves in leisure hours." Sterner et al.[21] reported on a prospective study of 356 patients with a whiplash trauma to the cervical spine. Of the patients, 32% reported persisting disability at 1-year follow-up. Pretraumatic neck pain, low educational level, and female gender were found to be significantly associated with poor prognosis. The Bone and Joint Decade 2000–2010 Task Force on Neck Pain and its Associated Disorders found that eliminating insurance payments for pain and suffering was associated with a lower incidence of whiplash-associated disorder injury claims. They did not find any evidence in the literature of a demonstrable ligamentous injury on MRI in patients with whiplash-associated disorders.[22]

Natural History and Prognosis Factors for Neck Pain

Knowledge of natural history provides perspective on the patient's history of pain, and sets patient expectations on the course of their pain. It also helps study if the interventions provided have altered the course of neck pain and associated disability in a particular patient. Understanding the natural history of neck pain can also identify modifiable and nonmodifiable risk factors that affect prognosis. This can help the physician determine which individuals have a higher risk of persistent or worsening disability.

Cote et al.[23] reported on incidence and course of neck pain by studying a cohort of 1100 randomly selected adults and following up on them at 6 months and 1 year. They found that annual incidence of neck pain was 14.6%. On follow-up of adults with neck pain, 36.6 % had complete resolution of neck pain and another 32.7% reported improvement, while 37.3% reported persistent neck pain and 9.9% reported worsening of their symptoms. In general, in the population with neck pain, most subjects did not have complete resolution of neck pain. A quarter of the people who reported neck pain improvement at interim follow-up complained of recurrence of pain on final follow-up. The authors found that women were more likely to develop neck pain and have persistent pain on follow-up as compared with men. In another cohort of 7669 adults from the general population, neck pain was reported by 17.7%.[24] At 1-year follow-up of people with neck pain at baseline, 48% reported neck pain lasting for more than 1 day in the previous month. Baseline characteristics that predicted persistent neck pain were age between 45 and 59 years (odds ratio [OR], 3.4), being off work at the time of the baseline survey (OR, 1.6), comorbid low back pain (OR, 1.6), and cycling as a regular activity (OR, 2.4).[24] Vos et al.[25] followed 187 patients who presented with acute neck pain to a general practice for 1 year. Of the 138 that provided follow-up data, 76% had fully or

partially recovered, although 47% reported some persistent symptoms. Almost half the patients who were on sick leave at baseline returned to work in 7 days. Interestingly, they found that the highest association with recovery was the advice of the general practitioner "to wait and see" (OR, 6.7), while a referral to physical therapy or to a medical specialist showed the highest association (OR, 2.8) with a prolonged sick leave.

In a study from Sweden, Pernold et al.[26] reported on a follow-up of 439 patients seeking care for neck and shoulder disorders. The highest improvements in pain and disability, both in men and in women, were seen after 3 months. After that, improvements were minor. At 5 years, 22% of the men and 15% of the women from the initial group had no neck pain, while 75% of the men and 59% of the women had reported some decrease in neck pain intensity. Van Eard et al.[27] describe the course of lost time claims involving neck pain in workers compensated by the Ontario Workplace Safety and Insurance Board (WSIB). They reported that, although most workers who had a lost work claim for neck pain at baseline did not have a second claim for neck pain in the following 2 years, 14.1% of the initial claimants had repeated claims for lost work due to neck pain. Overall, in a segment of the population that has neck pain, recurrence and persistence is frequent. These individuals usually seek a surgical opinion.

Clinical Evaluation of the Patient With Neck Pain

Patients with long-standing neck pain have typically tried a variety of conservative treatment modalities prior to being seen by a surgeon. The chronicity and severity of their disability, associated with failure of multiple prior treatment modalities, leads to frustration and overall disenchantment with medical modalities. It is important that a solid patient-physician relationship is established, as this will play an important role in surgical decision making. A thorough history and physical examination is the first step in that direction.

Axial neck pain is typically along the posterior musculature of the cervical spine, occasionally radiating to the trapezius, shoulder blade, or interscapular areas. Radiation of pain along the trapezius, particularly if unilateral and accompanied by tingling, may suggest C4 radiculopathy. Neck pain and suboccipital headaches radiating to the retroauricular region has been noted in patients with high cervical (C3, C4) radiculopathy.[28,29] Even when neck pain is dominant, care should be taken to rule out neurologic symptoms or findings of cervical radiculopathy and myelopathy.

Some patients with instability will report feeling occasional "clunks" as they move their neck through a range of motion. Worsening of neck pain with flexion or pain exacerbated by whole body vibration during driving may indicate a discogenic source of pain. In patients with axial neck pain, the physician needs to be vigilant to detect any red flags that may suggest serious underlying pathology (Table 40.1).[30]

Obtaining a social history can play an important role in determining treatment options. Exaggeration of pain, history of litigation, clinical depression, drug-seeking behavior, and lack of even temporary pain relief with any treatment modalities previously tried will have an adverse impact on prognosis following surgery. Such patients should have a formal psychosocial evaluation and should be referred to a multidisciplinary pain program.

TABLE 40.1 Red Flags in the Patient With Axial Neck Pain

Red Flag	Potential Source of Pain
Minor trauma leading to fracture	Pathologic fracture from osteoporosis or spinal metastasis
A history of malignancy with unexplained weight loss and constitutional symptoms	Spinal metastasis; pathologic fracture
A history of ankylosing spondylitis or inflammatory bowel disease	Inflammatory arthropathy affecting the spine, unsuspected trauma, epidural hematoma
Fever in patients with immunosuppressed status or history of recent urinary tract, dental, or skin infections	Osteomyelitis, discitis, epidural abscess

The visual analog scale SF-36 and the Neck Disability Index questionnaire can help understand the patient's current perceived disability and are used to monitor changes in symptoms and disability over time. Pain diagrams and patient expectations may impact the patient's prognosis after surgery.[31] A nonorganic pain diagram as opposed to one suggesting an anatomic source of pain (Fig. 40.1), when associated with drug-seeking behavior or litigation, can increase the risk of a poor outcome after surgical fusion.[32] Together, these surveys can help the surgeon and the patient choose appropriate and effective treatment.

On physical examination, specific areas of tenderness, range of motion of the cervical spine, and any worsening of radicular symptoms on provocation should be noted. The Spurling test has been reported to have low to moderate sensitivity and high specificity for detecting nerve root impingement.[33,34] A detailed neurologic examination is necessary to rule out radiculopathy or myelopathy.

In patients with purely axial neck pain, an exaggerated pain response to light touch can be an indication of a nonorganic basis of pain. Waddell described signs of nonorganic pain in the lumbar spine,[35] which can be similarly utilized in patients with cervical symptoms.[36] Nondermatomal numbness, cogwheel or jerking motion on strength testing, and inconsistencies when certain tests are repeated are signs of nonorganic origin of pain. Although nonorganic signs may not be necessarily associated with secondary gain, they have been correlated with a poor outcome after surgical management.[37] In these patients, a multidisciplinary pain clinic referral should be sought.

Imaging Studies

Radiographs

In the absence of any red flags, plain radiographs are obtained for the patient who continues to have axial neck pain despite 6 weeks of conservative treatment. Anteroposterior, lateral,

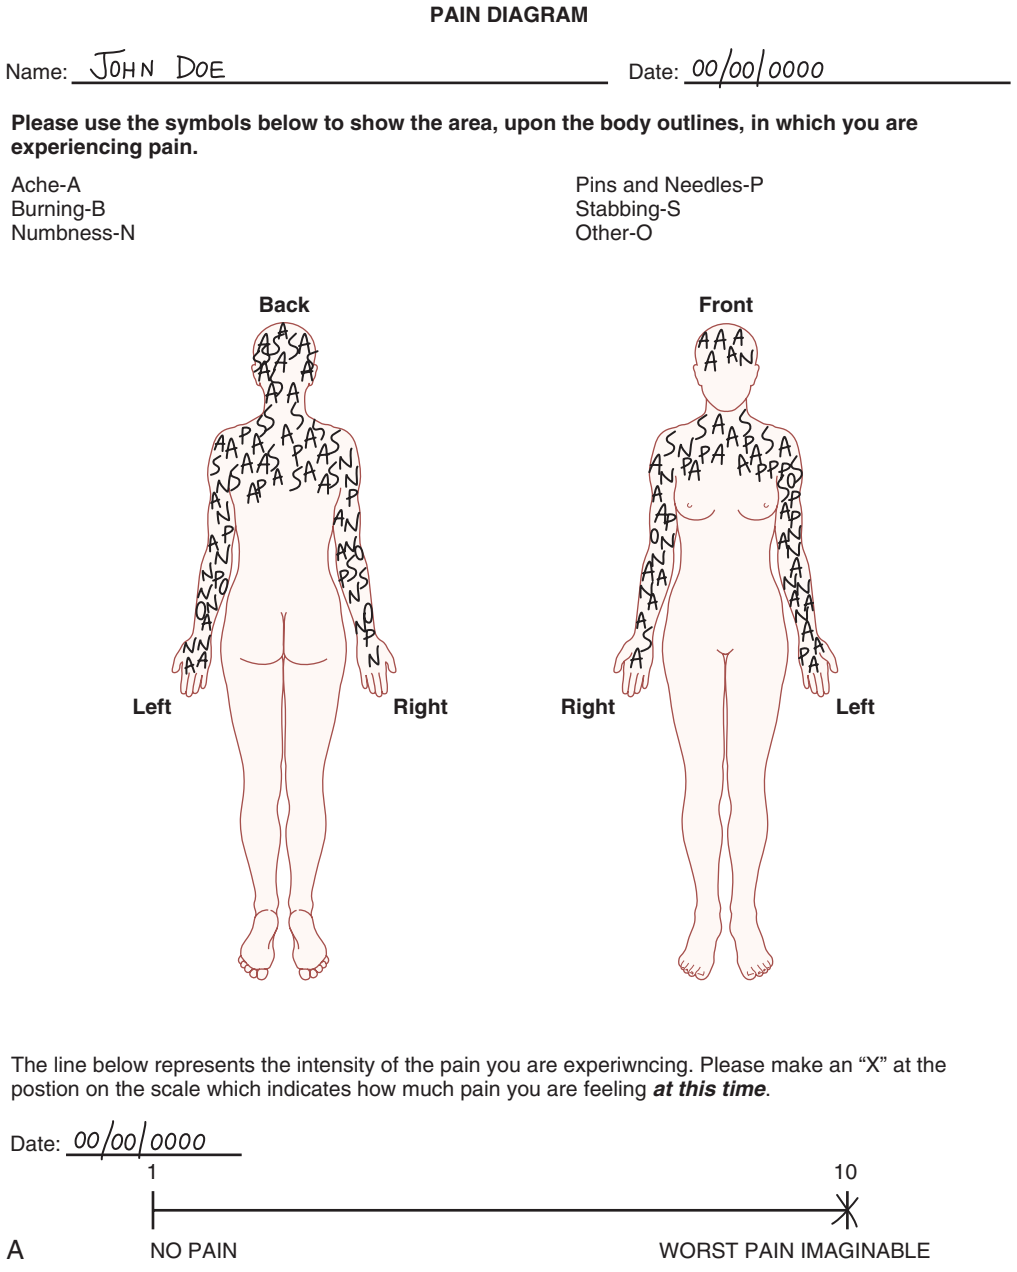

FIG. 40.1 Pain diagram suggestive of (A) nonorganic pathology compared with the pain diagram suggestive of (B) organic pathology presenting as axial neck pain.

and flexion-extension views are obtained. Overall alignment and any evidence of instability are noted. Degenerative changes—such as loss of disc height, endplate sclerosis, and bone spurs—are ubiquitous in the population and will generally be present in the patient with axial neck pain as well. The clinical significance of these radiographic changes and their correlation with neck pain and disability is debatable. Peterson et al. reported that there was no difference in reported pain and disability levels between those with and those without evidence of cervical spine degeneration on plain radiographs.[38] Gore et al. also reported that degenerative changes are common in plain radiographs in asymptomatic people.[39] They later reported on a radiographic and clinical follow-up of a group of 159 previously asymptomatic people at 10 years from their first evaluation. There was an increase in degenerative changes with increasing age. Neck pain was reported by 15% of the previously asymptomatic subjects. In this study, presence of degenerative changes at C6–C7 was a statistically significant predictor of pain.[40] Other serious and destructive pathologies, such as metastatic tumors or discitis-osteomyelitis, can be detected on plain radiographs if advanced enough. Such findings should lead to prompt referral for advanced imaging studies.

Advanced Imaging Studies

In the absence of red flags in patients with predominant axial neck pain, advanced imaging studies should be obtained if the patient has persistent disability despite 4 to 6 months of conservative management. Magnetic resonance imaging (MRI) shows degenerated and narrowed discs, vacuum disc phenomenon, annular tears, or disc bulges. However, such changes are

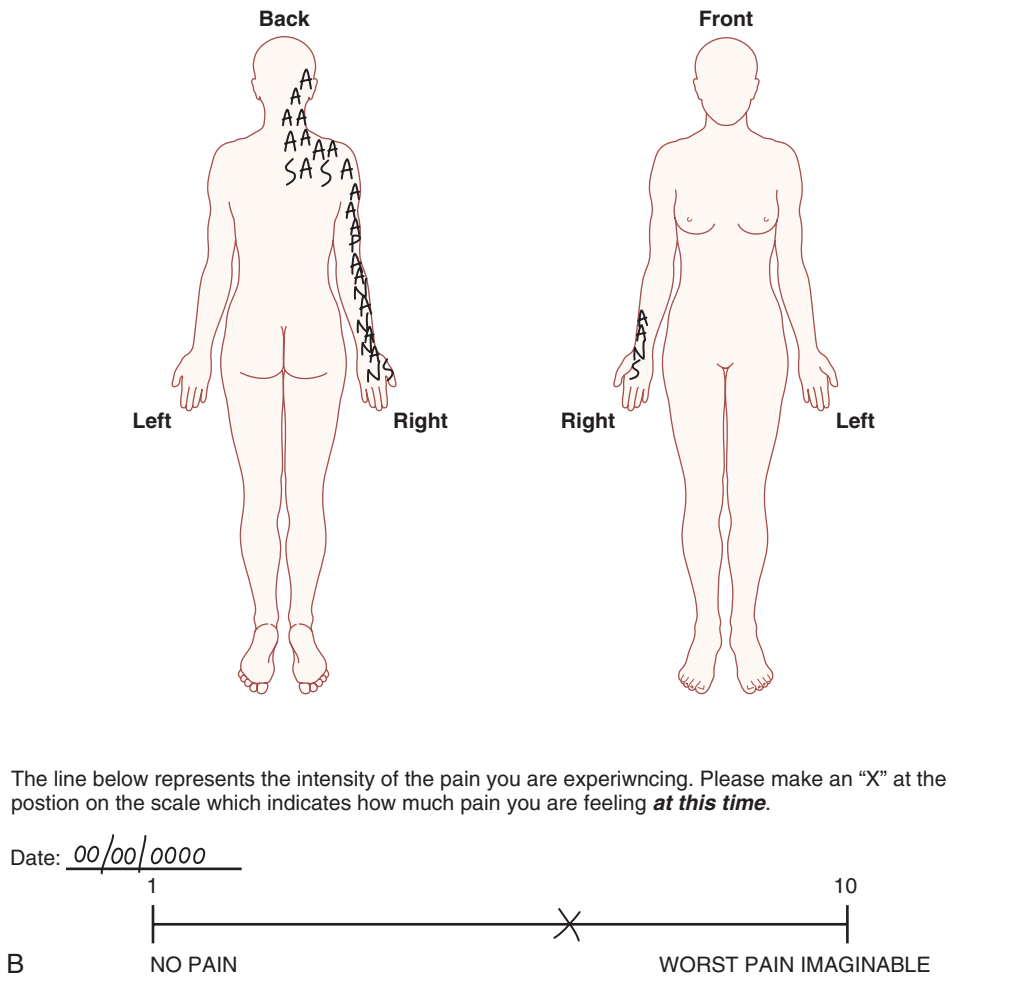

FIG. 40.1, cont'd

also frequently seen in asymptomatic patients,[12–17] and the utility of these findings in determining a clear pain generator is limited. CT scans are done in patients with a contraindication for MRI. CT scans provide more details about bony anatomy, especially in patients with trauma, tumor, or infection. As is the case with MRI, utility of the CT scan in determining the pain generator in patients with axial neck pain is limited.

Cervical Discography

The need to more definitively identify a disc that may be a pain generator led to cervical discography. Cervical discography was described in 1957 by Smith and Nichols,[41] and in 1958 by Cloward.[42] Using image-guided techniques, the cervical disc is cannulated and contrast material injected into the disc (Fig. 40.2). Abnormal morphology of the disc as well as concordant pain provocation by the injection are both considered diagnostic of pain-generating disc levels. Despite its frequent use in prior decades, the procedure is now generally regarded with caution due to risks from its invasive nature and the operator-dependent nature of the technique and interpretation.

Yin et al.[43] carried out a retrospective review of patients with neck pain who underwent diagnostic blocks and provocative discography to determine the causes of neck pain. Among the 46% of the patients who completed all investigations, the prevalence of zygapophyseal joint pain was 55%, discogenic pain was 16%, and lateral atlantoaxial joint pain was 9%. Bogduk and Aprill[44] reported on the causes of neck pain in 56 patients with posttraumatic neck pain. They reported that only 20% of the patients had exclusively discogenic pain with positive discograms.

A high false-positive rate is a major argument against cervical discography. Schellhas et al.[45] compared responses to discography

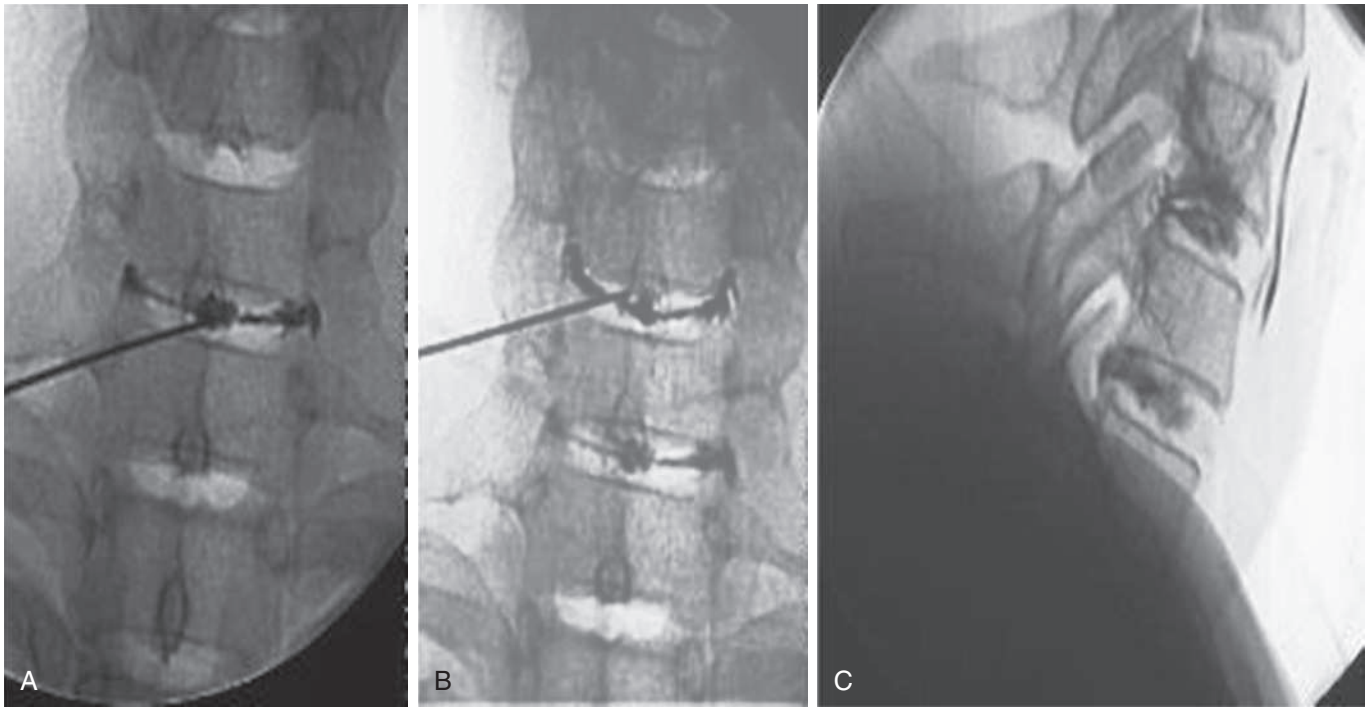

FIG. 40.2 (A) Anteroposterior (AP) view after discogram at the C6–C7 level demonstrates extravasation of contrast beyond the lateral disc margin. (B) AP view after discogram at the C5–C6 level, which was injected as the control, showing the normal distribution of the contrast that remains within the disc margins. (C) Lateral view after the discogram in (A) and (B) showing that the contrast remains predominantly in the center of the disc at the C5–C6 level, whereas it leaks beyond the posterior margin of the disc at C6–C7 level. (Courtesy Dr. A. Gangi, Dr. Sveta Trikha, Neuroradiology, Syracuse VA Medical Center, and www.openradiology.org.)

in asymptomatic volunteers and patients with neck pain. They reported that asymptomatic subjects had a painful response to disc injection, usually a 4 to 5 on a scale of 0 to 10. Although the patient group reported greater mean pain responses with disc injection compared with the asymptomatic group ($P < .0001$), production of pain on discography in both symptomatic and asymptomatic groups underlines the risk of false-positive responses on discography. However, it is difficult to determine the exact false-positive rate of discography, as a positive discogram, by definition, has to elicit concordant pain, which is not possible in asymptomatic subjects.

There is lack of standardization in terms of number of levels to be injected during a cervical discogram, with recommendations ranging from injecting all cervical levels[46] to injecting at least one level below and one level above the suspected level based on imaging studies.[6,47] There is lack of consensus on pain threshold level and on what constitutes a positive response on discogram. Schellhas et al.[45] recommend that the patient must rate the intensity of produced pain as 7 or greater on a 10-point numeric scale for it to be considered positive on discogram. Singh et al.[46] suggest that the discogram is positive when the patient reports pain that closely resembles symptomatic pain in intensity and location. Zheng et al.[48] consider moderate to severe reproduction of the patient's typical pain as the determinant for a symptomatic disc.

Nordin et al.[30] reviewed the literature available on cervical discography and did not find any scientifically admissible phase III or phase IV studies that tested the validity of discography as demonstrating primary discogenic pain in the cervical spine. On the other hand, Onyewu et al. concluded that there was level II-2 strength of evidence for diagnostic accuracy of cervical discography. This recommendation should be taken lightly, as they also point out in this review that there was a paucity of literature with widespread discrepancies in methodology of cervical discography and outcome measurement. They found only five studies in the post-MRI era reporting surgical outcome based on cervical discography,[6,48–51] of which there was only one study that had employed controlled provocation discography, with two adjacent discs being injected as controls.[6] Additionally, there are concerns about the effects of annular puncture of control discs during a discogram. Carragee et al.[52] reported accelerated disc degeneration and an increased incidence of disc herniation after lumbar discography as compared to matched controls at 10-year follow-up after discography. Although these results were reported after lumbar discography, it is possible that, in the longer term, annular puncture during cervical discography can lead to accelerated degeneration, even if a small-gauge needle is used with low pressurization. For the surgeon considering surgery in a patient with axial neck pain, discography remains a controversial choice.

Surgery for Axial Neck Pain

Determination of fusion levels in the patient with axial neck pain requires deliberate evaluation of all available clinical and radiographic information. Improved surgical outcomes

will be obtained if multiple clinical and radiographic findings all point to the same disc as the source of pain. This clinical algorithm should include (1) clinical judgment on the need for surgery, given the patient's reported pain and disability; (2) clinical assessment of secondary gain or other potential nonstructural issues that may be contributing to the patient's pain level and will result in a diminished surgical outcome; (3) assessment of current or historical clinical findings that may point to a specific level, such as unilateral tingling over the trapezius muscle may suggest ipsilateral C4 nerve root irritation; (4) radiographs that show degenerative changes prominently at a single level with relatively normal adjacent levels; (5) lateral radiographs or flexion-extension radiographs that show translation at a specific level suggestive of instability; (6) MRI showing marked disc space narrowing at a single level, or marked endplate changes at the level; and (7) discography with clearly concordant pain at the same disc. In patients with axial neck pain considering surgery, determination of surgical levels is largely surgeon dependent, will remain controversial, and needs careful and deliberate decision making.

The surgical treatment for axial neck pain is anterior cervical discectomy and fusion at the presumed painful disc level. The removal of the degenerated discs theoretically eliminates the pain generator and also stabilizes the uncovertebral joints and facet joints, thereby reducing their role. Using a Smith-Robinson approach,[9] all disc material is removed and endplates cleaned of all cartilaginous material while preserving the bony endplate. A few small perforations through the endplate using a high-speed burr or a curette facilitate fusion across the disc space. Under gentle distraction, an interbody spacer is inserted. Anterior cervical plating provides immediate stability and allows early mobilization, diminishing the need for postoperative external immobilization. In multilevel fusions, use of an anterior cervical plate reduces pseudarthrosis rates[53–55] and graft-related complications.[53,56] Instrumentation also maintains overall lordosis better and significantly improves segmental lordosis compared with unplated constructs.[57] The length of the plate chosen should allow at least 5 mm between the ends of the plate and adjacent disc levels. Segmental screw fixation is carried out for multilevel fusions.

Several options are available in choosing the interbody spacer and bone graft for anterior cervical fusion. Structural iliac crest bone graft is still considered the gold standard for success of fusion, but is increasingly viewed as an unacceptable option due to the morbidity and pain at the harvest site.[58,59] Earlier reports showed high pseudarthrosis rates with allograft use for ACDF compared with iliac crest autograft, especially for multilevel fusions and in smokers.[60,61] Recent reports, however, show fusion rates and clinical outcome comparable to that of autograft when using allograft spacers with rigid plate fixation, even in multilevel fusions.[62–64] Today, polyetheretherketone (PEEK) interbody spacers filled with allograft and/or demineralized bone matrix are being increasingly used. Fusion rates for PEEK interbody spacers with anterior cervical plating have not been evaluated in prospective studies. In retrospective studies, fusion rates with PEEK spacers have been found to be comparable to that of tricortical iliac crest autograft.[65] In our experience, both tricortical allograft spacers and PEEK spacers filled with bone graft extenders are reasonable alternatives to iliac crest autograft in one- or two-level anterior cervical fusion procedures (Fig. 40.3).

Cervical disc arthroplasty offers a motion-sparing treatment modality for cervical disc pathology with the potential advantage of avoiding increased stresses at the adjoining discs and reduction in the risk of adjacent-segment disease. In patients with cervical radiculopathy, short-term and midterm data comparing cervical disc arthroplasty and ACDF have shown comparable results.[66–71] Some recent studies of cervical disc arthroplasty have included patients with neck or arm pain but have not reported outcome data separately for the subset of patients with predominant axial neck pain.[70,71] The complex multifactorial etiology of neck pain, the difficulty in identifying a pain generator in this subset of patients, and the absence of outcome data on benefits from a motion-sparing device in these patients suggest that disc arthroplasty should not be recommended for these patients.

Axial Neck Pain Secondary to Pseudarthrosis From Prior Surgery

Despite a reduction in the incidence following the use of cervical plating, pseudarthrosis following anterior cervical fusion surgery is reported to occur with an incidence of 10% to 40% in multilevel anterior fusion procedures.[54–56] Pseudarthrosis rates after posterior cervical laminectomy and fusion have been reported to range from 1% to 38%.[72–75] A pseudarthrosis associated with a stable fibrous union can be asymptomatic, but a small proportion of patients with pseudarthrosis present with neck pain due to instability.[76,77] Interbody graft collapse associated with nonunion can result in foraminal stenosis as well as recurrent axial neck pain and radiculopathy. Failure of hardware and progressive deformity can contribute to the symptomatology. CT is the imaging modality of choice to diagnose a nonunion and assess the status of the interbody graft and the hardware.

The treatment approach in patients with symptomatic anterior pseudarthrosis remains a matter of debate. Both anterior revision fusion and posterior stabilization have been reported as effective approaches[78–81]; however, there are no randomized controlled trials comparing the outcomes of these approaches for treating cervical pseudarthrosis. While the anterior procedure allows access to the site of nonunion and lets the surgeon address hardware failure, graft collapse or dislodgment, recurrent foraminal stenosis, and kyphosis, it requires dissecting through the surgical scar with potentially increased risks of iatrogenic injury to neurovascular structures, the esophagus, and the trachea, as well as increased incidence of postoperative dysphagia.[82] On the other hand, posterior fusion surgery involves larger intraoperative blood loss, longer hospital stay, and a higher complication rate compared with anterior revisions.[83] McAnany et al.[84] carried out a meta-analysis of clinical outcomes following treatment of symptomatic cervical pseudarthrosis with either anterior revision surgery or posterior fusion. While the fusion rate was significantly higher in the posterior group as compared to anterior revision (97.1% vs. 86.4%; $P = .028$), clinical outcome

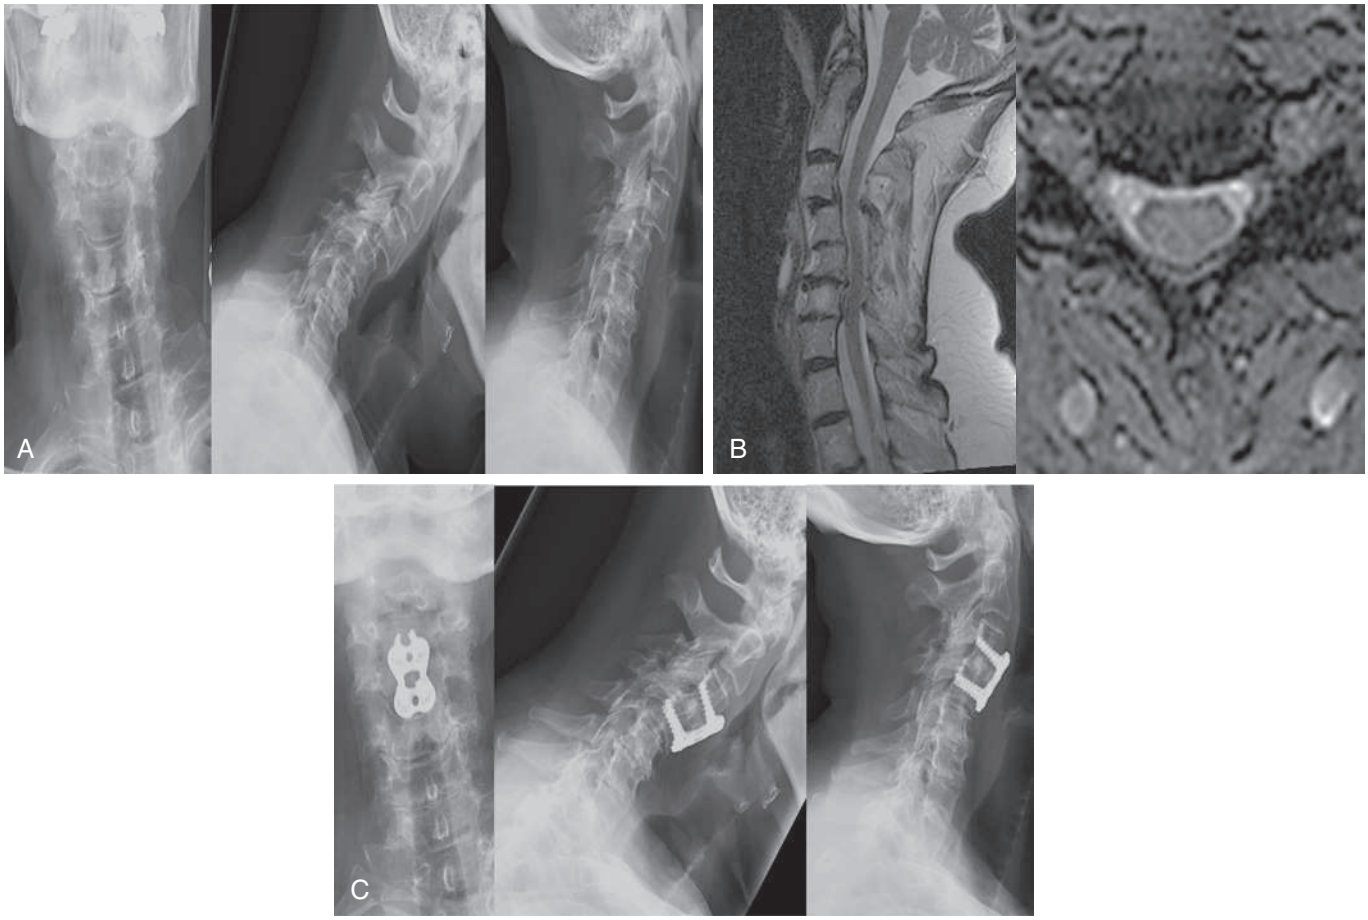

FIG. 40.3 A 70-year-old woman with chronic, intractable axial neck pain in the posterior cervical musculature and no evidence of cervical radiculopathy or myelopathy. (A) Preoperative radiographs and (B) sagittal and axial weighted T2-weighted magnetic resonance images show degenerative changes at multiple levels throughout the cervical spine, with spondylolisthesis at the C3–C4 level. (C) Postoperative radiographs 2 years following anterior fusion at the C3–C4 level with allograft bone and an anterior plate. The patient had complete resolution of her symptoms and return to active function.

was similar. They suggested that this divergence could be due to the higher complication rate and postoperative neck pain associated with posterior fusion.

Outcome After Surgery for Axial Neck Pain

The earliest reports of anterior cervical fusion procedures include axial neck pain as an indication for surgery. In their 1958 article describing the surgical technique for anterior cervical discectomy and fusion, Smith and Robinson reported that three of the 14 patients in the study had disc degeneration alone without nerve root irritation.[9] Yet, surgical intervention for patients who present with axial neck pain alone has always generated controversy. In 1978, Rothman and Rashbaum[85] reported that 23% of the patients with significant cervical degenerative symptoms remained partially or totally disabled after conservative management at 5-year follow-up. However, little functional difference was noted in patients who underwent surgery for dominant neck pain. DePalma et al.[86] reported that 78% of 255 patients treated conservatively for "cervical syndrome" obtained either complete or partial relief, with 22% of patients having poor results. They reported on the results of 58 patients who underwent an anterior fusion procedure after failure of 6 months of conservative management. The outcome was rated as excellent in 74%, improved in 15%, and poor in 11%. They concluded that anterior surgery has "improved to excellent" outcome in this group of patients, with better results than posterior fusion.

Variations of the ACDF procedure have been reported by several authors. Kambin et al.[87] reported on anterior cervical discectomy and fusion using a vertical self-locking T graft. In the group of 50 patients who had neck pain without neurologic findings, "excellent" results were reported in 37, "good" in 10, and "satisfactory" in 3. Brodke and Zdeblick[88] reported on using Caspar pins for intervertebral distraction and a reversed iliac crest graft in 51 patients. Neck pain was the primary symptom in nine of the 51 patients. Outcome was reported as excellent in 36, very good in 11, good in 3, and poor in 1 of the 51 patients. Outcome in patients with neck pain as the primary symptom was not reported separately.

Kikuchi et al.[89] reported on the outcome of surgical fusion in a mixed group of 41 patients with predominant axial neck pain alone as well as 97 patients who had neck pain and radicular symptoms. Diagnostic discography was performed in all patients on four adjacent discs. The discogram was considered positive on production of concordant pain. One

year from surgery, 80% of all patients were reported to be either totally free of symptoms or had discomfort that did not interfere with their work or social life. The outcome in patients with only neck pain was not reported separately. Zheng et al.[48] attempted to correlate discography findings with MRI findings in 55 patients undergoing ACDF for axial neck pain. The authors considered 79 of 161 levels to be discogram positive. At a minimum follow-up of 2 years, successful fusion was achieved in 95% of the patients, and an overall satisfactory result was achieved in 76%. Abnormal MRI morphology was found in 100 of the 161 levels that underwent discography. Of the 79 levels that were discogram positive, MRI was abnormal at 58 levels. Based on these findings, they determined that MRI had a false-positive rate of 51% and a false-negative rate of 27%.

A frequently cited study in support of surgery for axial neck pain is a retrospective review of 38 patients by Palit et al.,[6] published in 1999. Cervical discography, MRI, and CT scans were used to determine the levels at which fusion was carried out. Discography was carried out at the disc that was suspected of being the pain generator based on the imaging studies and at least two adjacent levels as controls. Anterior cervical discectomy and fusion was carried out using tricortical iliac crest allograft. All patients completed a numeric rating scale (NRS) to measure pain and the Oswestry Disability Index (ODI) to measure function. After an average follow-up period of 53 months after surgery (range, 24–87 months), the mean NRS for neck pain reduced from 8.3 to 4.1 ($P < .001$). The ODI score improved from 57.5 to 38.9 ($P < .001$). Although the results of the study are generally supportive of surgery for neck pain, there are certain methodologic problems that should be pointed out. The author elaborates that patients with 75% or more neck pain and 25% or less arm pain were considered eligible for inclusion in this study. Thus, it seems that this group included patients with some radicular symptoms. They also excluded some patients based on psychological evaluation. However, the number of patients excluded on this basis was not reported. Although they reported obtaining radiographs at 1 and 3 months after surgery, outcome parameters were reported only for the final follow-up, which was performed by telephone at a widely variable period from surgery (24 to 87 months). At final follow-up, 30 of 38 patients (79%) reported that they were satisfied with surgery and 8 patients (21%) reported that they were not satisfied. However, while 20 patients were not working before surgery because of neck pain, 15 were still not working at final follow-up.

Garvey et al.[90] conducted a retrospective review on 87 patients who had undergone an anterior cervical discectomy and fusion for dominant mechanical neck pain, defined as neck pain greater than arm pain. At a mean follow-up period of 4.4 ± 1.5 years, this group of patients completed outcome questionnaires that included a visual analog pain score, a modified ODI, and a modified Roland Morris disability index. The authors reported that 82% of the patients reported their outcome to be good, very good, or excellent. The average visual analog score reduced from 8.4 ± 1.7 before surgery to 3.8 ± 2.8 ($P < .01$) after surgery. The ODI improved from 58.8 ± 19.8 before surgery to 30.7 ± 21.4 at final follow-up ($P < .01$), while the Roland Morris disability score improved from 15.8 ± 6.4 before surgery to 7.6 ± 6.5 at final follow-up ($P < .01$). Although this retrospective study reports an overall positive outcome after surgery for axial neck pain, the indications for surgery appear to be heterogeneous. The authors report that 66 of 87 patients who underwent surgery had preoperative discography, but 31 of 66 (46%) had nonclassic findings on discography with pain greater than 4 or 5 out of 10 at adjacent segments. The role of routine imaging studies in determining indication for surgery is not clarified. The authors point out that, despite improvement in pain and self-rated disability scores, global patient satisfaction after surgery showed a mixed distribution and did not seem to correlate well with improvements in pain scores and disability ratings.

A small number of reviews of available literature on surgery for axial neck pain have been reported. In a report on best evidence synthesis for utility of surgical interventions for neck pain, as part of the Bone and Joint Decade 2000–2010 Task Force on Back Pain and its Associated Disorders, Carragee et al.[91] reported that they found no well-designed randomized controlled trials of open surgery for treatment of neck pain alone in patients with common degenerative changes on imaging in the absence of radiculopathy, myelopathy, or serious pathology, such as tumors or infection. They did not find any evidence in the available literature that showed a better outcome after surgery for neck pain that could be attributed to surgery and not to the natural history of neck pain in patients with degenerative pathology. They concluded that there was no evidence in the literature to support use of anterior cervical discectomy and fusion, or disc arthroplasty in patients with neck pain without radiculopathy or serious structural pathology.

Riew et al.[92] conducted a systematic review of articles published up to 2010 to examine the clinical outcome in patients who underwent ACDF for axial neck pain without radicular or myelopathic symptoms. They did not identify any comparative studies. The authors reported three case series that met the criterion to be included in their review.[6,7,90] They reported that all studies showed a mean improvement of pain of 50% at approximately 4-year follow-up with patients' satisfaction rates ranging from 56% to 79%. They concluded that there is low evidence in the literature that patients with axial neck pain without radicular or myelopathic symptoms will receive some improvement in pain and function following an ACDF. Additionally, there is no evidence to clarify whether the benefit from surgery is better than no treatment or other conservative treatment modalities.

Summary

Neck pain is a widely prevalent, though frequently self-limiting, condition. Some individuals develop persistent and disabling neck pain, refractory to conservative treatment. The etiology of neck pain is multifactorial, and degenerated discs may be the primary pain generator in only a minority of cases; identification of a pain generator is frequently difficult. Discography has been frequently used in the past in an attempt to identify

the pain-generating disc level. The procedure is currently more controversial due to a lack of standard methodology, variation in outcome measurement, limited evidence to its utility in improving surgical outcome, and the potential for annular injury to uninvolved discs. Currently available review of literature points to a lack of reliable and controlled studies that show improved outcome with surgery for axial neck pain as compared to nonsurgical modalities or nonintervention. Commonly cited case series supporting surgery for axial neck pain suffer from methodological flaws, lack of control groups, and the absence of long-term outcome data. Further long-term studies may help us better understand the utility of surgical intervention in patients with axial neck pain.

41 CHAPTER Cervical Radiculopathy: Surgical Management

Sheeraz A. Qureshi
Steven J. McAnany
Dante Leven

Introduction

Cervical radiculopathy was first described in the early 20th century and recognized as a common type of nerve root impingement.[1] Stookey first reported on the presentation of symptoms, which resulted from a cervical disc causing compression of cervical nerve roots in 1928. Originally, the disc pathology was thought to be a type of chondroma, though later histologic studies proved that these findings were incorrect. The underlying degenerative process was then thought to be inflammatory or infectious, thus the condition was given the name *spondylitis*. Brain et al.[2] later recognized the compressive effect of cervical disc herniations causing nerve root compression and subsequent radicular burning pain in a series of 10 patients. Several recent studies have shown that cervical radiculopathy can be a debilitating condition with a significant impact on quality of life.[3–7] The presentation commonly occurs in the setting of degenerative cervical pathology, most commonly spondylosis, which complicates the diagnostic workup and management options.[4,7]

Studies have shown that about 10% of individuals have radiographic signs of cervical spondylosis by 25 years old and about 95% have these findings by 65 years old.[2,5] The annual incidence of cervical radiculopathy has a rate of 107 per 100,000 in men and 64 per 100,000 in women in the United States.[8] The growing number of elderly people will increase the prevalence of cervical radiculopathy over the next few decades. The demands on spine surgeons to provide efficacious and financially sound treatment options begins with a comprehensive understanding of this condition.

Pathophysiology

Cervical radiculopathy is a condition that results from nerve root compression in the cervical spine, causing various upper extremity symptoms, which include impaired sensation, parasthesias, weakness, and burning pain.[4,7,9] This can lead to impaired ability to function, work, and perform normal daily activities.

The mechanism of nerve root impingement is most commonly from one of two causes: (1) osteophyte formation or (2) disc herniation posterolaterally, typically in the neural foramen. Spondylosis, trauma, tumors, deformity, or spinal instability can also cause radiculopathy.[10,11] However, most commonly (75% of cases), a combination of degenerative changes and disc space narrowing leads to osteophyte formation and facet joint spondylosis, which encroach on the exiting nerve root. In cases of severe disc herniations causing radiculopathy, usually some degree of underlying spondylosis is contributory.[1,5]

This progressive degenerative process often begins with the cervical discs (nucleus pulposus and anulus fibrosus) losing water, proteoglycans, and nutritional support with aging, which subsequently leads to a decrease in viscoelasticity and inability to properly distribute weight and transfer load. Disc material may then bulge posteriorly (worsened by flexed postures of the neck) into the spinal canal or exiting neural foramen. The surrounding structures experience an increase in loading, which causes excess force through the uncovertebral, intervertebral, and zygaphophyseal joints. Similar to other osteoarthritic processes, osteophyte formation develops as a reactive process and an attempt to increase the stability of these joints, which have developed excessive motion.

The ligamentum flavum, anterior longitudinal ligament, and posterior longitudinal ligament (PLL) undergo hypertrophy during the degenerative process and some degree of buckling and stiffening as disc height is lost.[10] As the process progresses in severity and time, these changes produce prolonged compression and ischemic changes within the nerve roots and spinal cord. Typically, radiculopathy develops prior to the onset of myelopathic changes.

Both myelopathy and radiculopathy have been described based on dynamic and static mechanisms. During motion (dynamic), the nerve roots can be compressed by osteophytes, disc herniations, or hypertrophied ligaments. For example, with the Spurling maneuver (flexion and ipsilateral rotation and lateral bending), the posterolateral uncovertebral osteophytes encroach on the exiting nerve root, producing radicular symptoms. Over time, chronic compression (static) on the nerve roots can produce radicular symptoms and pain from ischemia and neuroinflammation, which may respond differently once the compressive force is removed with a discectomy or foraminotomy. With this prolonged compression,

demyelination, scarring, atrophy, interneuronal loss, and degeneration of the spinal tracts may eventually develop, which can also alter the postoperative course.[7,10,11]

The prolonged dynamic or static compression on the nerve roots increases the permeability of the endothelial cells lining the blood vessels along the blood-brain barrier and decreases the total number of endothelial cells.[9] This allows for entry of inflammatory cells and toxins into the spinal parenchyma. The combination of neuroinflammation and toxins can worsen the compression and hypoxic environment, which worsens the underlying pain and radicular symptoms. Chemical mediators released from the disc tissue and sensory neurons perpetuate the inflammatory response, and chronic edema may increase the sensitivity of the nerve roots to pain. The dorsal root ganglion has also been implicated in the development of radiculopathy, as these cell bodies produce chemical mediators and the surrounding membrane is more permeable than other regions of the nerve root.

Though less common with radiculopathy, spinal deformity may contribute to this cascade of events. The degenerative process often results in segmental or global cervical kyphosis and the nerve roots and spinal cord are driven anteriorly, which tensions these structures, exacerbating the inflammatory and compressive pathologies. The C5–C7 spinal levels are responsible for the greatest amount of motion and force distribution in the subaxial spine and are most commonly involved in cervical radiculopathy. The apex of the cervical lordosis is found at C5, and loss of the normal cervical curvature in the sagittal or coronal plane places excessive stress on adjacent spinal levels. If the underlying process is left untreated, the degenerative changes commonly proceed cephalad and caudally.

Radiographic Evaluation

Patients presenting with an acute episode of cervical radiculopathy do not require immediate imaging in the setting of a normal neurologic examination. If the patient continues to be symptomatic after 6 weeks of appropriate conservative management, plain cervical radiographs consisting of an anteroposterior and lateral radiograph can be obtained (Fig. 41.1). The lateral radiograph is particularly helpful in determining the space available for the cord in the anteroposterior diameter (Fig. 41.2).

Flexion and extension radiographs should be considered to rule out segmental instability (Fig. 41.3). Oblique cervical radiographs can also be helpful, as they can identify areas of foraminal stenosis that may be correlated with the clinical symptoms of the patient. Overall, the series of plain radiographs is useful for identifying areas of foraminal stenosis, the presence of significant osteophytes/spondylosis, and the presence of spinal instability.

Magnetic resonance imaging (MRI) remains the gold standard for the diagnosis of cervical radiculopathy. Wilson et al.[12] were among the first groups to correlate MRI findings of nerve root compression with intraoperative findings. MRI offers several advantages, including excellent visualization of the neural elements and soft tissues, the ability to directly identify soft disc herniations, and no radiation exposure for the patient (Fig. 41.4). Park at al.[13] recently evaluated the diagnostic utility of oblique MRI images for improving the

FIG. 41.1 Anteroposterior radiograph of the cervical spine demonstrating normal alignment with no significant uncovertebral arthrosis.

FIG. 41.2 Lateral cervical radiograph demonstrating preserved cervical lordosis, and no evidence of central stenosis or cervical spondylosis.

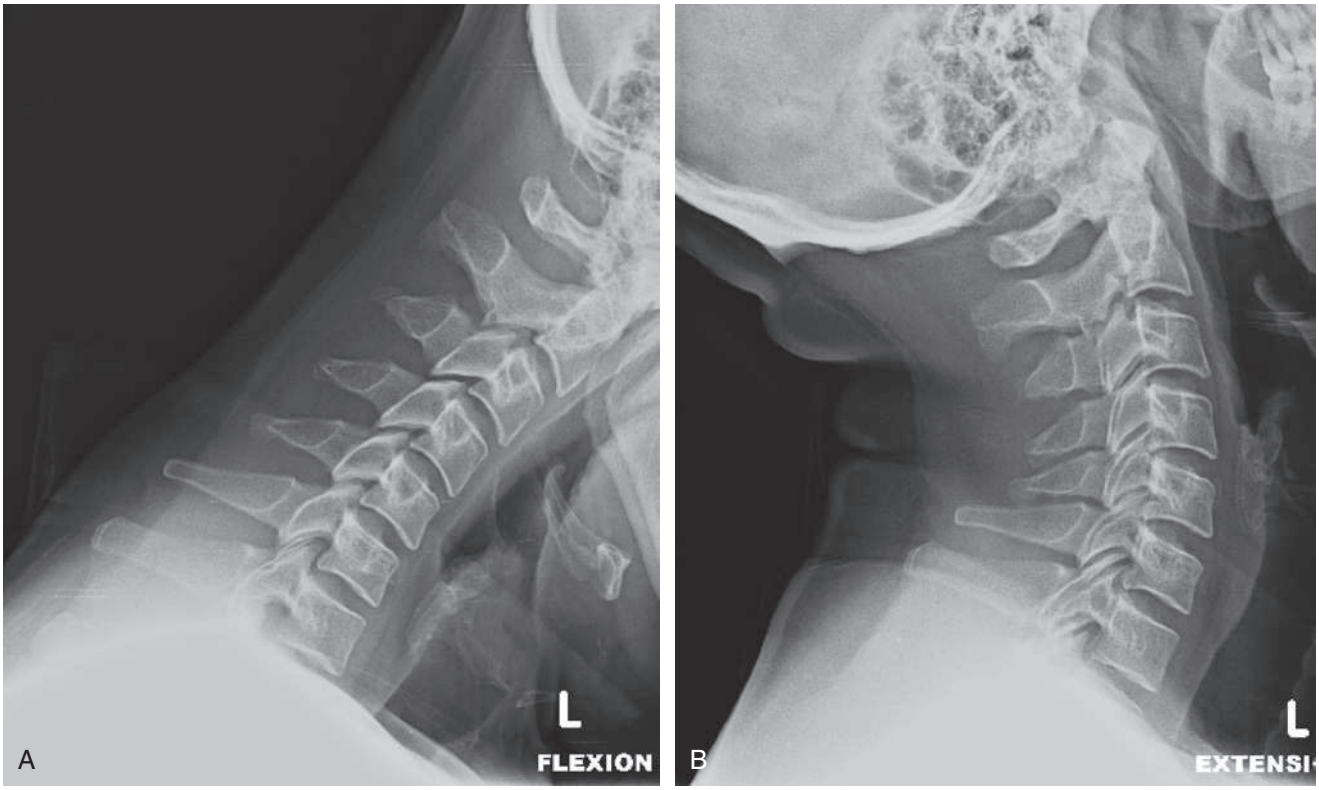

FIG. 41.3 (A) Flexion and (B) extension lateral cervical radiographs with no evidence of segmental instability.

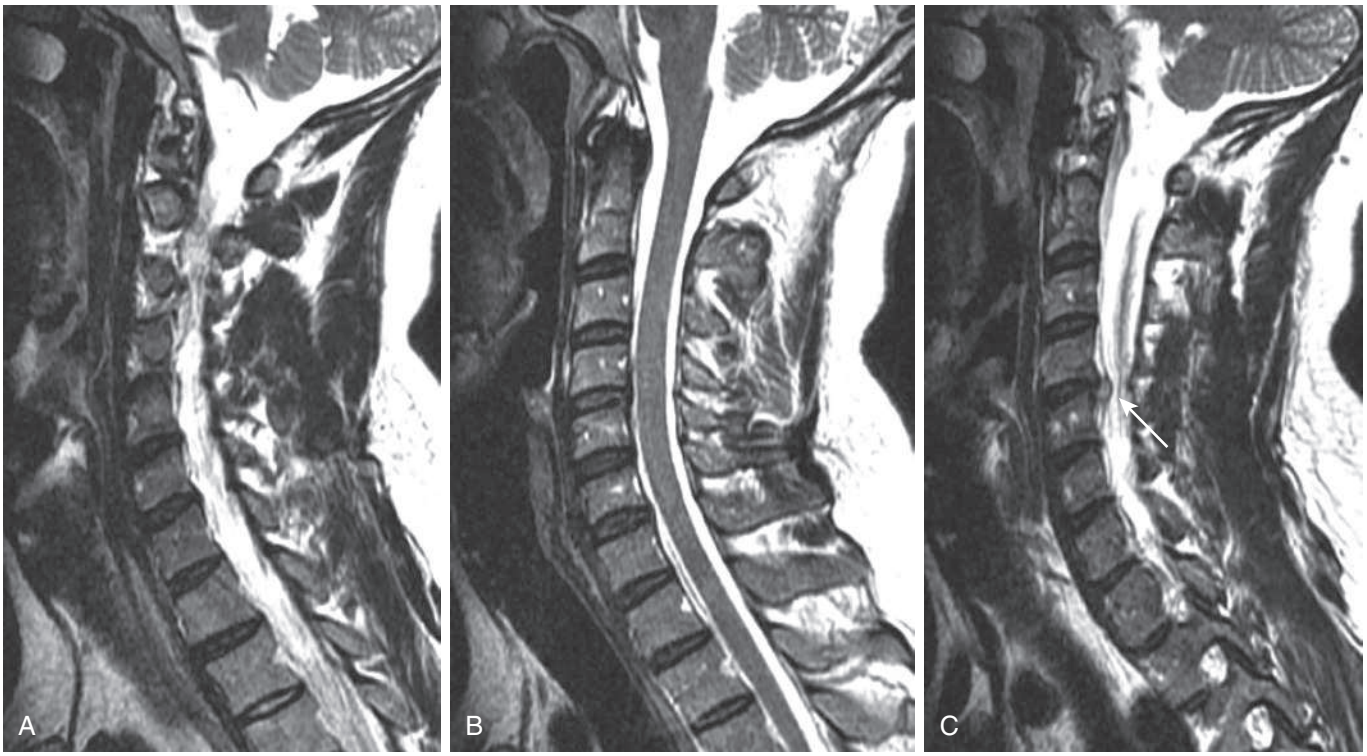

FIG. 41.4 (A–C) Sagittal and parasagittal T2-weighted cervical magnetic resonance images demonstrating a right C4–C5 disc herniation with root compression *(arrow)*.

diagnostic accuracy in foraminal stenosis. The authors concluded that oblique MRI views of the cervical spine significantly reduce the degree of intraobserver and interobserver variabilities and increase observer confidence in the assessment of foraminal stenosis.

Computed tomography (CT) myelography remains a useful tool in the diagnosis of cervical radiculopathy, particularly in patients who have had previous instrumentation in the cervical spine. Myelography can also be used in patients who have a contraindication to receiving an MRI.

Surgical Indications

The surgical indications for the treatment of cervical radiculopathy include (1) persistent radicular symptoms that have not improved with an appropriate trial of conservative care, (2) a neurologic deficit that is progressive, and/or (3) a neurologic deficit that is associated with significant radicular pain.

Surgical Treatment

Several studies have shown that the majority of patients with cervical radiculopathy (75–90%) will improve with nonoperative treatment.[8,14] However, other studies have shown that more than 55% of patients presenting with cervical radiculopathy have little or no improvement in symptoms.[15] Regardless, with patients presenting without significant motor weakness, a reasonable course of conservative treatment—including nonsteroidal antiinflammatory drugs, physical therapy, and epidural steroid injections—should be considered.

If nonoperative treatment is unsuccessful and there is a clear concordance between symptoms and imaging findings, several surgical strategies may be considered. Surgical indications include (1) progressive cervical radiculopathy, (2) persistent radicular symptoms after 4 to 8 weeks of nonoperative treatment, (3) instability with radicular symptoms, and (4) motor deficits. Posterior foraminotomy/laminotomy, anterior cervical discectomy and fusion (ACDF), and disc arthroplasty are all surgical options that should be considered after a careful review of the risks and potential benefits of each procedure. In a randomized trial of patients with cervical radiculopathy, Peolsson et al.[16] placed patients in one of three cohorts: ACDF, physical therapy, or collar immobilization. They found improved pain scores at 4 months in the surgical group, but no difference in the three groups at 12 months. However, the surgery group had favorable disability ratings at 12 months. These findings may support surgical intervention, though only following the completion of a structured physical therapy program.

Anterior Approach

The anterior approach was first described in the 1960s by Robinson and Smith, and later modified by several surgeons to include a formal discectomy, foraminotomy, and corpectomy (when necessary).[17–19]

The anteromedial approach is the most common approach utilized for anterior procedures. The patient is placed supine, with the neck in neutral or slight extension and a towel roll, intravenous bag or blood pressure cuff placed behind the neck or scapular region to enhance access. Fig. 41.5 demonstrates the typical anatomic landmarks that can be used for localization.

For surgery on lower cervical levels (C6–C7), the shoulders are carefully taped down (tensioned caudally) to improve radiographic access. Gardner-Wells tongs may be used to help position the head and provide slight traction during the approach.

A transverse or oblique incision is utilized in line with the skin creases for optimal cosmesis (Fig. 41.6). For multilevel

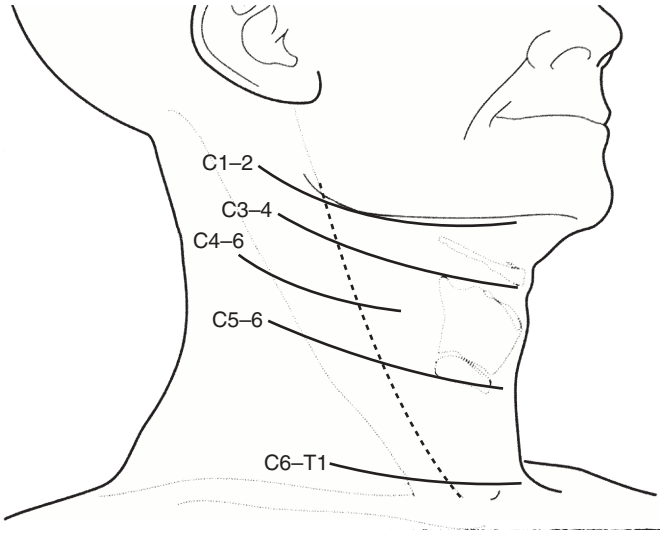

FIG. 41.5 Superficial landmarks are helpful in identifying the correct level for skin incision.

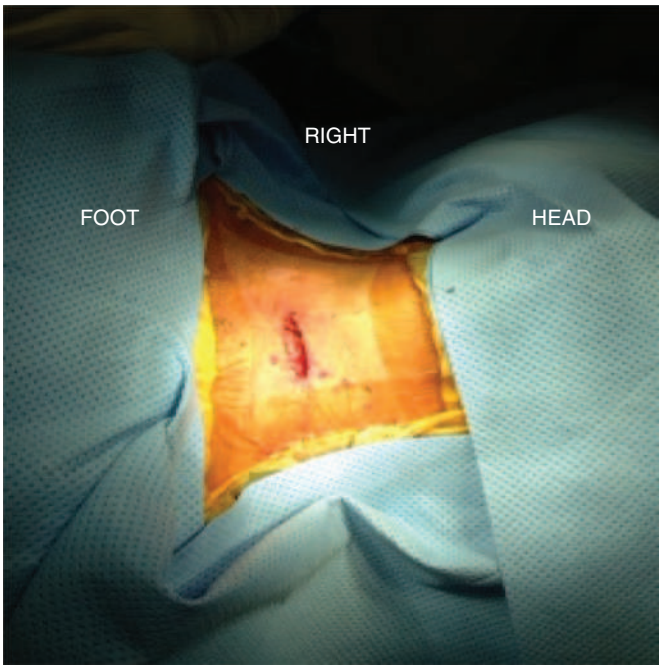

FIG. 41.6 Intraoperative image with a typical Smith-Robinson anterior cervical type approach.

procedures, an oblique incision is more commonly used in line with the medial edge of the sternocleidomastoid. For primary procedures, the left- or right-sided approach may be utilized; no studies have shown a consistent advantage of either approach. The side of surgical approach is dictated by surgeon preference, though the concerns regarding the recurrent laryngeal nerve support a left-sided approach, as the course of this nerve is more consistent within the carotid sheath. However, the thoracic duct may potentially be injured from the left side with access to more caudal cervical levels.

The superficial fascia is often encountered overlying the platysma, which runs from the midline of the mandible vertically to the medial border of the sternocleidomastoid. The muscle is sectioned transversely, perpendicular to the muscle fibers, which allows visualization of the deep cervical fascia. Depending on the number of spinal levels being addressed, the platysma may be undermined in a cephalad and caudal direction to mobilize the soft tissue window. Careful palpation is utilized to identify the carotid sheath and identify the plane between the sternocleidomastoid laterally and the trachea and esophagus medially. A combination of blunt and sharp dissection is used to continue through the deep cervical fascia, which is encountered in layers. Palpation of osteophytes can help identify the midline of the anterior cervical spine. The pretracheal and prevertebral fascia are released with an elevator or electrocautery to expose the anterior vertebral body and intervertebral disc. The longus colli are encountered and also released laterally to the lateral border of the vertebral body. Once the disc space is clearly identified, a bent 18-gauge needle is placed into the disc space to confirm the spinal level with a lateral radiograph.

Typically, the disc is incised with a long No. 15 blade scalpel and the anterior anulus is removed with a straight pituitary (Fig. 41.7A). The disc is then removed with curettes and Kerrison rongeurs in a systematic manner, proceeding posteriorly with awareness of the uncovertebral joints laterally and the posterior depth within the disc space (Fig. 41.7B). A high-speed burr is used to prepare the endplates of the caudal and cephalad levels until punctate bleeding is encountered.

Overall, this is a muscle-sparing approach with little muscle dissection and minimal postoperative pain. The advantages include low infection rates, low wound complications, and less pain, which may improve the rate of postoperative recovery and minimize the use of postoperative narcotics.[9]

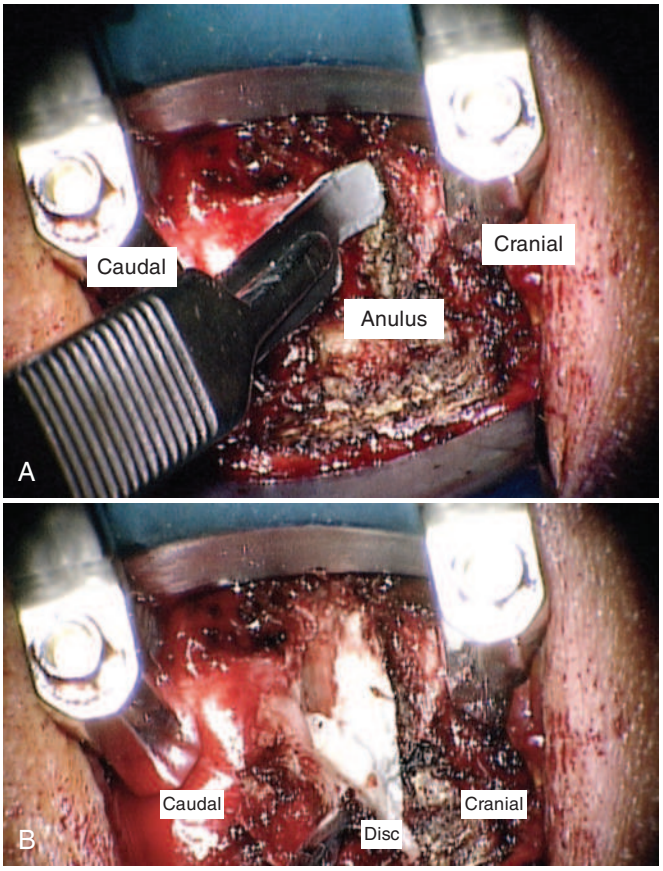

FIG. 41.7 Intraoperative images showing (A) incision of the anulus and (B) removal of the disc material.

Anterior Cervical Discectomy and Fusion

ACDF allows access to the majority of compressive pathologies (intervertebral discs, ventral osteophytes, foraminal compression, and ossification of the posterior longitudinal ligament) and is a good option for most single- and two-level pathologies (Fig. 41.8). The efficacy of ACDF for relief of arm pain and neurologic deficits and successful patient-reported outcomes has been extensively reported.[19–23] Additional benefits of ACDF include the restoration of cervical lordosis, decompression in the presence of kyphotic deformities, and the indirect decompression that is also provided by placement of the spacer or bone graft within the disc space. Axial neck pain from underlying spondylosis or disc degeneration can also be addressed with ACDF, although the results may be inferior compared to relief of radicular pain.

Overall complication rates with anterior procedures are often higher than with posterior procedures, which include pseudarthrosis, adjacent-segment degeneration (ASD), plate- and graft-related complications, and approach-related complications.[23–28] Important variables include patient factors, number of spinal levels, and use of plating or ventral fixation. Recent literature has shown comparable complication rates between anterior and posterior procedures, with higher complication rates in combined anterior-posterior procedures. Zhu et al. compared anterior (n = 245) and posterior (n = 285) procedures; the reoperation rate was significantly higher in the anterior group (21/245, 8.57% vs. 1/285, 0.3%; $P < .001$). Of the 21 who underwent reoperation, 13 of 21 (62%) were for pseudarthrosis, 7 of 21 (33.3%) for adjacent deterioration, and 1 of 21 (4.8%) for loosening of implant. In the posterior group, only 1 (0.3%) required reoperation for radiculopathy due to a new herniation, which is consistent with other studies.[29] However, postoperative neurologic function and outcomes were more favorable in the anterior group ($P < 0.05$).

In several well-designed investigations, anterior plating has been shown to improve fusion rates compared with stand-alone grafts and cages.[30–32] Newer-design stand-alone spacers with anterior fixation need further long-term studies

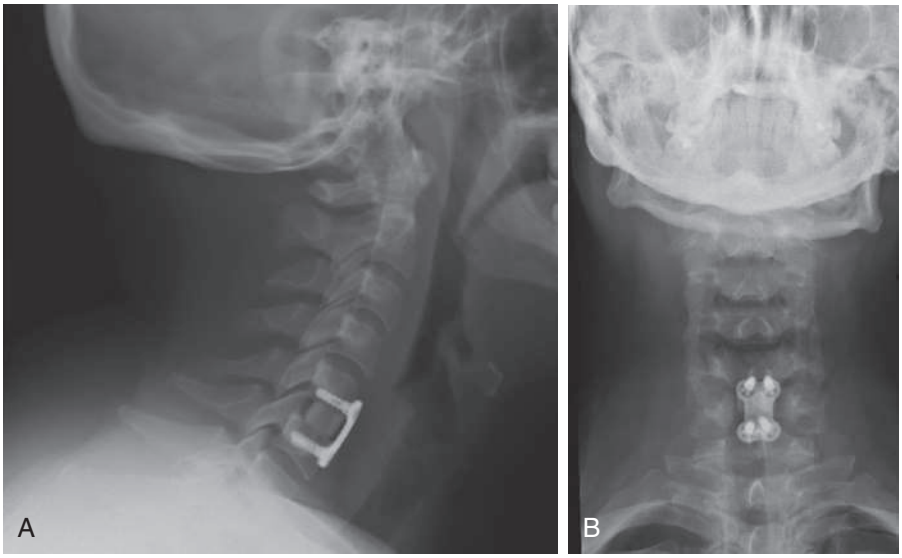

FIG. 41.8 (A) Lateral and (B) anteroposterior cervical radiographs in a patient after anterior cervical discectomy and fusion at C5–C6.

to analyze patient outcomes, complications, and fusion rates. Fusion rates of 96% and 91% for one- and two-level ACDF with anterior plate fixation compared with 90% and 72% without anterior fixation ($P < .05$) were shown in a retrospective review of 540 patients.[13] In a meta-analysis of 2682 patients, Fraser et al.[31] assessed fusion rates in ACDF and anterior cervical corpectomy and fusion (ACCF) procedures with and without plate fixation. Plate fixation improved fusion rates for all one-, two-, and three-level ACDFs (P <.0001, .0001, and .05, respectively). They also concluded that for three-level procedures, corpectomy with plate placement was associated with slightly higher fusion rates than discectomy without plate placement (82.5% vs. 96.2%; $P < .05$).

ASD is a common complication following ACDF with an incidence of 2.9% per year.[35,36] Lee et al.[33] showed that patients undergoing posterior arthrodesis were 7.5 times more likely to undergo reoperation due to ASD than patients undergoing posterior decompression only, and three times more likely to undergo reoperation due to ASD than patients undergoing anterior arthrodesis.

In a large recent study of approach-related complications in patients undergoing ACDF, the overall incidence of dysphagia, hoarseness, and unilateral vocal cord paralysis was 12.3%, 4.9%, and 1.4%, respectively.[34] Dysphagia and hoarseness are common postoperative complications that require close monitoring, though typically resolve by 6 months.

Multilevel Pathology

Cervical radiculopathy commonly involves one spinal level, though with prolonged degenerative changes, several levels may become involved. Bolesta et al. found high pseudarthrosis rates in a review of patients undergoing three- and four-level ACDFs with iliac crest autograft and locking plates.[35] Pseudarthrosis was found in 53% (8/16) of patients, though less than half (3/8) had enough pain to warrant a revision procedure. The authors concluded that, though plating may improve fusion rates for ACDFs, three- and four-level fusions appear to have unacceptably high failure rates.

The choice of interbody implant remains an area of controversy and interest. Historically, iliac crest autograft has been the gold standard, with fusion rates approaching 100% in some series. However, harvesting of iliac crest autograft is not without complications. These include chronic graft site harvest pain, infection, hematoma formation, and pelvic bone fracture. Allograft bone, while it eliminates the possibility of graft harvest complications, may have a slower time to union compared with autograft. Additionally, the overall fusion rate for a single-level ACDF may be lower than what is seen with autograft. Additional interbody options after ACDF include polyetheretherketone as well as titanium cages. Both have shown fusion rates comparable to allograft.

Cervical Arthroplasty

Cervical disc arthroplasty (CDA) is an option for patients with cervical radiculopathy that provides decompression without a fusion, and good midterm patient-reported outcomes have been reported[36–40] (Fig. 41.9). The surgical approach is essentially the same as for ACDF; thus, approach-related complications are reportedly similar, though some have reported longer operative times and more blood loss with cervical arthroplasty.[41] This motion-sparing procedure may minimize the complications of ASD, plate and screw complications, plate and soft tissue irritation, and nonunion. Additionally, ACDF may lead to higher rates of surrounding joint arthropathy and disc degeneration as a compensatory mechanism to the fusion, though some studies support that this is a natural development in the patient with underlying spondylosis and degenerative changes.[42] For example, the ASD rate of 2.9% per year has been reported regardless of the index procedure (ACDF, CDA, posterior foraminotomy),[33,43,44] and several studies

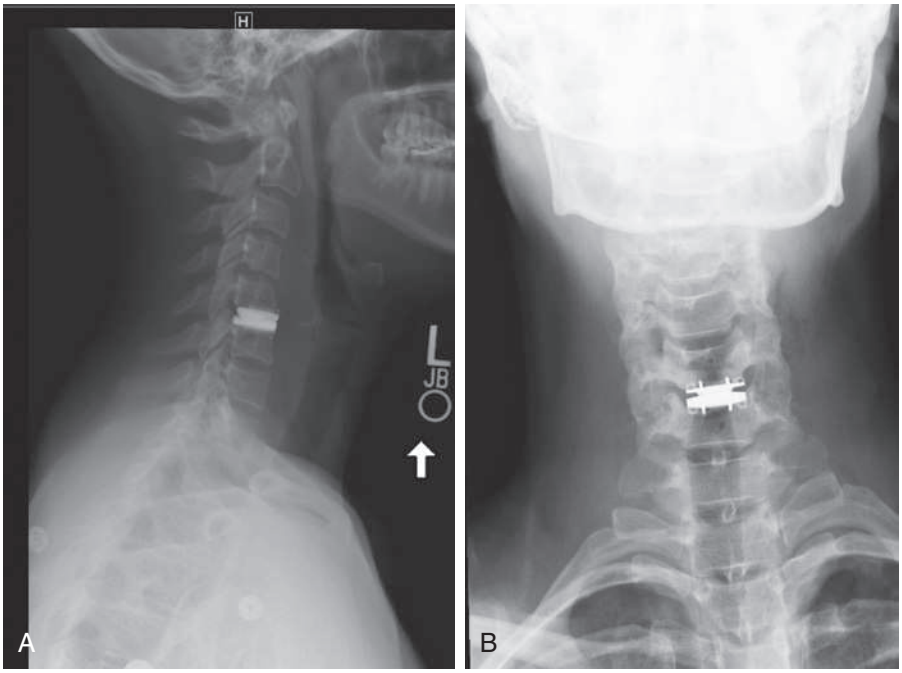

FIG. 41.9 (A) Lateral and (B) anteroposterior cervical radiographs in a patient who underwent a C5–C6 cervical disc arthroplasty.

comparing arthrodesis with motion-sparing procedures have shown comparable rates of ASD.[27,42] There are limited studies analyzing the development of long-term changes in patients following CDA compared with ACDF.

As some patients with ASD are asymptomatic, describing this complication based on whether surgery was indicated may be a more relevant factor. Lee et al.[33] conducted a study of 1358 patients undergoing ACDF, laminoplasty, foraminotomy, CDA, posterior or combined anterior and posterior arthrodesis. The rate of ASD that required a reoperation (ASD that occurred at a level cephalad or caudal to the index procedure that did not respond to conservative treatment, which was consistent with the patients' symptoms and imaging) was compared between the groups. The positive predictors were female sex, smoking, and posterior or combined anterior and posterior fusion ($P < .05$). Patients undergoing ACDF, CDA, or posterior decompression had similar rates of ASD. These findings support that the development of ASD may be more related to the natural progression of the underlying pathology than the type of procedure.

In a meta-analysis by Gao et al.[41] comparing ACDF and CDA, neurologic outcomes and neck and arm pain scores were more favorable in the arthroplasty cohort, while the neck disability index (NDI) was similar between the two groups. The underlying etiology of these findings could not be determined; however, the ACDF group had a higher rate of requiring a secondary surgical procedure (odds ratio [OR], 0.52; $P = .01$).

Sasso et al[39] reported promising 4-year results in a study comparing CDA with ACDF. Statistically significant outcomes favoring the CDA cohort were found for Short Form-36 scores and arm pain while NDI, range of motion and adverse events were similar between the two groups. Another investigation reported on 7-year follow-up of patients treated with CDA or ACDF. Patients in the CDA cohort were found to have lower rates of subsequent procedures for ASD and lower reoperation rates. NDI and neurologic improvement were also favorable in the CDA group.[45] As more long-term studies come to fruition, the mid- and long-term complications and patient-reported outcomes associated with CDA will be better understood and the optimal treatment options can be more clearly discussed during patient counseling.

Posterior Cervical Foraminotomy

A number of surgical techniques have been employed for the treatment of cervical radiculopathy. Surgeons have at their disposal a number of evolving technologies, including the use of minimally invasive surgery (MIS), to treat the pathology. The decision to treat cervical radiculopathy from an anterior- or posterior-based approach or through an open or MIS approach is determined by both the surgeon's comfort with the particular technique and, highly important, the location of the pathology.

The use of a posterior-based approach for the treatment of cervical radiculopathy was first described over 65 years ago by Mixter.[46] Frykholm[47] and Scoville[48] further popularized the posterior cervical foraminotomy technique. In the 1980s, the technique underwent advancement and refinement with the development of the keyhole laminoforaminotomy, as popularized by Fager,[49] Epstein,[50] and Casotto.[51] In small case series, a clinical success rate approaching 90% was found with this new technique. More recently, success rates approaching 95% have been reported using the open technique.[52] Furthermore, recent studies have shown no difference in clinical outcomes or surgical complication rates when comparing posterior

cervical laminoforaminotomy and ACDF.[53,54] Critics of the open posterior cervical foraminotomy cite increased postoperative axial neck pain and spasms that likely result from increased muscle damage and disruption.

As an alternative to the traditional open technique, minimally invasive posterior cervical foraminotomy techniques have been developed. Proponents of the MIS technique cite a shorter hospital stay, less blood loss, faster recovery time, and equivalent or better clinical outcomes.[55–57] Furthermore, by eliminating the subperiosteal dissection of muscle, the MIS techniques result in less acute muscle injury and denervation, which may improve long-term cervical biomechanics when compared with the open technique.

Indications for Posterior Cervical Foraminotomy

Posterior cervical foraminotomy via an open or MIS approach is indicated for patients with cervical radiculopathy resulting from compression of the nerve root within the neural foramen as a result of an osteophyte, spondylosis, or a lateral disc herniation. Patients should have received appropriate conservative management for a minimum of 6 weeks prior to being indicated for surgery. Furthermore, the patient's pattern of radiculopathy should correlate with findings on advanced imaging, including CT, MRI, or a CT myelogram. Absolute contraindications for posterior cervical foraminotomy include local segmental kyphosis or instability, evidence of spinal cord compression or myelopathy, or symptomatology not referable to findings on the imaging studies.

Open Technique

The open posterior cervical laminoforaminotomy is performed with the patient in the prone position. Mayfield three-pin tongs may be applied to secure the head to the table. The head of the patient is placed into gentle flexion to decrease the cervical lordosis, which facilitates visualization of the superior facet of the caudal vertebral segment. The bed is then positioned in the reverse Trendelenburg position, with the knees flexed to less than 90 degrees, which helps to reduce epidural venous bleeding. Surgical tape may be used to lower the shoulders to facilitate imaging of the lower cervical levels as well as to flatten any possible skin creases. A lateral cervical radiograph using a metallic marker or needle is used to determine the appropriate operative level.

A midline skin incision is made centered over the spinous process of the intended level. For a single-level foraminotomy, the length of the skin incision should be approximately 2 cm. The skin incision is carried down to the fascia of the nuchal ligament, which is divided in the midline to expose the spinous processes. A metal clamp can then be attached to the spinous process, and a lateral cervical radiograph is used to again confirm the correct operative level. Dissection is then continued in a subperiosteal fashion, elevating the paravertebral muscles from the lamina. The dissection is carried laterally to the facet joint with careful attention paid to not violate the facet capsule. Once the inferior articular process (IAP) of the cephalad vertebra is identified, a high-speed burr is used to remove the medial third of the IAP and the inferior portion of the superior lamina. A Kerrison rongeur (1 or 2 mm) is used to enlarge the space until the ligamentum flavum is identified. Once this is removed, the exiting nerve is able to be identified within the foramen. Additional bone can be removed until a nerve probe can be easily placed within the neuroforamen.

If there is a discrete disc herniation, the nerve root can be gently retracted superiorly to expose the extruded disc fragments or the distended PLL. A discectomy can be performed by sharply incising the PLL overlying the herniated fragments. Once all of the visible fragments are removed, irrigation of the disc space and the use of reverse angle curettes and upgoing pituitaries can remove any additional fragments that are not readily visualized.

After completing the decompression, the wound is copiously irrigated with antibiotic saline. The fascia is then reapproximated, and the wound is closed in layers.

Minimally Invasive Technique

Following the induction of anesthesia, the bed is positioned so that the operative side is away from the anesthesia equipment. The patient is then placed in a sitting or semirecumbent position utilizing a Mayfield three-point head fixation. Similar to the positioning utilized in the open technique, the patient's head is placed into gentle flexion. The bed is placed in the reverse Trendelenburg position, with knee flexion.

The target level is initially localized by placing a spinal needle lateral to the neck and checked fluoroscopically. A longitudinal 1.5- to 1.8-cm incision is made 1.5 cm lateral to the midline on the operative side. The ideal trajectory is to angle slightly cephalad from the skin to the lamina. A Kirschner wire (K-wire) is then introduced through the skin incision and advanced to the inferomedial edge of the rostral lateral mass at the operative level. A lateral fluoroscopic image is obtained to confirm the level. It is important at this step to fully release the deep cervical fascia with a pair of scissors, as this can restrict the passage of the tube dilators. Once this is done, serial dilators are passed to create the appropriately sized working portal.

Once confirmed to be on the lamina, the first dilator is passed over the wire to the bone, and the wire is removed (Fig. 41.10). Once the final dilator is in place, the operative tube is positioned caudally over the lamina with fluoroscopic confirmation until centered over the target disc space before anchoring to the table-mounted arm (Fig. 41.11).

The remaining muscle overlying the bone is removed with a pituitary rongeur. At this point, the microendoscope is brought in to use from the cephalad side for visualization. The medial facet and lateral lamina can usually be visualized at this point. Any remaining soft tissue obstructing the view is either removed or cauterized to shrink out of the way. The laminoforaminotomy is then initiated using a high-speed drill, removing the outer cortical layer and cancellous bone of the lamina as well as the medial aspect of the facet. Once a small opening is made through the deep cortical bone over the lateral canal, a Kerrison rongeur is used to complete the

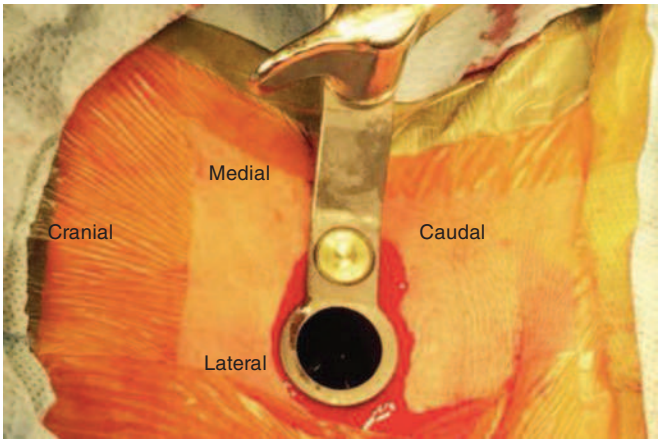

FIG. 41.10 Intraoperative image demonstrating the tube placement during a minimally invasive posterior cervical foraminotomy.

FIG. 41.11 Intraoperative lateral cervical radiograph showing the tube placement overlying the C5–C6 lateral mass.

foraminotomy. Identifying the medial and cephalad margins of the pedicle is useful for medial/lateral orientation. The foraminotomy is extended laterally until the lateral margin of the pedicle begins to fall away. At this point, only a third to a half of the medial facet has been removed and should not impact stability. A small laminotomy in the caudal lamina is useful to visualize the lateral margin of the thecal sac. A nerve hook can be introduced to retract the nerve root superiorly to allow access to the disc space. Loose disc fragments can be mobilized into the axilla, where they can be removed with a micropituitary rongeur. Similar to the open procedure, contained fragments may require an incision of the PLL and the use of reverse-angle curettes and downgoing pituitaries to facilitate removal of the disc herniation.

Once hemostasis is obtained with electrocautery or hemostatic foam, the wound is carefully irrigated. The operative cylinder is removed and the wound closed in a standard layered fashion.

Surgical Outcomes

The posterior cervical foraminotomy is a safe, highly efficacious procedure that provides significant symptom relief to those patients with foraminal-based compression of the nerve root resulting in radiculopathy. The traditional open, midline-based approach has been refined over several decades. In recent years, MIS-based techniques have been developed as an alternative to the standard open procedure. Proponents of the open technique cite the familiarity of the posterior approach to the cervical spine, avoidance of the steep learning curve associated with MIS techniques, and avoidance of the complications associated with MIS techniques, including misplacement of the percutaneous K-wire and medial/lateral migration of the tubular retractor, causing spinal cord/nerve root injury. Advocates of the MIS approach cite shorter hospital stays, less blood loss, and a quicker return to function.

Many small case series have reported on the results of either the open or MIS technique. Kang et al.[58] performed a retrospective review of 135 patients who underwent a posterior cervical foraminotomy, with 117 also receiving a discectomy. Clinical success was determined by excellent or good outcomes as defined by Odom criteria. Overall, 106 of 117 (90.6%) patients were deemed to have a successful outcome. Additionally, neck and radicular visual analog scale (VAS) scores improved by 2.1 and 3.2 points, respectively. Witzmann et al.[59] reported similar findings following an open posterior cervical foraminotomy, with a clinical success rate of 90%. Ruetten et al.[54] performed a randomized controlled trial of endoscopic foraminotomy versus ACDF. Clinical success was achieved in 96.6% of the foraminotomy patients. Another retrospective review of 100 patients undergoing a microendoscopic posterior cervical foraminotomy found that at an average follow-up of 14.8 months, 97% of patients were deemed to have achieved a clinical success.[55]

There are a limited number of studies directly comparing the results of open versus MIS posterior cervical foraminotomy. Winder et al.[60] found significant differences favoring the MIS cohort with respect to decreased intraoperative blood loss, postoperative analgesic use, and length of hospital stay. However, there were no differences in operative time or operative complications. The authors also noted that the results did not take into account the associated learning curve of the individual surgeons, which could have an impact on the observed complication rates. It is important to consider the learning curve when mastering any sort of novel technique. In one study, blood loss, operative time, and complications were all higher during the initial learning curve.[56] The authors noted an initial durotomy rate of 9%, which fell to less than 1% as experience increased. Lee et al.[61] found that surgeons reach the end of their initial learning curve after 30 cases with the MIS transforaminal lumbar interbody fusion technique.

In the only prospective, randomized clinical trial comparing open and MIS posterior cervical foraminotomy techniques, Kim et al.[62] performed an open procedure in 19 patients and a tubular retractor–assisted MIS technique in 22 patients. The length of incision, duration of hospital stay, and amount of postoperative narcotic use all favored the MIS group. However, there were no significant differences found in radicular pain at any time point. At 2-year follow-up, clinical success was achieved in 16 of 19 (84.2) of the open cohort and 19 of 22 (86.4%) of the MIS cohort.

A recent systematic review by Clark et al.[63] compared open and MIS foraminotomy results. The authors were able to identify 19 studies that met inclusion criteria. Summative results indicated that patients undergoing MIS foraminotomy had lower blood loss, a shorter operative time, less analgesic utilization, and a shorter hospital stay. McAnany et al.[64] in a meta-analysis comparing the open and MIS techniques found an overall clinical success rate as defined by Odom or Prolo criteria of 92.7% in the open group and 94.9% in the MIS group, which did not achieve statistical significance.

The anterior approach to the cervical spine, as pioneered by Smith and Robinson[18] and Cloward,[17] has largely remained the gold standard for the treatment of cervical radiculopathy. However, the posterior cervical foraminotomy has been shown over the last 4 decades to be a highly efficacious procedure with excellent clinical outcomes. Advantages of the posterior approach when compared to the anterior approach include improved access to posterolateral disc herniations, decreased risk of iatrogenic kyphosis, no risk for graft subsidence, and no risk for pseudarthrosis.[52,65] Furthermore, the risk of adjacent-segment disease remains a clinical concern following an ACDF.[66] After an ACDF, biomechanics studies have demonstrated that an arthrodesis affects the mechanical properties of the adjacent discs, resulting in hypermobility and increased internal stress responses.[42,67,68] A purported advantage of posterior cervical laminoforaminotomy is the motion preservation that can potentially prevent ASD. However, in a recent study by Skovrlj et al.,[69] the authors found a rate of ASD of 0.9% per year, which is similar to recent rates found in the literature following ACDF. Similarly, Lubelski et al.[70] found no difference in the reoperation rates between ACDF and posterior cervical foraminotomy at 2 years. A recent cost analysis comparing ACDF and posterior cervical foraminotomy found that ACDF is 89% more expensive and in the context of equivalent outcomes may not be the ideal surgical strategy.[71]

Summary

Cervical radiculopathy remains one of the most common complaints treated by spine surgeons. While most patients can be effectively managed with conservative care, surgical treatment of cervical radiculopathy is associated with good clinical outcomes and resolution of symptoms. The pathology associated with cervical radiculopathy can be effectively managed with either an anterior- or posterior-based approach. From an anterior-based approach, ACDF and CDA have been shown to have equivalent outcomes. Posteriorly, foraminal-based compression of the nerve can be treated with an open or MIS laminoforaminotomy. There are no differences in clinical outcomes when choosing between open and MIS-based approaches.

PEARLS

1. Flexion-extension radiographs should be obtained prior to considering a posterior-based laminoforaminotomy, as this procedure can worsen any preexisting segmental instability.
2. Oblique cervical radiographs and/or MRI can be utilized to more accurately assess foraminal-based pathology and can be used to correlate with clinical symptomatology.
3. During anterior-based procedures, taping of the shoulders can often facilitate radiographic visualization of lower cervical levels.
4. Palpation of bony landmarks, including the thyroid cartilage (C4–C5), cricoid cartilage (C6), and the carotid tubercle (C6), can be useful when planning the incision for anterior-based procedures.
5. When preparing the endplates during cervical disc arthroplasty, it is important to remove all of the disc material or the implant may shift position.
6. The lateral fluoroscopic radiograph is critical when implanting a cervical disc arthroplasty, as splaying of the facet joints may indicate that the implant is too large and a gap between the implant and the endplate indicates that the implant is undersized.
7. In a revision anterior procedure, the surgeon should consider an otolaryngology evaluation to assess the status of the vocal cords and function of the recurrent laryngeal nerve.

PITFALLS

1. Cervical disc arthroplasty should not be considered in those patients with significant facet joint degeneration or severe cervical spondylosis.
2. When localizing with the Steinmann pin in MIS foraminotomies, it is important to accurately place the pin, as medial placement can damage the spinal cord in the interlaminar space and lateral placement can damage the exiting nerve root.
3. Violation of the endplates during cervical disc arthroplasty can result in implant subsidence and the need for a revision procedure.
4. When performing a posterior cervical foraminotomy, care should be taken to avoid removal of greater than 50% of the facet joint, as this may result in segmental instability.

42 CHAPTER Management of Cervical Myelopathy: Surgical Treatment

Brett D. Rosenthal
Barrett S. Boody
Wellington K. Hsu
Alpesh A. Patel

Introduction

Cervical myelopathy is a condition of chronic progressive atraumatic spinal cord compression that, over time, may cause a decline in physical function and quality of life. Cervical spondylotic myelopathy (CSM) is the most common form of spinal cord dysfunction in the world and is more common in men than women.[1] In a separate disease process, Asian individuals are at increased risk of cervical myelopathy due to the increased prevalence of ossification of the posterior longitudinal ligament (OPLL) in this population.[1,2] The natural history of CSM results in progressive neurologic deterioration that is frequently recalcitrant to nonoperative measures. Surgical management, on the other hand, can often successfully halt, and potentially reverse, patients' neurologic decline. Thus, operative management is the standard of care for patients with moderate to severe myelopathy. The choice of which operative procedure to perform is a complex issue that must be determined based on the patient's individual symptoms, radiographic findings, and risk profile.

Pathophysiology

Cervical myelopathy is a syndrome of clinical findings caused by spinal cord compression secondary to narrowing of the spinal canal, which can be attributed to developmental stenosis, degenerative spondylosis, and/or OPLL. Furthermore, congenitally stenotic cervical spines with a canal diameter of less than 13 mm are associated with increased risk of pathologic changes in cervical intervertebral discs, which may further accelerate the development of cervical myelopathy.[3] Degenerative changes of intervertebral discs are commonly the first changes seen in the development of cervical stenosis. Subsequent alterations in cervical spine biomechanics result in hypertrophy of the ligamentum flavum and facet joint laxity.[4] With aging, osteophyte formation, vertebral subluxation, facet osteoarthritis, and uncovertebral joint thickening may also occur and further contribute to cervical cord compression.[5] Although degenerative changes in the cervical spine are commonly seen with advanced age, the association with myelopathic symptoms is unclear. One study found that among 200 asymptomatic individuals aged 60 to 65 years, radiographic signs of degeneration were found in 95% of men and 70% of women.[6] The clinical signs and symptoms of myelopathy have multiple hypothesized etiologies aside from the direct compression of nervous tissue, including (1) vascular disruption, (2) blood–spinal cord barrier disruption, (3) neuroinflammation, and (4) hypoxia-induced apoptosis of neurons and oligodendrocytes.[4]

Natural History

Early literature by Lees and Turner depicted myelopathy as a disease largely characterized by long periods of stable disability punctuated by intermittent exacerbations.[7] Nurick's retrospective review of the disease's natural history also identified prolonged static periods throughout conservative management of the disease process.[8] It has been hypothesized that these exacerbations may be triggered by minor traumas. While this has been supported by the literature in the setting of patients with OPLL,[9] a recent systematic review found insufficient evidence to support or refute this claim in patients with either asymptomatic spondylotic cord compression or myelopathy in the absence of OPLL.[10]

Symptomatic patients are commonly recommended for surgical management of cervical myelopathy because of the risk of progression; however, nonoperative care may be reasonable in those with mild manifestations. In a systematic review of the literature performed by Rhee et al. in 2013, a strong recommendation was made against routinely prescribing nonoperative treatment as the primary modality for patients with moderate to severe myelopathy given the naturally progressive history of this disease.[10] The same review cautioned that frequent monitoring should be performed

TABLE 42.1 Ranawat Classification

Class	Exam Findings
I	Pain, no neurologic deficits
II	Subjective weakness, hyperreflexia, dysesthesias
IIIA	Objective weakness, long tract signs, ambulatory
IIIB	Objective weakness, long tract signs, nonambulatory

to identify subtle neurologic deterioration in patients who are treated nonoperatively with mild myelopathy. Patients undergoing conservative management should be counseled on the prevalence of disease progression and the importance of the longitudinal follow-up for subtle progression of CSM symptomatology. Neurologic decline in conservatively managed patients with CSM occurs in 20% to 62% of patients at 3- to 6-year follow-up.[4,11–13] Likewise, with 6.5 years of follow-up, one retrospective comparative study identified a failure of nonoperative treatment with conversion to operative management rate of 37%.[12]

Classification

A major limitation of current research is the dearth of an ideal classification/grading system for cervical myelopathy. Historically, the Nurick classification system classified patients with cervical spondylotic myelopathy on the basis of symptoms and lower extremity functional status.[14] Criticisms of this classification system include the lack of assessment of upper extremity dysfunction and difficulty with use in elderly. The Ranawat classification improves upon the Nurick scale by emphasizing both subjective complaints and objective findings,[15] but it is limited by having only three classification groups (Table 42.1). The Japanese Orthopaedic Association (JOA) scoring system measures function as a continuous variable, allowing it to identify and classify subtle deterioration and/or improvement (Table 42.2). The JOA assessment tool contains a 24-item self-administered questionnaire that was devised based on statistical analysis of an initial, much larger survey.[16] The final score system has six subscores based on the patient's following functions: upper extremity motor, lower extremity motor, upper extremity sensory, truncal sensory, lower extremity sensory, and bladder. Test-retest reliability has been shown to be acceptable when comparing patients' responses at 4 weeks apart with no changes in symptoms.[17]

History and Physical Examination

Patients with cervical spondylotic myelopathy have been shown to have severely impaired quality of life in comparison to the general population, as measured by the Medical Outcomes Study Short Form Health Survey (SF-36).[18] Specifically, the most notable declines in health-related quality of life were noted in the role-physical, role-emotional, and social function subscales of the SF-36 survey.

TABLE 42.2 Japanese Orthopaedic Association Myelopathy Scoring System

Neurologic Status	Score
Lower Limb Motor Dysfunction	
Unable to walk	0
Able to walk on flat floor with walking aid	1
Able to walk up and down stairs with handrail	2
Lack of stability and smooth reciprocation of gait	3
No dysfunction	4
Lower Limb Sensory Deficit	
Severe sensory loss or pain	0
Mild sensory deficit	1
No deficit	2
Trunk Sensory Deficit	
Severe sensory loss or pain	0
Mild sensory deficit	1
No deficit	2
Sphincter Dysfunction	
Unable to void	0
Marked difficulty in micturition	1
Minor difficulty in micturition	2
No dysfunction	3

Cervical myelopathy can display a variety of upper and lower extremity symptoms and signs due to the location of neurologic compression. It is important to obtain an in-depth history in order to identify the patient's overall level of disability as well as that likely attributable to CSM. Patients with cervical myelopathy may complain of loss of upper extremity dexterity, gait imbalance, and/or nonspecific weakness. Bowel and bladder symptoms are less commonly the primary complaint.[19] An understanding of the duration of symptoms, severity of disability, and course of disease progression aids clinical decision making. Clinical presentations often include a combination of radicular (lower motor neuron) and long tract (upper motor neuron) signs. Most commonly, lower motor neuron signs, such as radicular pain and weakness, will be present at the presumed clinically significant level of cervical stenosis with upper motor neuron signs, such as hyperreflexia and spastic gait, at the levels discussed later.[19]

Certain upper motor neuron reflexes can frequently be elicited in myelopathic patients. To elicit a Hoffman reflex, the examiner flicks the terminal phalanx of the middle or ring finger. A positive test is signified by the reflexive flexion of the terminal phalanx of the thumb and index finger. To elicit an inverted brachioradialis test, the examiner strikes the brachioradialis tendon with a reflex hammer. A positive test is present when there exists a diminished brachioradialis reflex alongside a reflexive contraction of the finger flexors. In the lower extremity, a Babinski sign may indicate upper motor neuron compression, resulting in damage to the corticospinal tract. To perform this test, a blunt, pointed instrument is stroked in a curved trajectory along the lateral aspect of the sole of the foot from the heel toward the toes. A positive test result is indicated by an extension of the hallux.

Although each patient is different, cervical spondylotic myelopathy often involves compression of the lateral corticospinal tracts, which are responsible for voluntary skeletal muscle control, and the spinocerebellar tracts (anterior and posterior), which convey proprioceptive information to the cerebellum.[20] Together, these deficits are responsible for the wide-based spastic gait with clumsy upper extremity function that is classic to cervical myelopathy. Additional commonly involved spinal cord regions are the spinothalamic tracts, which are responsible for contralateral pain and temperature sensation, the posterior columns, which are responsible for ipsilateral position and vibration sense, and the dorsal nerve root, which is responsible for dermatomal sensation.[19]

Concomitant spinal pathologies may further complicate the clinical picture and surgical planning. Patients with OPLL, ankylosing spondylitis, and diffuse idiopathic skeletal hyperostosis require special consideration when formulating preoperative plans.

Tandem stenosis should be considered as a possible contributing factor to the patient's reported symptoms. One cadaveric study identified the presence of stenosis in one region of the spine (cervical or lumbar) as positively predicting stenosis of the other 15.3% to 32.4% of the time.[21] This may be partly explained by the positive association between congenital stenosis of the lumbar and cervical spines.[22] Clinically speaking, a patient's presentation may be an amalgam of signs from each disease process, and disability from lumbar stenosis should be considered. If the surgeon deems the lumbar stenosis to be clinically relevant, surgical planning for these patients may include consideration of single-stage versus two-stage decompression. One retrospective cohort study did not identify a significant difference between single- and two-stage decompression with respect to JOA or Oswestry Disability Index scores.[23]

A comprehensive understanding of all prior treatments received, including surgical procedures, assists with further treatment recommendations and preoperative planning. An account of the patient's comorbidities should be taken into consideration to determine the patient's suitability for surgical procedures. Given the progressive natural history of the disease process, timely medical optimization of comorbidities, when possible, is preferred in patients at increased perioperative risk.

Imaging

Preoperative imaging is essential for confirming the presence of cervical stenosis and preoperative planning. Every patient undergoing a workup for CSM should have upright cervical spine radiographs, including flexion/extension views. The clinician should note degeneration of uncovertebral and facet joints, subluxation, the presence of osteophytes, narrowing of disc spaces, or decreased sagittal diameter of the spinal canal.

On the lateral radiographs, the Pavlov ratio, which is the ratio of the canal diameter (measured from the posterior aspect of the vertebral body to the corresponding spinolaminar line) to the vertebral body width (measured anterior to posterior), should be determined. If the ratio is less than 0.8, congenital narrowing of the spinal canal is present, which greatly increases the patient's risk of symptomatic stenosis and cord compression.[24] The Pavlov ratio has been found to have excellent correlation to narrowing identified on computed tomography (CT) and magnetic resonance imaging (MRI; Fig. 42.1).[25] Based on a lateral radiograph, a canal diameter of 12 mm or less will often indicate cord compression, whether or not the patient is symptomatic, because the spinal cord diameter is approximately 10 mm in the midcervical spine and soft tissues are not accounted for on plain films. The surgeon should also note the presence of any radiographic evidence of OPLL, although CT is the most diagnostically accurate method of identifying this abnormality, especially if it is segmental or localized.[26] CT provides additional information regarding the extent of OPLL and/or osteophytes. CT myelography, although invasive, may be useful in patients who cannot have an MRI or have a substantial artifact secondary to local hardware.

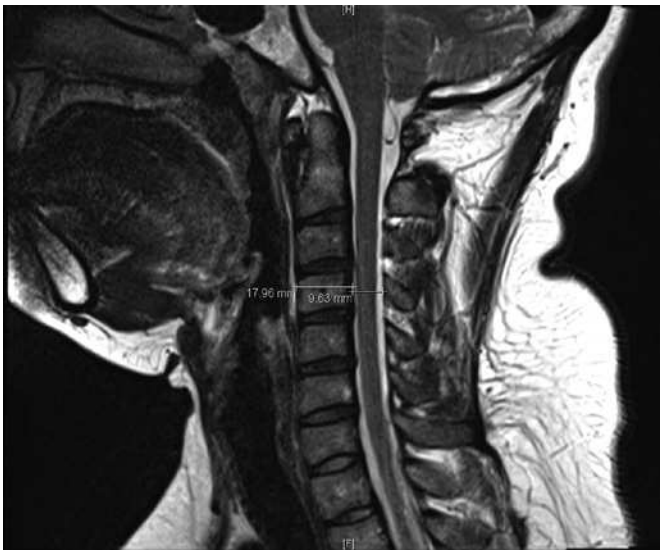

FIG. 42.1 T2-weighted midsagittal magnetic resonance imaging (MRI) slice from a 26-year-old woman with congenital stenosis of the cervical spine. Although Pavlov's ratio is traditionally measured on a lateral radiograph, this MRI slice demonstrates a ratio of 0.53 and highlights the limited space available for the spinal cord.

Sagittal plane alignment should also be assessed on the upright lateral radiographs. Sagittal plane malalignment can contribute to neurologic decline by increasing tension, increasing pressure, and flattening/deforming the spinal cord.[27] Additionally, small feeder blood vessels to the cord can be compromised as deformity ensues, further compromising the patient's neurologic status.[28] With progressive kyphosis, the cord is increasingly tensioned and draped across the anterior vertebral body osteophytes and/or disc herniations, which may necessitate anterior decompression. Flexion-extension views are used to identify the presence of any angular or translational instability that may be present. Hypermobility, or "compensatory subluxation," of segments one or two levels away from stiff segments is not uncommon, and may contribute to cord compression. The sagittal plane alignment

is significant in preoperative planning because the neurologic compression from cervical stenosis with kyphosis may not be completely addressed with posterior spinal procedures.

MRI is a crucial imaging modality in the setting of neurologic deficits. It is an essential part of the preoperative workup for a patient whose presentation is concerning for CSM. The MRI is integral to confirming the diagnosis and providing prognostic information with regard to surgical intervention. A systematic review by Tetreault et al. in 2013 identified 3 important negative predictors of neurologic recovery after surgery.[29] First, high signal intensity (SI) changes on T2-weighted images (T2WI) in combination with low SI changes on T1-weighted images (T1WI) correlated with a poorer JOA recovery rate[30,31] and poorer motor symptom (e.g., weakness, spasticity, wasting, and so on) recovery.[32] Second, a high ratio of T2 SI between compressed and noncompressed (C7–T1) segments also was repeatedly associated with a poorer JOA recovery rate.[33,34] Third, greater numbers of high SI segments on T2WI had a negative association with JOA recovery[35] and Neurosurgical Cervical Spine Scale (NCSS) recovery.[36] These findings should not deter surgical intervention when it is indicated; they should simply be used to guide expectations during preoperative discussions with the patient.

Goals of Management

The overlying goals of management for cervical myelopathy are cord decompression, stabilization, preservation and improvement of cord vascularity, and restoration of normal sagittal alignment. As discussed previously, nonoperative management for patients with significant and/or progressive symptoms should not be routinely recommended.[10] Law et al. identified several poor prognostic factors for conservative treatment and put them forward as absolute surgical indications. They recommended surgery for the following: progression of signs or symptoms, duration of symptoms greater than 6 months, compression ratio (cord sagittal diameter/transverse diameter) 0.4 or less, or transverse area of the cord less than 40 mm^2.[37] More recently, a consensus statement recommended surgical intervention once a diagnosis of CSM was made.[38] Regardless, timeliness of intervention is critical as patients with milder myelopathy and those with symptom duration less than 6 months have improved outcomes after surgery.[39]

Contraindications for surgical management of CSM are based on the patient's inability to tolerate the physiologic stresses of surgery. As always, patient-specific risk factors should be identified preoperatively and discussed openly with the patient. Increased surgical mortality has been associated with patients who have heart failure (odds ratio [OR], 4.59; 95% confidence interval [CI], 3.62–5.82), pulmonary circulatory disorders (OR, 11.29; 95% CI, 8.24–15.47), and pathologic weight loss (OR, 5.43; 95% CI, 4.07–7.26) preoperatively.[40] Tetreault, Karpova, and Fehlings reviewed the literature and, by metaanalysis, identified age as the most powerful predictor of perioperative morbidity and worse neurologic recovery.[41] Similarly, a recent clinical prediction model that was internally and externally validated (on different subject populations) identified the following as the most significant predictors of surgical outcome: preoperative severity of myelopathy, age, smoking status, and presence of impaired gait.[42] While most of these are nonmodifiable risk factors, smoking cessation should be encouraged for all patients.

Surgical Approach Considerations

Many factors must be considered when determining the procedure needed to adequately achieve the aforementioned goals of management. The sagittal alignment, source of compression, number of segments involved, presence of axial neck pain, shape of pathoanatomy, and/or history of prior surgeries must all be taken into account when planning. The first decision point is whether an anterior, posterior, or combined approach is necessary to manage the patient's pathology. Each approach has its own merits and unique risks.

Posterior approaches should be considered for surgical management of multilevel (more than three) cervical stenosis, OPLL, congenital stenosis, and posterior compression. The posterior approaches provide direct and/or indirect decompression of the spinal cord. Direct decompression may occur in cases of compressive posterior element pathology (e.g., ossification of the yellow ligament or infolding of ligamentum flavum). Indirect decompression, more frequently the goal of posterior procedures, allows the spinal cord and thecal sac to drift posteriorly away from anterior sources of compression, but is most successful in the absence of kyphosis. Kyphotic alignment is often regarded to be an absolute contraindication to posterior approaches in isolation.[43] The two primary procedures performed with a posterior approach are (1) laminectomy with or without posterior spinal fusion and (2) laminoplasty. Both are useful when treating a patient with more than three levels of pathology because, in this situation, the posterior techniques have less additive morbidity.[44–47]

Laminectomy without fusion places the spine at risk for postlaminectomy kyphosis with delayed neurologic deterioration.[48–55] The incidence of postlaminectomy kyphosis ranges from 6% to 47% in adults and nearly 100% in children.[56] While most patients have neurologic recovery in the short term regardless of their sagittal alignment, delayed neurologic deterioration has been documented in 10% to 39% of patients who have cervical laminectomy without fusion.[56] The review of the literature by McAllister et al.[56] identified two predictors of success for laminectomy without fusion: preoperative lordosis greater than 10 degrees and absence of instability on flexion-extension views. These authors still reserved isolated laminectomies only for elderly patients with multiple comorbidities who had these predictors for success because posterior spinal instrumentation and arthrodesis by means of lateral mass fixation is a relatively safe, expedient, and successful procedure. Postlaminectomy kyphosis has multiple hypothesized etiologies. Some believe that it is due to disruption of the posterior tension band with load redistribution; others attribute it to iatrogenic destabilization from aggressive facet resection. Regardless, arthrodesis is indicated in the vast majority of patients. An additional benefit of arthrodesis, in

addition to the avoidance of instability and sagittal malalignment, is the possibility of alleviating pain generators responsible for axial neck pain.

Laminoplasty evolved as a technique to minimize stripping of the posterior elements, maintain the posterior tension band, and maintain the patient's range of cervical motion. While many variants of the technique have been described, they all aim to expand the spinal canal by opening the posterior arch without removing it. Laminoplasty should not be performed in the setting of instability because a fusion procedure is required to avoid iatrogenic sagittal malalignment. The decision to perform a laminoplasty or a laminectomy with fusion is a complex issue that depends upon the presence of axial neck pain, surgeon preference, and desire to maintain cervical motion.

Anterior approaches allow for direct decompression of anterior compressive structures. In the presence of kyphosis, anterior approaches are preferred. Cord compression at only the level of the discs (retrodiscal) can be successfully managed with an anterior cervical discectomy and fusion (ACDF). If the pathology extends above or below the disc space (retrovertebral), anterior cervical corpectomy and fusion (ACCF) should be considered because the surgeon cannot safely address this pathology through the exposure afforded by discectomy alone. Extensive, multilevel anterior pathology can be seen with OPLL as well as spondylosis. Due to the limitations of exposure and technical challenges with multilevel fixation and fusion, a combined approach is recommended when addressing pathology at greater than three levels requiring anterior decompression.

One review of prospectively collected data identified a higher postoperative wound infection rate in patients undergoing a posterior approach but no difference in overall complication rates, C5 palsies, or dysphagia.[57] Luo et al.[58] conducted a systematic review and meta-analysis of the literature pertaining to multilevel CSM management, identifying anterior approaches as having significantly better postoperative JOA scores. Recovery rates, however, were no different between anterior and posterior approaches. The anterior approach had higher blood loss, operation times, and complication rates but a shorter length of stay than posterior approaches. However, given the heterogeneity of patients and disease processes included in the metaanalysis, these generalizations may not be completely accurate reflections of approach-related morbidity, especially since the analysis did not control for number of levels, extent of disease, and procedures performed. Without a clear consensus of superiority, most reviews of the literature conclude that, given equivalent effectiveness of anterior and posterior approaches, an individualized approach based on the patient's specific pathology should be taken.[37,59,60]

Anterior Procedures for the Cervical Spine

Anterior procedures can address spinal cord compression secondary to uncovertebral osteophytes, spondylotic bars, and disc osteophyte complexes. Anterior procedures also have the benefit of being able to restore sagittal malalignment much more than posterior techniques. In the setting of significant axial neck pain with spondylotic changes of the intervertebral discs, anterior fusion procedures are preferred over posterior approaches. While stand-alone anterior procedures are successful when treating one or two levels of appropriate pathology, controversy exists over whether a three-level procedure is best handled anteriorly or posteriorly.[37,61] As the number of surgically treated levels increases to greater than three, anterior procedures commonly need to be supplemented with posterior procedures to provide the necessary stability for fusion.

Anterior Approach to the Cervical Spine

Both ACDF and ACCF procedures can be performed with the anterior approach to the cervical spine, the Smith-Robinson approach, which provides access from C2 to T1, spanning the majority of cervical spondylotic pathology. The course of the vertebral arteries should be reviewed on all available imaging preoperatively to note any aberrancies. Prior to the induction of general anesthesia and intubation, the degree of neck extension that the patient can tolerate is important to determine; fiber-optic intubation may be necessary.[62]

The patient is positioned supine with neutral head rotation. The use of a foam donut to prevent pressure sores of the occiput is encouraged. A bump at the level of the shoulders allows for additional extension of the cervical spine, improving access to the anterior elements. For low cervical pathology, the shoulders may be taped down to allow for easier radiographs.

The incision can be made transversely when treating one or two levels of pathology in order to provide a more cosmetic scar. Alternatively, a longitudinal incision provides access to three or more levels at the expense of scar cosmesis. Surface landmarks help guide the level of the incision: C2 at the level of the angle of the mandible, C3 at the level of the hyoid, C4–C5 at the level of the thyroid cartilage, and C6 at the level of both the carotid tubercle and the cricoid cartilage (Fig. 42.2). Preoperative and intraoperative radiographs should also be used to determine the level of the incision.

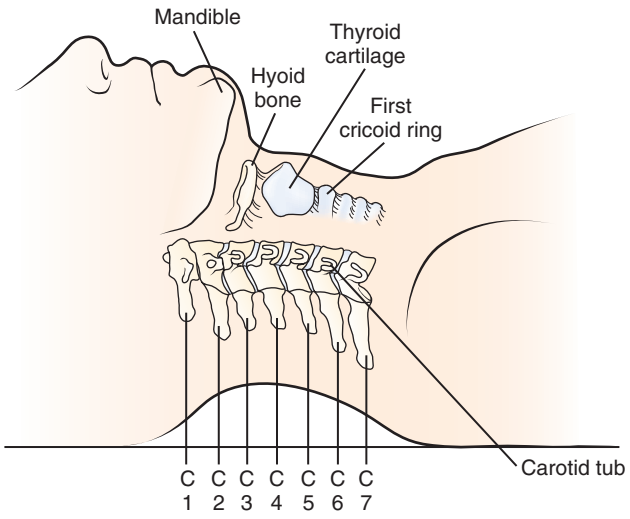

FIG. 42.2 Palpable landmarks and their relationship to the cervical spine. (From Hoppenfeld S. *Physical Examination of the Spine and Extremities.* Norwalk, CT: Appleton & Lange; 1976:110.)

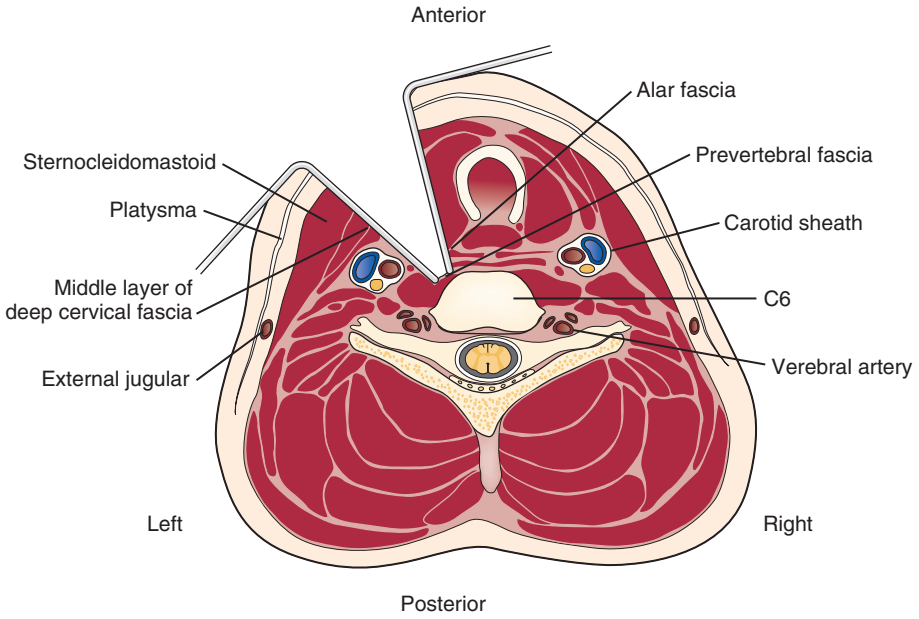

FIG. 42.3 Plane of surgical dissection during the anterior approach to the cervical spine. The carotid sheath is lateral to the plane of dissection, and the esophagus is medial to it. (From Silber JS, Albert TS. Anterior and anterolateral, mid and lower cervical spine approaches: transverse and longitudinal [C3 to C7]. In Herkowitz HN, editor. *The Cervical Spine Surgery Atlas,* ed 2. Philadelphia: Lippincott Williams & Wilkins; 2004:91.)

After the incision is made with a scalpel, electrocautery can be used to dissect down through the subcutaneous fat to the level of the platysma, which is subsequently divided in line with the incision using electrocautery. Care must be taken during this stage to avoid injury to the external jugular vein or other superficial veins that may be crossing the operative field; ligation may be necessary if the veins cannot be adequately mobilized.[62]

With the platysma retracted, the anterior border of the sternocleidomastoid is identifiable. The dissection is continued through the deep cervical (investing) fascia just medial to the sternocleidomastoid (SCM). The SCM can subsequently be retracted laterally; the carotid pulse is then palpated. The pretracheal fascia that is contiguous with the carotid sheath can be split in a plane between the sheath (lateral) and the medial structures that it envelops (trachea, esophagus, and strap muscles).

Dissection is then continued medially bluntly with the surgeon's finger behind the esophagus, which is retracted to the contralateral side of the approach (Fig. 42.3). The prevertebral fascia and longus colli overlying the vertebral bodies are split in the midline and lifted subperiosteally out laterally to the level of the uncinate processes. Failure to lift this muscle subperiosteally or extending the deep dissection too far laterally will endanger the vertebral artery and the sympathetic chain, which overlies the longus colli.

After elevating the longus colli from the anterior portion of the vertebral body, a spinal needle is used to confirm the correct level of the procedure. Wide, smooth-edged retractors are preferred in the coronal plane to avoid damage to the adjacent structures. Sharp retractors can cause inadvertent injury to the esophagus medially or carotid sheath laterally. Narrow retractors can inadvertently damage the vertebral artery by slipping between the transverse processes.[63]

Complications and Risks of the Anterior Approach to the Cervical Spine

Certain risks are associated with the Smith-Robinson approach, regardless of the spinal procedure performed. Esophageal perforation is a devastating complication that may occur secondary to improper retractor placement or inadvertent injury with a sharp instrument or the burr. The incidence is estimated as 0.2% to 0.4%.[64,65] A general or thoracic surgery consultation should be made intraoperatively if there is any concern for potential esophageal perforation.

Vertebral artery injury is a rare, but significant, potential complication of anterior cervical spine surgery. Failure to identify aberrancy in the vertebral artery course preoperatively can increase the risk of inadvertent injury. Excessively wide corpectomies can increase the risk of vertebral artery injury, as can off-center or oblique corpectomies. A retrospective review of 1976 cases reported an incidence of iatrogenic vertebral artery injury as 0.3%.[66] In the setting of vertebral artery injury, temporary hemostasis can be achieved via tamponade, and a vascular surgery consultation should be made. Intraoperative angiography should be performed prior to considering ligation as a definitive method of attaining hemostasis. Repairs should be performed if possible.

Dural tears are also a possibility during anterior cervical spine procedures. One large series identified an overall CSF leak rate of 1% with no significant difference between anterior or posterior approaches.[67] Patients with OPLL were 13.74 (95% CI, 4.53–41.61) times more likely to have a cerebrospinal

fluid (CSF) leak than patients without OPLL.[67] The treating physician should be prepared to place a lumbar CSF drain in the presence of a substantial dural tear that cannot be closed with a watertight primary repair.

Radiculopathies have also been attributed to anterior cervical spine procedures. The incidence is most frequently reported as 2% to 4%.[68–70] Most often, C5 is the level involved. Previous studies have found that higher rates of radiculopathy are present as the number of levels fused increases.[70] While the etiology of this is not entirely elucidated, some theorize that the more obtuse angle that the C5 nerve root attaches to the cord and/or increased posterior drift at this level may be responsible for its increased susceptibility to injury.

The recurrent laryngeal nerve is also at risk of injury with this approach. Traditionally, it was believed that the surgery should be approached from the left side preferentially due to the increased risk of aberrancy of the right recurrent laryngeal nerve, but recent studies demonstrate no appreciable difference in injury rates.[71,72] Our preferred technique is to approach from the side contralateral from radicular symptoms (if any) such that a foraminotomy can be performed intraoperatively with greater ease. If there are no radicular symptoms preoperatively, the approach should be from the side the surgeon finds most comfortable. In revision surgery, preoperative evaluation should include direct laryngoscopy prior to approaching from the contralateral side of previous surgeries. Any prior injuries to the recurrent laryngeal nerve need to be identified before a contralateral approach is attempted to prevent bilateral recurrent laryngeal nerve injury, a devastating complication that could compromise the patient's airway. In the setting of unilateral vocal cord dysfunction, procedures should be approached from the dysfunctional side.

Dysphagia is also a frequent complication of anterior approaches to the cervical spine. Most often, it is transient. The reported incidence of dysphagia after an anterior cervical approach is highly variable, from 3% to 67%.[73,74] The reason for such variability of reported incidences is unclear, but is likely due to the variation in methods of measurement, surgical technique used, definition of dysphagia, and reporting consistency. One series has demonstrated 80% underreporting of dysphagia by surgeons in comparison to patient surveys.[75] Evidence has suggested that increased retraction pressures,[76] scar tissue,[77] osteophytes,[77] vagus nerve dysfunction,[77] and soft tissue swelling[73] may all be contributing factors. Although many series have conflicting data, various risk factors have also been implicated, including preoperative swallowing difficulties, increased age,[47,78] increased duration of pain prior to intervention,[79] gender,[47] bone morphogenetic protein use,[47] smoking,[80] and number of levels.[73]

Dysphonia, like dysphagia, is a frequent complication of anterior cervical spine surgery. The reported prevalence ranges from 1% to 51%.[81,82] Similar to dysphagia, one series identified greater than 85% underreporting by spine surgeons compared with patient surveys.[75] Dysphonia is one potential manifestation of a recurrent laryngeal nerve palsy. More severe injuries may present with other symptoms, such as postoperative airway obstruction, persistent cough, or aspiration. The mechanism of injury is most often a stretch-induced neurapraxia.[83] Risk factors of developing postoperative dysphonia include more extensive dissection, aggressive retraction,[84] longer cuff inflation time,[85] and elevated endotracheal tube pressures.[85]

Depending on the level of dissection, various other structures are at risk as well. The superior thyroid vessels typically cross the operative field around C3–C4, and the inferior thyroid vessels usually cross around C6–C7. These should be preserved if possible but may require ligation without any substantial deficit incurred to the patient. The omohyoid is also crossing the operative field obliquely at approximately the level of C6; it may be divided if needed to extend the exposure in the rostral-caudal direction.

Access to C2–C3 may be limited in the Smith-Robinson approach by the mandible, thus should be assessed with a lateral radiograph preoperatively. To further facilitate access to C2–C3, nasotracheal intubation should be considered so that the mandible can be fully closed. With the rostral extents of this approach, there is an increased risk of injury to the hypoglossal nerve, hypopharynx, and the hypoglossal and mandibular branches of the facial nerve.[86]

Access to the cervicothoracic junction is also limited in the Smith-Robinson approach without the use of special techniques to increase exposure, which include detaching the SCM from its insertion, sectioning strap muscles, and mobilizing the clavicle and manubrium. This approach is outside the scope of this current chapter.

Anterior Cervical Discectomy and Fusion

Procedure

Preoperative planning for an ACDF must include considerations of the graft or implant to be used. Historically, an autologous tricortical iliac crest bone graft has been used for grafting, but our current preferred approach is to use a cage device to avoid donor site morbidity. Shriver et al. reviewed the literature and found that fusion occurs in 99.1% of autograft cases compared with 95.2% of allograft cases.[87]

After exposure and confirmation of the appropriate level, Caspar posts are placed into the vertebral bodies above and below the disc to be excised, providing distraction at the level of the disc. These will assist with visualization of the posterior aspect of the disc space once the discectomy is underway. The Caspar pins should be placed in the midline to avoid screw path issues from the subsequent plating procedure. Alternatively, an intervertebral spreader can be used once the discectomy has been initiated. Anterior vertebral body osteophytes should be removed, which will (1) improve visualization within the disc space, (2) facilitate placement of the implant at an appropriate depth, and (3) minimize plate prominence.

A rectangular annulotomy is performed with a No. 15 scalpel blade on a long handle. A pituitary rongeur can then be used to excise the majority of the disc material. A straight curette can be used to further remove disc material and begin the resection of the cartilage from the endplates. The lateral extent of the resection should be made to the level of the uncinate process. The use of a Kerrison rongeur may facilitate resection

of disc material at the edges of the uncinate processes. Resection farther laterally can risk injury to the vertebral artery. Decortication of the endplate can subsequently be continued with a burr. Care should be taken to not decorticate deeper than the subchondral bone to reduce the risk of graft/implant subsidence. Uncovertebral osteophytes must be resected to fully decompress the foramina. If the posterior aspect of the anulus is intact, a curette may be used to create a vertical rent in the anulus to provide subsequent access for a Kerrison rongeur.

If a foraminotomy is necessary, the PLL should be left intact until it is completed because it plays a protective role. The medial posterior uncinate process can be thinned with a burr. The surgeon should keep in mind the location of the vertebral arteries as determined from preoperative imaging to avoid inadvertent arterial injury. The microscope (if used) should be angled into the wound toward the foramen to be decompressed. Decompression of the contralateral side can subsequently be performed with a Kerrison rongeur and curette. When probing with a nerve hook to assess the adequacy of the foraminotomy, one must remember that the nerve exits at an approximately 45-degree angle ventrolaterally; thus, the nerve hook should glide along the posterior surface of the uncinate to avoid inadvertent injury. A blush of blood from the neural foramen often signifies an adequate decompression. The PLL can be excised with a Kerrison rongeur after the foraminotomy is completed. After the disc material has been resected, the endplates have been decorticated, and the PLL has been excised, a nerve hook should be used to identify any further sources of compression. Attention should be paid to the cranial and caudal aspects of the disc space to identify posterior osteophytes behind the adjacent vertebra.

Trial sizers should be used next to identify the appropriate size for the final graft/implant. Sequential sizers are inserted until there is a snug fit within the disc space. Typically, the graft/implant should measure 2 to 3 mm greater than what is measured on a lateral preoperative film. After the height of the trial is determined, the depth should also be assessed with a depth gauge. The appropriately sized graft or implant can be inserted using a tamp and mallet. The graft should be countersunk approximately 2 mm relative to the anterior cortex of the adjacent vertebral bodies. Excessive countersinking should be avoided to prevent spinal canal intrusion. After the graft has been positioned, anterior plating to the adjacent vertebral bodies is commonly performed. The plate should be the shortest length possible to span the fusion site, and screws should be angled away from the graft to improve screw length. Minimizing plate contact with the adjacent motion segments is thought to decrease adjacent-segment ossification. Final implant and plate positioning should be confirmed on intraoperative radiographs or fluoroscopy.

A layered closure, with or without a drain, is performed. The drain is pulled on postoperative day 1, barring excessive drainage. Postoperatively, patients typically do not need further immobilization if anterior plating is performed, but a soft collar may be provided for additional comfort. No postoperative rehabilitation is required. Postoperative diet must account for the higher incidence of dysphagia, and often slowly advancing from mechanical soft to general diets is appropriate. Full activity is often resumed by 3 months.

Fig. 42.4 depicts a case example of a patient treated with ACDF for cervical myelopathy. This patient had previously had a C5–C6 and C6–C7 ACDF. Adjacent-segment degeneration of C3–C4 and C4–C5 subsequently occurred, resulting in recurrence of myelopathy. Given the presence of predominantly anterior pathology and segmental kyphosis, ACDF of C3–C4 and C4–C5 was our preferred treatment. The patient was sent to an ear, nose, and throat specialist for preoperative evaluation of vocal cord function for the reasons discussed previously.

Outcomes, Complications, and Other Considerations

ACDFs have highly reproducible outcomes. Fusion rates have improved over time, whether it has been due to surgical technique or advancements in anterior cervical plating. Fusion rates vary based on the number of levels addressed. Single-, two-, and three-level ACDFs have fusion rates of 97.1%, 95.9%, and 89.8%, respectively, when anterior plating is used.[88] Fusion rates prior to routine use of anterior cervical plating were substantially lower.[89,90] Long-term outcomes demonstrate maintained improvements in JOA scores and a change in the disease course of cervical myelopathy.[91]

Pseudarthrosis rates are lower among patients whose fusion used autograft bone instead of allograft (0.9% vs. 4.8%, respectively).[87] Many of the patients who do develop a pseudarthrosis after ACDF remain asymptomatic. An additional risk of arthrodesis from an anterior approach is the risk of accelerated spondylosis of a vertebral segment adjacent to the level of the procedure. The incidence of symptomatic adjacent-segment disease (ASD) is 2.9% per year, with 26% symptomatic at 10-year postoperative follow-up.[92] One retrospective cohort study identified an overall revision rate after single-level ACDF (for all diagnoses) of 15%, with a mean follow-up of 31 months. ASD and pseudarthrosis were the most common reasons for revision, accounting for 47.5% and 45.5% of cases, respectively.[93]

Substantial controversy exists as to whether a hard cervical collar is needed for two-level or greater level fusion procedures. The literature has not shown any benefit for the use of a collar for single-level ACDFs. One survey of treating physicians identified 70% of spine surgeons reporting the use of a cervical collar (the majority rigid) for two-level ACDF procedures.[94] We prefer, however, to not use a cervical collar for two-level ACDFs given the increased risk of neck disability in the perioperative period, increased neck stiffness, and lack of proven benefit.[95]

Anterior Cervical Corpectomy and Fusion

Procedure

ACCFs require more extensive preoperative planning than ACDFs, including considerations for graft donor site and obtaining appropriately sized grafts. For single-level, and sometimes two-level, corpectomies, autologous iliac crest

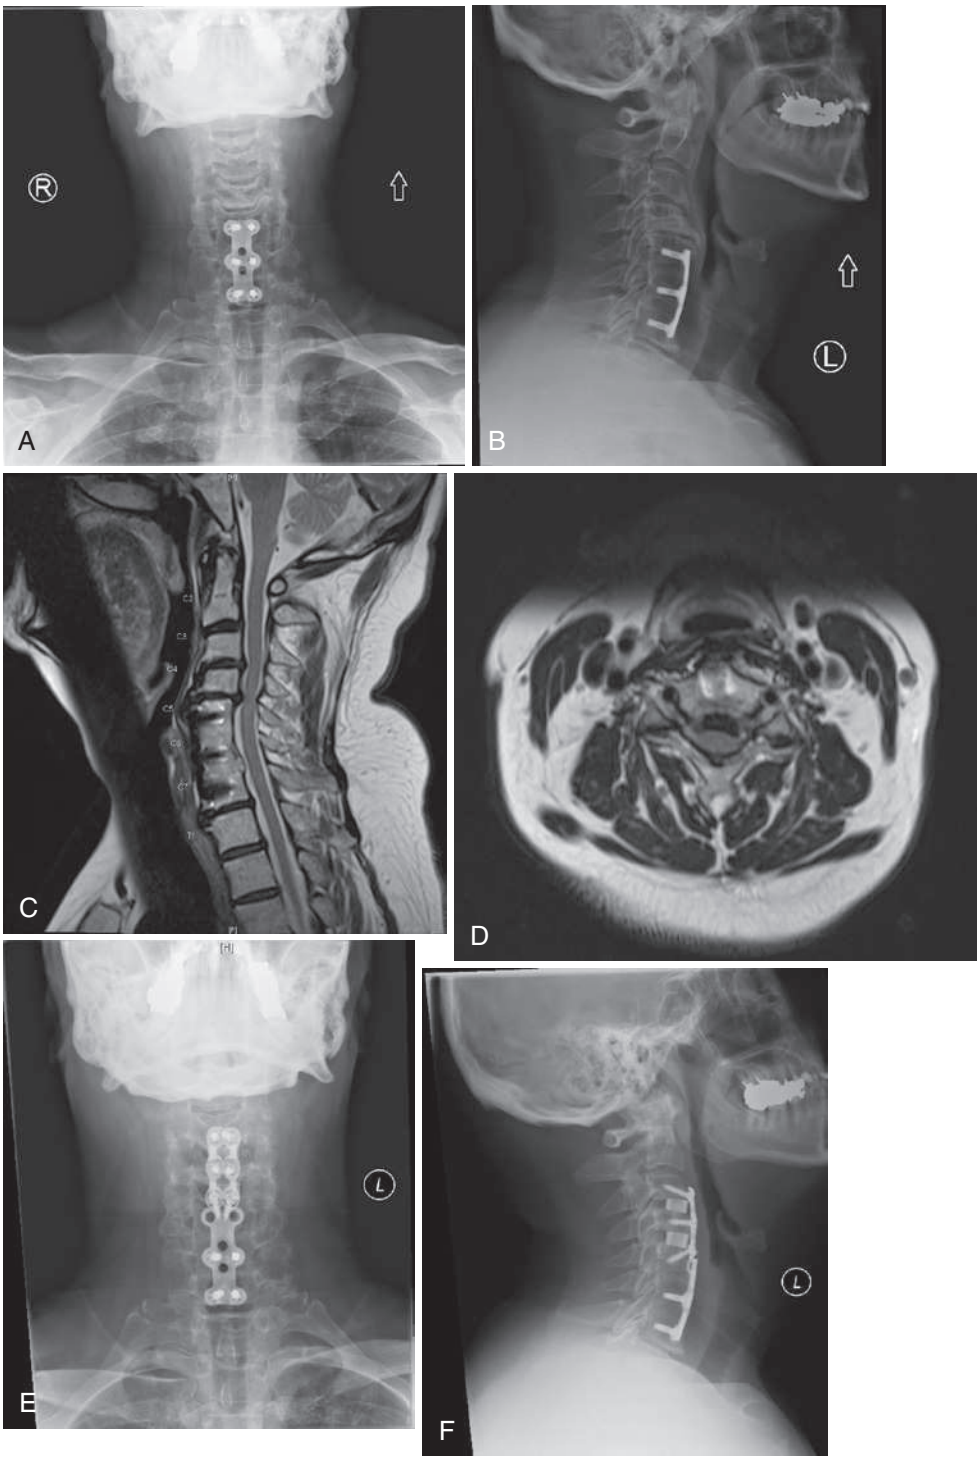

FIG. 42.4 Patient treated with anterior cervical discectomy and fusion for cervical myelopathy. (A) Preoperative anteroposterior radiograph. (B) Preoperative lateral radiograph. (F) Postoperative lateral radiograph.

graft can be considered, while autograft or allograft fibula is often used in larger reconstructions. A cage or spacer is an alternative to structural allograft/autograft that avoids donor-site morbidity and is easy to use.

After exposure and confirmation of the appropriate level, Caspar posts are placed into the vertebral bodies above and below the levels to be excised to provide distraction. Discectomies are performed at the levels cranial and caudad to the planned resection. Osteophytes are removed to improve visualization of the uncovertebral joints, which are used to center the resection. The ventral aspects of the vertebral bodies are debulked with a Leksell rongeur (Fig. 42.5). A 5-mm

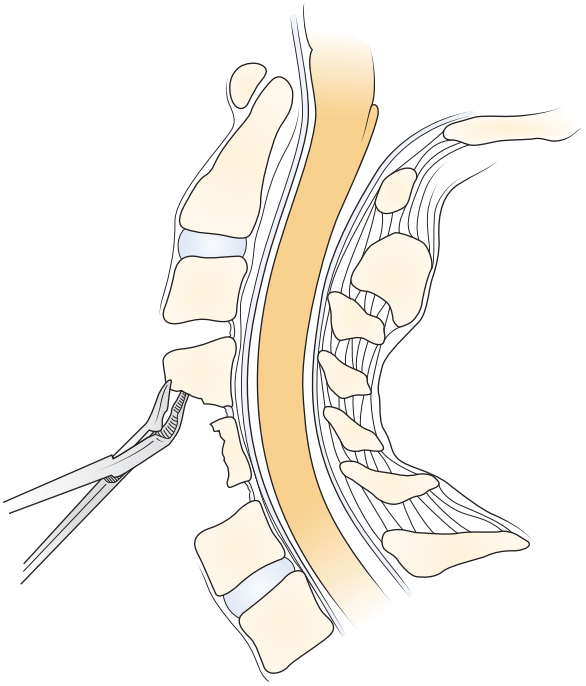

FIG. 42.5 After discectomies are completed, the anterior two-thirds of the vertebral bodies to be removed can be safely excised with a rongeur. (From Whitecloud TS. Multilevel cervical vertebrectomy and stabilization using cortical bone. In: Sherk H, Dunn EJ, Eismont FJ, et al, eds. *The Cervical Spine: An Atlas of Surgical Procedures.* Philadelphia: JB Lippincott; 1994:202.)

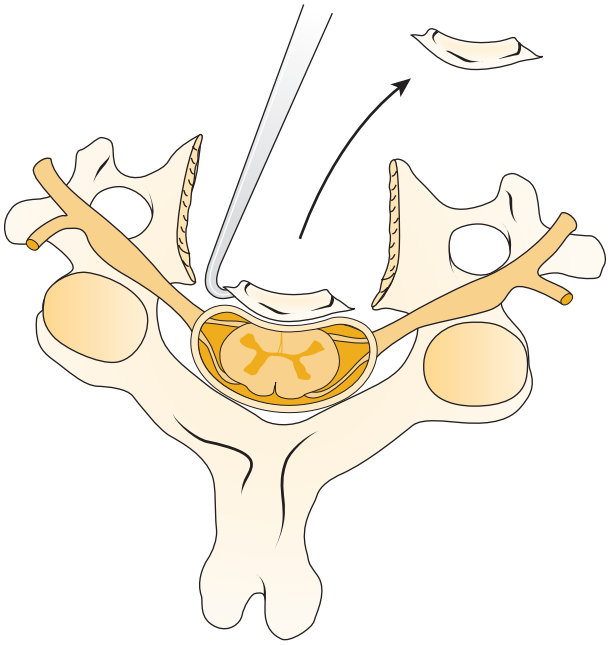

FIG. 42.6 A small angled curette can be used to excise the thinned posterior cortex of the vertebral body. Force must be directed anteriorly to avoid inadvertent damage to the dura and spinal cord. (Modified from Smith MD. Cervical spondylosis. In: Bridwell KH, DeWald RL, eds. *The Textbook of Spinal Surgery*, ed 2. Philadelphia: Lippincott-Raven; 1997:1411.)

midline trough is developed to minimize the risk of the burr causing inadvertent injury. Subsequently, the high-speed burr is used to resect the vertebral bodies in line with the uncovertebral joints. The width should be approximately 15 to 18 mm such that a graft can be accommodated. The burr should be used to debulk a majority of the vertebral body down to a thin posterior cortex, which can be subsequently excised with small angled curettes pulling away from the PLL and dura (Fig. 42.6). The PLL can then be excised with a small Kerrison rongeur. In the setting of OPLL, this may not be possible because the PLL may be adherent to the dura; aggressive attempts at resection can cause dural tear or, rarely, neurologic injury.[96] In cases of OPLL, a small bone island, decompressed and separated from all four borders but still adherent to the PLL, can be left behind. Hemostasis can be achieved with bone wax and thrombin-soaked sponges.

Regardless of whichever graft is selected, the endplates must be prepared to appropriately dock the graft and provide a good bed for subsequent fusion. A high-speed burr is used to remove the cartilage from the endplates, exposing punctate bleeding subchondral bone, which facilitates fusion. After the endplates are prepared, they are measured with a ruler or 18-gauge wire. The depth of the defect should also be measured before harvesting or selecting the graft/cage to use.

Iliac crest bone graft may be used due to its simplicity of harvesting, subcutaneous location, and autogenous source with robust osteogenic, osteoinductive, and osteoconductive properties. Tricortical grafts should be harvested with an oscillating saw. The anterior surface of the iliac crest graft may be best used to recreate the posterior vertebral body wall.[63] Alternatively, fibular graft or cage implants may be used.

Insertion of the graft is performed by increasing cervical traction to distract the bony defect further (~30 lb). The graft is placed in the appropriate position by means of a Kocher clamp and bone tamp, and the traction is subsequently released (Fig. 42.7). The position of the graft should be confirmed fluoroscopically, monitoring for any displacement or subsidence. The appropriate positioning is for the graft to be centered on the cephalad and caudad endplate subchondral bone. The graft's stability can be tested by using an instrument to gently pull on it.

Plating may be performed to increase construct stability. The plate size should adequately span the region of the corpectomy. Fixation is obtained via purchase into the vertebral body cephalad and caudad to the corpectomy. After plate placement, its position should be confirmed fluoroscopically. Following final radiographs, hemostasis should be confirmed, and a layered closure is performed.

Postoperatively, patients may have supplemental immobilization with a semirigid orthosis for 6 to 10 weeks based on the final construct's stability, as determined intraoperatively. Until fusion is completed, cervical spine twisting/bending and overhead lifting should be avoided.[63]

Fig. 42.8 depicts a case example of a patient who underwent a corpectomy for cervical myelopathy. The anterior source of spinal cord compression led to the decision to perform an anterior decompressive procedure. Given the retrovertebral (as opposed to retrodiscal) pathology at C5, an ACDF was not optimal for that level because it would inadequately decompress the spinal canal. For these reasons, our preferred

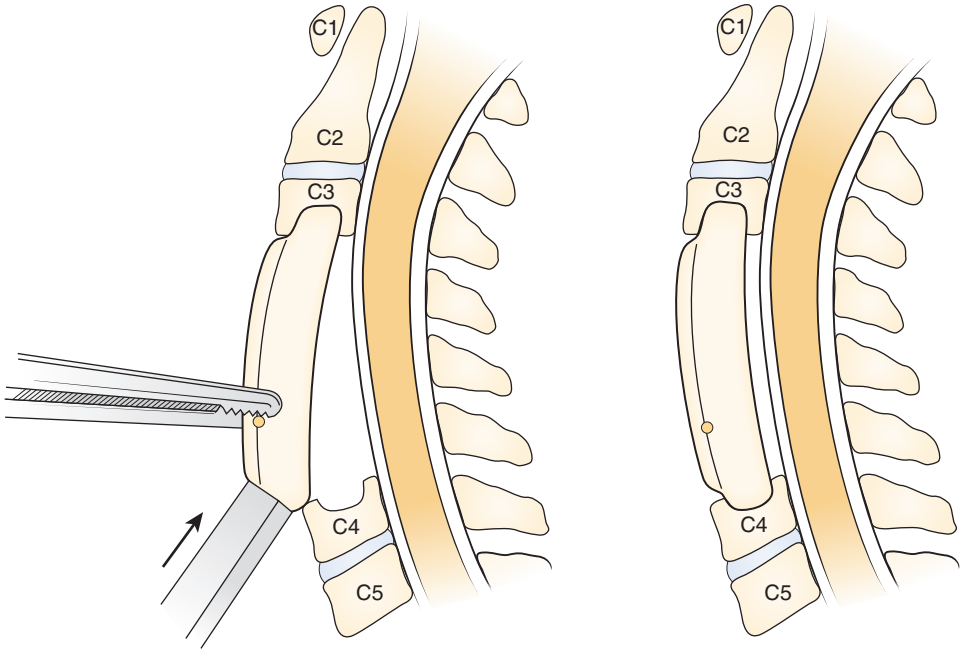

FIG. 42.7 The graft is seated into the cranial end of the corpectomy defect. Traction is subsequently applied to the patient's head. The distal end of the graft is seated with a tamp. A Kocher clamp is used to prevent graft displacement during this process. (Modified from Smith MD. Cervical spondylosis. In: Bridwell KH, DeWald RL, eds. *The Textbook of Spinal Surgery*, ed 2. Philadelphia: Lippincott-Raven; 1997:1411.)

management of this condition was a C5 corpectomy with a C6–C7 ACDF.

Outcomes, Complications, and Other Considerations

ACCF is an effective procedure in the management of cervical myelopathy. Mean JOA scores have shown lasting improvement at long-term follow-up.[97,98] Successful fusion rates are 92% to 96%.[97–99] Improvements in sagittal alignment have also been long-standing.

In addition to the aforementioned risks associated with the Smith-Robinson approach to the cervical spine, additional complications have been described specifically in relation to the ACCF procedure. An association between postoperative axial neck pain and lack of restoration of cervical lordosis has been identified.[98] The ACCF graft is at risk of migration, subsidence, and frank dislodgement. Graft dislodgement is a well-described complication that has been estimated to occur in 4.9% to 29% of multilevel reconstructions.[100–104] In the setting of these complications, neurologic injury and the need for revision surgery may arise. Attempts to minimize the incidence of these complications have been made with anterior plating techniques that gain fixation at the cephalad and caudad vertebral bodies adjacent to the graft. Unfortunately, these have been associated with hardware failure and pseudarthrosis rates of up to 40%, which are partially attributed to the plate inadvertently distracting across the intended fusion site.[103] Buttress plates have also been used to counteract graft displacement, but success was also limited, and complications were occasionally devastating.[103] To provide additional stabilization and minimize the risk of graft dislodgement, posterior stabilization should be considered in addition to ACCF for larger reconstructions.

Successful fusion of multilevel cervical corpectomies requires an understanding of optimal cervical plate and screw placement, as the anterior cervical plates used for multilevel cervical corpectomies are vulnerable biomechanically. Singh and colleagues[105] reviewed multilevel cervical corpectomies (two or more levels), noting significant increases of approximately 30% greater motion in flexion-extension, lateral bending, and axial rotation for stand-alone anterior fixation compared with anterior fixation augmented with posterior lateral mass fixation and stand-alone posterior lateral mass fixation. Brodke and colleagues[106,107] showed that dynamic plates, including translational and variable angle screw constructs, retain their load sharing capabilities in a graft subsidence model, whereas statically locked plates lose nearly 70% of load sharing capacity. Furthermore, cervical plating techniques for corpectomies requires understanding of screw biomechanics. Locking screws exhibit greater rigidity than nonlocking screws for both initial and cyclic loading, and the length of screws positively correlates to pullout strength.[108] Finite element analysis of screw trajectory suggests that higher stresses are imparted onto the graft with divergence from the endplates, yet rotational stability is not affected by the trajectory of the screw. With increased screw angulation away from the endplate, the construct becomes more load sharing.[109] However, screws placed perpendicular to the vertebral endplate have higher pullout strength than angled screws, despite longer screw length with divergent trajectories.[110]

Due to the significant risk of pseudarthrosis and graft complications, interest in developing stable fixation for cervical corpectomies has produced a variety of instrumentation options. Anterior cervical plating provides buttress support for cervical corpectomies to stabilize the graft as well as prevent displacement and excessive settling. Risks for pseudarthrosis and graft complications increase exponentially with increasing length of corpectomy procedures, ranging from 7% for one-level corpectomies to upward of 75% for multilevel corpectomies.[111–113] Avoiding postoperative hyperlordosis can reduce the risk for construct failure, since extension can excessively load the graft.[113,114] Furthermore, use of ACDF to reduce length of cervical corpectomy can decrease failure rates.[113] Multiple authors have found that hybrid techniques using ACDF at appropriate levels in order to shorten the required length of the cervical corpectomy procedure can reduce construct failure rates (graft dislodgement and construct revision) seen with long cervical corpectomy procedures.[115,116] Various modifications for anterior cervical plating have been designed to improve fusion rate and minimize complications. Dynamic plating with variable angle screws in nonslotted plate designs may allow a degree of toggling to provide translation with graft subsidence while avoiding uncontrolled graft settling.[117] Similarly, translational plating allows for telescoping of the plate to provide continued fixation and improved graft loading with graft subsidence when compared with conventional locked plating.[118] However, excessive settling with these dynamic plating options can lead to implant failure, kyphosis, and construct failure.

Despite our understanding of optimal cervical plate and screw biomechanics, the data on clinical outcomes for ACCF plating techniques are sparse. Early experience with hybrid plating (use of variable angled screws at inferior margin of plate) has produced successful fusion and clinical results for one-level anterior cervical corpectomies.[119] Additionally, data on translational plating for corpectomies are largely limited to ACDF studies. Despite conceptual improvements over existing technology, similar rates of fusion have been reported with use of static, dynamic, and translational plating for two-level ACDF.[120–122] While dynamic plate designs with variable screw angle and translational designs to maintain load sharing with graft subsidence still may be conceptually useful in ACCF clinical scenarios, there are limited clinical data to support this.

Anterior Cervical Discectomy and Fusion Versus Anterior Cervical Corpectomy and Fusion

ACDF and ACCF are both successful techniques in the management of anterior compression sources in cervical myelopathy, especially in the setting of kyphosis when posterior approaches should not be done in isolation. A recent meta-analysis compared the two procedures. Operative times, fusion rates, postoperative JOA scores, JOA recovery rates, and visual analog scale pain scores were not significantly different between the two techniques. Blood loss was greater and

complications were more frequent in ACCF compared with ACDF.[123] One systematic review identified graft dislodgement as having a significantly higher incidence in ACCF procedures than ACDF (4.9% vs. 1.7%).[104] Review of the literature suggests that the greater the number of levels involved, the higher the risk of nonunion for both procedures. One systematic review identified a nonunion rate of 18.4% for two-level ACDFs (compared with 5.1% for single-level ACCF) and 37.3% for three-level ACDFs (compared with 15.2% for two-level ACCFs).[104] Although the data available are limited by low numbers, multiple metaanalyses agree that ACDFs provide better restoration of cervical lordosis postoperatively compared with ACCF when treating multilevel CSM.[124,125]

Posterior Procedures for the Cervical Spine

Posterior approaches to the cervical spine have the benefit of familiarity of the surgical approach. Additionally, the easily expansile nature of the approach allows for straightforward management of multilevel spinal pathology, including OPLL and congenital cervical stenosis. Irreducible kyphosis is a contraindication to posterior procedures done in isolation because their success is contingent on posterior drift of the spinal cord (Fig. 42.9).

Posterior Approach to the Cervical Spine

As with the anterior approach, an assessment of the patient's asymptomatic cervical range of motion (ROM) should be assessed preoperatively to determine whether a fiber-optic intubation is necessary. Awake intubation may be considered for severely myelopathic patients.[126]

The patient is placed prone with slight neck flexion to open the posterior elements and facilitate access. Mayfield clamps or Gardner-Wells tongs may be used for additional stabilization of the cervical spine. Bony prominences and peripheral nerves must be padded to prevent pressure ulcerations and neurapraxias, respectively. The abdomen should be allowed to hang freely, and a slight reverse Trendelenburg position should be used, which both reduce epidural venous congestion as well as intraoperative bleeding. The patient's shoulders should be pulled and taped caudad to allow for easier radiographic assessment intraoperatively. Before prepping and draping, radiographs should be taken, and the appropriate level of surgery should be identified with a radiopaque marker to help guide the position of the incision.[126]

A midline posterior incision is made centered around the level(s) of interest. Sharp dissection is performed down through the midline. The dissection should attempt to remain within the relatively avascular region of the median raphe of the ligamentum nuchae because it will minimize blood loss that would otherwise obscure visualization. Once the spinous processes are reached, the interspinous musculature is elevated off of the laminae bilaterally in a subperiosteal fashion. A Cobb elevator is helpful for both the dissection and retraction. As the dissection continues laterally, care must be taken not to disturb the facet joint capsules unless arthrodesis is planned.[126] The interspinous ligaments at the cephalad and caudad ends of the planned construct should be spared. Additionally, the C2 and C7 spinous processes should be left intact because they serve as an attachment site of the nuchal

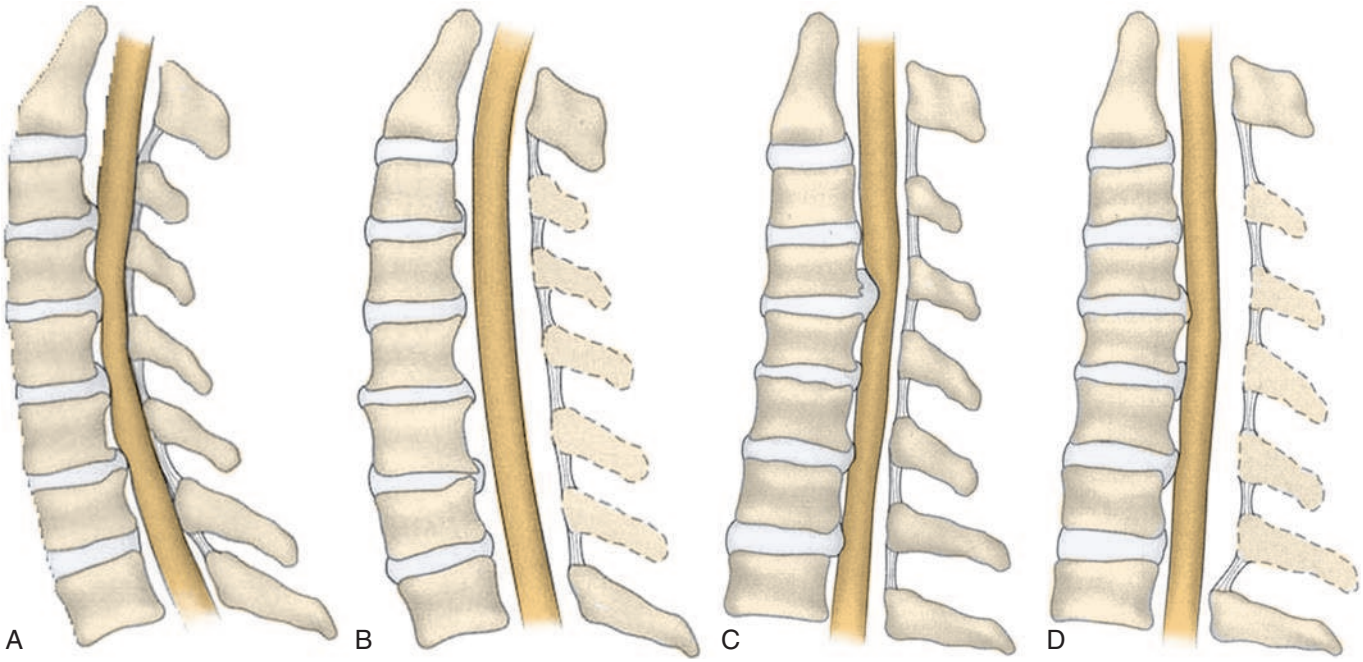

FIG. 42.9 Effect of cervical sagittal alignment on the success of posterior cervical decompressive procedures. (A) Multilevel cord compression in the setting of lordotic cervical alignment. (B) Dorsal drift of the spinal cord away from impinging structures after multilevel laminoplasty. (C) Multilevel cord compression in the setting of kyphotic cervical alignment. FIG. 42.10 Bilateral laminotomies are made with a high-speed burr at the lamina-facet junction. (From Komotar RJ, Mocco J, Kaiser MG. Surgical management of cervical myelopathy: indications and techniques for laminectomy and fusion. *Spine J.* 2006;6:258S.)

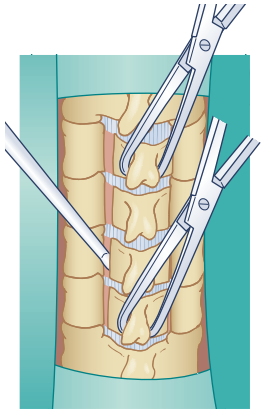

FIG. 42.11 Towel clamps on the most cranial and caudal spinous processes are used to carefully lift the laminae and ligamentum flavum en bloc. (From Komotar RJ, Mocco J, Kaiser MG. Surgical management of cervical myelopathy: indications and techniques for laminectomy and fusion. *Spine J.* 2006;6:259S.)

ligaments and may result in increased risk of postoperative kyphotic deformity and axial pain if disrupted.[127,128] If needed, dome laminectomies can be performed at these levels with minimal disruption to the attachment points.

Laminectomy and Fusion

Procedure

The levels of dissection should be confirmed radiographically with a radiopaque object (e.g., Kocher clamp on the spinous process). The extents of the planned construct should be demarcated with a Leksell rongeur by removing a fragment of the spinous processes. Subsequently, the lamina-facet junction should be identified bilaterally. A high-speed burr may then be used to initiate the lamina trough. An attempt should be made to remove the laminae en bloc (Fig. 42.10). After the burr is used to create a trough through the outer cortex and cancellous layers of bone, either a diamond burr or a 1-mm Kerrison rongeur may be used to remove the far cortex. This trough is performed bilaterally, allowing full mobilization of the laminae en bloc. Towel clamps placed on the most cranial and most caudal spinous processes allow the surgeon to carefully lift the laminae and ligamentum flavum en bloc (Fig. 42.11). Prior to removal of the laminae, the surgeon must carefully assess for adhesions between the bone or ligamentum flavum with the dura. Any adhesions present should be removed with an angled curette prior to attempting elevation of the laminae. An en bloc resection is considered less time consuming and is a safe technique because it avoids instrument intrusion into the central canal prior to completing the decompression.[129]

If any foraminotomies were preoperatively deemed necessary due to radicular symptoms, they may now be performed. Alternatively, some surgeons prefer to perform keyhole foraminotomies prior to the en bloc laminectomy to use the lamina as a protective barrier during drilling.[129] The surgeon should orient himself or herself to the margins of the foramen and assess the degree of compression with a nerve hook. The high-speed burr can then be used to resect the medial half of the facet articulation until a thin shell of bone remains. A Kerrison rongeur should be used to carefully remove the bone just dorsal to the nerve root. No more than 50% of the facet should be resected at a single level, or iatrogenic instability may occur.[130] The nerve hook can be used once again to confirm the adequacy of the decompression.

Instrumented fusion via a screw and rod–based construct is our preferred method of fixation. Lateral mass fixation can be achieved successfully at C3 to C6. Pedicle screw fixation is possible at C2 and C7 due to the pedicle size and relatively safe location from adjacent vasculature. Traditionally, it was believed that a hybrid construct of lateral mass screws and pedicle screws at C7 would be biomechanically superior; however, this may not be the case.[131] Regardless, we recommend fixation distal to the cervicothoracic junction in most multilevel cases even though rod contouring may prove more challenging.

Entry sites for pedicle screws should be drilled with the burr before decompression is performed because anatomic landmarks will be more recognizable. Screw placement, however, should occur after decompression such that the pedicle can be palpated with a nerve hook to improve accuracy. The hemostatic agent can be packed into the entry sites until it is time to place the screws.

Many techniques have been described for the placement of lateral mass screws. These techniques evolved as a result of insufficient pedicle diameter and excessive risk to the vertebral arteries for traditional pedicle screws in the subaxial cervical spine. The Roy-Camille technique uses the midpoint of the lateral mass as the entry point with 10-degree lateral angulation and 0-degree rostrocaudal angulation. The Jeanneret and Magerl technique has an entry point 1 to 2 mm medial and superior to the lateral mass midpoint with a 15- to 25-degree lateral angulation and 30-degree rostral angulation. Advantages of this technique include a decreased risk of facet violation and improved pullout strength[132,133]; no differences in morbidity between the two techniques were identified.[132] Both techniques were designed to have the screw miss the vertebral

artery laterally. The Roy-Camille trajectory aims the screw to miss the exiting nerve inferiorly; the Magerl technique misses the exiting nerve superiorly. The Anderson et al.[127] technique is a modification of the Magerl technique, with a starting point 1 mm medial to the midpoint of the lateral mass, with 20-degree lateral angulation and 30-degree rostral angulation. For simplicity's sake, one can approximate these angles by leaning the drill on the next caudal spinous process. If adequate lateral angulation cannot be achieved due to impingement on the spinous process, it may be removed with a rongeur. Unicortical lateral mass screw placement is recommended by drilling in 2-mm increments until the ventral cortex is reached. There appears to be no obvious biomechanical advantage to bicortical screw placement, but there are risks (vascular and neurologic) to such a procedure.[134]

Pedicle screw fixation can be achieved at C2 and C7, which in some studies has been shown to have superior biomechanics over lateral mass fixation. Preoperatively, pedicle diameters should be measured based on the available imaging. While hybrid constructs have not shown improved biomechanics, the ability to place a pedicle screw at these levels should be a part of any surgeon's armamentarium. C2 "pedicle screws" are actually placed through the pars interarticularis. The screw entry point is in the superior medial quadrant of the lateral mass, 3 mm lateral to the medial edge of the isthmus, and in line with the superior margin of the C2 lamina. The trajectory is 15 to 25 degrees medially and 20 to 30 degrees cranially.

Preoperative imaging should be reviewed carefully prior to placement of C7 pedicle screws. Approximately 0.6% to 0.8% of patients have a vertebral artery present within the C7 transverse foramen.[135,136] C7 pedicle screws have a trajectory parallel to the C7 endplate and 20 degrees medial.

A well-prepared fusion bed is crucial to achieve bony fusion. A high-speed burr is used to decorticate the proximal and dorsal aspects of the facet joints to be fused. The facet capsule and the cartilaginous endplate should also be removed. We prefer the use of autograft bone from the laminectomies to maximize fusion potential, although allograft or synthetic materials may be used to supplement the fusion.

With unclear benefits, but minimal risk, many surgeons add 1 g of vancomycin powder overlying the paraspinal musculature to minimize the risk of surgical site infection.[137,138] A layered closure over a drain is then performed. A watertight closure is critical.

Fig. 42.12 demonstrates a case example of a laminectomy with fusion and instrumentation performed for cervical myelopathy. The patient's multilevel pathology as well as cervical scoliosis made a C2–T1 laminectomy with fusion our preferred treatment because it allowed for decompression and stabilization.

Outcomes, Complications, and Other Considerations

Anderson et al.[48] performed a systematic review in which it was determined that laminectomy with fusion resulted in neurologic improvement consistently in 70% to 95% of patients. The neurologic recovery rate was typically around 50% of the JOA score deficit.

Concomitant posterolateral arthrodesis is routinely recommended with cervical laminectomy; otherwise, postlaminectomy kyphosis may occur. The incidence of postlaminectomy kyphosis ranges from 6% to 47% in adults who have cervical laminectomies in isolation.[56] Fusion rates using lateral mass screw fixation in large series have been reported as over 97%.[139]

Emerging evidence suggests that the width of the C5 laminectomy performed, as well as the degree of spinal cord posterior drift, are associated with the incidence of postoperative C5 nerve palsy.[140] It is unclear currently if strategies to reduce the width of this laminectomy will reduce the rate of postoperative C5 palsies.

Cervical Laminoplasty

Many varieties of cervical laminoplasty have been described, most of which are derivatives of Hirabayashi's "open-door" or Kurokawa's "French door" procedures. Our preferred technique, the "open-door" laminoplasty, is described later. Both of these techniques evolved with the intention of avoiding the devastating postlaminectomy kyphosis while maintaining ROM and providing safe, predictable neurologic recovery. These procedures relatively spare the posterior column, allowing it to retain its load-bearing abilities. As such, it is rare to have postoperative instability secondary to laminoplasty procedures. Most laminoplasty innovations have come out of Japan due to the high rates of OPLL and congenital cervical stenosis within the native population requiring multilevel reconstructions. Traditional teaching on the matter is that laminoplasty does not reliably provide relief for axial neck pain; thus, arthrodesis should be considered if that is the patient's primary complaint, although some attribute postoperative axial neck pain after laminoplasty to overly protective immobilization used in historic protocols. A recent meta-analysis does not identify differences in axial pain between laminoplasty and laminectomy with fusion[141]; thus, this may not be an appropriate consideration during preoperative planning.

Open-Door Laminoplasty Procedure

Open-door laminoplasty requires the creation of two osteotomy troughs, one complete and one incomplete, which will be used as the hinge to open the posterior elements. After exposure is completed and the appropriate levels are determined, the lamina–lateral mass junction is identified bilaterally and can be marked with a marking pen. Arthrosis may obscure these landmarks; thus, preoperative imaging should be reviewed for additional guidance. A high-speed burr is used to create the troughs at the bilateral lamina–lateral mass junctions, which usually have a subtle inflection point to guide the surgeon intraoperatively. The trough should not be greater than 4 mm in depth; trough depth greater than this should clue the surgeon to an excessively lateral trough, which could result in vertebral artery injury.

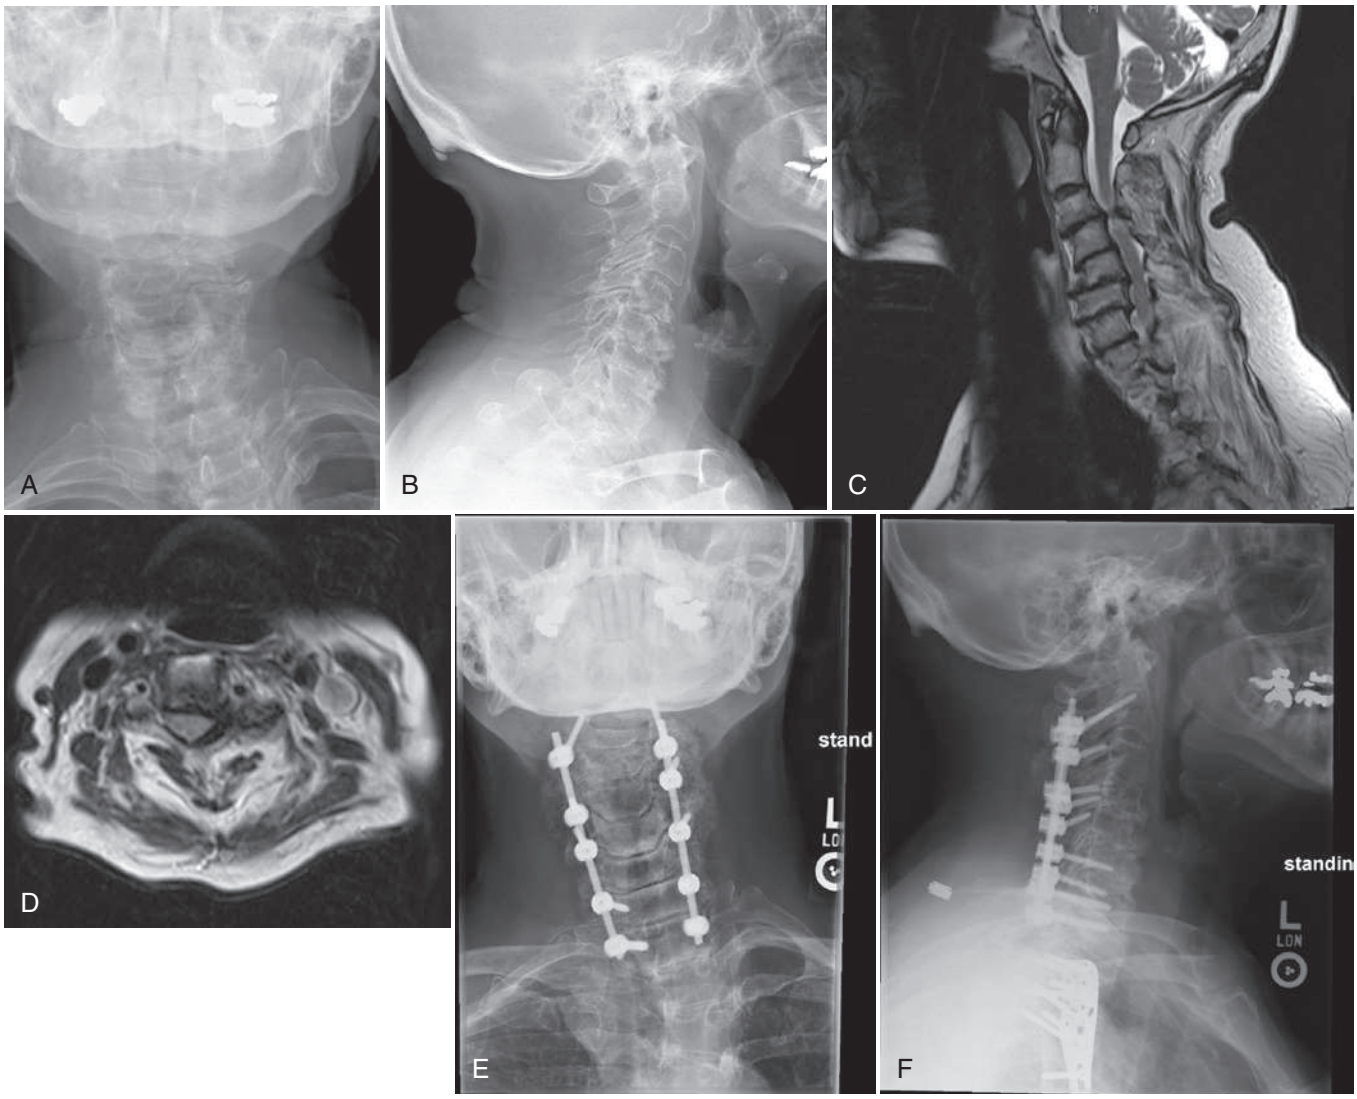

FIG. 42.12 (A) Preoperative anteroposterior radiograph of the cervical spine. (B) Preoperative lateral radiograph of the cervical spine. (C) Preoperative midsagittal magnetic resonance imaging (MRI) slice of the cervical spine. (D) Preoperative axial MRI slice of the cervical spine. (E) Immediately postoperative anteroposterior radiograph of the cervical spine. (F) Immediately postoperative lateral radiograph of the cervical spine.

Our preferred method is to perform the complete osteotomy first, starting at the inferior aspect of each lamina. Once the osteotomy has reached the appropriate depth, the ligamentum flavum will be visible. The remainder of the osteotomy to the superior half of each lamina can be completed with a diamond-tipped burr or a Kerrison rongeur. On the contralateral side, the hinge/incomplete osteotomy is performed at the same inflection point between the lamina and lateral mass. The dorsal cortical bone and cancellous bone are removed with a burr until a thin unicortical hinge remains. Excessive removal of bone should be avoided because it may result in a weak hinge.

The spinous processes of each level can subsequently be used to lever away from the complete osteotomy and toward the hinge osteotomy (Fig. 42.13). The surgeon must be extremely careful to avoid the devastating complication of having the posterior elements spring back and cause spinal cord injury. We recommend placing a thumb on the spinous process and curette within the complete osteotomy site while performing this levering maneuver. After levering, open the posterior elements; the spinal canal area is enlarged. Any fibrous adhesions between the dura and the undersurface of the lamina can be divided with scissors.[142]

Historically, suture fixation was used to keep the laminoplasty door open.[142] Alternatively, bone graft could be wedged into the defect. Our preferred approach, however, is the use of a laminoplasty plate to maintain the integrity of the door and avoid the "spring-back" complication (Fig. 42.14). Laminoplasty plates typically involve the placement of screw fixation into both the lamina and the lateral mass to rigidly fix the space between the two structures.

Fig. 42.15 demonstrates a case example of a laminoplasty with plating performed for cervical myelopathy. Given the multilevel pathology, stability on plain radiographs, as well as autofusions of C4–C5 and C5–C6, preventing ACDF, our preferred technique for management was a C3–C6 laminoplasty with laminectomy and foraminal decompression of C7.

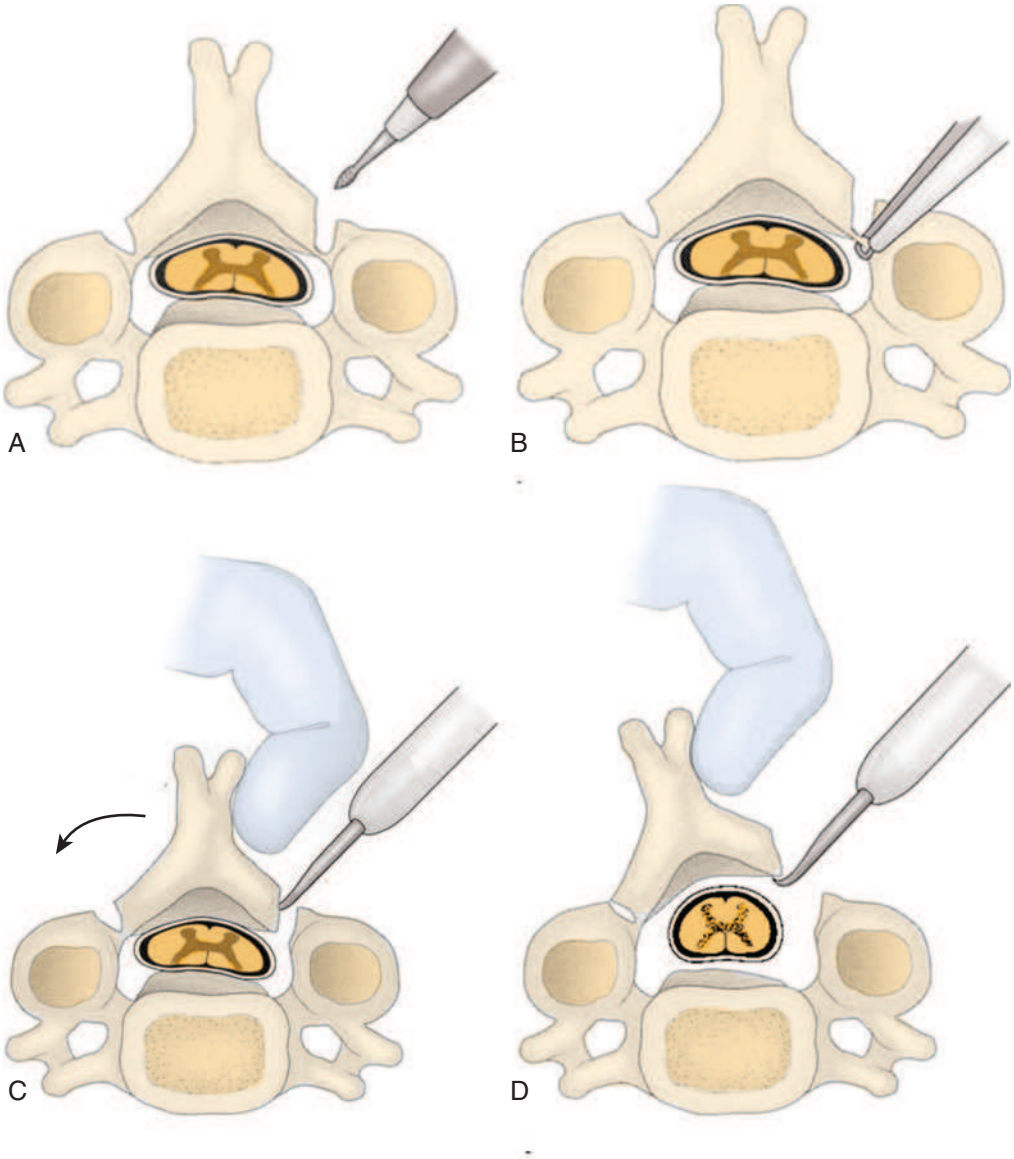

FIG. 42.13 Open-door laminoplasty technique. (A) Unicortical gutters at the lamina-facet junction are created with the high-speed burr. (B) A curette or micro-Kerrison rongeur is used to breach the ventral cortex on the side to be opened. (C–D) With the concomitant use of a finger and an instrument, the posterior arch is expanded by pushing, elevating toward the hinge side.

Outcomes, Complications, and Other Considerations

Laminoplasty is reproducible and effective in the management of cervical myelopathy. It is also a very useful technique in the setting of OPLL.[143] JOA scores reliably improve and demonstrate maintained improvement, even with long-term follow-up.[144,145] The mean JOA recovery rate at minimum of 10-year follow-up was over 55% in one series.[144]

Preoperatively, it is critical to assess the shape of the pathoanatomy responsible for the patient's myelopathy prior to performing laminoplasty. Hill-shaped lesions of OPLL have been associated with poorer neurologic outcomes due to the focal anterior compression that they cause.[146,147] Furthermore, Iwasaki et al.[147] determined that OPLL lesions with an occupying ratio (maximal anteroposterior [AP] thickness of OPLL/AP diameter of spinal canal at the same level) greater than 60% had poor or fair neurologic outcomes. An anterior procedure may be required to fully decompress the cord in these situations.

Similarly, Fujiyoshi et al.[148] described a radiographic marker known as the K-line, which can preoperatively predict the neurologic recovery of patients with OPLL undergoing laminoplasty. The K-line is a straight line that connects the midpoints of the spinal canal at C2 and C7 on a lateral radiograph. If the OPLL lesions lie entirely anterior to the K-line, they are referred to as K-line positive; otherwise, they are considered K-line negative. K-line-negative patients had less posterior shift of the spinal cord after laminoplasty and worse neurologic recovery; thus, anterior decompression was recommended instead.[148]

Although no fusion is intended, laminar autofusions may occur, which limit ROM. At 10-year follow-up, the mean cervical ROM of patients who had undergone laminoplasty was 25% to 47% that of its preoperative level.[144,149]

Laminectomy With Fusion Compared With Laminoplasty

A recent meta-analysis concluded that laminoplasty and laminectomy with fusion are similarly effective in the treatment of cervical myelopathy with insufficient evidence to identify which procedure is safer.[141] While some surgeons believe that laminectomy with fusion provides better axial pain relief due to the arthrodesis, there was low evidence demonstrating no difference upon metaanalysis.[141]

One benefit of laminoplasty is the retention of some cervical ROM. A prospective cohort study identified a time dependence to the postoperative loss of cervical ROM associated with laminoplasty; patients with OPLL and autofusion of the laminae had worse cervical ROM. Postoperative ROM was not associated with axial neck pain, however.[150]

Dome Laminectomy

One useful technique to minimize soft tissue dissection at C7 is the dome laminectomy. This technique has evolved as a means of preventing the detachment of the cervical extensor muscles, which heavily attach to C7. The technique involves creating a dome-shaped resection of the superior lamina of C7 and, in doing so, sparing the C7 spinous process. Proponents of this technique believe that it reduces the incidence of postoperative axial neck pain.[151] In a recent systematic review of the literature by Riew et al.,[152] it was determined that there is conflicting evidence as to whether preservation of muscular attachments to C7 (and C2) reduces axial neck pain postoperatively. Regardless, the authors recommended preserving the C7 (and C2) spinous processes whenever possible as long as the decompression is not compromised.

Combined Approaches

In certain scenarios, a combined anterior and posterior approach is required to safely and effectively manage a patient's pathology. One scenario in which a combined approach may be required is in the setting of multilevel pathology with a kyphotic deformity. The kyphotic alignment can be corrected anteriorly, and decompression can subsequently be performed posteriorly. Alternatively, a combined approach may be needed in the setting of multilevel pathology with a

focal anterior source of compression. For instance, a patient with diffuse OPLL, but a hill-shaped thickening at a particular level, would likely require a combined approach for management. A patient with multilevel pathology addressed with an ACCF may require posterior arthrodesis for added construct stability as well. As mentioned previously, no single approach is optimal for all patients. An individualized treatment plan must be designed based on the patient's sagittal alignment, source of compression, number of levels involved, presence of axial neck pain, shape of pathoanatomy, and/or history of prior surgeries.

Conclusion

Cervical spondylotic myelopathy is the most common cause of spinal cord dysfunction in the world.[1] The condition is characterized by a generally progressive neurologic decline, which fails to respond to nonoperative measures and, once symptomatic, often benefits from operative management. Anterior and posterior spine surgical procedures can effectively halt or slow the neurologic decline associated with CSM. With a careful history, physical, and review of available imaging, an individualized treatment plan can be constructed to safely and appropriately care for a patient with cervical myelopathy.

43 CHAPTER Ossification of the Posterior Longitudinal Ligament

Bhavuk Garg
Alok Sharan

Ossification of the posterior longitudinal ligament (OPLL) is a common cause of cervical myelopathy. Nearly 25% of patients with cervical myelopathy have been estimated to have OPLL.[1] The highest prevalence of OPLL is seen in the Japanese population, with a reported range of 1.9% to 4.3% in patients older than 30 years.[2] In the United States, the reported prevalence is around 0.1% to 0.7%.[2] The usual age of onset of OPLL is 50 years and is found twice as often in males as compared to females.[3]

Although most common in the cervical spine, it is also found less commonly in the thoracic and lumbar spine. Approximately 70% of cases occur in the cervical spine, followed by 15% in thoracic and 15% in the upper lumbar spine from L1 to L3.[3] Park et al.[3a] reported a 33.8% occurrence of thoracic OPLL in patients with cervical OPLL and recommended that the whole spine should be screened in patients with cervical OPLL.

Key[4] published the first report of OPLL causing compressive myelopathy in 1838 in Guy's Hospital Report and Oppenheimer[5] published a report in 1942. Numasawa[6] reported the first case of compressive myelopathy in the Japanese population due to OPLL based on autopsy findings in 1960.

Etiology

OPLL is a multifactorial disease with both genetic and environmental factors playing a role. Broadly, OPLL can be divided into two types: primary, or idiopathic, and secondary, or syndromic. The majority of OPLL cases are idiopathic. Secondary OPLL has been described with hypophosphatemic rickets, osteomalacia, and various endocrine disorders, such as hypoparathyroidism, acromegaly, and gigantism.[7]

Genetic Factors

Many genomic, linkage, and association studies have shown a strong genetic predisposition for OPLL.[7] Matsunaga et al. reported a high prevalence of identical human leukocyte antigen haplotypes in families of 24 patients.[8] Karasugi et al. reported linkages on 1p, 2p, 7q, 16q, and 20p in a genome-wide linkage study of 410 Japanese individuals.[9] A number of candidate genes/loci, including nucleotide pyrophosphatase/phosphodiesterase ENNP1, transforming growth factor-β1, estrogen receptor, interleukin-1β, vitamin D receptor, bone morphogenetic proteins (BMP) 2 and 9, runt-related transcription factor 2, toll-like receptor 5, and interleukin-15 receptor subunit alpha have been studied and reported to enhance susceptibility to OPLL.[7] Candidate gene approach has also linked collagen genes *COL11A2* and *COL6A1* genes with OPLL.[6,10] Kawaguchi et al.[11] reported that transforming growth factor-β1 polymorphism is related to the extent of ossification in OPLL rather than in its pathogenesis.

Environmental Factors

Various environmental factors have also been linked to the pathogenesis of OPLL. Mechanical stresses on the head have been postulated as a cause leading to hyperexpression of several bone-forming proteins, such as BMP and osteopontin, leading to ossification of several ligaments, including OPLL.[12] There is a high prevalence of type 2 diabetes and glucose intolerance in patients with OPLL.[13,14] Increasing age, obesity, and a vitamin A–rich diet have also been linked with OPLL.[12,14,15] Various musculoskeletal disorders, including ankylosing spondylitis, diffuse idiopathic skeletal hyperostosis, and other spondyloarthropathies have also been associated with OPLL.[16–19] Matsunaga et al.[20] reported a 20% incidence of OPLL in schizophrenia patients.

Various other environmental factors, such as the excessive consumption of pickles, hypertension, family history of myocardial infarction, high body mass index at age 40, long working hours, and working the night shift have also been reported as risk factors for OPLL. On the other hand, frequent intake of chicken or soy products and good sleeping habits have been shown to reduce the risk of OPLL.[3,16]

BMP is also believed to play an important role in OPLL. BMP-2 induces differentiation of ligament cells and leads to ossification by enchondral ossification.[21,22] Li et al.[23] reported that elevated insulin levels lead to an increased expression of insulin receptors, proliferation of spinal ligament cells, and induction of osteogenic differentiation through the PI3-K/Akt pathway in rats. This may explain the high association of

OPLL in type 2 diabetes. Some studies have also correlated high serum levels of activin with OPLL.[22]

Pathology

Ossification of the posterior longitudinal ligament occurs due to both enchondral and intramembranous ossification, resulting in the formation of ectopic lamellar bone; however, enchondral ossification plays the major role.[24] McAfee et al.[25] extensively reported the histopathology of OPLL, which is composed of lamellar bone with mature haversian canals. Ishida and Kawai reported that cells from nonossified areas in patients with OPLL have a high alkaline phosphatase activity and a high response to calcitonin and calcitriol.[26] Epstein et al.[1] reported that ossification of the PLL starts with vascular fibrosis, leading to calcification, cartilage proliferation, and then ossification.

Classification

The Japanese Investigation Committee on the Ossification of the Spinal Ligaments classified OPLL into four subtypes depending on its extent[3,27]:

Continuous: OPLL extends over several contiguous vertebrae.
Segmental: OPLL is seen behind several vertebrae, but there is interruption at the disc level.
Mixed: Combination of continuous and segmental type.
Others: OPLL is confined to the disc space only.

In terms of distribution, the segmental type is the most common (39%), followed by mixed (29%), continuous (27%), and focal (5%).[3,28] Some authors have also classified OPLL into the plateau type and hill type depending on its sagittal morphology. The plateau type is common in the segmental and continuous variety, whereas the hill type is common in the focal type.

Natural History

OPLL is a disease most commonly seen in individuals after the fifth decade of life. Chiba et al[29] and Hori et al[30,31] studied the progression of OPLL and found that the rate of progression was maximal for continuous and mixed types. They also found that C3 involvement was an important predictor of progression, with frequent progression seen at the C2–C4 level. Matsunaga et al[32] studied 450 patients with OPLL for at least 10 years and reported that only 17% of patients without myelopathy at the initial visit developed myelopathy; thus, they recommended that prophylactic decompression is not always required.

Clinical Features

Most of the patients with OPLL are asymptomatic and are diagnosed when imaging is done for other reasons or for nonspecific symptoms. As discussed earlier, OPLL is most common in the cervical region, followed by the thoracic and lumbar regions. Patients with OPLL in the cervical and thoracic regions usually present with myelopathy, whereas in the lumbar region stenosis is the presentation.[3] Usually, these symptoms are gradual in onset; however, some minor trauma may lead to an acute presentation in these patients.

On physical examination, these patients may reveal upper motor neuron signs, such as a Hoffman sign, finger escape sign, inability to perform the grasp and release test after 10 seconds, inverted brachioradialis reflex, and Babinski sign. These patients may also exhibit gait abnormalities. Axial tenderness is usually absent, except in patients with a history of trauma. Patients with lumbar spine involvement may show signs of canal stenosis, including sensory abnormalities in lower limbs.

Risk Factors for Myelopathy

Many static and dynamic risk factors[3,32,33] have been identified for the development or progression of myelopathy in patients with OPLL. These may include:

- More than 60% canal involvement by OPLL
- Laterally deviated OPLL
- Progression of OPLL
- Type of OPLL, with segmental type having the greatest risk
- Increased cervical range of motion

Imaging

Improvement in imaging techniques, including computed tomography (CT) and magnetic resonance imaging (MRI), has led to a better understanding of OPLL. However, plain radiographs still remain useful and are the simplest screening tool for OPLL.

Plain Radiographs

Plain radiographs can diagnose OPLL in a majority of cases. A longitudinal ossified strip along the posterior border of the vertebrae on lateral radiographs is a distinctive finding. Radiographs may also show the presence of other associated diseases, such as diffuse idiopathic skeletal hyperostosis or ankylosing spondylitis. It is not uncommon to see findings of cervical spondylotic myelopathy in the form of degenerated collapsed disc spaces; however, the disc space is usually preserved in the OPLL involved area. Dynamic radiographs can be useful if there is any doubt regarding instability or if the surgeon is planning to add instrumentation.

Lateral radiographs can also be used for calculation of canal occupancy by OPLL. Fujiyoshi et al.[34] presented the concept of a K line to help in choosing the optimal approach for OPLL. This K line extends from the midpoint of the spinal canal at C2 to the midpoint of the spinal canal at C7. He defined two groups: K line positive and K line negative. In K line positive patients, the OPLL lies ventral to the K line; in K line negative patients, it extends dorsal to it. Their series found

FIG. 43.1 This 35-year-old female presented with neck and midback pain, along with increasing gait disturbance and difficulty with fine hand coordination. Sagittal T2-weighted magnetic resonance imaging demonstrates stenosis due to ossification of the posterior longitudinal ligament and C3–C4 and C4–C5.

FIG. 43.2 Sagittal computed tomographic scan demonstrating ossification of the posterior longitudinal ligament at the C3–C4 level.

that posterior decompression was effective only in the K line positive group; the spinal cord had very little potential for shifting following posterior decompression in the K line negative group. Recently, the same K line has been described on MRI instead of radiographs.

Computed Tomography

CT has emerged as an invaluable modality to assess the type and extent of OPLL.[3,35] Axial CT scan best demonstrates the OPLL with an ossified mass extending from the posterior margin of the vertebrae into the cervical canal. It is also necessary to image the whole spine due to a very high association of thoracic and thoracolumbar OPLL, along with ossification of the ligamentum flavum (Figs. 43.1 through 43.5).[36] A sagittal section best shows the extent of OPLL, helping in classification. CT myelography can show the extent of cord compression and is particularly useful in patients for whom MRI is contraindicated.

A single- or double-layer sign[35] has been described for possible penetrance of the dural sac by OPLL on bony window CT cuts. A single-layer sign is defined as the presence of a single hyperdense ossified tissue behind the vertebral window, while double-layer is defined as two hyperdense ossified masses separated by a central hypodense linear rim produced by a hypertrophied, but nonossified, remnant of the PLL. The double-layer sign is more pathognomonic of dural involvement. Dural penetrance creates a surgical challenge, as removal of the mass will lead to a dural defect and cerebrospinal fluid leak in the postoperative period. A canal occupancy of more than 60% with OPLL has also been linked to a high incidence of dural penetrance. The anterior approach is not favorable in such cases and should be planned with careful consideration of this possibility. Dural ossification is more common in thoracic OPLL. Min et al.[36a] reported an 80% dural ossification rate in thoracic OPLL.

Magnetic Resonance Imaging

MRI has emerged as an essential modality to evaluate spinal cord status in OPLL. However, it may not reveal much information about OPLL itself. Classic OPLL is hypointense both on T1- and T2-weighted images. A T2-weighted image can show the presence of edema, gliosis, or myelomalacia.[3] Presence of intramedullary high signal intensity on T2-weighted MRI images has also been linked to poor surgical outcome following surgery.

Matsuyama and colleagues[36b] classified OPLL based on the MRI cross-sectional appearance of the spinal canal shape at the level of maximum compression. He classified the spinal canal as triangular, boomerang, and teardrop types. He found that neurologic outcome was worst for the triangular and best for the teardrop type, while the boomerang type had moderately good prognoses.

Treatment for OPLL Involving the Cervical Spine

Conservative Treatment

Conservative treatment is warranted when patients present with minimal or no symptoms. Treatment may consist of

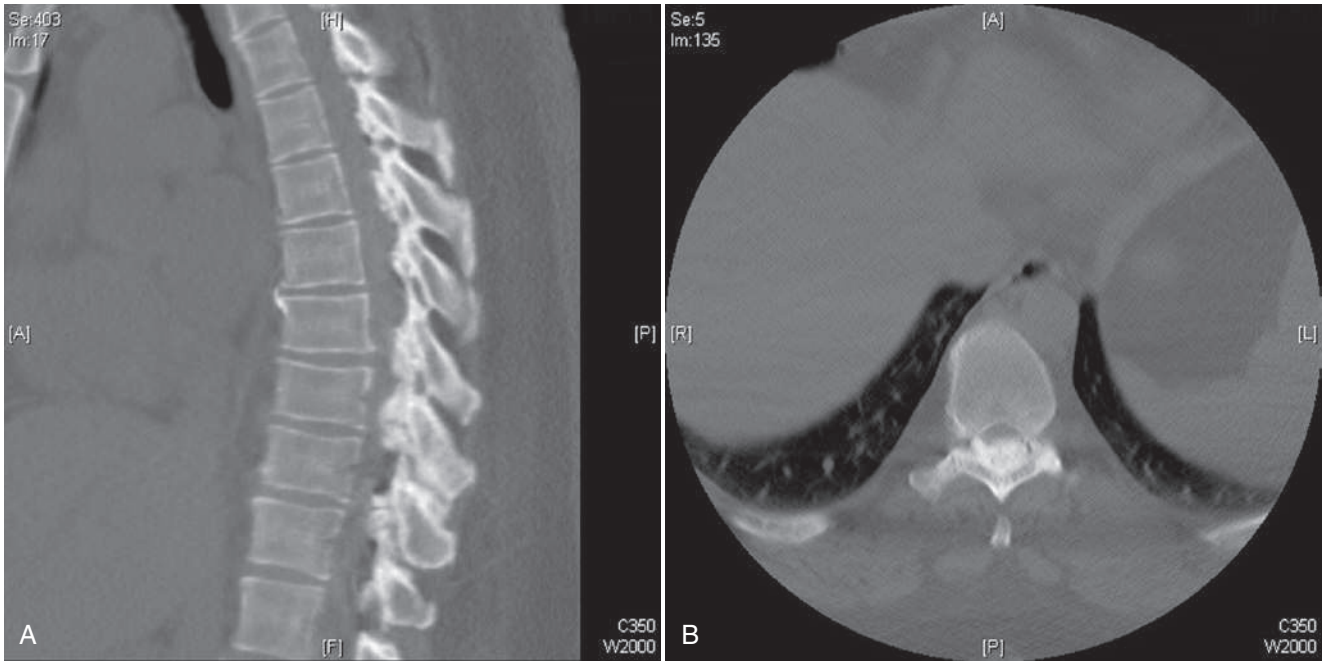

FIG. 43.3 (A) Sagittal and (B) axial computed tomographic scans of the thoracic spine demonstrating the presence of severe concomitant ossification of the ligamentum flavum.

FIG. 43.4 Postoperative sagittal computed tomographic scan of the cervical spine demonstrating decompression and instrumentation through a posterior approach.

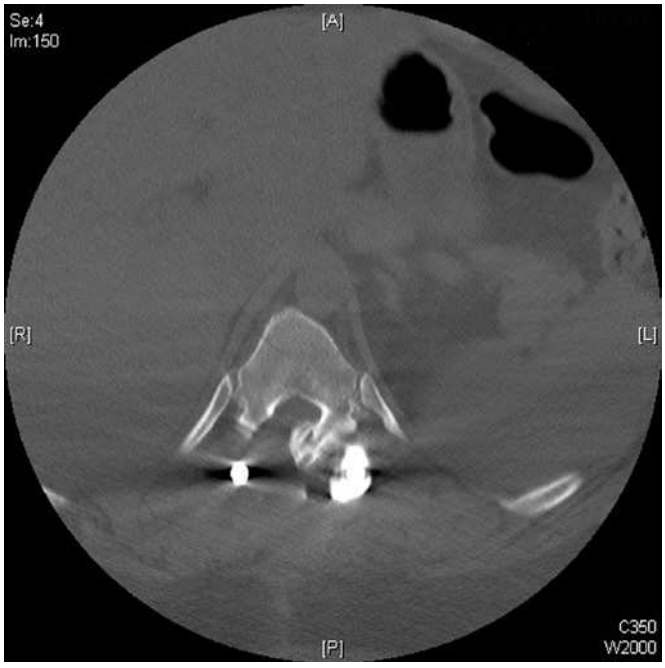

FIG. 43.5 Postoperative axial computed tomographic scan of the thoracic spine demonstrating decompression of the thoracic segment.

observation, use of cervical orthotic devices, traction, and the use of nonsteroidal antiinflammatory drugs. Recently, famotidine has been found to suppress progression of OPLL in mice and thus may be a useful drug in the future.[37]

Surgical Treatment

The surgical treatment of OPLL can be divided into anterior or posterior surgeries depending on the approach. The anterior approach usually directly targets the ossified mass and its removal; posterior approaches involve standard techniques of decompression, as used for cervical spondylotic myelopathy, such as laminectomy, laminectomy with fusion, or laminoplasty. Intraoperative neuromonitoring should be strongly considered for these surgeries.

Anterior Approaches

The usual indication for an anterior approach is a localized or segmental type involving fewer than three levels, between C2 and T1 without the presence of congenital stenosis. The other factors favoring an anterior approach are the presence of local kyphosis and a higher than 60% canal occupancy ratio. The anterior approach usually involves corpectomy and the excision of the ossified mass, followed by fusion.[3] Other options are skip corpectomy, oblique corpectomy, open-window corpectomy, and anterior decompression through a transvertebral approach.

Complications associated with the anterior approach involve graft extrusion, pseudarthrosis, hardware failure, and dural tear with cerebrospinal fluid leak. The risk of dural tears following anterior surgery for OPLL has been quoted as 4.3% to 32% in various series.[38] Some surgeons prefer to use the "floating dura" technique, in which they leave just the thin shell of ossification as an island to the dura.[39]

Posterior Approaches

The posterior approach is usually reserved for patients with more than three-level involvement, age greater than 65 years, and cervical lordosis.[3] Posterior options include laminectomy with or without instrumentation and laminoplasty. Although laminectomy is a straightforward surgery with a low complication rate, the risks of late complications include spinal instability, postlaminectomy kyphosis, and OPLL progression. The addition of posterior instrumentation prevents postlaminectomy kyphosis, but it is ineffective in the presence of preoperative severe kyphosis and large OPLL. There are two main techniques for laminoplasty: open-door and double-door techniques. While useful for certain cases, both types of laminoplasty are ineffective in the presence of preoperative severe kyphosis and large OPLL.[21]

Outcome of Surgical Treatment

The anterior approach in patients with OPLL is relatively difficult. However, the surgical results are much better (as high as 92%), with fewer complications compared to posterior approaches (67% for laminoplasty, 42% for laminectomy).[3,32,40–42] Tani et al[41] reported a 58% success rate with anterior surgery as compared to 13% with laminoplasty. He also reported significant neurologic deficit in 5 patients following laminoplasty. OPLL has been shown to progress even after laminoplasty, and the frequency is reported to be very high (70%), leading to late-onset neurologic decline. Symptomatic neurologic deficit is relatively rare, however.[3,42,43] Iwasaki et al. reported 16% late neurologic deficit following laminoplasty.[43] Recently, Katsumi et al. reported that the addition of posterior instrumentation following laminoplasty reduces the progression of OPLL.[44]

Factors Associated With Poor Surgical Outcome

Several risk factors have been identified that are associated with poor surgical outcome following surgery of OPLL[3,40,45–48]:

- Advanced age
- Malalignment of the cervical spine
- Greater than 60% canal occupancy by OPLL
- OPLL segmental type having the greatest risk
- Preoperative neurologic status
- Dural penetrance
- Intramedullary high signal intensity on T2-weighted MRI images
- Diabetes mellitus[49]

Treatment for OPLL Involving Thoracic Spine

Outcome of thoracic OPLL has been linked to preoperative duration of symptoms as well as severity of OPLL. Results of surgical treatment of OPLL in the thoracic spine are poorer compared to the cervical spine. Several factors[3] have been implicated for this poor outcome:

- Natural kyphosis of the thoracic spine prevents posterior translation of the spinal cord after laminectomy, thus limiting its effectiveness.
- Poor vascularity of the spinal cord at the site of compression.
- Presence of the rib cage limits the anterior approach.

Posterior approaches alone are usually not effective for thoracic OPLL. However, in a multicentric study, Matsumoto[50] reported that laminoplasty is a useful and safe technique for OPLL involving the upper nonkyphotic thoracic spine from T1 to T4. Tokuhashi et al[51] studied the critical kyphotic angle and found that if kyphosis at the decompression site is more than 23 degrees, posterior decompression alone is not effective. The anterior approach for OPLL removal is technically demanding and carries a poor prognosis.[21]

Tomita et al.[52] described a circumferential decompression technique in 1990 for removal of OPLL, which was modified in 2001 by including dekyphosing stabilization.[53] This is a two-stage operation that initially consists of performing a wide posterior laminectomy. The inner part of the facets and pedicles are then drilled down lateral to the dura. Lateral gutters are made in the vertebral body. Doing so allows the posterior release of any adhered OPLL laterally. In their original paper, these authors describe placing the patient in a lateral

decubitus position for the second stage. A corpectomy is then completed of the affected level. This exposes the adhered OPLL, which allows the surgeon to perform a microscope-assisted removal of the OPLL. A strut allograft is then subsequently placed into the corpectomy defect. Yang et al.[54] reported that the posterolateral approach is a safe and effective technique for treating thoracic OPLL. In view of current surgical advances, anterior decompression can be done by an anterior, lateral, or posterior approach. Recently, Liu et al.[55] reported that circumferential decompression via the posterior approach is an effective surgical technique for thoracic spinal stenosis caused by multilevel OPLL of the thoracic spine. They also emphasized that complete resection of the OPLL gives better results compared with the floating technique.

Summary

Ossification of the posterior longitudinal ligament can present in a variety of different forms. A small percentage of patients who present with OPLL do not develop any symptoms. Unfortunately, the majority of patients do develop myelopathic symptoms that progress to require intervention. Nonoperative treatment in these patients tends not to alleviate their symptoms; surgery is therefore indicated in the majority of these patients. Due to adhesions of the OPLL on the dura, careful consideration must be taken of the approach that is used because of the high complication rate typically seen. Depending on the region of the spine, anterior, posterior, and combined approaches with or without instrumentation have been described, all with mixed success rates. Spine surgeons should be aware of the various complication rates seen in patients with OPLL before undertaking treatment of these patients.

44 CHAPTER Cervical Disc Replacement

Abhishek Kannan
Wellington K. Hsu
Rick C. Sasso

Background

The cervical spine consists of seven vertebrae that comprise the axial skeleton of the neck. The five vertebral bodies of the *subaxial cervical spine,* C3 to C7, have unique structural characteristics that affect normal physiology and pathophysiology and directly influence considerations of surgical management. The vertebral bodies, the axial load-bearing elements of the vertebral column, are mobile segments joined by cartilaginous intervertebral discs. A single intervertebral disc is composed of a central nucleus pulposus with a surrounding anulus fibrosus (composed of highly elastic mucoprotein gel and collagen fibers, respectively). The vertebral column is the central axis of the human body, serving roles in biomechanical function through muscular attachment and motion. The spine also serves a neuroprotective role, as it houses the spinal cord and exiting spinal nerve roots.

Disc degeneration is a disease state marked by progressive wear and tear on the intervertebral discs, which contributes to changes such as mild to more severe spondylosis and spinal stenosis. Disc degeneration can compress or stretch nerve roots, resulting in myelopathy, radiculopathy, and repeated trauma to the spinal cord. Historically, surgical management of patients with symptomatic degenerative disc disease (DDD) included removal of pathologic disc material and fusion of the interspace.

Since its introduction in the 1950s by Robinson and Smith,[1] anterior cervical discectomy and fusion (ACDF) has been widely used to treat spondylotic radiculopathy and myelopathy while demonstrating long-term clinical success.[2,3] ACDF has become one standard of care for treating cervical disc disease in symptomatic patients, as it achieves neural decompression and segmental stabilization. ACDF consists of neurologic decompression by discectomy followed by the use of intervertebral graft to maintain disc height and instrumentation (plating) to improve the rate of fusion. Anterior cervical plates may span the rostral to caudal vertebral bodies included in discectomies and have thereby made postoperative immobilization less critical. Furthermore, plating has been shown to decrease pseudarthrosis rates for multilevel fusions[4] while maintaining sagittal balance through segments within the construct.[5]

ACDF, however, can pose a number of limitations, including loss of cervical range of motion (ROM), dysphagia, pseudarthrosis, autograft harvest site pain, and increased segmental motion leading to adjacent disease.[6–11] Adjacent segment degeneration remains a major concern and is a direct result of altered biomechanics of the cervical spine. Arthrodesis at any given level can lead to increased load bearing at levels above and below the construct, accelerating the degenerative process. The radiographic demonstration of these changes is called *adjacent segment degeneration*, while consequent clinical symptomatology in the form of myelopathy or radiculopathy is diagnosed as *adjacent segment disease*. Goffin et al. report the radiographic incidence of adjacent segment degeneration to be as high as 92% after anterior cervical interbody fusion.[3]

Clinical studies have demonstrated the postoperative occurrence of adjacent segment disease, including Hilibrand et al., who reported an annualized incidence of 2.9% per year in 374 patients after ACDF.[12] In the 10 years following ACDF, they estimated 25% of patients undergoing cervical fusion will develop radiographic degeneration of adjacent spinal segments, of which two-thirds would go on to require additional surgery. In a retrospective clinical study of 888 patients undergoing ACDF, Xu et al.[13] identified 108 patients who developed adjacent segment disease necessitating a reoperation. Of the 108 who underwent a revision procedure, 27 developed recurrent disease requiring a third cervical fusion. This study demonstrates that patients who underwent a second cervical fusion developed adjacent segment disease at both higher and faster rates, which were statistically significant. Notably, patients who were revised via an anterior approach had a higher chance of recurring disease versus patients who underwent a posterior procedure. Bydon et al. reported that patients are more likely to develop disease above the index level of fusion as compared to below, even for patients undergoing a revision procedure, and predicted a rate of adjacent segment disease development of 31% at 10 years.[14]

Biomechanical analyses have also demonstrated that vertebral levels adjacent to the index level ACDF have demonstrated

increased intradiscal pressures and ROM during both flexion and extension.[9,15] Clinical prevalence of adjacent segment disease coupled with in vitro biomechanical findings suggest that ACDF accelerates degeneration of intervertebral discs, resulting in altered physiologic biomechanics and the resultant pathogenesis of adjacent segment disease.

Cervical pseudarthrosis is another well-established complication of ACDF, described as failure of solid arthrodesis at 12 months. Pseudarthrosis rates following ACDF have been reported in the range of 3% to 20% for single-level fusions and 21% to 46% for two- and three- level fusions, respectively.[16,17] Factors that impact fusion rates include number of levels involved, surgical technique, patient comorbidities, and choice of graft.

In an effort to improve on fusion rates after ACDF, an extensive body of literature has emerged investigating various choices of bone graft. Historically, iliac crest bone graft (ICBG) was considered the gold standard for use in ACDF, utilizing the anterior crest as a donor site. However, a significant drawback of this option is the involved donor site morbidity, manifesting as persistent pain, numbness, and ambulatory impairment.[18] ICBG harvest has also been associated with superficial infection, wound complications, sensory abnormalities, hematomas, and tissue herniation through donor site, with reported complication rates of 10% to 39%.[19,20]

While the use of allograft avoids the donor site morbidity and associated risks of ICBG, there have been reports of disease transmission and bioincompatibility.[21] Although advances have been made in cadaveric tissue screening and processing, interest in bone graft substitutes continues to grow, with emerging in vitro and in vivo studies investigating the use of demineralized bone matrix, ceramic-based bone grafts, and nanofiber-based collagen scaffolds.[22,23]

Recombinant human bone morphogenetic protein-2 (rhBMP2) was first approved by the US Food and Drug Administration (FDA) for use in an anterior lumbar interbody cage in 2002. It was initially received as a novel bone graft substitute to ICBG, demonstrating fusion rates as high as 98%[24] with shorter length of surgery and shorter hospital stays.[25] However, multiple studies have demonstrated potential adverse effects in the cervical spine, including postoperative prevertebral swelling, hematoma formation, and heterotopic ossification.[26–28] The increasing prevalence of off-label use coupled with controversial indications for clinical use of rhBMP-2 have led to significant criticism of its application in both academic and clinical settings.[29,30] These considerations make a strong case for fusion alternatives in the treatment of DDD of the cervical spine.

There is a growing body of literature surrounding the use of total intervertebral disc arthroplasty (TDA) as an alternative to traditional fusion in restoring mobility and function at the involved spinal segments. Proposed advantages of TDA include maintenance of cervical ROM, restoration of cervical disc height and spinal alignment, as well as avoidance of pseudarthrosis, adjacent segment degeneration, and adjacent segment disease. The procedure also avoids the potential surgical morbidity of autograft harvest while avoiding complications associated with postoperative immobilization.

History of Disc Arthroplasty and Device Design

Arthroplasty aims to provide a stable, biomechanically efficient construct that is safe for patient use and reduces symptomatology associated with disc disease. The unique anatomic characteristics of the cervical spine necessitate specific considerations regarding TDA device design that may not be applicable in other major joint replacements. Bone stock in the cervical spine is limited, resulting in less flexibility when making bony cuts to accommodate an implant prosthesis. In contrast to knee and hip joints, the intervertebral disc plays a major role in spinal stability by maintaining balance of the anterior and middle columns. TDA candidates are typically younger than patients receiving lower extremity joint replacements; a longer expected lifespan (between 30 and 50 years longer) entails an estimated 100 million flexion cycles for a given implant. This raises concern for device bearing and wear characteristics as well as articular constraint. Given the proximity of the implant to the spinal cord and critical structures of the anterior neck, wear debris and the potential ensuing inflammatory reaction are major topics under investigation. Local and systemic responses to debris may be evaluated in the context of biocompatibility, neurologic response, tissue response, and toxicity. Extremes of motion may lead to abnormal wear, contributing to debris formation. Therefore, static and dynamic characterization of a given device should involve compression-shear testing using the maximum theoretical ROM in one or more directions.[31]

The earliest application of TDA in humans was in the late 1980s by Cummins et al. in the United Kingdom.[31a] This group developed a metal-on-metal ball-and-socket device for implant in the cervical spine. Over the past 2 decades, the original artificial disc has been further developed to incorporate newer materials and methods of fixation in the cervical vertebral bodies. The Prestige ST (stainless steel; Medtronic), a direct descendant of the original Bristol-Cummins device, is made of stainless steel and was approved by the FDA for human use in 2007 (Figs. 44.1 and 44.2). The Prestige low-profile (LP) (Medtronic), the fifth iteration of the original Bristol-Cummins device, was also recently approved for use in the US market. Other FDA-approved devices include ProDisc-C Total Disc Replacement (DePuy Synthes) (Figs. 44.3 and 44.4), Bryan Cervical Disc (Medtronic) (Figs. 44.5 through 44.7), Mobi-C Cervical Disc (Zimmer Biomet), and SECURE-C Cervical Artificial Disc (Globus Medical Inc.).

A more recent addition to the metal-on-metal category of arthroplasty devices includes the Kineflex-C disc (SpinalMotion) for which the FDA investigational device exemption (IDE) trial has been completed. A summary of the design characteristics of each of these devices is presented in Table 44.1. The seventh FDA-approved cervical disc arthroplasty device is the PCM disc (NuVasive).

The Cervical Spine Study Group classifies TDA devices as nonarticulating, uniarticulating, and biarticulating. The device may be modular (with replaceable components) or nonmodular (with nonreplaceable components).[32] Disc prostheses can also be classified as unconstrained, semiconstrained, and

FIG. 44.1 The Prestige ST Cervical Disc prosthesis is currently approved by the Food and Drug Administration for use in the United States. This stainless steel uniarticulating device attains primary fixation to the vertebral bodies via use of locked screws. (Courtesy Medtronic, Minneapolis, MN.)

constrained, depending on the degrees of freedom allowed by a specific design. The ball-and-socket motif, consisting of a gliding interface between two rigid components, is shared by all three designs.[33] Devices considered constrained in certain planes restrict motion to less than that seen physiologically. Semiconstrained designs allow motion similar to that seen physiologically. Devices are considered unconstrained if there is no mechanical stop to motion relying on soft tissues and the inherent compression across the disc space to provide the primary restraint to extremes of motion.[34]

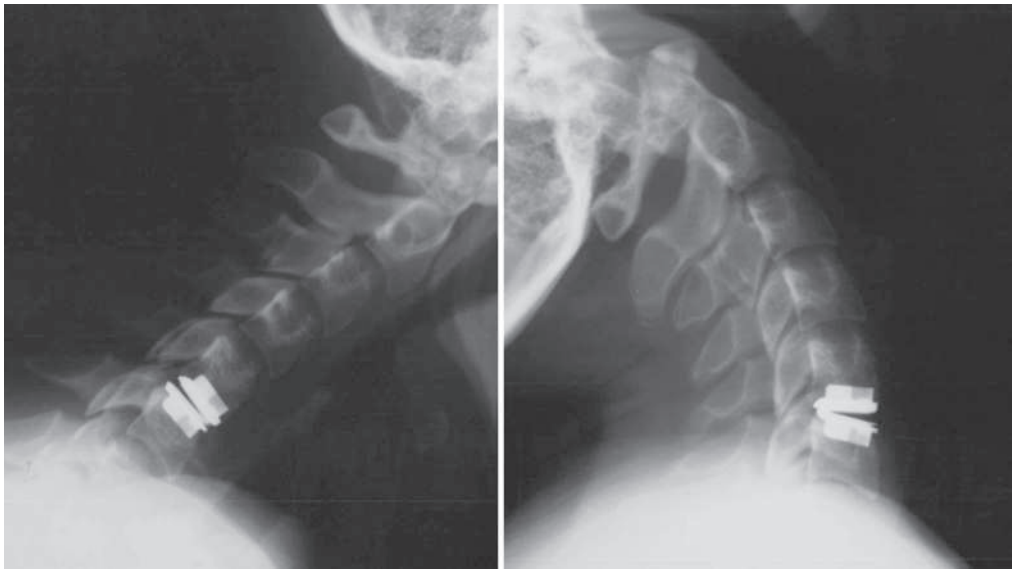

FIG. 44.4 ProDisc-C is visualized on lateral flexion-extension radiographs. The device retains motion at the index surgical level in this patient successfully treated with arthroplasty at C5–C6. (Courtesy DePuy Synthes Spine, Raynham, MA.)

Indications for Use, Contraindications, and Complications

The FDA-approved indication for cervical disc arthroplasty is single- and double-level cervical DDD causing radiculopathy and/or myelopathy in patients of adult age.[35] Exhaustion of conservative management options for single-level spondylosis should precede the discussion of operative management. Additional indications for TDA include soft- or hard-disc herniation or foraminal osteophytes causing radiculopathy, and soft-disc herniation causing myelopathy.[36] There is concern that motion preservation may not create an environment for maximum neurologic recovery in patients with

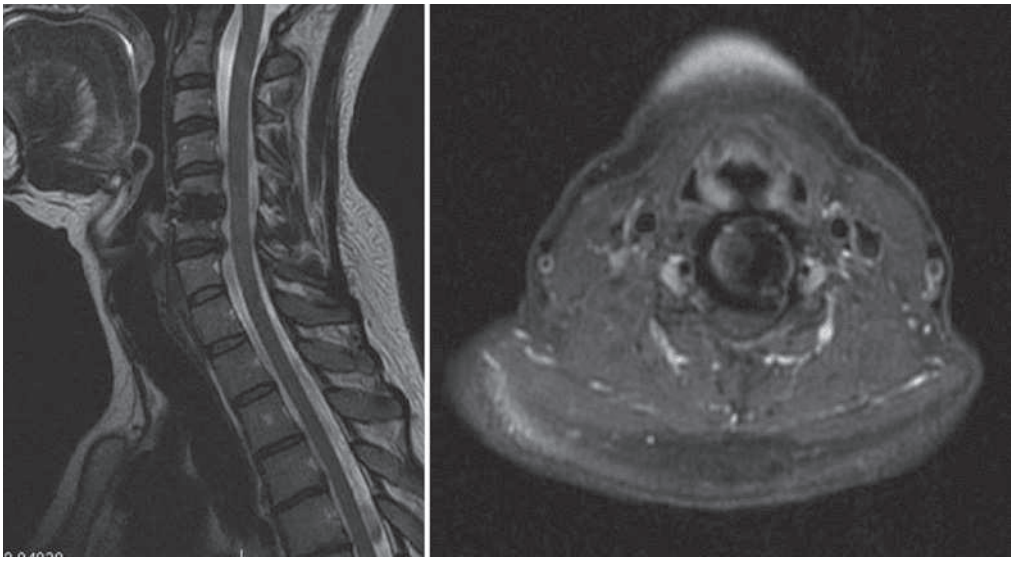

FIG. 44.6 Bryan Cervical Disc prosthesis is visualized on postoperative magnetic resonance imaging (MRI). Titanium alloy devices such as the Bryan device may have less MRI artifact than similar devices constructed with cobalt-chromium or stainless steel. These images show the imaging characteristics of this device at index and adjacent surgical levels. (Courtesy Rick Sasso, Indianapolis, IN.)

cervical myelopathy. However, Riew et al. have shown that in patients with single-level disease, clinical improvement measured via Nurick grade, neck disability index, 36-Item Short Form Health Survey (SF-36) scores, and visual analog scale (VAS) was similar between patients treated with fusion and those treated with arthroplasty.[37] Thus, for cervical myelopathy not caused by retrovertebral compression secondary to ligamentum flavum hypertrophy, ossification of the posterior longitudinal ligament, or congenital stenosis, a cervical disc prosthesis accompanied by a meticulous decompression would be a reasonable treatment option.[38]

Complications and adverse events associated with cervical disc arthroplasty involve both surgical approach and device-related issues. General postoperative complications include infection, newly occurring neurologic deficits, implant migration, intervertebral subluxation, vascular injury, dural injury, cerebrospinal fluid leak, and epidural abscess formation.

Heterotopic ossification (HO) in the region of the arthroplasty device is a unique complication reported after TDA. The proposed mechanism of HO involves differentiation of mesenchymal cells originating from bone or muscle to osteoblasts, which are able to spread into the vasculature of surrounding soft tissue. The osteogenic agents released from tissues attached to bone are a result of local intraoperative injury.[39] HO tends to develop relatively early postoperatively following cervical disc arthroplasty, and may be seen in as high as 34% of patients at 4 years and in 38% of patients at 6 years.[40] Early postoperative use of nonsteroidal antiinflammatory drugs is reported to decrease the incidence and severity of HO, similar to its effect in HO prevention after total hip replacement. Delayed hypersensitivity reactions also pose a threat after TDA, in which critical structures, primarily the spinal cord, are at risk of exposure to implant materials and wear debris.

Contraindications for cervical disc arthroplasty include active or prior infection, severe osteoporosis, severe facet arthrosis, ankylosis, congenital cervical stenosis, and segmental cervical instability (>3.5 mm of translation or >11 degrees of kyphosis). Additionally, as intact posterior elements are essential to prosthesis stability, prior laminectomy or excessive facet removal are contraindications to disc arthroplasty. The current approval status of cervical disc arthroplasty devices can be found in Table 44.2.

TABLE 44.1 Design Characteristics of Past and Present Cervical Arthroplasty Devices

Device	Design	Modular	Articulating Method	Implant Composition	Bearing Surface	Primary Fixation	Secondary Fixation	Manufacturer
Bristol/ Cummins	Ball and socket	No	Uniarticulating	316L stainless steel	316L on 316L	Vertebral body screws	Vertebral body screws	None; technology by Medtronic
Bryan	Biarticulating contained bearing	No	Biarticulating	Titanium, central polymer	Titanium alloy on polymer	Milled vertebral endplates	Endplate ingrowth	Medtronic
CerviCore	Ellipsoid saucer	No	Uniarticulating	Cobalt-chromium	Cobalt-chromium on cobalt-chromium	Ridged rails	Endplate ongrowth to titanium spray	Stryker, IDE status revoked
DISCOVER	Spherical bearing between superior titanium endplate and UHMWPE core	No	Uniarticulating	Titanium and UHMWPE	Titanium on UHMWPE	Teeth on superior and inferior endplates	Endplate ongrowth	DePuy Synthes, IDE in progress
Frenchay/ Prestige I[a]		No	Uniarticulating	316L stainless steel	316L on 316L	Locked vertebral body screws, posterior endplate lip	Locked vertebral body screws, posterior endplate lip	None; technology by Medtronic
Kineflex-C	Modular three-piece bearing system with two endplates and mobile metallic core	Yes	Biarticulating	CCM	CCM modular core between two CCM endplates	Vertical keel and ridged endplate surface	Endplate ongrowth	SpinalMotion
Mobi-C	Superior endplate with ball and socket motion; inferior endplate with sliding constraint	Yes	Biarticulating	Titanium	Titanium on polyethylene modular core	Lateral self-retaining teeth	Endplate ongrowth	Zimmer Biomet
Prestige II[a]	Ellipsoid saucer	No	Uniarticulating	316L stainless steel	316L on 316L	Locked vertebral body screws	Locked vertebral body screws	None; technology by Medtronic
Prestige LP	Ellipsoid saucer	No	Uniarticulating	Titanium/ ceramic composite	Titanium/ ceramic composite	Dual rails	Endplate ongrowth	Medtronic
Prestige ST	Ellipsoid saucer	No	Uniarticulating	316L stainless steel	316L on 316L	Locked vertebral body screws	Locked vertebral body screws	Medtronic
Prestige STLP[a]	Ellipsoid saucer	No	Uniarticulating	316L stainless steel	316L on 316L	Dual rails	Endplate ongrowth	None; technology by Medtronic
ProDisc-C	Ball and socket	No	Uniarticulating	Cobalt-chromium, UHMWPE	Cobalt-chromium on UHMWPE	Central keel	Endplate ongrowth	DePuy Synthes
PCM	Upper endplate translation on fixed UHMWPE	No	Uniarticulating	Cobalt-chromium, UHMWPE	Cobalt-chromium on UHMWPE	Ridged metallic endplates	Endplate ongrowth	NuVasive
SECURE-C	Metal on polyethylene		Biarticulating	Cobalt-chromium, UHMWPE	Cobalt-chromium on UHMWPE	Ridged central keel	Endplate ongrowth	Globus Medical

CCM, cobalt-chrome-molybdenum; IDE, investigational device exemption; UHMWPE, ultrahigh-molecular-weight polyethylene.
[a]Devices not currently in production, current/known clinical use, or IDE investigation at the time of this writing.

Preoperative Imaging

Preoperative imaging for TDA should include anteroposterior (AP) and lateral radiographs of the cervical spine (including neutral, flexion, and extension views) and bilateral oblique views. Care must be taken to ensure visibility of potential short neck, high shoulders, and the C6–C7 level on lateral radiograph. The surgeon should assess preexisting spondylosis, making note of anterior or posterior osteophytes and ligament ossification. It is important to ensure proper disc height and motion in operation segments, as both are prerequisites for

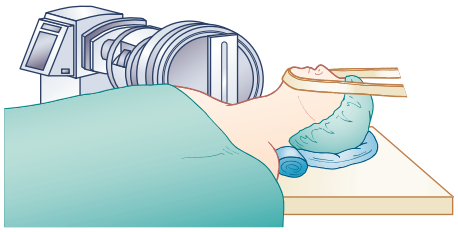

FIG. 44.8 Positioning for cervical arthroplasty is as crucial to the technique as any portion of the procedure. Correct positioning of a patient maintains physiologic lordosis without creating hyperlordosis in the cervical spine, and may be facilitated through use of a towel roll placed under the cervical spine. Techniques have moved away from traction through the spine (as shown in this illustration). Preoperative and intraoperative use of fluoroscopy allows for confirmation of patient positioning and device alignment. (Courtesy Rick Sasso, Indianapolis, IN.)

successful arthroplasty. Computed tomography (CT) and/or magnetic resonance imaging (MRI) are also essential to observe surrounding anatomy and potential pathology.

Technique of Implantation

Intraoperatively, patient position is even more critical than that of a fusion procedure. A "physiologic" or slightly lordotic cervical spine position is preferred.[41] Assessment prior to incision via fluoroscopy (C-arm) is crucial to patient positioning, as well as the implant insertion and fixation portions of these procedures. It is important to keep the head, neck, and shoulders in a stable and neutral position throughout this surgical procedure. A small towel roll may be placed under the neck to assist with appropriate positioning of the neck and shoulders, and to keep a physiologic lordosis without creating a hyperlordosis (Fig. 44.8). This positioning technique differs from the typical placement of a roll under the shoulders or thoracic spine, which could place the cervical spine in hyperlordosis. The head can be placed on a doughnut-type pillow or a folded towel to keep it from rolling during the procedure. Careful positioning of the shoulders with a taping technique can also allow for less motion during this procedure, but must be carefully weighed against the risk of traction to the shoulders.

A standard right- or left-sided Smith-Robinson approach may proceed, with appropriate localization and exposure of the index surgical level being the intent of this exposure. It is crucial to obtain a surgical exposure that facilitates identification of the center of the index disc and vertebral bodies for later placement of the arthroplasty device. Disc arthroplasty implantation is performed only after adequate decompression of the affected cervical level. At the surgeon's discretion for treatment of the index neurologic complaint, this may involve a complete discectomy from ventral to dorsal that also allows for placement of a device of appropriate width and adequate decompression, symmetrical resection of uncovertebral osteophytes and spurs, resection of all or part of the posterior longitudinal ligament, and any resection of central spondylotic osteophytes associated with DDD. A thorough and complete decompression is even more critical in a TDA procedure compared to an ACDF because of the incidence of recurrent radiculopathy from persistent foraminal stenosis. Meticulous hemostasis is recommended throughout this procedure to diminish blood loss and minimize the risk of heterotopic ossification. It may become clear at any point during the neurologic decompression, endplate preparation, or device trialing process that arthroplasty is contraindicated. Should this occur, the surgeon must adjust the surgical plan intraoperatively and proceed with a fusion-based alternative.

After neurologic decompression, assessment for placement of an appropriately sized disc and planning for proper orientation of the implant are crucial to successful arthroplasty. To this end, it should be the surgeon's goal to place an appropriately sized implant (depth, width, and height) in the prepared space.[42] Device-specific tools may aid in this assessment. Before any intervention that prepares the endplates, it is important to ensure the exact sagittal position of the vertebrae with lateral fluoroscopic imaging. AP views are important to place the spinous processes at the target disc level between the pedicles to ensure perfect alignment and centering in the coronal plane. Sizing of a cervical arthroplasty device may be determined with a combination of preoperative templates and preoperative radiographic studies, including CT. The use of intraoperative trials and fluoroscopic imaging allows for additional assessment of proper device sizing and placement in the coronal and sagittal planes.

Endplates are prepared in a manner consistent with the device to be implanted. This preparation may include milling of the endplate (as in the Bryan device) or creation of a bony trough to accommodate an endplate keel (as in the ProDisc-C device). Preservation of subchondral bone is otherwise crucial to the prevention of implant subsidence. Instrumentation specific to each arthroplasty device may be of great assistance in endplate preparation and may include special endplate distracters, keel preparation mills, rasps, and endplate mills. After the endplate preparation has been completed, it is appropriate to reassess the centering of the preparation and recheck the neurologic decompression.

Insertion of the artificial disc device may proceed, and is implant specific. Common to all devices is the principle of

implantation to an appropriate depth based on implant design, with a repeat assessment of implant centering and endplate coverage. After an assessment of the implant position in the coronal and sagittal planes has been done, the implant may be fixed to the spine with any implant-specific instrumentation, such as screws.

Final imaging of the device implantation is performed before wound closure. Hemostasis is rechecked, and the surgical wound is closed in a standard fashion. Postoperative immobilization is not required. Upright flexion-extension radiographs may be obtained before discharge from the hospital and serve as a comparison to postdischarge radiographs for the purposes of follow-up.

Postoperative Imaging

The current generation of disc arthroplasty devices retains metallic components in either the endplate or bearing mechanism, making radiation-based imaging the preferred modality for postoperative evaluation. Plain radiography, including flexion and extension views of the cervical spine, is a mainstay in the postoperative period, and is useful for observing device placement, identifying potential displacement or dislodgement of device components, and assessing maintenance of motion. Special attention should be paid to device fixation at the endplate-device interface, and sagittal balance of the entire cervical spine (C2–C7) must be assessed.

MRI has been proposed as an alternative modality for follow-up imaging, allowing for postoperative assessment of the spinal canal, neural foramina, and neurologic status at the index and adjacent levels. When evaluating the amount of metal artifact on MRI with spinal implants, Wang et al. found that titanium-based devices produced significantly less artifact as compared to stainless steel and other alloys.[43] Sekhon et al.[44] used a scoring system to analyze surgeon interpretation of randomized postoperative MRI and found that the titanium-based devices (Bryan and Prestige LP) scored significantly higher than chromium-cobalt-molybdenum (Cr-Co-Mb) devices (ProDisc-C and PCM). These findings suggest that titanium-based devices produced less artifact while the Cr-Co-containing devices obscured the index and adjacent levels.

Although the MRI characteristics of all devices on the market (including those utilizing 316 stainless steel and/or Cr-Co-Mb) have not been studied, device composition may play a role in surgeon preference with regard to follow-up imaging. Initial MRI studies and the resulting image obscurity caused by such devices may affect future material choices and design strategies for cervical disc prostheses in the future.

As postoperative use of MRI may not be optimal secondary to artifacts generated by instrumentation, CT myelogram is a viable option to visualize the neural canal and offers superior visualization of neurologic and motions segments. CT imaging may also be used to identify complications, including implant malpositioning, subsidence, failure, or fracture.[45] A disadvantage of CT is high-dose radiation exposure to the patient.

Clinical Studies

The primary rationale for cervical disc arthroplasty in the treatment of DDD and symptomatic spondylosis is motion preservation, as well as reduction of adjacent-segment degeneration and consequent adjacent-level disease. The evidence-based literature is rapidly evolving as both short- and mid-term results become available.

Prestige Disc

The Prestige ST artificial disc is a ball-and-trough design made of stainless steel and contains iron, carbon, chromium, nickel, and molybdenum. The device design includes two-screw fixation to each adjacent vertebral body with thin anterior flanges. The 2-year and 5-year results of the Prestige ST FDA IDE clinical trials were published in 2007 and 2010.[35,46] Mummaneni et al.[35] published the 2-year results of a prospective, randomized, multicenter study comparing single-level cervical disc arthroplasty with the Prestige ST to single-level ACDF in the treatment of cervical DDD and radiculopathy. At 24-month follow-up, the arthroplasty group demonstrated a statistically significant higher rate of neurologic success, lower rate of secondary surgeries, and a lower rate of adjacent segment reoperations (1.1% in the arthroplasty group vs. 3.4% in the ACDF group; $P < .05$). The arthroplasty group also demonstrated earlier return to work compared to the ACDF group (45 vs. 61 days, respectively).[47]

In 2010, Burkus et al.[46] published the 5-year results of the aforementioned FDA IDE clinical trial, which showed significant improvements in the Neck Disability Index (NDI), SF-36 scores, and Neck and Arm Pain Numerical Rating Scale scores in both the arthroplasty and ACDF groups. Segmental motion was preserved at the index level at 3 years (mean, 7.3 degrees) and 5 years (mean, 6.5 degrees) postoperatively. Notably, reoperation rates differed significantly between treatment groups, with 0% of the arthroplasty group requiring revision surgery (defined as any procedure that adjusted or modified the original implant configuration) compared to 1.9% of the ACDF group undergoing revision procedure ($P = .028$).

The Prestige LP is a titanium and ceramic composite disc with rails that provide friction against migration and a plasma spray coating on the superior and inferior surfaces to promote bony ingrowth from vertebral endplates.[32] In 2015, in a prospective, multicenter investigational device exemption study, Gornet et al.[48] collected Prestige LP data from 20 investigational sites and compared the data with the control ACDF patients in the initial Prestige ST FDA IDE study.[35] Clinical outcomes data included NDI, SF-36, Neck and Arm Pain scale, work status, ROM, disc height, adverse events, additional procedures, and neurologic status. Clinical and radiographic evaluations were completed preoperatively, intraoperatively, and postoperatively up to 24 months. Significant improvements were achieved with respect to NDI, neck/arm pain, SF-36, and neurologic status in both the Prestige LP and ACDF groups by 1.5 months and were sustained at 24 months postoperatively. Mean angular motion with the Prestige LP

device was maintained at 12 months (7.9 degrees) and 24 months (7.5 degrees). Neurologic success at 24 months was 93.5% in the investigational group and 83.5% in the control group. The authors of the study supported Prestige LP superiority on overall success and as a safe and efficacious alternative to ACDF for cervical DDD with radiculopathy and/or myelopathy. In mid-2014, Medtronic announced FDA approval to market the Prestige LP Cervical Disc System for the treatment of single-level cervical disc disease (radiculopathy and/or myelopathy).

ProDisc-C

The FDA IDE trial for ProDisc-C was a prospective, randomized, controlled multicenter trial that studied patients with single-level symptomatic cervical disc disease between C3–C7 who were unresponsive to 6 weeks of conservative treatment, with a total of 209 patients enrolled: 106 underwent ACDF, and 103 underwent TDA with ProDisc-C. Both groups showed significant improvement from baseline, but there was no statistical significance in the improvement between groups at 24 months. Device success, defined as lack of revision surgeries at the index level, was 98.1% in the ProDisc-C group and 91.5% in the ACDF group; this difference was statistically significant ($P < .05$). Overall success was 68.3% in the ACDF group compared to 72.3% in the ProDisc-C group, demonstrating noninferiority of the ProDisc-C cervical disc arthroplasty.

Zigler et al.[49] reported the 5-year interim results for the ProDisc-C IDE study, which demonstrated that ProDisc-C patients had statistically significantly reduced neck pain intensity and frequency when compared to the ACDF-treated group. There were no reports of device failures or implant migration 5 years postoperatively, and ProDisc-C patients had a lower rate of reoperation compared with ACDF patients (2.9% vs. 11.3%, respectively), which was also statistically significant.

Kelly et al.[50] compared adjacent segment motion in patients following TDA with ProDisc-C and those treated with ACDF. Nearly complete elimination of motion was observed at the index level in patients who underwent ACDF, while a small but statistically significant increase in ROM (1.01 degrees) was observed in the TDA group. This study demonstrated no significant difference in adjacent-segment ROM between the two groups. Long-term clinical follow-up is necessary to determine whether differences in adjacent-segment motion may ultimately affect the prevalence of adjacent-segment disease in those treated with ProDisc-C arthroplasty or ACDF.

Bryan Disc

Heller et al.[51] conducted a prospective, randomized, multicenter study as part of the 2009 FDA IDE trial investigating the safety and efficacy of TDA using the Bryan Cervical Disc. The investigational group included 242 patients treated with arthroplasty; the control group included 221 patients who underwent single-level ACDF. Patients completed clinical and radiographic follow-up at regular intervals for 24 months. Pain and function were assessed using NDI and SF-36 scores, as well as numerical rating scales for neck and arm pain. While both groups showed improvement compared to preoperative scores, the investigational group demonstrated significantly favorable results in several outcomes, including NDI, neck pain, and return to work. Arm pain scores, SF-36 physical and mental components, and rates of neurologic success, while significantly reduced in both treatment groups compared with preoperative levels, did not show significant differences between groups. At 24 months postoperatively, overall success was achieved in 82.6% of the TDA group and 72.7% of the ACDF group, which was statistically significant.[51]

Sasso et al.[52] reported 48-month follow-up to the pivotal FDA clinical trial, including 319 subjects (181 arthroplasty, 138 fusion). While at every time point the two groups were significantly improved from their respective preoperative state with regard to the NDI, the arthroplasty group was significantly superior when compared to the arthrodesis group. At every time point postoperatively, the percentage of the arthroplasty group with reduction of greater than 15 points in NDI scores was significantly higher than that of the fusion group, with NDI success achieved in 90.6% of the TDA cohort and 79.0% of the ACDF cohort. Neurologic success rates at 48 months were similar to those observed at the 24-month time point, and difference in mean rates between the two groups was not statistically significant. Mean cervical spine motion in the single-level TDA group increased from 6.5 degrees at baseline to 8.08 degrees at 24 months and 8.5 degrees at 48 months; this increase was significant at all time points after 3 months. Ryu et al.[53] completed an in vivo prospective study of patients treated with single-level BRYAN disc arthroplasty investigating whether artificial disc replacement could maintain physiologic kinematics at the index and adjacent levels, concluding that there is minimal change in the device kinematic behavior at early follow-up and that kinematics of the BRYAN Disc are predictable and durable at 5 years postoperatively.

Mobi-C

The Mobi-C cervical disc prosthesis remains the only FDA-approved prosthesis for two-level cervical disc arthroplasty.[54] Twenty-three patients were included in a retrospective study on single-level TDA that showed statistically significant improvements in VAS arm and neck pain scores at 6-month follow-up. All patients were able to return to work within 1 month postoperatively, and there were no complications observed. Cervical mobility was preserved at the index and adjacent levels at 6-month follow-up. Park et al. retrospectively studied a cohort of 53 patients who underwent operative treatment (21 treated with single-level TDA and 32 treated with ACDF) for cervical disc herniations.[55] This study demonstrated statistically significant improvements in return to work and shorter mean hospital stays in the TDA patients. While there were no postoperative complications in the group treated with the Mobi-C prosthesis, there were five instances of cage subsidence in the fusion group.

In a prospective study analyzing sagittal balance in 40 patients after TDA, Guérin et al. demonstrated maintenance

of ROM, cervical lordosis, and sagittal alignment 2 years postoperatively.[56] This study also showed statistically significant improvements in NDI, VAS, and SF-36 scores for patients who underwent TDA with Mobi-C. Beaurain et al. reported the intermediate results of an ongoing multicenter prospective study of 76 patients treated with Mobi-C TDA.[57] The study showed improvements in NDI, VAS arm and neck pain indices, and SF-36 scores, all of which were statistically significant. Through radiologic evaluation, the authors demonstrated preservation of segmental motion, with flexion-extension ROM of treated levels averaging 9.9 degrees preoperatively and 9 degrees at 2 years postoperatively.

In regard to two-level TDA, Davis et al. published the results of a prospective, randomized, FDA IDE trial that compared Mobi-C TDA to ACDF for two-level contiguous cervical DDD with 2-year follow-up.[58] Of 330 patients enrolled in the study, 225 (68%) were treated with two-level TDA while 105 (32%) underwent ACDF. Both groups demonstrated statistically significant improvements in NDI and VAS arm and neck pain scores when compared to preoperative values. The TDA group experienced significantly greater improvement in the NDI score when compared to the fusion group. The ACDF group also demonstrated a higher reoperation rate (11.4% vs. 3.1% reoperation after TDA).

While one-level Mobi-C TDA is noninferior, but not superior, to one-level ACDF, and two-level Mobi-C TDA may be superior to two-level ACDF, long-term studies are necessary to evaluate outcomes and to elucidate complications associated with the device. Critics would also argue that substantial evidence beyond the findings of studies with significant conflict of interest is still lacking.[59]

Future Direction

Several of the aforementioned studies published in the last decade, regardless of arthroplasty device, have attempted to demonstrate that cervical TDA reduces the incidence of adjacent-segment degeneration in the cervical spine. However, there is a growing segment of the current literature critical of the data comparing TDA to ACDF with regard to the incidence of adjacent-segment disease (ASD) postoperatively. Points of contention include short follow-up period, cohort size, disproportionate numbers of subjects among treatment groups, and parameters used for assessing the incidence of ASD.

Nunley et al. studied 173 patients among the FDA IDE trials for four separate disc replacement devices, with the primary objective of identifying the incidence of and factors influencing ASD after TDA.[60] Patients included in the analysis demonstrated one- and/or two-level symptomatic cervical DDD, had failed at least 6 months of active conservative management, and completed at least 4 years' follow-up. This study identified a 3.1% annual incidence of symptomatic ASD after cervical TDA, regardless of patient's age, sex, smoking habits, and implant device. Meanwhile, patients participating in the control arm treated with ACDF had a 2.8% annual incidence of ASD—a difference that was not statistically significant.

In addition to a lower incidence of ASD, the proposed benefits of TDA include better function (per NDI, pain assessment, SF-36, and neurologic status) and a lower incidence of reoperation. Yin et al. performed a meta-analysis of functional scores, reoperation rates, and major complications following TDA, identifying 2227 patients from 10 randomized controlled trials.[61] Fewer major surgical complications (including implant wear, migration, dislodgement and subsidence, graft donor site morbidity, and graft extrusion) occurred in TDA patients than in fusion patients; this difference was statistically significant. While segmental motion at the index level was retained in the setting of TDA, motion at adjacent levels was not greater than that of the fusion group. Furthermore, there was not a statistically significant difference in reoperation rates at adjacent levels after TDA or fusion at 4 to 5 years' mean follow-up. Verma et al. described similar results in a meta-analysis of 6 prospective studies, including IDE and non-IDE trials with at least 2 years' follow-up.[62] In a sample size of 1586 patients (777 ACDF, 809 TDA) and 70% follow-up, there was no detectable difference in reoperation rates between groups.

While the FDA IDE trials remain a primary source of truly randomized, collected, and validated data, independently funded, blinded, long-term follow-up prospective studies are necessary to further compare the effects that motion-preserving devices and fusion methods have on adjacent spinal levels. The fact that osteopenia and concurrent lumbar DDD significantly increase the risk of ASD has been established in the literature. However, the theoretical assumption that motion-sparing TDA may significantly reduce the incidence of future ASD when compared to ACDF requires further corroboration.

Biomechanics

The goals of TDA with respect to biomechanical parameters are as follows: restoration of physiologic kinematics and mobility while avoiding spinal instability; protection of biologic structures including adjacent discs, facet joints, and ligaments from overloading; restoration of correct spinal alignment; and device stability and response to wear debris.[33] The most studied parameter concerning spinal kinematics after TDA is ROM, that is, the rotation from one extreme to the other of the physiologic range of rotation of a specific motion. The majority of ex vivo studies that quantify motion alternations after TDA find a general preservation of motion at the index level, with ROMs nearly similar to physiologic values regardless of prosthesis design.[6,63–65]

Normal cervical spine motion exhibits AP translation during flexion and extension. The cervical spine motion segments are complex joints, each consisting of three compartments: the disc and two facets. Disc prosthesis design must consider the three compartments as well as the multiple ligamentous structures of the cervical spine.

Biomechanical studies suggest that the semiconstrained design (ball-in-trough) of the PRESTIGE cervical disc provides for normal kinematics in all ROMs. However, DiAngelo et al. reported that a constrained design (ball-in-socket), such

as that of the ProDisc-C prosthesis, failed to reproduce normal motion in extension.[63] The ball-in-socket design does not reproduce the natural AP translation seen in the normal motion of the facet joint. The complexity of the cervical spine requires a "balance" of all the significant structures, including facets and ligaments.

The most significant effect of this change in balance is in extension. When the spine goes into flexion, the facets "unshingle" and reduce their involvement in constraining the motion of the functional spine unit. When the spine goes into extension, the facets "shingle" and become more involved in constraining the motion. With a constrained facet joint and a constrained disc joint, one would expect to see binding or limited motion (also known as *kinematic conflict*), as one joint works against the other. This binding would give rise to decreased motion or increased stress on the system.

Balancing the kinematics in the functional spine unit is crucial. A constrained disc replacement may be unable to provide the normal kinematics of the cervical spine. AP translation is anatomic and must be allowed to restore normal motion. The Prestige Cervical Disc was shown to maintain normal kinematics through all ROMs. Similar results would be expected from the Bryan Cervical Disc system because it is also semiconstrained and allows for AP translation in flexion and extension.

Sasso and colleagues[66] studied the kinematics of cervical motion from patients enrolled in a prospective, randomized, multicenter clinical trial. Radiographic data, including flexion, extension, and neutral lateral radiographs, were obtained preoperatively and at regular postoperative intervals up to 24 months. All patients had received either a single-level anterior cervical plate (Atlantis anterior cervical plate, n = 221) or a single-level artificial cervical disc (Bryan Cervical Disc prosthesis, n = 242) at C3 to C7. Cervical vertebral bodies were tracked to calculate the functional spinal unit motion parameters. Parameters measured included flexion-extension ROM and translation. These data were recorded at the index surgical level and, if visible, at the functional spinal units cranial and caudal to it.

More motion was retained in the disc replacement group than the plated group at the index level, a statistically significant finding. At 24 months, the arthroplasty group retained an average of 7.95 degrees (average, 6.43 degrees preoperatively). In the control ACDF cohort, the average ROM in the fusion group was 1.11 degrees at the 3-month follow-up and gradually decreased to 0.87 degrees at 24 months (average, 8.39 degrees preoperatively). In the Bryan cohort, index-level functional spinal unit translation averaged 0.36 mm at 24 months, a data point that was statistically unchanged from the first postoperative measurement of translation at 3 months. No investigational devices showed radiographic evidence of subsidence at 24 months, and no HO was observed in the BRYAN cohort.

Angular ROM at adjacent levels cranial and caudal to the index surgical functional spinal unit was measured and was not statistically different between the two cohorts preoperatively. At 24 months, these differences were unchanged in both groups (statistically similar). There was no consistent correlation between angular ROM at adjacent or index levels and standard outcome measures of success in the investigational group. These data were not analyzed in the control. This study showed that the Bryan disc maintains mobility at the level of the prosthesis over 24 months. No conclusions with regard to the adjacent segments could be statistically reached at this early follow-up interval.

In an in vitro biomechanical analysis, Gandhi et al.[67] found that after single-level arthroplasty, the motion at implanted levels increased in all directions. The Prestige LP disc demonstrated increased motion by 26% in flexion-extension, 33% in lateral bending, and 6% in axial rotation. TDA with the Bryan disc demonstrated an increase of 25% in flexion-extension, 8% in lateral bending, and 1% in axial rotation.[67]

PEARLS

1. Disc arthroplasty is the most favorable intervention when degenerative conditions of the anterior cervical spine are largely limited to pathology of the disc with a sparing of degeneration of the facet joints.
2. During the procedure, the surgeon should intermittently relax retraction to allow recovery of surrounding soft tissues. This has been suggested to decrease the duration and severity of postoperative dysphagia.
3. Care should be taken to size the disc prosthesis appropriately.[68] A prosthesis should be selected that optimally covers the vertebral body endplates on AP and lateral fluoroscopic views. Implant-specific sizing and alignment guides should be used judiciously.
4. Proper orientation of the implant is crucial to a successful outcome.[68] The AP fluoroscopic view should be oriented so that the spinous process is equidistant between the pedicles of the cranial and caudal vertebral bodies. The surgeon should ensure that the midline is well marked after it has been determined fluoroscopically and should be careful not to stray from the midline during implant preparation. The surgeon should ensure that the implant is directly in the center of the disc space on the AP view. Implant-specific instrumentation should be employed for the purposes of endplate preparation and distraction.

PITFALLS

1. Lack of meticulous hemostasis has been implicated as a factor in HO.
2. Care should be taken not to overdistract the posterior facets during implantation of the device.

KEY POINTS

1. Cervical disc arthroplasty is proposed as a safe, effective alternative to ACDF in patients with symptomatic cervical radiculopathy or myelopathy related to cervical DDD.
2. Cervical arthroplasty is designed to preserve motion and avoid some of the limitations and morbidity of cervical fusion, such as pseudarthrosis, bone graft harvest and allograft issues, anterior cervical plating, and cervical immobilization.
3. In addition to the primary goal of relief of symptoms from cervical DDD, the technique of cervical arthroplasty has been theorized to provide an advantageous biomechanical environment that may counter the adjacent-segment degeneration that has been observed in patients treated with ACDF.

4. At 24 months, arthroplasty seems to compare favorably with traditional ACDF in prospective randomized multicenter trials examining the outcomes of devices including the Bryan, Prestige ST, and ProDisc-C devices.
5. Intermediate-term and long-term follow-up are crucial to the assessment of devices used in this technique because the short-term data may not be an appropriate representation of the primary and secondary outcomes for motion-sparing technologies.

SECTION VI

THORACIC AND LUMBAR DISC DISEASE

This page intentionally left blank

45 CHAPTER Thoracic Disc Disease

Bradford L. Currier
Jason C. Eck
Frank J. Eismont
Barth A. Green

Thoracic disc herniation is an uncommon disease. Diagnosis is often difficult owing to myriad presenting symptoms. Advances in diagnostic methods, specifically magnetic resonance imaging (MRI), have led to earlier diagnosis of both symptomatic and asymptomatic disc herniation. The natural history of thoracic disc herniation is unclear because improved diagnostic methods identify an increasing prevalence of asymptomatic thoracic herniated discs. The vast majority of thoracic disc herniations remain asymptomatic and are treated nonoperatively. However, surgery generally is regarded as the treatment of choice for a symptomatic herniated thoracic disc with myelopathy to prevent the sequelae of spinal cord compression. The prognosis associated with surgical decompression has improved dramatically with selection of surgical approach and the advent of techniques for disc excision without cord manipulation.

Historical Background

In 1838, Key[1] wrote the first report of a thoracic herniated disc causing spinal cord compression. Middleton and Teacher[2] reported the second case 73 years later. The first reported surgical treatment of a thoracic herniated disc was in 1922 by Adson, who performed a laminectomy and disc removal.[3] In their classic 1934 monograph on ruptured intervertebral discs, Mixter and Barr[4] described four cases of thoracic disc herniation; two of three patients treated surgically via laminectomy were rendered paraplegic, emphasizing the challenge in the management of the disease. In the ensuing years, many reports helped define the disease and document that treatment by laminectomy was unpredictable and very risky.[3,5–16]

The costotransversectomy approach was introduced by Menard[17] in 1900. Capener[18] later modified the procedure for use in the treatment of Pott disease. At Alexander's suggestion, Hulme[19] was the first to use this approach in the management of a herniated thoracic disc. Hulme reported his experience with six patients treated by costotransversectomy and showed that it was a safer, more effective approach than laminectomy. In a later literature review of 49 surgical cases using costotransversectomy, Arce and Dohrmann[20] noted that 82% of patients improved, the condition was unchanged in 14% of patients, and only 4% of patients experienced worsening of their condition.

Hodgson and Stock[21] popularized the anterior approach to the spine for the treatment of Pott disease. In 1958, Crafoord and colleagues[22] reported the first transthoracic procedure on the spine for a herniated disc. They performed a *fenestration,* or windowing, of the disc without any attempt at disc removal or cord decompression. The one patient described in their article did well. Simultaneous reports by Perot and Munro[23] and Ransohoff and colleagues[24] in 1969 established transthoracic spinal cord decompression as a viable alternative to costotransversectomy. The posterolateral approach to the thoracic disc space was described by Carson and colleagues[25] in 1971 and was modified by Patterson and Arbit[26] in 1978.

All the surgical approaches have undergone minor modifications, including the application of microsurgical techniques.[27–29] Developments in the use of video-assisted thoracoscopic surgery (VATS) have provided an additional option in surgical treatment of a symptomatic thoracic herniated disc.[30–33] Each technique has advantages and disadvantages, and all but laminectomy are currently acceptable.

The diagnostic use of MRI has had a profound influence on the treatment of thoracic disc herniation.[34–42] At most centers, MRI has replaced myelography as the standard for the diagnosis of this condition. Because MRI is rapid, noninvasive, and increasingly available, its use is likely to decrease delay in diagnosis and lead to earlier treatment and perhaps improved prognosis. A new challenge is likely to be avoiding overdiagnosis and unnecessary operations on asymptomatic lesions.[41,43]

Epidemiology

The true incidence of thoracic herniated discs is unknown; many cases go unrecognized, or patients are asymptomatic. Most patients are in the fourth through sixth decades of life (Fig. 45.1).[3,6,44,45] In a review of 288 cases reported in the literature, Arce and Dohrmann[44] noted a slight male preponderance (1.5:1), although most series show an approximately even sex

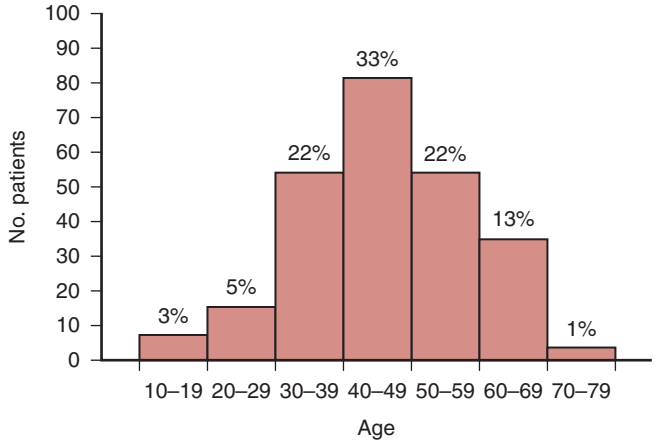

FIG. 45.1 Distribution of 280 cases of thoracic disc herniation according to age. (From Arce CA, Dohrmann GJ. Herniated thoracic disks. *Neurol Clin.* 1985;3:383–392.)

distribution.[5,11,46,47] Cases have been reported in patients ranging in age from 11 to 75 years.[25,48,49]

Historically, only 0.15% to 4% of all symptomatic protrusions of an intervertebral disc are in the thoracic spine.[3,5,6,12,44,50–52] Surgically, thoracic disc excision accounts for 0.2% to 1.8% of all operations performed on symptomatic herniated discs.[5,29,39,44,53–56] In 1950, Love and Kiefer[47] reported on 17 cases seen over 26 years. Logue[12] reported a thoracic herniated disc in 11 of 250 discectomies (4%). Otani and colleagues[51] later reported symptomatic thoracic disc herniation in 15 of 857 discectomies (1.8%) over a 15-year period. In a cadaveric study, Haley and Perry[57] showed that 11% of unselected autopsies revealed protruded thoracic discs; 2 of 99 specimens in their series had discs protruding 4 to 7 mm into the canal. The prevalence of herniated thoracic discs with an associated neurologic deficit has been estimated to be 1 per 1 million population.[25,42,47,52,58]

Improvements in imaging techniques have resulted in an increased detection of thoracic abnormalities and, concurrently, of herniated thoracic discs. Ryan and colleagues[59] reviewed 270 patients undergoing computed tomography (CT) of the thorax for suspected malignancy and found four (1.5%) who had asymptomatic calcified herniated thoracic discs. In a retrospective review of combined CT and myelography in 360 patients, Awwad and colleagues[60] found 54 herniations of a thoracic disc in 40 patients (11%) who were asymptomatic. In their study, 88% of the asymptomatic thoracic discs showed some deformity of the spinal cord; there was no single feature or combination of features clearly separating asymptomatic from symptomatic thoracic herniated discs.

The advent of MRI and its inherent sensitivity has increased further the reported incidence of thoracic disc herniations. Williams and colleagues[41] retrospectively reviewed 48 patients who underwent MRI for oncologic evaluation and reported a thoracic herniated disc in seven (15%). Ross and colleagues[39] diagnosed 20 cases (16 confirmed) by MRI in a 2-year period compared with the initial report of Love and Kiefer[47] in 1949 of 17 cases seen over a 26-year period. Wood and colleagues[42] reported that 66 of 90 asymptomatic individuals (73%) had positive anatomic findings at one or more thoracic levels. Findings included herniation of a disc in 33 subjects (37%), bulging of a disc in 48 (53%), an annular tear in 52 (58%), and deformation of the spinal cord in 26 (29%). These investigators reported no association between age and the prevalence of disc herniation. Compared with the MRI findings of 18 patients treated operatively for thoracic disc herniations in their study, the overall prevalence of these findings in the group that had thoracic pain was not significantly different from the asymptomatic population.

Williams and colleagues[41] suggested that thoracic disc herniation may be common enough to be considered a normal variant on MRI. More recently, Niemelainen and colleagues[61] reported that degenerative thoracic MRI changes were less common than previously reported. In a cross-sectional study of men 35 to 70 years old from the Finnish Twin Cohort study, only 9.2% of subjects had posterior disc bulging. Anterior disc bulging was much more common, found in 45.2%. The presence of anterior disc bulging was positively correlated with age ($r = 0.15$ to 0.23, $P < .005$). Moderate to severe disc height narrowing ranged from 5.4% to 9.5% by level in the thoracic spine.

Etiology

Most authors favor degenerative processes as the major cause of thoracic disc herniation.[3,20,57] This theory is supported by the higher incidence of herniation in the thoracolumbar spine, where greater degenerative changes occur.[34,40,62] In a review of MRI findings and their relationship to thoracic and lumbar disc degeneration in a cohort of 232 subjects, Videman and colleagues[40] noted that moderate and severe osteophytes were most common at the T11–T12 level (20.7% of subjects); upper endplate irregularities were most common at levels T8–T12, typically in the middle of the endplates in the thoracolumbar spine compared with more peripheral endplate changes in the lumbar spine. These results were later supported by Niemelainen and colleagues,[61] who reported moderate to severe disc height narrowing in 21.4% of subjects.

The role of trauma as a cause of herniated thoracic discs is controversial. A history of trauma can be elicited in 14% to 63% of patients.[35,45] The mean prevalence in 10 random series was 34%. In some patients, the causal relationship is undeniable; in others, trauma may have been an aggravating factor or purely coincidental. The degree of reported trauma responsible for herniation ranges from minor twisting strains and chiropractic manipulation to major falls or motor vehicle accidents.[63]

Several authors[35,54,64] have suggested an association between Scheuermann disease and herniated thoracic discs. The primary pathogenic process of the disease or secondary disc degeneration may be the factors promoting herniation. Wood and colleagues[42] noted that endplate changes consistent with Scheuermann disease were more prevalent in their symptomatic patient group than in the asymptomatic population.

Pathogenesis

The pathogenesis of neurologic compromise secondary to herniated thoracic discs is believed to be a combination of direct neural compression and vascular insufficiency.[2,3,6,12,26] Middleton and Teacher[2] suggested this in a case reported in 1911. Severe back pain developed while this patient was lifting a heavy object. Approximately 20 hours later, he felt a sudden severe pain shoot from his chest to his feet and he became almost completely paraplegic. The patient died 16 days later of urosepsis. The autopsy revealed a herniated thoracic disc opposite a section of cord that was compressed, degenerated, and hemorrhagic. A thrombosed vessel was found in the section of cord showing the most hemorrhage.

Several anatomic features make the thoracic cord vulnerable to manipulation and trauma.[26] The thoracic spinal canal is small, and most of its available space is occupied by the cord. The blood supply to the cord is tenuous in this region, especially in the "critical zone" of T4–T9.[65] In addition, thoracic disc protrusions are more common centrally than laterally, are often calcified, and may adhere to or penetrate the dura.[3,12,16,20,23,66,67]

The theory of direct compression causing neural compromise is supported by the report by Logue[12] of a patient who died after a 14-month course of progressive paraplegia. The autopsy showed extreme distortion of the cord, but the anterior spinal artery and vein were patent and showed no evidence of damage. Kahn[68] suggested that, in addition to direct anterior compression by the herniated disc, the dentate ligaments may resist posterior displacement of the cord, leading to traction and distortion of neural structures.

Vascular insufficiency has been the explanation for unusual cases, such as cases with transitory paresis and instances in which the segmental level of involvement was higher than expected from the location of the herniated disc.[3,6] Significant neural deficits may be caused by herniations that appear too small to cause significant compression. This theory also helps explain patients who show no improvement after complete decompression and patients who had an abrupt onset of paraplegia in the presence of a chronic calcified disc. The theory is supported by patients in whom the disc herniation has been shown to cause anterior spinal artery thrombosis.[12]

Doppman and Girton[69] performed an angiographic study on animals on the effect of laminectomy in the presence of acute anterior epidural masses. They found that when decompression restored normal arteriovenous hemodynamics, the animals were neurologically intact despite significant cord distortion. When either the artery or the vein remained obstructed, however, the animals remained paraplegic.

Clinical Presentation

There is extreme variation in the clinical presentation of patients who have a herniated thoracic disc. This variation explains why no clear-cut syndrome has been identified. The signs and symptoms may depend on the location of herniation in the sagittal plane and transverse plane. Additional factors may include size of the lesion, duration of compression, degree of vascular compromise, size of the bony canal, and health of the spinal cord.

In symptomatic cases, the condition is dynamic and can progress.[9] Tovi and Strang[16] outlined the usual chronologic progression, which begins with thoracic pain followed by sensory disturbances, weakness, and finally bowel and bladder dysfunction. Arce and Dohrmann[20] confirmed this pattern in their review of the literature: of 179 patients who described their initial symptoms, 57% described pain, 24% described sensory disturbance, 17% described motor weakness, and 2% described bladder dysfunction (Table 45.1). By the time of presentation, 90% of the patients had signs and symptoms of cord compression, 61% had motor and sensory complaints, and 30% had bowel or bladder dysfunction (Table 45.2). The duration of symptoms before presentation ranged from hours to 16 years in one series.[3] In a report of 55 patients initially treated conservatively, Brown and colleagues[70] reported anterior bandlike chest pain as the most common early symptom in 67% of patients; lower extremity complaints were present in 20% of patients and ranged from paresthesia (4%) to frank muscle weakness (16%). Additional symptoms included intrascapular pain (8%) and epigastric pain (4%).

Thoracic pain can be midline, unilateral, or bilateral, depending on the location of the herniation. In some cases, there may be no pain. Coughing and sneezing may aggravate pain, as with herniated discs in the cervical and lumbar regions. With herniation of the T1 disc, the pain may be in the neck and upper extremity, and simulate a cervical disc problem, causing upper extremity numbness, intrinsic muscle weakness, and Horner syndrome.[5,26,71]

When the herniation is in the midthoracic spine, radiation of pain into the chest or abdomen can simulate cardiac or abdominal disease, clouding an already complex clinical

picture. In the four cases reported by Epstein,[7] one patient underwent an unnecessary thoracotomy for excision of a pericardial cyst, hysterectomy and salpingo-oophorectomy were performed in another patient, and a third patient almost underwent an abdominal exploration for endometriosis before the true cause of her symptoms was identified. Pain from a lower thoracic disc herniation may radiate to the groin or flank and simulate ureteral calculi or renal disease.[62,72,73] Abdominal wall paresis and abdominal hernia have also been presenting signs for thoracic disc herniations.[74,75] Herniated discs at the lowest thoracic levels can impinge on the cauda equina and on the distal spinal cord, causing lower extremity pain or weakness and mimic a herniated lumbar disc.[76,77] On physical examination, flexion of the neck may induce back or root pain with lesions below the midthoracic level.[25] A thorough neurologic examination is mandatory; the examiner should pay close attention to long tract signs and other evidence of myelopathy. Cases of unexplained abdominal pain or lower extremity complaints with normal abdominal and lumbar imaging should be evaluated for the possibility of thoracic disc herniation.[78,79]

Some investigators believe that the occurrence of pronounced sensory changes with relatively minor motor deficits is highly suggestive of a herniated thoracic disc.[25,80] Sensory disturbances, motor weakness, sphincter dysfunction, and gait abnormalities should direct the examiner's attention to the nervous system as the source of the problem.

Level and Classification of Herniation

Three-fourths of cases occur between T8 and L1; the peak is at T11–T12, where 26% to 50% of herniations occur (Fig. 45.2).[20,40] Herniations are uncommon in the upper thoracic spine.[20,26,71] Haley and Perry[57] found a similar distribution in their cadaveric study of 99 spines and theorized that the increased incidence in the thoracolumbar area is due to the greater degree of motion in this region. The reason that the incidence at T11–T12 is greater than that at T12–L1 (9%) may be the facet orientation. Malmivaara and colleagues[81] believed that the coronally oriented facets in the upper thoracolumbar region have less torsional resistance than the sagittally oriented facets at T12–L1; thus, the T11–T12 disc is exposed to greater stress and has a high likelihood of degeneration.

Herniated thoracic discs can be classified by location or by symptoms. Most authors describe the location of the herniation as central, centrolateral, or lateral, and roughly 70% of the cases are either central or centrolateral.[20,60] In a comparison of characteristics on CT myelography of asymptomatic and symptomatic herniated thoracic discs, Awwad and colleagues[60] reported that 90% of herniations were central or parasagittal versus lateral in asymptomatic patients, whereas 80% were central or parasagittal in symptomatic patients. No identifiable radiographic features could reliably classify a herniated thoracic disc as symptomatic or asymptomatic. Abbott and Retter[5] classified cases by symptoms and reported that lateral protrusions cause root compression, and that patients have radicular

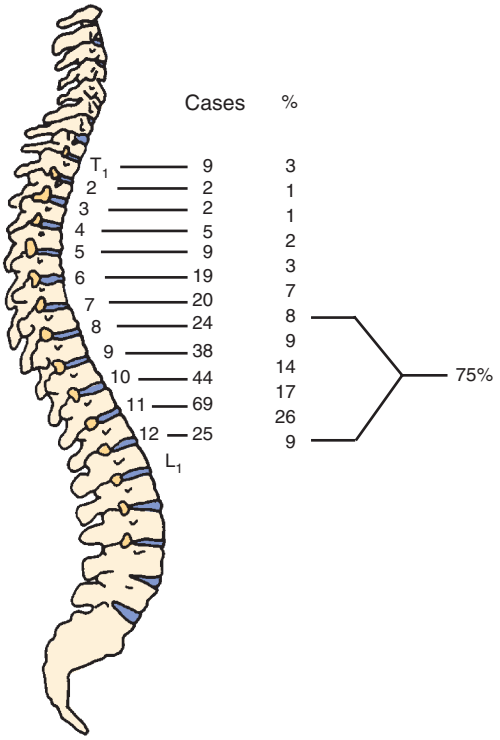

FIG. 45.2 Levels of thoracic disc protrusion in 280 cases. (From Arce CA, Dohrmann GJ. Herniated thoracic disks. *Neurol Clin.* 1985;3:383–392.)

pain and minimal or no signs of cord compression. Patients with central disc herniation in the upper and middle thoracic spine can have signs of myelopathy caused by spinal cord compression. Protrusions at T11 and T12 compress the conus medullaris and cauda equina, and may cause pain referred to the lower limbs and sphincter disturbance.

Few cases of intradural herniation of thoracic discs have been reported, suggesting that the incidence is low.[3,8,16,26,82–86] Love and Schorn[3] reported a series of 61 cases in which seven (11%) showed disc erosion through the anterior dura. In a review of the literature, Epstein and colleagues[83] noted that 5% of all intradural disc herniations were found in the thoracic spine. Similar to the cervical spine, the low incidence was attributed to the lack of significant dural adhesions of the thoracic dura to the posterior longitudinal ligament and anulus fibrosus. Patients with intradural thoracic disc herniations tended to present with a higher incidence of Brown-Séquard syndromes and paraplegia.[44] In most cases, the presence of an intradural thoracic disc herniation is not identified preoperatively. CT myelography seems to have a higher sensitivity to detect this than MRI even with the addition of gadolinium.[82]

The exact incidence of multilevel herniations is unknown.[5,14,35,87] Arseni and Nash[6] reviewed the literature in 1960 and found multiple herniations in only 4 of 106 cases reported. A report by Bohlman and Zdeblick[35] suggested, however, that the incidence may be much higher than previously recognized. Of their 19 patients, three (16%) had herniations at two levels. The sensitivity of MRI may be partially responsible for this increased frequency.[37,39] Ross and colleagues[39] reported that three of 13 patients (23%) whose

herniation was diagnosed by MRI had multilevel involvement; Wood and colleagues[42] reported multiple disc herniations in 39% of asymptomatic volunteers that were diagnosed by MRI. These rates are similar to the findings in the autopsy study by Haley and Perry,[57] in which two of seven patients had more than one protruded disc.

Van Landingham[64] suggested an association between Scheuermann disease and multilevel herniation. Wood and colleagues[42] noted that endplate changes consistent with Scheuermann disease were more prevalent in the group with thoracic pain and disc herniation than in the asymptomatic population. Conversely, Lesoin and colleagues[54] reported six cases of single-level herniations only in patients with Scheuermann disease, suggesting a lack of significant association with multiple herniations.

Natural History

There are few long-term reports of untreated adults with herniated thoracic discs. In 1992, Brown and colleagues[70] reported a 2-year follow-up on 55 patients found to have thoracic disc herniation on MRI and concurrent pain; 11 (20%) initially had lower extremity complaints. Initial treatment in 54 patients included bed rest; nonsteroidal antiinflammatory drugs; and controlled physical therapy involving hyperextension strengthening, postural training, and body mechanics education. Ultimately, 15 patients (27%) underwent operation. Of the remaining 40 patients treated nonoperatively, 31 (78%) returned to their prior level of activity. Nine of the 11 patients presenting with lower extremity complaints of pain or weakness underwent operation; 55% of herniated discs in the operative group were at or below T9. In contrast, 48% of the discs in the nonoperative group were at T6–T9.

In patients with lower extremity complaints, the natural history of the disorder is typically one of progression, and nearly all patients eventually undergo operation for progressive neurologic deficit or unremitting pain.[3,11] The most characteristic chronologic progression of symptoms is pain followed by sensory disturbance, weakness, and bowel and bladder dysfunction.[16] The course can be extremely variable, however, and it is unknown whether neurologic signs or symptoms ever would have developed in patients operated on for pain alone. Some patients might have improved spontaneously if not subjected to surgical treatment. Haro and colleagues[88] reported on two patients with acute onset of symptomatic thoracic disc herniation with signs of myelopathy that resolved without surgery. Both patients had lower extremity signs of myelopathy, but neither developed bowel or bladder dysfunction or progressive motor weakness. Treatment with steroids and prostaglandin E_1 led to resolution of symptoms and resorption of thoracic disc herniation on follow-up MRI scans.

Arseni and Nash[6] described two general patterns for the time course of symptoms. The first, which occurs in younger patients with a history of trauma, is backache that can be followed by a rapidly evolving myelopathy. In the second pattern, which typically occurs in patients past middle age who have degenerative disc disease without any significant trauma, signs and symptoms of cord compression develop slowly and progressively. Tovi and Strang[16] found that when the first symptom to develop was unilateral, the course tended to be one of slow progression with periods of stabilization and occasional slight remission. Rapid, irreversible progression generally was noted in cases with a bilateral onset.

Calcification of the disc in children is considered to be a painful but self-limited process, with eventual resolution of the pain and resorption of the calcified deposit. It generally occurs in the cervical spine. About half of cases are preceded by a history of trauma (30%) or upper respiratory tract infection.[89,90] The natural history of herniated calcified thoracic discs in children was reviewed by Nicolau and colleagues.[91] The course was similar to cases without herniation; the patients improved spontaneously as the calcified fragment resorbed. The progression is not always benign, however. Two cases in children have been reported in which myelopathy developed from cord compression and required operation.[13,67]

Disc calcification in adults differs from that in children. The thoracolumbar spine is the most frequent site of calcification, and the condition is generally asymptomatic unless herniation of the disc occurs.[89] The deposits may accelerate degeneration by interfering in the biomechanics and nutrition of the disc.[89,92] Disc calcification is found on routine radiographs in 4% to 6% of patients without disc herniation compared with up to 70% of patients with disc prolapse.[12,89] The natural history of disc herniation in adults has not been conclusively shown to be altered by disc calcification.

Differential Diagnosis

Love and Schorn[3] reported that before myelography the correct diagnosis was made in 13 of 61 patients and was considered in the differential diagnosis in only 7 others; even after myelography, the correct diagnosis was made preoperatively in only 56% of patients. With greater awareness of the diagnosis and improved imaging techniques now available, the correct diagnosis should be made before operation in almost all cases.

The differential diagnosis of back pain includes spinal tumors, infection, ankylosing spondylitis, fracture, intercostal neuralgia, herpes zoster, and cervical and lumbar herniated discs. Diseases of the thoracic and abdominal viscera may have a similar presentation. Neurosis is another possibility. The differential diagnosis of myelopathy includes demyelinating and degenerative processes of the central nervous system (CNS), such as multiple sclerosis and amyotrophic lateral sclerosis.[93,94] Intraspinal tumors, brain tumors, and cerebrovascular accidents also should be considered.[20,63]

In patients who have a neurologic deficit and radiographic evidence of Scheuermann disease, the differential diagnosis includes an extradural cyst or compression from an angular kyphosis.[54,95] In the series by Lesoin and colleagues,[54] the mean age of the patients who had a herniated thoracic disc in association with Scheuermann disease was 44 years, similar to the population without Scheuermann disease. This is in contrast

to a mean age of 17 years in three patients in whom neurologic compromise developed secondary to bony cord compression at the apex of the kyphosis.[95]

Diagnostic Evaluation

Spine Radiographs

Plain radiographs of the spine generally are diagnostic only if they show disc calcification. The calcified disc is not always the one that is herniated, but the association at least suggests the diagnosis.[3,96] A calcified disc in the canal is pathognomonic of disc herniation.[12,27,28,96] Baker and colleagues[96] identified two radiographic patterns of calcification (Fig. 45.3). One consisted of extensive calcification posteriorly in the interspace and bulging into the canal. The other pattern, which is subtle and often overlooked initially, is a small nidus just posterior to the narrowed interspace. Studies[35,59] of adult lumbar discs have shown that the deposits may be calcium pyrophosphate dihydrate or calcium hydroxyapatite. The clinical significance of the different radiographic patterns or chemical compositions has not been determined.

The proposed association between Scheuermann disease and herniated thoracic discs has been discussed previously. A patient found to have kyphosis with vertebral body wedging and endplate irregularity in association with back pain or a neurologic deficit should undergo other studies to eliminate the possibility of a herniated disc. Other radiographic findings, such as narrowing and hypertrophic changes, are nonspecific and are not helpful in the diagnosis.[3,12,96]

Myelography

The thoracic spine is difficult to image by myelography because of the thoracic kyphosis and superimposition of mediastinal structures. Myelography alone is diagnostic in only 56% of cases and has a false-negative rate of 8%.[3] A complete block is found in 10% to 15% of cases.[16,96] Myelography is performed by injecting water-soluble contrast agent in the lumbosacral canal, removing the spinal needle, and placing the patient supine so that the contrast agent pools in the dependent thoracic kyphosis.[36] Anteroposterior and lateral films are essential. A herniated disc appears as a central filling defect at the level of the disc space (Fig. 45.4). Central protrusions produce discrete oval or round filling defects. In large protrusions, a complete block occurs with a blunt, convex leading edge.[12,96] Lateral discs produce triangular or semicircular indentations with displacement of the cord to the opposite side (Fig. 45.5).[96] Evaluation of cerebrospinal fluid (CSF) at the time of myelography is nonspecific.[9] The protein content is increased in less than 50% of patients and helps only to focus attention on the central nervous system. It generally is in the range of 50 to 100 mg/dL but may be greater than 400 mg/dL.[53] Currently, myelography is most helpful in localizing lesions to allow directed CT and in preparation for operation.[35,97]

Computed Tomography

Enhanced CT after myelography with a water-soluble contrast agent is an extremely valuable technique, which has been the diagnostic standard (Fig. 45.6).[35,36,39,44,50,60] When combined with standard myelography, CT not only improves sensitivity and accuracy, but also detects intradural penetration of the disc.[44,83]

CT alone may be helpful when the disc is calcified (Fig. 45.7), but it is not as sensitive as CT with intrathecal injection of a contrast agent.[65] The criterion for diagnosis of a herniated disc by CT is a focal extension of the disc beyond the posterior aspect of the vertebral body with spinal cord compression or displacement.[39]

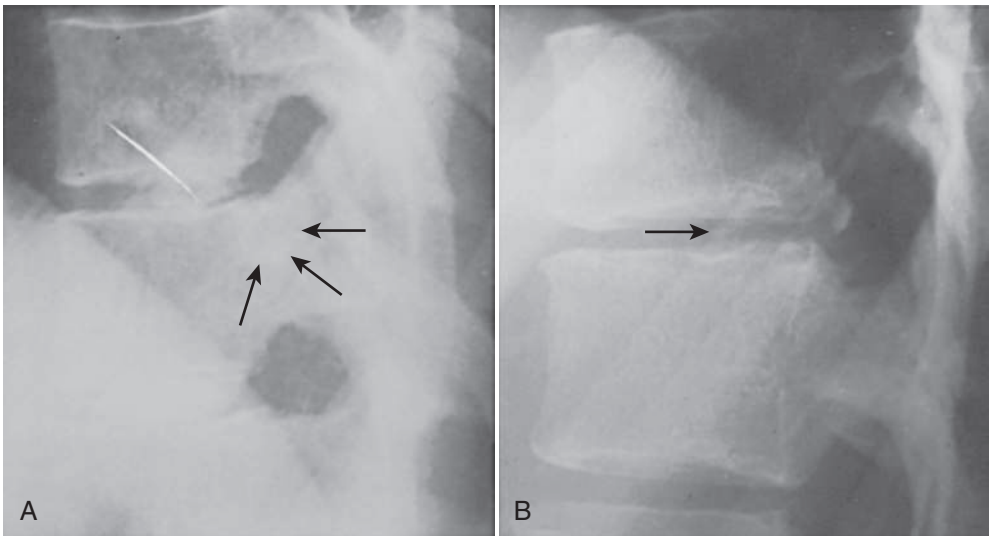

FIG. 45.3 Plain radiographs can be used to diagnose herniated discs only when calcification is seen within the spinal canal. (A) Large calcified disc within canal (*arrows*) is nearly obscured by overlying ribs (see Figs. 45.7 and 45.8, respectively for computed tomographic and magnetic resonance images from the same patient). (B) Tiny nidus of calcium is visible in the canal posterior to the narrowed 11th interspace (*arrow*).

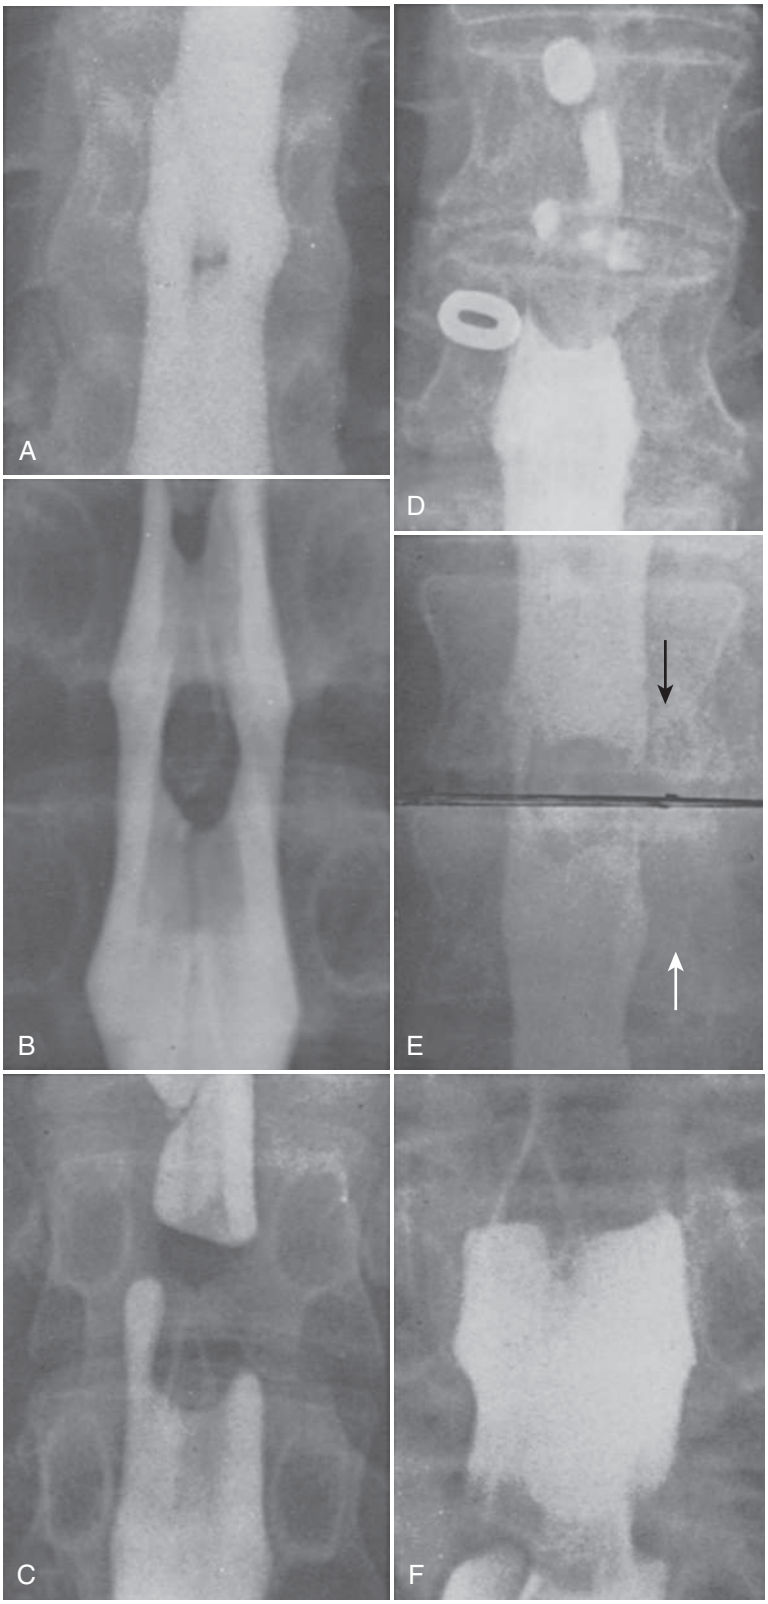

FIG. 45.4 Oval filling defects in the opaque column of an iophendylate (Pantopaque) myelogram resulting from central protruded thoracic discs. Note the midline position of the spinal cord in all cases. (A) Tiny protrusion visible at the T9 interspace. (B) Small protrusion at T12. (C) Moderately large, slightly obstructing protrusion at T12. (D) Large, severely obstructing protrusion at T12. (E) Upper margin was outlined only when oil flowed caudad (*arrows*). (F) Completely obstructing protrusion at T12. Note the blunt, convex leading edge of column. (From Baker HL Jr, Love JG, Uihlein A. Roentgenologic features of protruded thoracic intervertebral disks. *Radiology.* 1965;84:1059–1065.)

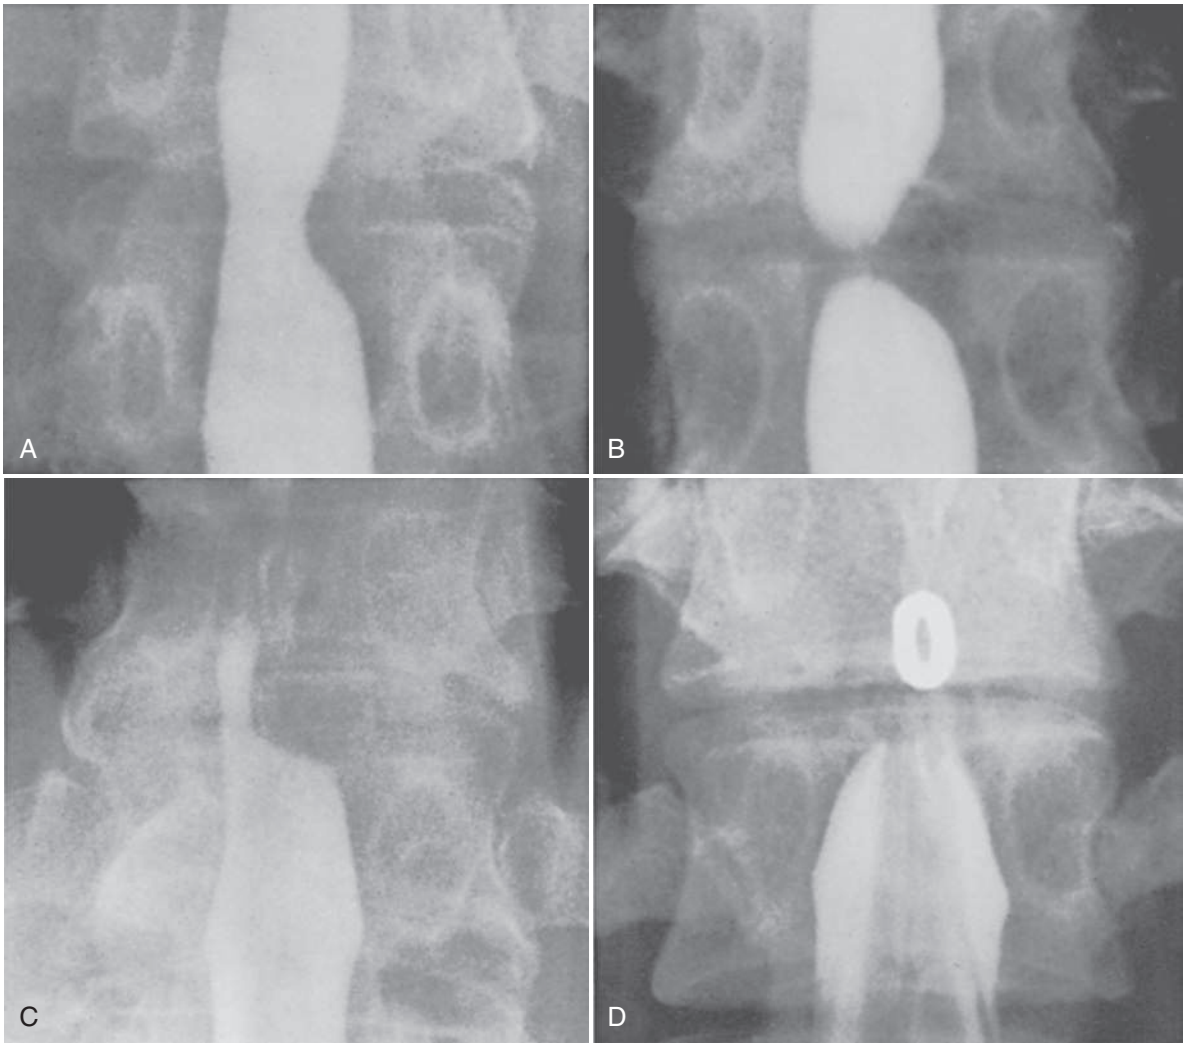

FIG. 45.5 Filling defects in the opaque column of an iophendylate (Pantopaque) myelogram resulting from a lateral protruded thoracic disc. Note the lateral displacement of the spinal cord in several cases. (A) Small lateral protrusion at T11. (B) Moderately large, slightly obstructing protrusion at T10. (C) Large obstructing protrusion at T9. (D) Completely obstructing protrusion at T10. Note the pointing of the column and deviation of the spinal cord to the left. (From Baker HL Jr, Love JG, Uihlein A. Roentgenologic features of protruded thoracic intervertebral disks. *Radiology.* 1965;84:1059–1065.)

Magnetic Resonance Imaging

MRI has revolutionized the diagnostic evaluation of thoracic disc disease. Most centers rely on MRI almost exclusively, but others still perform myelography and CT when operative treatment is being considered.[35–37] MRI is a rapid, noninvasive outpatient procedure that does not use ionizing radiation and causes no morbidity. It is a sensitive and specific technique that makes it easy to obtain sagittal sections of the entire thoracic spine.[36,37,39] Findings on MRI are similar to findings of myelography and CT, but it is necessary to use information from sagittal T1-weighted and T2-weighted and axial T1-weighted images to achieve similar sensitivity (Fig. 45.8).[39]

MRI is a highly technical procedure; the expertise of the radiologist and the design of the scanner determine the accuracy of the test to a great degree. There are pitfalls of MRI, such as partial volume averaging (owing to the relatively large section thickness), the CSF flow void sign (regions of low signal intensity within the fluid owing to its pulsatile motion), signal dropout from calcified discs, chemical shift artifacts from marrow fat, and mismapped signal from cardiac motion.[36,39,98] Addition of gadolinium as a contrast agent has been reported to help in differentiating between thoracic disc herniations and small meningiomas; herniated disc material does not enhance, whereas spinal meningiomas show a very early, homogeneous, and intense uptake of contrast agent.[38]

Despite improved imaging and increased sensitivity, findings of thoracic disc herniation on MRI must be interpreted with caution and closely correlated with clinical findings. Several reports noted significant disc protrusion and spinal cord deformation in 30% of asymptomatic individuals.[42,60] In their large MRI series, Wood and colleagues[42] noted that the overall prevalence of thoracic disc herniation in the group with thoracic pain was not significantly different from the asymptomatic population.

Discography

The general sensitivity but lack of specificity of thoracic MRI in diagnosing painful thoracic disc disease sometimes may require the supplemental use of provocative discography to identify a specific thoracic disc pain source. In a retrospective review, Schellhas and colleagues[99] showed thoracic discography as a safe and reliable technique.

In a controlled prospective study, Wood and colleagues[100] compared MRI and discography in asymptomatic and symptomatic individuals. In asymptomatic volunteers, the mean pain response with discography was 2.4 out of 10. On discography, 27 of 40 discs were abnormal, with endplate irregularities, annular tears, or herniations. Ten discs read as initially normal on MRI showed annular pathology on discography. In symptomatic patients with chronic thoracic pain, the pain response with discography was 6.3 out of 10. Of the 49 discs studied in this group, 55% had a concordant pain response, 39% had a discordant pain response, and 6% had no pain. On MRI, 21 of 49 discs appeared normal; however, on discography, only 10 were judged as normal. The only correlative pathology seemed to be Scheuermann endplate pathology, as seen on MRI, and Schmorl nodes as seen on discography.

In a systematic review of the literature, Buenaventura and colleagues[101] reported there is limited evidence to support the role of discography for the diagnosis of chronic thoracic discogenic pain. Given the general prevalence of degenerative thoracic disc pathology in asymptomatic individuals, discography apparently should be reserved for individuals with interdiscal pathology on MRI and thoracic axial pain unresponsive to an appropriate duration of nonsurgical treatment. Additionally, results from discography can be highly variable based on the examiner. Consideration should be given to the possibility of needle penetration by discography and

deleterious effects from the contrast agent leading to progressive degenerative changes as reported clinically in the lumbar spine as well as in vitro studies.[102,103]

Treatment

The majority of thoracic disc herniations remain asymptomatic and are even considered a normal incidental finding. In these cases, observation is the treatment of choice. Indications for surgery include (1) progressive myelopathy, (2) lower extremity weakness or paralysis, (3) bowel or bladder dysfunction, and (4) radicular pain refractory to conservative measures. Brown and colleagues[70] reported that 77% of patients with radicular pain as the primary presentation improved after a course of physical therapy. In cases of radicular presentation only, some authors believe that if the protrusion is far lateral with nerve root compression only, the situation is not urgent, and the decision to operate should be based on the degree of pain.[7] Conversely, there have been reports of lateral lesions causing severe neurologic deficits from compression of a major medullary feeder vessel.[55] Small herniations also should be respected because abrupt, severe, and irreversible deficits can occur. Some investigators have concluded that there is no relationship between the size of the herniation and the gravity of the clinical picture.[11,27]

In cases of myelopathy and lower extremity involvement, most authors recommend early decompression. In cases of late treatment, favorable results are still possible despite significant delays and the presence of major neurologic deficits.[35] A less aggressive approach may be taken in children because the natural history of the disorder seems to be different.[91]

The surgical management of this disorder has evolved in recent years. Laminectomy with disc excision was the benchmark approach 30 years ago, but has been abandoned because of the risk of neurologic deterioration (Fig. 45.9). After the introduction of alternative techniques of decompression, Ravichandran and Frankel[104] noted a significant decrease in admission to spinal cord injury centers of patients with paralysis after treatment of herniated thoracic discs. In a review of 135 cases, Arce and Dohrmann[20] found that after laminectomy 58% of the patients were improved, 10% were unchanged, 28% were worse, and 4% had died. There is also evidence that patients who do not improve or who are made worse by laminectomy are less likely to be helped by later anterior decompression.[93] The best results are achieved in patients who have lateral lesions above T11, who have minimal neurologic deficits, who have a soft disc, and who are operated on early after the onset of symptoms.[3,7,16,23,84,105,106]

Patients with myelopathy caused by ossification of the posterior longitudinal ligament have worse rates of recovery.[105] Although laminectomy is still occasionally advocated for lateral lesions, most authors think that the procedure is contraindicated.[28,107] Singounas and Karvounis[108] described good results in patients treated by decompressive laminectomy alone without attempted disc removal. Several studies[8,12] described disastrous results with this technique, however. Studies in animals found consistent neurologic deterioration after decompressive laminectomy alone for anterior epidural masses.[69,109]

Costotransversectomy is an effective technique for managing herniated thoracic discs (Fig. 45.10).[10,45,110] Disc excision is performed through a paramedian incision with the patient prone[10] or in a modified lateral decubitus position.[110] The paraspinal muscles are either retracted medially or split transversely.[10,45] The posterior portion of each rib on the side of the herniated disc is excised, and the pleura is mobilized and reflected anterolaterally. The transverse processes and remaining head and neck of each excised rib are removed. The intervertebral foramen is located by tracing the intercostal nerve medially. The foramen is enlarged by partial removal of the corresponding pedicles, and the dural sac is exposed. A

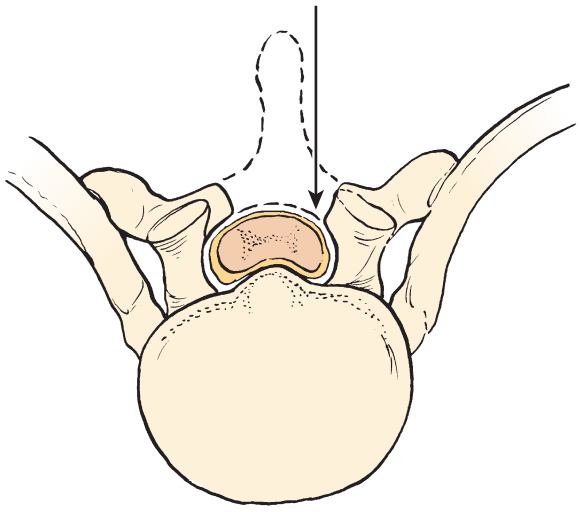

FIG. 45.9 Attempted decompression by laminectomy would require manipulation of the cord and a high risk of neurologic deterioration.

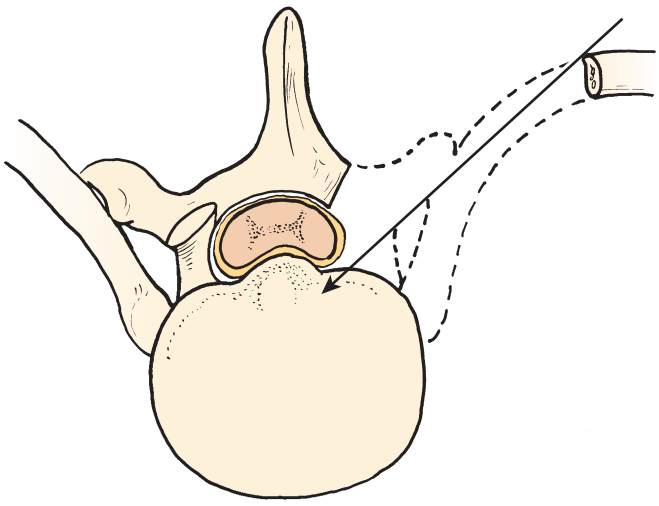

FIG. 45.10 Decompression by costotransversectomy is possible without manipulation of the cord.

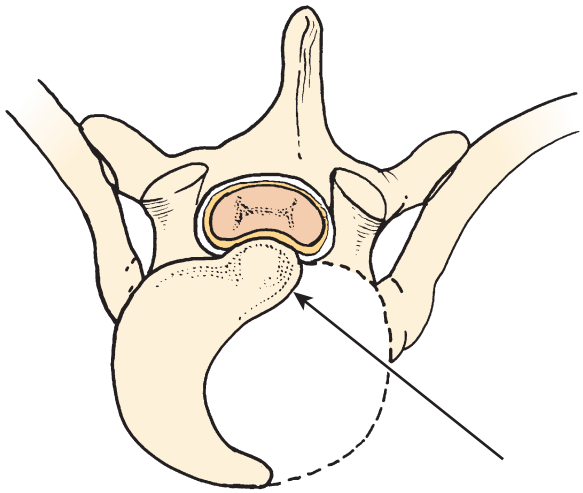

FIG. 45.11 Transthoracic decompression allows the most direct approach to the lesion without manipulation of the cord.

cavity is created in the posterior aspect of the bodies and disc, allowing gentle removal of disc fragments through the defect without manipulation of the spinal cord.[10,45,111,112]

Transthoracic spinal cord decompression has been shown to be a viable alternative to costotransversectomy (Fig. 45.11).[23,24] Advantages include a more direct approach to the lesion and better visualization, facilitating excision of central herniations and herniations with intradural penetration. Disadvantages of the procedure include the potential complications associated with a thoracotomy.

Although many complications have been described after thoracotomy for other disorders, few have been reported after discectomy.[20,23,24,35,46,93,113,114] The results of transthoracic decompression are similar to results of costotransversectomy. In 53 cases collected from the literature, 52 patients improved, and 1 was unchanged. Bohlman and Zdeblick[35] reported the outcome in 19 patients treated by costotransversectomy or transthoracic decompression. The two poor outcomes in their series were in cases treated by costotransversectomy. They concluded that the transthoracic approach with its superior exposure was the preferred procedure. Lubelski and collegues compared results of the lateral extracavitary versus costotransversectomy approaches to the thoracic spine and found similar rates of complications, but slightly increased rates of blood loss and hospital stay with the more invasive extracavitary approach.[115]

Some authors[23,24,49,84,116] recommended preoperative angiography to determine the location of the artery of Adamkiewicz and other major medullary feeder vessels. If such a vessel is found at the level of the disc herniation, the spine could be approached from the opposite side. Alternatively, by carefully avoiding dissection in the neural foramina, this problem can be obviated without the need for an arteriogram. There is generally abundant collateral circulation in the region of the neural foramina that provides blood flow to the cord even with ligation of the artery of Adamkiewicz.[65,117,118] We routinely ligate the segmental vessels adjacent to the herniated disc midway between the foramina and the aorta, and have not observed any untoward effects (Fig. 45.12).[93]

The patient is placed in the lateral decubitus position. A lateral prolapse is best approached from the ipsilateral side; a midline herniation may be approached from either side. In the upper or middle thoracic spine, the right side has the advantage of avoiding the great vessels and the heart. There also is statistically less risk to the artery of Adamkiewicz because this vessel is on the left in approximately 80% of patients.[65] When the herniation is in the lower thoracic spine, a left thoracotomy is preferred because it is easier to mobilize the aorta than the vena cava, and the liver does not crowd the field.[23,35]

The level of rib resection is chosen to give the most direct access to the affected disc (see Fig. 45.12A). A horizontal line drawn on a chest radiograph from the disc space to the chest wall intersects the rib that should be resected. This is generally one to two ribs above the affected disc in the middle and lower thoracic spine.[84] In the upper thoracic spine, the exposure is limited by the scapula; it is generally necessary to excise the fifth or sixth rib, then work craniad.

The recommended extent of bone and disc removal varies from a relatively small trough in the posterior aspect of the disc to complete discectomy with partial corpectomy of the adjacent bodies (see Fig. 45.12B).[23,28,35,84,93] We believe that the latter approach is safer because it provides the greatest degree of visualization and allows complete discectomy without disturbing the foraminal vessels. In either case, great care is taken to perform the decompression without any manipulation or pressure to the spinal cord.

Fusion is indicated when stability is compromised by the decompression and in cases associated with Scheuermann disease.[45] When only a small amount of bone and disc is excised, fusion generally is not recommended.[23,28,35,84] Conversely, with complete discectomy, fusion is mandatory (see Fig. 45.12C). In addition to providing stability, fusion may limit local pain secondary to motion of the degenerated segment. Recurrence of thoracic disc herniation has not been reported, but complete discectomy and fusion theoretically is the best way to prevent this complication. At the conclusion of the procedure, a chest tube is placed and attached to water-seal suction. If fusion has been performed, a thoracolumbosacral orthosis brace should be used.

Otani and colleagues[49] described a modification of the transthoracic procedure in which the pleura is dissected away from the chest wall after rib excision. This modification allows the approach to be entirely extrapleural. Their results were similar to results in other series of transthoracic decompressions. The advantage of the technique is the avoidance of a chest tube postoperatively. Claims of a lower incidence of pulmonary complications may be more theoretical than real because few such complications have been reported, but the reduction in pain caused by the chest tube is a definite advantage.

A posterolateral approach was described by Carson and colleagues[25] in 1971 (Fig. 45.13). They performed a complete laminectomy of the vertebrae adjacent to the herniated disc combined with a medial facetectomy and excision of the transverse process. A T-shaped incision through the erector

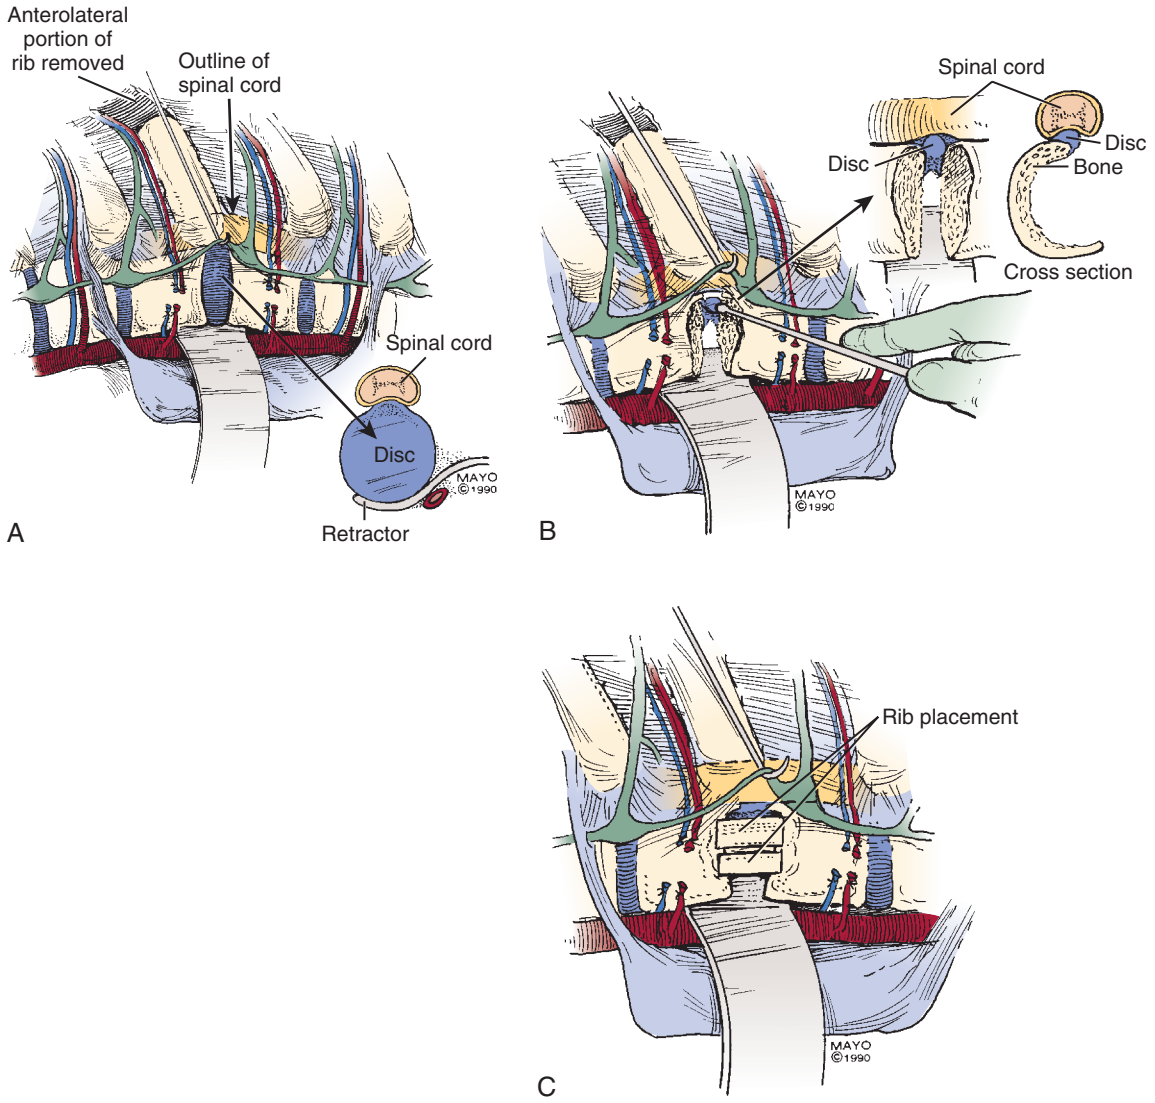

FIG. 45.12 (A) Exposure provided by the transthoracic approach. The great vessels are mobilized by ligation of the segmental vessels midway between the aorta and neural foramina. A malleable retractor may be placed for protection of the great vessels. (B) Complete discectomy and partial corpectomy of adjacent vertebral bodies provides excellent visualization and allows complete decompression without disturbance of collateral vessels within the neural foramina. (C) Fusion is indicated when stability is compromised by decompression. (Courtesy the Mayo Foundation.)

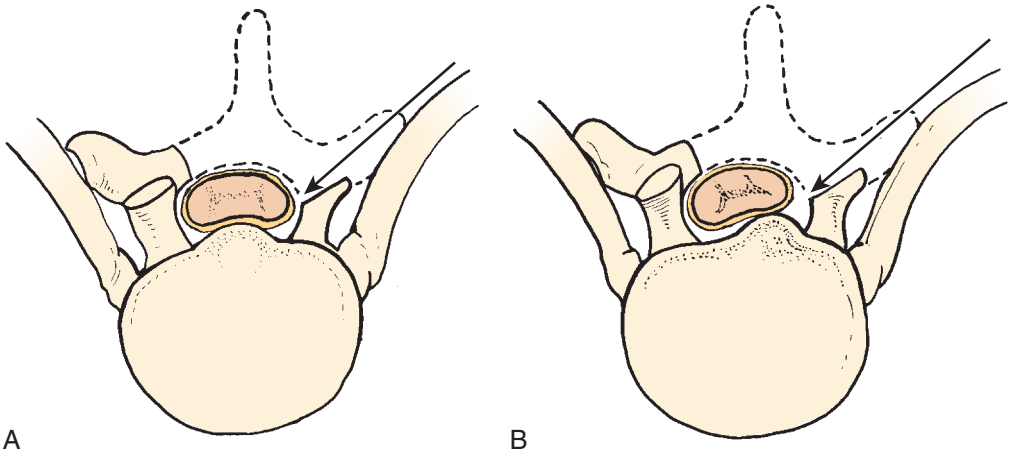

FIG. 45.13 Posterolateral decompression. (A) Removal of central herniation would require some manipulation of the cord. (B) Lateral herniations may be approached by this technique without manipulation of the cord.

muscle of the spine allowed an oblique approach to the anterior epidural space. Patterson and Arbit[26] modified the approach in 1978 to include the removal of the facet and pedicle of the vertebra caudal to the protruded disc through a straight midline incision. The central portion of the disc is removed by creating a cavity. The protruded material is excised by reduction of disc and bone into the cavity before removal. After anterior decompression, a complete laminectomy can be performed. Le Roux and colleagues[53] reported the results of the transpedicular approach and use of the operative microscope in 20 patients; all patients symptomatically improved postoperatively, 40% became asymptomatic, and no complications were noted.

Lesoin and colleagues[27] reported good results with a slightly more extensive exposure in which the transverse process, articular facets, and portions of the adjacent pedicles are removed. The extent of bone removal requires that a fusion be performed; these authors recommended unilateral Harrington rod instrumentation. Spinal deformity has been reported to occur after posterolateral decompression without fusion.[15] In the 45 cases in the literature, 40 patients noted improvement (89%), the condition was unchanged in 3 patients, and it was worse in 1 patient; 1 patient died.[30] Some authors claim that intradural disc herniation can be dealt with much more easily with this approach than with any other; however, approaching anterior dural erosion by this technique requires some degree of manipulation of the cord.[99]

Zhuang and collegues[119] reported on a posterior transfacet approach to thoracic disc herniations. A complete laminectomy was performed, and bilateral facet joints were removed. The disc was exposed and removed bilaterally through the intervertebral foramen. The anterior thecal sac was released posterior to the longitudinal ligament and anulus with a down-biting curette. The superior and inferior portions of the vertebral bodies were then removed as needed with an L-shaped osteotome to allow access to central calcified thoracic discs. This remaining portion of the disc could then be safely removed with down-biting curettes. This technique was performed on 27 patients with excellent recovery in 12 patients, good in 6, fair in 5, and unchanged in 1. No patients were worse postoperatively.

Other, less common approaches have also been described for upper thoracic disc herniations. Ulivieri and colleagues[120] described a transmanubrial osteomuscular-sparing approach for T1–T2 disc herniations. A transvertebral herniotomy has also been reported for a T2–T3 lesion.[121]

Video-Assisted Thoracoscopic Surgery

The continuing evolution of VATS has provided experienced surgeons an alternative approach for thoracic disc herniation decompression. The VATS technique was first described by Mack and colleagues[122] in 1993 for the drainage of thoracic paravertebral abscess. In 1994, Horowitz and colleagues[123] reported the clinical application of VATS for the treatment of thoracic disc herniation. Subsequently, several authors reported larger clinical series documenting the outcome of VATS-treated thoracic disc herniation.[1,19,30–32,56,124–126]

Reported advantages of VATS include reduced perioperative morbidity from minimal surgical dissection and avoidance of rib resection or spreading, enhanced visualization for the operating surgeons and support team, reduced postoperative pain with improved ventilatory excursion, shorter hospitalization and rehabilitation, and consequent decreased overall medical costs.[1,26] Disadvantages of VATS include the required coordination of two operative surgeons, an acquired technical skill set with a steep learning curve, specialized thoracoscopic instrumentation, and the required deflation of the ipsilateral lung for the procedure to be successful.

Indications for VATS application for thoracic disc herniation are similar to the indications for the anterior thoracic approach. The procedure can be performed in patients ranging in age from pediatric to geriatric. The minimally invasive nature of the VATS approach and consequent reduced postoperative pain and inspiratory splinting make this approach applicable in patients less able to tolerate the physiologic effects of open thoracotomy, such as patients with chronic obstructive pulmonary disease or interstitial fibrosis. Patients with contraindications for VATS include patients intolerant of single-lung ventilation and patients with severe or acute respiratory insufficiency, high airway pressures with positive-pressure ventilation, and pleural scarring. Relative contraindications include previous tube thoracostomy or previous thoracotomy. For technical details of the VATS technique, see Chapter 25.

In addition to numerous case reports, several authors have reported on large series of thoracic disc herniation treated by VATS.[30,32,56,124,125] In 1998, Regan and colleagues[32] reported their preliminary experience in 29 patients. Mean operative time was 175 minutes. The surgical complication rate was 14%, primarily from intercostal neuralgia and atelectasis. At 1-year follow-up, 76% of patients related satisfactory results; 24% of patients reported dissatisfaction or no change.

In a further extension of their series, Anand and Regan[30] reported outcomes on 100 consecutive cases with minimal 2-year follow-up. In 100 patients, 117 discs were excised; 40 patients underwent fusion: 27 with autologous rib strut and 13 with a threaded interbody fusion cage. Mean operative time was 173 minutes, mean blood loss was 259 mL, and average length of stay was 4 days. The surgical complication rate was 21%; 75% of the complications were pulmonary related (pleural effusion, pneumothorax, atelectasis, and pneumonia). Intercostal neuralgia occurred in six patients (6%) early in the series and declined subsequent to use of soft flexible intercostal trocars. One patient incurred a 2500-mL blood loss; open conversion to thoracotomy was done in one patient. Five patients underwent reoperation: four for secondary fusion secondary to discogram-positive intractable axial pain and one for pseudarthrosis with a threaded interbody fusion device that was removed and replaced with a rib graft strut.

At final follow-up, 88 patients were available for evaluation. Of the 68 who responded to the patient satisfaction survey, 18% rated their procedure satisfaction as excellent, 54% as good, 16% as fair, and 12% as poor. Oswestry scores improved with 36% of patients with preoperative scores greater than 50 and 23% of patients with preoperative scores less than 50.

Patient satisfaction was greatest in patients with preoperative findings of myelopathy or lower extremity radicular pain or both and least in patients with pure thoracic radicular pain as the preoperative presentation.

Kim and colleagues[124] reported on the use of VATS in 20 consecutive patients with various thoracic pathologies. These investigators found VATS to be an effective minimally invasive technique, but with a steep learning curve.

McAfee and colleagues[56] reported on the incidence of VATS complications in a series of 78 consecutive patients, 41 of whom underwent VATS for thoracic discectomy. Six patients showed a transient postoperative intercostal neuralgia; the incidence diminished with subsequent use of soft trocars. Atelectasis or effusion resulting in a prolonged hospital stay was seen in five patients. Blood loss greater than 2500 mL occurred in two patients. Penetration of the right hemidiaphragm occurred in one case, with mild parenchymal laceration to the liver repaired thoracoscopically without postoperative sequelae. Intraoperative conversion to open thoracotomy was required in one patient secondary to scarring from a previous costotransversectomy.

Hur and colleges[126] used VATS combined with an O-arm CT-based navigation system for treatment of 10 patients with thoracic disc herniation. They reported the addition of 29.4 minutes for the use of the image guidance system, but reported no complications in their series. Additional reported advantages of combining VATS with computer guidance were improved visualization of the operative field, improved surgical planning, optimization of the surgical approach involving the establishment of correct drilling trajectory, and safe decompression of the spinal cord.

Methodologic review of VATS emphasizes the necessity of initial portal placement at the midaxillary sixth or seventh intercostal space to avoid injury to vital organs. The recommended use of soft trocar portals and a meticulous technique emphasizing the constant visualization of all instrumentation tips was believed to be cardinal in the reduction of VATS-associated complications. Gille and colleagues[125] reported on the results of VATS in 18 cases of hard thoracic disc herniation. In 11 of the patients, there was no definitive plane between the calcified disc and the dura. Seven patients developed a dural tear with a high risk of CSF fistula. Four of these seven patients required revision surgery.

Minimally Invasive Techniques

There have been several more recent reports of using minimally invasive techniques for the surgical treatment of thoracic disc herniations.[127–131] In a cadaveric and initial clinical study, Lidar and colleagues[129] reported the minimally invasive technique to be safe and effective. These investigators used a series of sequentially larger tubular dilators inserted on the lateral border of the rib head to allow visualization of the space between the costotransverse joint and caudal border of the costovertebral joint (Fig. 45.14). The joints are disarticulated, and the rib is freed and cut 2 cm distal to the costotransverse joint. The neurovascular bundle is identified and gently retracted. The transverse process is removed. The working tube is inserted deeper and medially. The pedicle is removed, starting at the foramen, allowing access to the disc.

The feasibility of this technique was first verified using four cadaveric specimens. Following that, Lidar and colleagues[129] used the technique on 10 patients with myelopathy secondary to thoracic disc herniation. The mean operative time was 171 minutes (range, 150 to 220 minutes), mean blood loss was 215 mL (range, 60 to 350 mL), and all patients had a one-night hospital stay and returned to work within 4 weeks. There were no documented operative or postoperative complications.

Smith and colleges[131] reported on a series of 16 patients with thoracic disc herniation treated with a minimally

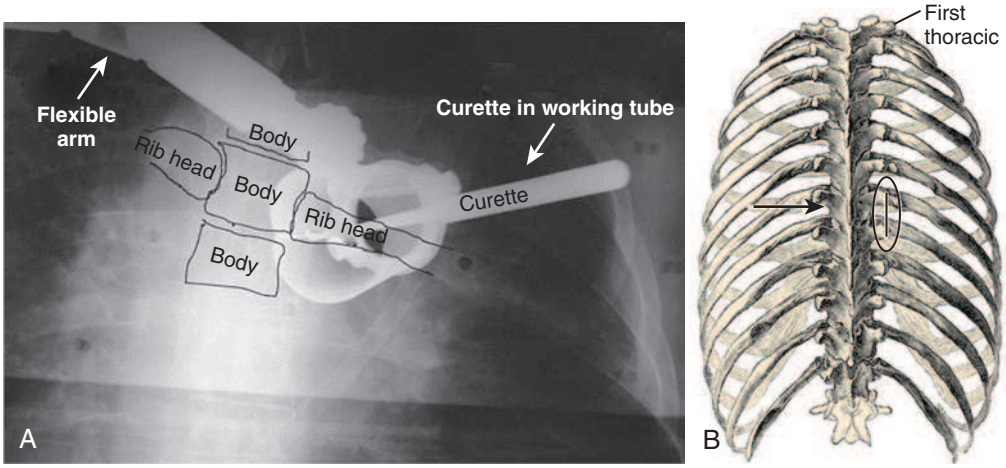

FIG. 45.14 (A) Intraoperative radiograph detailing minimally invasive approach through a dilated tube with a curette placed on the inferior border of the rib head. (B) Schematic drawing showing the working area of the tube. The *arrow* shows the desired discectomy level. The *oval* shows the working tube placement. The *vertical line* inside the oval shows the skin incision. (From Lidar Z, Lifshutz J, Bhattacharjee S, et al. Minimally invasive, extracavitary approach for thoracic disc herniation: technical report and preliminary results. *Spine J.* 2006;6:157–163.)

invasive thoracic microendoscopic discectomy technique. The approach was performed with a tunular retractor system placed through a muscle dilating technique and visualization through an endoscope. No complications were reported, with a mean operative time of 153 minutes per level and hospital stay of 21 hours. Reported outcomes were excellent or good in 13 (81%), fair in 1 (6%), and poor in 2 (13%). The two poor outcomes were related to neurologic diagnoses, not to the surgical approach or procedure.

Summary

Symptomatic herniated thoracic discs are uncommon lesions that usually affect middle-aged adults. Diagnosis is difficult owing to myriad symptoms, and there is no clear-cut clinical syndrome. The natural history is unclear; improved diagnostic techniques have identified an increasing prevalence of asymptomatic herniated thoracic discs. The natural history of symptomatic patients generally is progression, often starting with pain followed sequentially by sensory, motor, gait, and sphincter disturbances. Many patients complain of pain only; others present with painless myelopathy.

Most herniations occur in the lower thoracic region; central protrusions are more frequent than lateral protrusions. Multiple herniations and intradural penetration are uncommon. In most cases, the cause is a degenerative process, but a history of trauma can be elicited in approximately one-third of cases; an association with Scheuermann disease has been suggested by several authors. The pathogenesis of neurologic compromise in thoracic disc herniation is believed to be a combination of direct neural compression and vascular insufficiency. The differential diagnosis is long and requires careful consideration. Radiologic evaluation is essential for the diagnosis, but plain films are helpful only if disc calcification is present. Myelography, CT, and MRI are considered standard diagnostic tools, although no specific imaging features can reliably classify a herniated disc as symptomatic or asymptomatic.

Laminectomy is no longer indicated for treatment of thoracic disc herniation because of a high risk of neurologic deterioration and the fact that it may compromise the results of later anterior decompression. Discectomy may be performed by various surgical approaches: costotransversectomy, transthoracic, posterolateral, or video-assisted. The most rational way to manage the problem may be to select the approach best suited to the disease that is present and to the surgeon's experience. Posterolateral techniques are ideal for lateral lesions and may be the best choice for herniated discs with coexistent stenosis.[132] The transthoracic approach permits the best visualization for central lesions. Upper thoracic lesions are more difficult to approach through the chest and may be managed best by costotransversectomy. Depending on the experience of the surgeon, video-assisted approaches can provide an alternative with reportedly less surgical morbidity. Newer minimally invasive approaches are also being developed that may offer less pain and quicker recovery.

The prognosis of patients who have herniated thoracic discs treated surgically is favorable, and early operative intervention is advised in cases of myelopathy or refractory radicular pain. The techniques are exacting, however, and still carry a significant risk of neurologic deterioration.

PEARLS

1. Of asymptomatic adults, 73% have positive anatomic findings, including 37% with disc herniation and 29% with spinal cord deformation.
2. Disc calcification can be seen in 70% of patients with thoracic disc prolapse.
3. For symptomatic central thoracic disc herniation, the transthoracic approach is probably the safest.

PITFALLS

1. Surgical treatment of thoracic disc herniation by laminectomy has a 28% chance of worsening symptoms.
2. Blood supply to the spinal cord is tenuous in the thoracic spine, especially from T4 to T9, and ligation of blood vessels within the neural foramina should be avoided whenever possible because this may cause paralysis.

KEY POINTS

1. The true incidence of thoracic herniated discs is unknown; many cases are unrecognized, or patients are asymptomatic.
2. Surgically, thoracic disc excision accounts for 0.2% to 1.8% of all operations performed on symptomatic herniated discs.
3. The pathogenesis of neurologic compromise secondary to herniated thoracic discs is believed to be a combination of direct neural compression and vascular insufficiency.
4. A thorough neurologic examination is mandatory; the examiner should pay close attention to long tract signs and other evidence of myelopathy.
5. Indications for surgery include progressive myelopathy, lower extremity weakness or paralysis, bowel or bladder dysfunction, and radicular pain refractory to conservative measures.
6. The recommended extent of bone and disc removal varies from a relatively small trough in the posterior aspect of the disc to complete discectomy with partial corpectomy of adjacent bodies.
7. Reported advantages of VATS include reduced perioperative morbidity from minimal surgical dissection and avoidance of rib resection or spreading, enhanced visualization for the operating surgeons and support team, reduced postoperative pain with improved ventilatory excursion, shorter hospitalization and rehabilitation, and consequent decreased overall medical costs.
8. The prognosis of patients who have herniated thoracic discs treated surgically is favorable, and early operative intervention is advised in cases of myelopathy or refractory radicular pain.

46 CHAPTER Lumbar Disc Disease

Makarand V. Risbud
Gunnar B.J. Andersson

Introduction

The location of the anatomic pain generator in patients with low back pain is often difficult to discern. Pain can originate from several anatomic structures within the spine, making it difficult for both the patient and physician to localize. The intervertebral disc (IVD) is a widely accepted source of chronic low back pain (LBP). A study reviewing magnetic resonance images (MRIs) of patients with persistent LBP showed disc degeneration in 87% of participants.[1] Additionally, patients with severely degenerate discs are 3.2 times more likely to have LBP.[2] Despite this robust link between disc degeneration and back pain, degeneration is a normal consequence of aging that does not routinely cause discomfort, even with a corresponding reduction in biomechanical function.[3,4] However, there is still much work to be done to identify the underlying pathology that distinguishes painful degenerate disc disease from nonpainful age-related changes.

Common subgroups of LBP of IVD origin include lumbar disc herniation, internal disc disruption, and degenerative disc disease. Lumbar disc herniation causes an acute onset of pain, while degenerative disc disease is linked to chronic LBP. Degenerative disc disease also contributes to the pathogenesis of secondary spinal disorders such as spinal stenosis and degenerative spondylolisthesis. Improved understanding of the pathophysiology of IVD disorders has led to a resurgence of enthusiasm in the development of new pharmacobiologics and treatment techniques for this common disorder. New advances in physical therapy and operative technologies, such as IVD replacement and minimally invasive surgical techniques, are challenging traditional methods of treatment.

This chapter discusses the anatomy, pathophysiology, diagnosis, and treatment of primary disc disorders, namely internal disc disruption (IDD) and degenerative disc disease (DDD). Disorders arising secondarily from the IVD are beyond the scope of this chapter.

Natural History

Sixty to eighty percent of the adult population can be expected to experience LBP at some point during their lifetime. The annual incidence of back pain in the adult population is 15%, and its point prevalence is about 30%.[5] By the age of 30 years almost half the population will have experienced a substantive episode of LBP.[6] Fortunately, the vast majority of symptoms are short lived; it is generally believed that 80% to 90% of patients with episodes of LBP will recover within 6 weeks of onset regardless of the type of treatment.[7]

Even though resolution of symptoms is the common and expected outcome, there is also a high recurrence rate. Croft et al.[8] reported that although 90% of subjects stopped pursuing treatment for their symptoms within 3 months, most still had substantial LBP and related disability. In addition, only 25% of the patients who sought consultation for LBP had fully recovered within12 months. In a survey of the British general population, 38% of adults reported a significant episode of LBP within a 1-year period, of which one-third had experienced symptoms for longer than 4 weeks.[9] Inability to return to work within 3 months of symptom onset is a poor prognostic indicator. Only 20% of patients still disabled after 1 year will return to work, and only 2% return after 2 years.[10]

The clinical onset and course of LBP may be prolonged for many patients and may best be represented as a continuum of back-related disability and distress.[11] A significant number of patients presenting with acute LBP have a prior history of chronic back pain.[12] The strongest predictive factor for a new episode of LBP is a previous episode.[13,14]

The natural history of DDD is largely unknown. Smith et al.[15] reported on the outcome of 25 discogram-positive patients treated nonoperatively and found that 68% of patients improved by the 3-year minimum follow-up. Although 60% of the patients were involved with worker's compensation and 32% were being treated for psychiatric diagnoses, this study suggests that at least two-thirds of those with discogenic pain improve with conservative therapy. The retrospective study design and small sample size limit the conclusions, and since only patients with significant symptoms typically undergo discography, the natural history of untreated, less-severe cases of symptomatic DDD is likely to result in more improvement than the cited study.

In their classic description, Kirkaldy-Willis et al.[16] classified the degenerative process into three distinct phases: dysfunction, instability, and stabilization. In the first phase the disc

loses its normal function as the degenerative process begins. This is followed by a period of relative instability as degeneration progresses with intermittent episodes of pain. During the instability phase abnormal motion can occasionally be seen on flexion-extension radiographs; however, the spinal segments during this phase of degeneration more often show no demonstrable radiographic instability. The final phase—stabilization—results when the spinal segment has reached a new equilibrium because of loss of height and compression of disc tissue; at this point the patient typically no longer has episodes of back pain. A problem with this theory is that patients who meet either the radiographic diagnostic criteria of DDD—loss of height, osteophytes, or even olisthesis—or show the MRI signs of disc degeneration—signal changes when compared with adjacent levels—can be completely symptom free. Waris et al.,[17] in a study with 17 years of follow-up MRIs, showed that young patients with DDD did show radiographic evidence of progression, but it was not significantly associated with LBP or a higher rate of surgery.

Relevant Anatomy

The major functional role of the IVD is mechanical; it supports the compressive load of the torso while allowing for polyaxial flexion, extension, and torsion. Although the movement capable of a single spinal motion segment is quite limited, the range of motion supported by the 24 presacral motion segments of the spine in its entirety is remarkable. Found between two rigid vertebral bodies, the disc allows this movement while simultaneously supporting compressive loads. The discs themselves are complex organs comprising central proteoglycan-rich nucleus pulposus surrounded circumferentially by fibrocartilaginous anulus fibrosus. The nucleus pulposus is bound caudally and cephalically by the cartilage end plates of the contiguous vertebrae. Major characteristics of these tissue components of the disc are highlighted below.

Nucleus Pulposus

The central nucleus pulposus is derived from the embryonic notochord, and notochordal cells remain in the tissue after birth and into adult life. During development, the nucleus is highly cellular; after birth and an initial period of cell growth, the number of cells declines. In the adult, the cell density is very low.[18] The histology of the nucleus pulposus cells is unique and complex; large cells are arranged mainly in clusters separated by an abundant extracellular matrix. Among the large notochordal cells, much smaller cells, possibly derived from the notochordal sheath, can also be seen.[19] The large cells appear to have numerous vacuoles, which have prompted some to describe them as "physaliphorus."[20] Transition electron microscopic analysis showed that the nucleus pulposus contained cell clusters embedded in a proteoglycan-collagen matrix. The cells exhibit a well-defined Golgi system, an extensive endoplasmic reticulum, and a complex vesicular system filled with beaded structures. Neither necrotic nor apoptotic cells are evident. Although a defining characteristic of the cells is the presence of numerous cytoplasmic processes, a remarkable finding is that the cells contain few, if any, mitochondria. Moreover, since the nucleus pulposus has no blood supply, the oxygen tension within the disc is very low. These limitations have prompted one study group to note that nucleus pulposus cells "tune" their metabolism to the available oxygen supply.[21] In this case, nucleus pulposus cells rely to a large extent on the glycolytic pathway to generate metabolic energy.[22]

With respect to the extracellular matrix, nucleus pulposus cells secrete aggrecan as well as collagen II and, to a very small extent, collagen I. The matrix also contains collagen IX and XI, and collagen X has also been reported to be present during degeneration. Because of the presence of hydrophilic aggrecan, the disc exhibits a high osmotic pressure. The high water content of a healthy nucleus pulposus, as evidenced by the intense bright signal on T2-weighted MRI, is responsible for supporting compressive loads.

Anulus Fibrosus

Compressive deformation of the nucleus pulposus is limited circumferentially by the anulus fibrosus, which experiences the compressive loads of the torso as hoop stress. Since the anulus fibrosus experiences tensile stress as opposed to compression, its anatomy and biochemical composition are distinct from the nucleus pulposus. The anulus is not a homogeneous tissue; it is divided into an inner region and an outer, or peripheral, fibrous zone.[23] The outer anulus fibrosus is composed of very well-defined collagen I fibers that bundle to form long parallel concentric lamellae. Marchand and Ahmed[24] showed that the number of fiber bundles varies from 20 to 62. The thickness of lamellae varies both circumferentially and radially. Age, location, and vertebral type also influence lamellar architecture. The central anulus fibers insert into the end plate cartilage, whereas those at the periphery anchor to the vertebral bone.

The inner anulus fibrosus represents approximately 50% of the total radial thickness. Many consider the inner anulus a transition zone because it differs substantially from the outer region. Compared with the outer anulus fibrosus, where the cells are elongated and fusiform aligned with the long axis of the fibrils, the cells of the inner anulus are spherical in shape and more closely resemble chondrocytes. These cells are few in number with short processes. A further difference between the inner and outer anulus is their chemical composition. The inner anulus contains collagen I and II as well as versican. Although aggrecan is present in both regions of the anulus, decorin and biglycan are found mainly in the outer anulus. The other protein of significance is elastin, which accounts for 2% of the dry tissue weight and aids the anulus in its role of withstanding cyclic tensile forces.

End Plate Cartilage

The third component of the disc is end plate cartilage, which is located at the junction of the vertebral body and the disc. This thin layer of hyaline-like cartilage is most thick in the

newborn and thins with age. It serves as an interface between the soft nucleus pulposus and the dense bone of the vertebrae as well as a biomechanical barrier that prevents the disc from applying pressure directly to the bone. In addition, the end plate cartilage plays a role in maintaining nucleus pulposus cell viability and controlling biosynthetic activities.[18,25] In the adult human, the width of the end plate is up to 1 mm. It contains chondrocytes embedded in an aggrecan-rich and collagen II extracellular matrix. Although the cells do not undergo terminal differentiation, collagen X may be present in the central region of the end plate, perhaps in relationship to focal areas of endochondral bone formation. The end plate transitions into bone through a region of calcified cartilage. Work in rabbit and rat models suggests that end plate chondrocytes may contribute a cell fraction that makes up some of the nucleus pulposus and the anulus fibrosus in normal development and during injury.[26,27] However, cell lineage studies are required before a definitive contribution of such a homeostatic mechanism is understood. The presence of the cartilage layer provides the motion segment with its jointlike characteristics.

In his review on the end plate, Moore[28] noted that vascular channels penetrate the cartilage during development, but at maturity the vessels become narrow or even obliterated. It is likely that this change impacts the nutrient supply to both the cartilage and the disc. Nachemson et al.[29] showed that, at the tissue periphery, the cartilage is much less permeable to low-molecular-weight dyes. Supporting this, Crock and Yoshizawa[30] showed that the central region of the end plate, where there is a high concentration of channels, is freely permeable to small molecules. Clinically, it is not uncommon to note that the central region undergoes sclerosis or mineralization with alterations in the mechanical properties of the cartilage. When this occurs, nucleus pulposus tissue can be forced through the end plate into the underlying bone of the vertebrae. This phenomenon is referred to as Schmorl's nodes, which Schmorl himself considered to be linked to degenerative changes at the cartilage-bone interface.

Defining the IVD Niche: Molecular Characters

One overriding aspect of disc cell biology is that nucleus pulposus and cells residing in the inner anulus are removed from the blood supply. Blood vessels originating in the vertebral body traverse the superficial region of the end plates, but none of these vessels infiltrates the nucleus pulposus. Gruber and colleagues[31] showed that the anulus is avascular except for small capillary beds in the dorsal and ventral surfaces, and this vasculature never enters the nucleus pulposus.[32,33] The lack of penetrating vasculature suggests that the disc is a low-oxygen environment. Studies have confirmed that this logic holds true in vivo. Experimental measurements done in canine discs[34] as well as modeling studies by Bartels et al.[35] indicate that the pO_2 within the disc is indeed low. Thus, it is now widely recognized that the nucleus pulposus cells reside in a hypoxic niche.[36]

However, this raises an important question: How do cells survive in this unique niche? Due to pioneering studies by Semenza and others, it is now evident that the key molecule regulating energy metabolism and survival activity under hypoxia is hypoxia-inducible factor 1 (HIF-1),[37] a member of the basic helix-loop-helix (bHLH)–PER-ARNT-SIM family of proteins. HIF-1 is composed of a constitutively expressed β-subunit and a regulatory α-subunit. The α-subunit is stable under hypoxia but is rapidly degraded in normoxia.[38] Transactivation of HIF-1 target genes involves dimerization of the two subunits and binding to an enhancer, the hypoxia-response element in target genes. HIF-1 serves as a key transcription factor that regulates the expression of glycolytic enzymes, and enzymes that control the activity of the tricarboxylic acid cycle and oxidative phosphorylation.[37,39,40] Additional target genes include those that contribute to apoptosis, autophagy, and matrix synthesis pathways.[41-43] Details of these relationships are shown schematically in Fig. 46.1. Other isoforms of HIF exist, the most important being HIF-2α. Recent evidence suggests that HIF-1α and HIF-2α are not redundant, and that the relative importance of each of the homologues, in response to hypoxia, varies among different cell types.[44] In addition to these genes, the Sox family of transcription factors that are essential for the development and function of the nucleus pulposus are hypoxia and HIF sensitive.[45-48] However, the relationship between Sox proteins and HIF in the hypoxic niche of the IVD is not yet clearly demonstrated. The influence of HIF on cell function is vast, warranting further

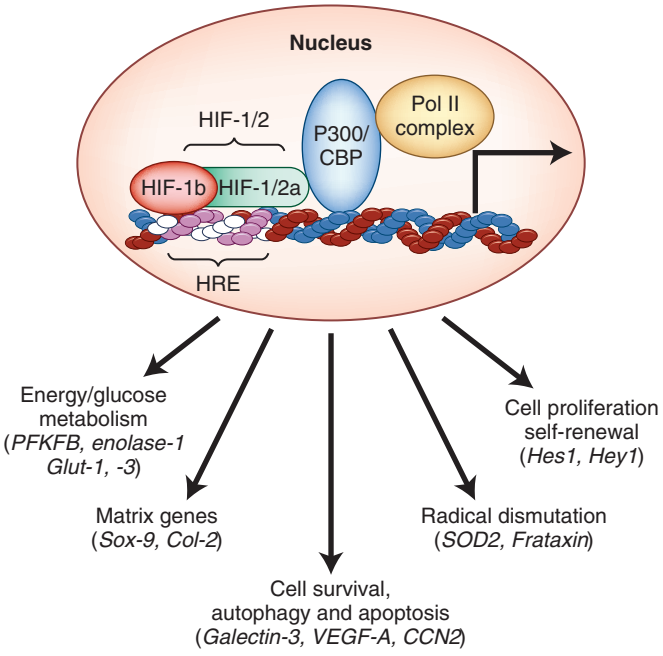

FIG. 46.1 Functional activity of hypoxia-inducible factor (HIF) target genes. Critical functions include energy metabolism, angiogenesis, cell survival, autophagy and apoptosis, matrix synthesis, proliferation, self-renewal and differentiation, radical dismutation, and pH regulation. Many of these functions are critical for survival and functioning of the nucleus pulposus cells in the avascular niche of the intervertebral disk. Hypoxia/HIF-sensitive proteins that are identified in the nucleus pulposus cells are shown in parentheses. (Modified from Risbud MV, Schipani E, Shapiro IM, et al. Hypoxic regulation of nucleus pulposus cell survival: from niche to notch. *Am J Pathol.* 2010;176[4]:1577–1583.)

study, but it is evident that this protein is responsible for nucleus pulposus survival in the hypoxic disc.

A number of reports showed that there is a robust HIF response by nucleus pulposus cells. The response is evident across species; more importantly, HIF-1α activity is unresponsive to the oxemic state of the tissue.[22,36,49] Accordingly, when compared with most other tissues, there are important underlying differences in the HIF status and reactivity of disc cells. HIF-1α expression and activity is always "on." This unique response suggests that stabilization of HIF-1α in nucleus pulposus cells ensures that transcriptional activity is a major governor of their function. The second HIF homologue, HIF-2α, is robustly expressed by nucleus pulposus cells. Like HIF-1α, steady-state protein levels are similar in both hypoxia and normoxia, suggesting that it is stabilized as well.[50] Recent work by Merceron and colleagues[51] has unequivocally demonstrated that HIF-1 is indispensable for nucleus pulposus cell survival in vivo. Conditional deletion of HIF-1α in mouse notochord by FoxA2-driven Cre recombinase results in massive apoptotic cell death in the nucleus pulposus at birth, likely due to energetic failure by decreased glycolysis. Eventually the nucleus pulposus is replaced with a fibrocartilaginous tissue with inferior biomechanical properties. Interestingly, lineage-tracing studies clearly showed the notochordal lineage of the nucleus pulposus cells, and their replacement with nonnotochordal cells, likely migrate into the tissue from the inner anulus or end plate cartilage (Fig. 46.2). Thus, because of the necessity of HIF-1α in maintaining nucleus pulposus cell survival and function, the constitutive expression of HIF-1α is considered a marker of their phenotype.[52] Before leaving this topic, it is important to comment that a growing body of literature now points to a unique relationship between HIF-1α and the O_2-sensing prolyl hydroxylase, enzymes that control HIF-α stability and activity. HIF is a key player in nucleus pulposus cell function and survival. Consequently it is likely that disturbance in the HIF–prolyl hydroxylase circuit would compromise cell function and exacerbate disease.

Another important niche condition that defines the IVD is the high proteoglycan content accounting for the elevated water content in these tissues; the percentage water of the nucleus pulposus and anulus fibrosus is approximately 77% and 70%, respectively.[53] Several reports indicate that the IVD is hyperosmolar when compared with other tissues. Values reported vary from 430 to 496 mOsm.[54,55] This unusually high extracellular osmotic pressure affects both cell function and matrix synthesis. Ishihara and colleagues were the first to demonstrate this relationship in disc tissue using bovine nucleus pulposus explants.[54] How extracellular osmolarity regulates the expression levels of specific matrix molecules has received intense study in recent years. In human nucleus pulposus and anulus cells, expression levels of aggrecan and collagen II were increased in cells under hyperosmotic conditions (500 mOsm), whereas collagen I expression was downregulated.[56] Similarly, in bovine nucleus pulposus cells, an increase in medium osmolarity from 300 to 500 mOsm increased aggrecan expression and decreased levels of matrix metalloproteinase (MMP)-3 mRNA.[57] To relate osmolarity to loading, rabbit discs were cultured under hyperosmotic conditions (485 mOsm 8 h/day); although loading did not influence proteoglycan content or disc cell viability, after 28 days in culture the raised osmotic pressure prevented aberrant overexpression of collagen I and appeared to influence aggrecan expression.[58]

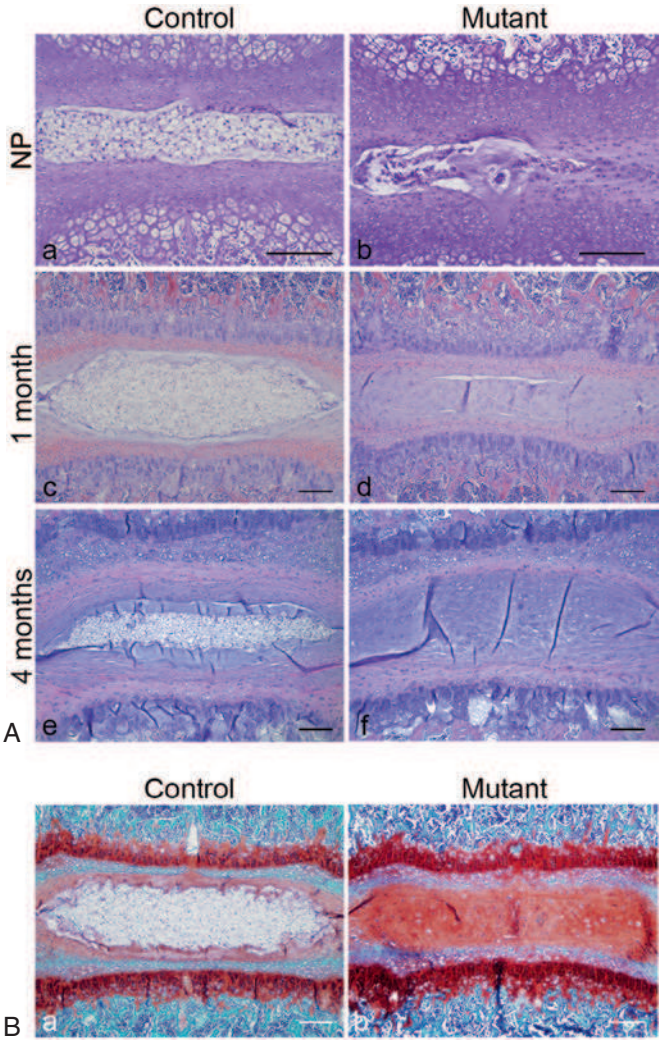

FIG. 46.2 Progressive disappearance of the nucleus pulposus (NP) postnatally in mice with conditional deletion of HIF-1α in NP. (A) Hematoxylin and eosin staining of newborn *(a,b)* and at 1 month *(c,d)* and 4 months *(e,f)*. Results are shown for control ($Foxa2^{Cre}$;$HIF\text{-}1\alpha^{f/+}$) and mutant ($Foxa2^{Cre}$;$HIF\text{-}1\alpha^{f/f}$) mice. Bar = 50 μm. (B) Safranin O staining of NP at 1 month *(a,b)* in control ($HIF\text{-}1\alpha^{f/f}$) and mutant ($Foxa2^{Cre}$;$HIF\text{-}1\alpha^{f/f}$) mice. Bar = 100 μm. (Modified from Merceron C, Mangiavini L, Robling A, et al. Loss of HIF-1α in the notochord results in cell death and complete disappearance of the nucleus pulposus. *PLoS One.* 2014;9:e110768.)

Loading of the hydrostatically pressurized IVD results in minute-to-minute fluctuations in extracellular osmolarity.[59,60] From this perspective, it is not surprising that tonicity enhancer binding protein (TonEBP), the only known mammalian transcription factor responsive to changes in osmolarity, is robustly expressed in both nucleus pulposus and anulus fibrosus tissues.[61] Importantly, decreased expression of TonEBP correlated to increased evidence of cell death, suggesting that this protein is necessary for nucleus pulposus cell viability

in the hypertonic milieu of the disc. Later studies showed that TonEBP controls expression of critical matrix-related targets as well as the water channel AQP2.[62,63] Analogous to the importance of HIF for the survival of the disc due to its hypoxic niche, TonEBP may prove to play a central role in disc survival in the hypertonic stress. For detailed discussion of osmosensing in intervertebral disc see recent review by Johnson et al.[64]

In addition to the above niche conditions, the IVD is also largely aneural, with innervation in a healthy disc limited to the peripheral fibers of the anulus. The sinuvertebral nerve innervates the disc, posterolateral ligament, ventral dura, posterior anulus, and blood vessels. It is composed of a sensory branch from the ventral root and a sympathetic branch from the gray rami communicans near the distal pole of the dorsal root ganglion. The sinuvertebral nerve is believed to have three segmental levels of overlap, which makes it difficult to localize pain originating in the disc, dura, and posterolateral ligament. Nakamura et al.[65] treated 33 patients with a selective L2 nerve root block and showed good relief of back pain. These authors hypothesized that the main afferent pathways of pain from lower lumbar IVDs in patients with discogenic back pain are sympathetic in nature and are mediated through the L2 nerve root via the sinuvertebral nerve; this hypothesis has yet to be validated, however.

Changes in Disc Structure With Aging and Degeneration

Changes that almost universally occur in the IVD with aging include reduction in disc volume, shape, and content. Alterations in gene expression and transcription factors may be responsible for cell senescence within the disc. These senescent cells lose biochemical and synthetic capabilities, which ultimately diminishes the ability of the disc to recover from deformation and renders the matrix more vulnerable to progressive fatigue failure. The nucleus pulposus gradually becomes less hydrated, and by the third decade of life there is usually already a significant decline in the number of viable cells and a loss of proteoglycans.

The early degenerative process affects the nucleus pulposus and the end plate more than the anulus fibrosus. Both anabolic and catabolic processes are upregulated during the early stages of degeneration; however, anabolic repair processes fail to keep up with the catabolic processes and matrix degeneration ensues over time. As the process progresses, the inner layers of the anulus and the nucleus pulposus gradually become indistinguishable and change into a stiff desiccated fibrocartilaginous material.

The number of arterioles supplying the peripheral disc diminishes significantly as remaining blood vessels are obliterated by calcification of the cartilaginous end plates. Loss of end plate vascularity and porosity leads to a reduction in the influx of nutrients and efflux of waste products. Lactate levels rise locally within the hypovascular disc secondary to increased production and decreased removal. Cell apoptosis occurs as a result of decreased tissue pH,[66] and the biosynthetic reparative capability of the disc is thus further impaired.

Thinning and microfracture of the end plate alter its diffusion properties. This may allow rapid outflow of fluid through the cartilage end plate upon loading, thereby rendering the hydrostatic pressure mechanisms involved in load transference less effective and uniform. Focal elevations in shear stresses at the disc level may further adversely affect the disc structure and result in anular damage. Over time cracks develop between and through the anular lamellae. Eventually communicating channels may develop between the peripheral layers of the anulus and the nucleus, and disc material can then herniate through these fissures. The weakened anulus can develop a full-thickness defect and allow near-complete herniation of the nucleus pulposus, particularly when the disc is loaded in flexion and torsion.

The degenerative process resulting from matrix changes and internal structural disruption sets the stage for abnormal motion at the degenerated segment. Changes in disc structure alter the loading response and alignment of the spinal column. These changes can influence the facet joints, ligaments, and paraspinal muscles, which may also become pain generators. However, pain does not always correlate with morphologic changes in the disc and mechanical compression.[67] MacNab[68] described traction osteophytes around the vertebrae originating 2 mm from the anterior end plate at the site of attachment of the outermost anular fibers. These osteophytes were thought to be signs of abnormal biomechanics caused by traction at the insertion of the anular fibers into the vertebral bodies. Subsequent studies found these osteophytes to be inconsistently present.

Thus multiple factors lead to disc degeneration, including insufficient nutritional supply, reduction in the amount of viable cells, degradative enzymatic activity, and cell senescence and apoptosis. Alteration in loading patterns between the end plate and disc leads to anular damage and the potential for herniation. Perturbation of the disc also leads to degeneration and pain in other segmental structures such as the facet joints, ligaments, and paraspinal muscles. The initiating event(s) leading to the onset of degeneration remains unknown.

Associated Factors

Various risk factors have been implicated in the pathogenesis of lumbar disc degeneration. Hangai et al.,[69] in a recent review of factors associated with IVD degeneration in the elderly, cited increased age, high body mass index, occupational lifting, sporting activities, and factors associated with atherosclerosis as risk factors. Multiple studies have demonstrated genetic contributions to degenerative LBP.[70] Battié et al.[71] estimated the familial contribution to IVD degeneration to be between 34% and 61%. Cigarette smoking has also been implicated and appears to have an adverse vasoconstrictive and atherosclerotic effect on the nutrition of the IVD.[72,73] Interestingly. effects of cigarette smoking on disc degeneration seem to be gender specific, with males, but not females, being prone to smoking-induced pathology.[74,75] Type of occupation has also been demonstrated to have an adverse effect on lumbar spinal segment degeneration,

increasing the risk of symptomatic DDD. Studies have implicated occupations that require repetitive lifting or pulling, prolonged sitting[76] (such as motor vehicle driving[77]), and whole-body vibration.[78]

Arun et al.[79] used serial postcontrast MRI to study the effect of prolonged mechanical load on diffusion into the IVD. These authors reported that 4.5 hours at a load corresponding to 50% body weight significantly retarded the diffusion of small solutes into the center of the IVD, and 3 hours in an unloaded recovery phase were required to return the diffusion rate to that seen in the unloaded disc. Prolonged mechanical load can therefore cause a disruption of diffusion that may accelerate disc degeneration; however, this hypothesis is yet to be confirmed clinically.

The genetic predisposition to lumbar DDD and lifetime exposures were studied in a classic monozygotic twin study by Battié et al.[71] They reviewed 115 male identical twin pairs for exposures to common risk factors such as occupation, recreational activities, driving, and smoking. Disc degeneration was determined by MRI and clinical evaluation. In the upper lumbar spine only 7% of the variability was explained by occupation, 16% by age, and 77% by familial aggregation. In the lower lumbar spine recreational physical loading explained 2% of variability, age explained 9%, and familial aggregation explained 43%. The authors concluded that primarily genetic and other unexplained factors result in DDD, whereas commonly implicated environmental factors have only modest effects. In a 5-year follow-up study of the same twin population, the authors reaffirmed that genetics have a dominant role in the progression of DDD, whereas occupational lifting and leisure activity had only modest effects.[80] The important role of genetic factors has been corroborated in other twin studies[81,82] but appears to be less of an explaining factor for back pain in older populations.[83]

Several gene loci have been determined to be associated with increased risk for DDD. Type IX collagen was one of the first gene loci identified with some aberrant alleles imparting a 3- or 4-fold increase in relative risk.[84-86] More recent publications also implicate collagen type XI, interleukin-1, aggrecan, the vitamin D receptor, MMP-3, and corticotropin-like immediate lobe peptide as candidate genes.[87] In a meta-analysis of 4600 subjects using disc space narrowing and osteophyte growth as a continuous trait, Williams et al.[88] identified four signal nucleotide polymorphisms with a P value $< 5 \times 10^{-8}$. Among these identified signal nucleotide polymorphisms was a polymorphism in the intron of the Parkinson protein 2, E3 ubiquitin protein ligase (PARK2) gene on chromosome 6 (rs926849) significantly associated with lumbar disc degeneration, a subset of the patients also exhibited differential methylation at one CpG island in the PARK2 promoter, providing additional evidence indicating the importance of this gene to DDD. Another study looking at 4043 DDD patients and 28,599 controls identified carbohydrate sulfotransferase 3 (CHST3) as a susceptibility gene for disc degeneration based on enhanced microRNA binding. CHST3 catalyzes proteoglycan sulfation.[89] The discovery of these genetic risk factors has yet to inform new useful diagnostic and treatment modalities, but they offer novel unbiased insight into the pathophysiology of disc degeneration.

Pathophysiology

Internal Disc Disruption

Henry Crock coined the term "internal disc disruption" in 1970 and defined it as a painful increase in biologic activity of the IVD after injury with normal radiographic, computerized tomographic, and myelographic examinations but an abnormal discogram.[67] IDD as a cause of discogenic back pain remains controversial. The advent of MRI has dramatically improved the suspect presence of this entity; IDD presents as a dark disc with relatively preserved height and contour. Pain in IDD is believed to be caused by mechanical and chemical stimulation of nociceptors within the anulus or on the surface layers of the anulus and the overlying ligamentous tissue. The hallmark of IDD is the absence of disc herniation, prolapsed disc material, segmental instability, or other radiographic abnormality.[67,90] Nerve root irritation, radicular pain, and neurologic deficits are also absent. Radiographic changes associated with DDD—such as significant disc space narrowing, end plate osteophyte formation, end plate sclerosis, and gas formation within the disc space—are not seen in IDD.[91] MRI (dark disc), and positive discography (concordant pain in the abnormal level, not at normal adjacent levels) are required to make the diagnosis of IDD. Because of the poor sensitivity and specificity of discography, there are many disbelievers of the existence of IDD as a clinical entity. It is important to note that there is a growing consensus spearheaded by Carragee that discography may accelerate disc degeneration, loss of disc height, and overall progression of pathology and symptoms.[92] Advanced imaging technologies offer a noninvasive way to measure degeneration in intact discs. T1ρ MRI imaging can discriminate painful from nonpainful discs, and T1ρ values strongly correlate with in vivo opening pressure measurements obtained by discography.[93]

Degenerative Disc Disease

The relationship between DDD and LBP is not well understood. Two potential sources that have been implicated as contributors to discogenic pain are sensitization of nerve endings by release of chemical mediators and neurovascular ingrowth into the degenerated disc. The precise pathophysiologic mechanism for chemically mediated induction of hyperalgesia within the disc has yet to be fully elucidated. Radial anular tears provide a route for nuclear material and noxious chemicals to leak from the disc and contact the dural sac and nerve roots; some studies have shown that autologous nucleus pulposus alone has the capacity to produce a robust inflammatory response. The presence of nerve endings in the disc is a controversial topic; abundance of neurovascular ingrowth into the degenerate disc has been

less substantiated by recent studies.[94] Some of the important features of the degenerating disc are described below.

Defining Features of the Degenerating Disc

Both nucleus pulposus and anulus fibrous cells are able to secrete a variety of inflammatory cytokines in response to various noxious stimuli and altered mechanics. During the degenerative process, disc cells secrete elevated levels of tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), IL-6, and IL-17. These cytokines stimulate the production of additional cytokines, induce matrix catabolism, alter cell protein synthesis, and affect the biophysical properties of nucleus pulposus cells. Matrix destruction is mediated by cytokine-induced expression of MMP and a disintegrin and metalloproteinase with thrombospondin motifs (ADAMTS).[95] This system amounts to a positive feedback loop in which disc degeneration stimulates cytokine production, which in turn stimulates more disc degeneration and cytokine production.

IL-1β and TNF-α are the two most widely studied cytokines in the pathogenesis of disc degeneration. IL-1β is synthesized in an inactive pro-IL-1β form and activated by caspase-1 before secretion. IL-1β binds to IL-1β receptor that acts through the myeloid differentiation primary response gene 88 (MYD88) to induce expression of matrix-degrading enzymes.[52,96] Expression of both IL-1β and its receptor increases in correspondence to the severity of disc disease. Not only does IL-1β signaling induce matrix catabolism by inducing matrix-degrading enzymes, signaling also interferes with aggrecan and collagen II synthesis.[97] TNF-α, on the other hand, is synthesized as a type II transmembrane cytokine. TNF-α-converting enzyme cleaves the membrane-bound portion to generate secreted TNF-α. Nuclear factor-κB light chain enhancer of activated B cells and mitogen-activated protein kinase pathways are the two primary downstream targets of TNF-α signaling in disc cells (see Fig. 46.1).[52] Importantly, in addition to transcriptional induction of several catabolic mediators, TNF-α promotes ADAMTS-5 processing and activation by elevating cell surface levels of syndecan-4, a heparan sulfate proteoglycan.[98] A recent study has also shown the critical contribution of syndecan-4 in controlling TNF-α–mediated transcriptional induction of MMP-3.[99] In addition to their well-described catabolic functions, higher levels of inflammatory cytokines TNF-α and IL-6 have been shown to cause cell death in dorsal root ganglion neurons.[100] Moreover, IL-6 and IL-8 are correlated with painful degenerate discs.[101] Both IL-1β and TNF-α also upregulate nerve growth factor, with IL-1β also inducing the expression of brain-derived neurotrophic factor and substance P.[102-104] Thus, not only could these neurotrophic factors cause pain by dorsal root ganglion sensitization and through retrograde signaling, but substance P has been shown to upregulate synthesis of inflammatory cytokines (IL-6, IL-8, and TNF-α), further exacerbating to progression of disc degeneration.[105] Although it is evident that inflammatory phenotype characterizes degenerate discs, little is known about how the inflammation is initiated and sustained to give rise to chronic LBP.

Subclinical Bacterial Infection of the Spinal Motion Segment as a Possible Initiator of Low Back Pain

There is growing interest and controversy in the notion that subclinical anaerobic bacterial infection could play a role in symptomatic disc degeneration. This subclinical infection is in contrast to LBP from overt discitis, in which 80% of patients present with elevations in erythrocyte sedimentation rate and 50% present with a fever.[106,107] Changes in end plate radiologic appearance may lead to clues to identifying patients who have bacteria-mediated LBP. Modic et al.[108] used MRI to detect changes in vertebral bone marrow associated with DDD. Type 1 changes were described as decreased signal intensity on T1-weighted images with increased signal intensity on T2-weighted images; type 2 changes were described as increased signal intensity on T1-weighted images with slightly increased intensity on T2-weighted images. Fat appears bright and increases the signal intensity on T1-weighted images, whereas water increases signal intensity on T2-weighted images. Consequently, painful type 1 changes are associated with edema in the vertebral bodies. More recently, Jensen et al.[109] showed that these same Modic type 1 changes are strongly correlated with LBP. Albert et al.[110] proposed that anaerobic bacteria, predominantly *Propionibacterium acnes,* might be responsible for radiologic changes associated with LBP. The discs in their study infected with anerobic bacteria were significantly more likely to have Modic type 1 changes than discs infected with aerobic bacteria or discs with no detectable infection.[110] (Of note, whenever bacterial culture is taken from a surgical sample, there is a chance of environmental contamination, which could have affected these authors' results.) However, they found a difference between the aerobic and anaerobic bacteria groups. Simple environmental contamination would not likely favor anaerobic bacteria over the more commonly aerobic skin flora. Moreover, other studies have also found anaerobic bacteria in nucleus material, thus adding strength to the notion that the hypoxic conditions in the inner anulus and nucleus pulposus may be preferable for survival and colonization of anerobic microorganisms.[111,112]

The hypothesis that subclinical bacterial infection can cause LBP is further supported by the ability of antibiotic treatment to resolve back pain in patients with Modic type 1 changes. In a double-blind, randomized, controlled clinical trial, Albert et al.[113] found that a 100-day course of amoxicillin-clavulanate resulted in significant improvement in both disability and pain of patients with LBP. This is one of the most strikingly successful experimental treatments for LBP to date; however, along with the possible shortcomings of their earlier study, there are possible confounding effects of amoxicillin-clavulanate. There is some evidence suggesting that clavulanate has antiinflammatory action in the treatment of ulcerative colitis and analgesic properties during morphine withdrawal in mice, which could lead to a misinterpretation of this clinical study.[114,115] It is important to note that treating back pain with long-term antibiotics also raises global health concerns by exacerbating the

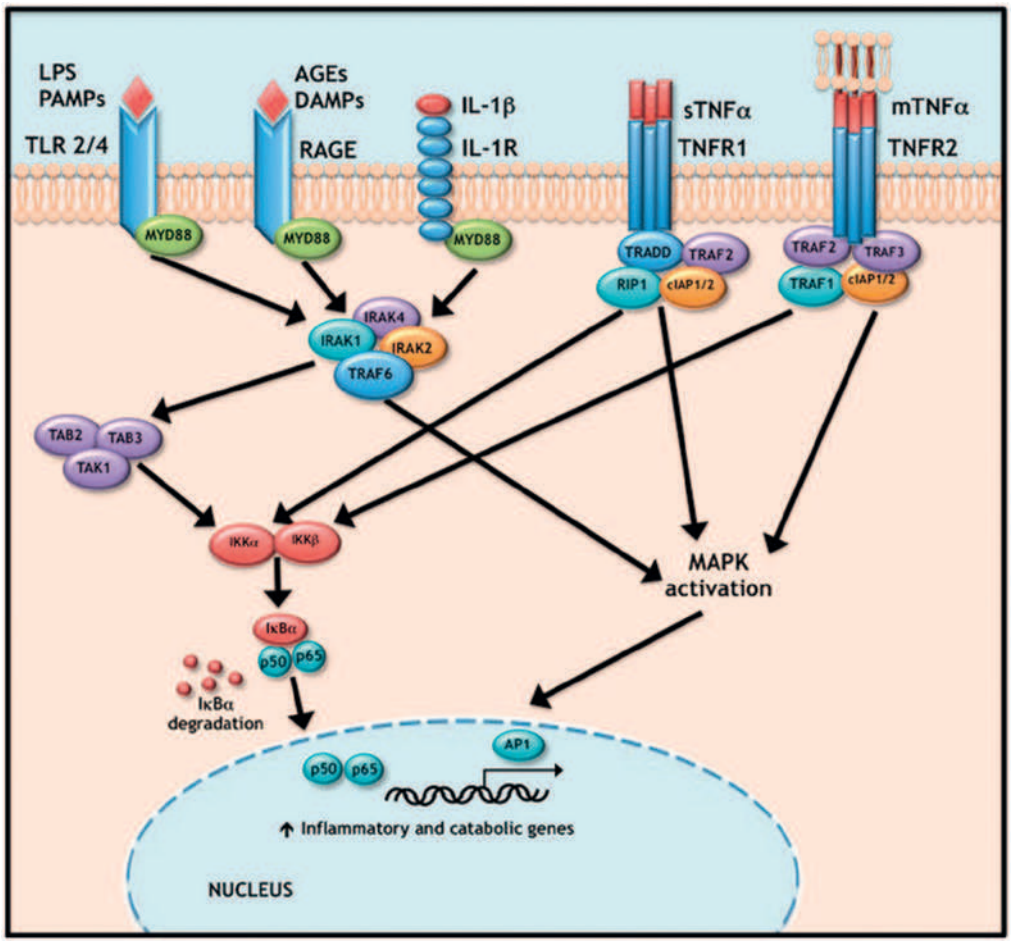

FIG. 46.3 Signaling pathways driving inflammation. Toll-like receptor (TLR), RAGE, and interleukin-1 (IL-1) all initiate their inflammatory effects through MYD88 with subsequent recruitment of members of the IRAK family that activate TRAF6. Tumor necrosis factor-α can stimulate the cell in both its soluble and membrane bound form by activating TNFR1 and TNFR2, respectively. TNFR1 ligand binding results in a conformational change leading to the recruitment of TRADD, RIP1, TRAF2, and CIAP1/2. Ligand binding to TNFR2 results in the recruitment of similar downstream factors. All five of these receptor pathways converge on nuclear factor (NF)-κB and mitogen-activated protein kinase (MAPK) activation to induce their inflammatory and catabolic effects. AGEs, advanced glycation end products; DAMP, damage-associated molecular patterns; LPS, lipopolysaccharide; PAMPs, pathogen-associated molecular patterns. (Reproduced from Gorth DJ, Shapiro IM, Risbud MV. Discovery of the drivers of inflammation induced chronic low back pain: from bacteria to diabetes. *Discov Med.* 2015;20[110]:177–184.)

already serious problem of antibiotic resistance.[116] Despite these limitations, subclinical bacterial infection is a promising new theory of LBP. Additional investigation into the underlying mechanisms linking anaerobic bacterial infection to LBP could enhance our collective understanding of the disease and identify treatments directly targeting the pathways contributing to painful disc degeneration.

Damage-Associated Molecular Patterns as Mediators of Chronic Inflammation and Low Back Pain

Some endogenous molecules and their atypical cleavage products have the ability to stimulate sterile inflammation in the disc. This family of molecules, collectively called damage-associated molecular patterns (DAMPs), include fragments of commonly found extracellular matrix molecules such as hyaluronan and fibronectin as well as high-mobility group protein B1 (HMGB1), a protein involved in chromatin assembly. Hyaluronic acid fragments (12–24 mer) have been reported to enhance the production of IL-1β, IL-6, IL-8, and matrix-degrading enzymes MMP-1, MMP-3, and MMP-13. These effects are mediated by Toll-like receptor-2 (TLR2) signaling and can be inhibited by high-molecular-weight hyaluronan.[117] The TLR2 signaling cascade activated by hyaluronan fragments is the same MyD88-IRAK-TRAF6–dependent cascade activated by both lipopolysaccharide and CpG sequence DNA binding (Fig. 46.3).[118,119] It is interesting to note that by binding TLR2 instead of TLR4 or CD44, hyaluronan fragments stimulate nucleus pulposus cells in a manner that more closely resembles macrophages than chondrocytes, hinting at the unique nature and origin of these cells.[120-122]

HMGB1 is another DAMP that is receiving attention in the disc field. HMGB1 is both passively released from necrotic cells and secreted by monocytes. It likely exerts its inflammatory function by binding to TLR2/4 as well as RAGE receptors.[122,123] It is important to note that redox status of HMGB1 is shown to play an important role in the biologic outcomes it produces.[124] Delivery of anti-HMGB1 reduces pain and TNF expression after application of nucleus pulposus tissue to DRG in a rat model.[125] Fibronectin fragments are another possible inflammatory mediator in disc degeneration. Fibronectin fragments are absent in infant human IVDs, but increase in concentration with aging and severity of disc degeneration.[126] Delivery of a 30-kDa fibronectin fragment into rabbit lumbar discs induced a degenerative phenotype similar to spontaneous human disc degeneration; it caused a significant decrease in disc height and proteoglycan synthesis.[127] These effects could be due to increased MMP-9 and MMP-13 expression along with decreased collagen II and aggrecan expression observed in vitro after stimulation with fibronectin fragments.[128] In contrast to signaling through RAGE and TLR, fibronectin fragments exert their catabolic effects through integrin $\alpha_5\beta_1$.[129] The enhanced catabolism caused by fibronectin fragments could also be a result of their outcompeting CCN2 for $\alpha_5\beta_1$ binding. CCN2 causes context-dependent effects in the disc, promoting aggrecan expression and inhibiting the catabolic effects of IL-1β when bound to $\alpha_5\beta_1$ and, conversely, possibly through HSPGs, promoting catabolism.[130] Thus, atypical matrix cleavage products may interfere with disc homeostasis, pushing the homeostatic balance more toward catabolism.

Systemic Metabolic Syndrome as a Driver of Disc Inflammation and Low Back Pain

Obesity and diabetes are two epidemics in Western society that increase the risk of developing painful disc degeneration. Beyond the greater forces that the spinal motion segments of an obese individual experiences, diabetes creates a niche environment that can drive disc degeneration. Advanced glycation end products (AGEs) associated with diabetes can accelerate disc degeneration by inducing catabolism and promoting inflammation. Although diabetes and obesity are linked, recent research has attempted to isolate the effects of diabetes from the effects of obesity by comparing both obese Sprague-Dawley rats to diabetic obese UCD-T2DM rats while using lean rats as an additional control. The diabetic rats alone had an elevated AGE concentration, which was associated with diminished glycosaminoglycan and water content of discs. These compositional changes resulted in an experimentally consistent decrease in disc mechanics.[131] In a separate study, Tsai and colleagues showed that treatment with AGEs of both rat and human nucleus pulposus cells caused a dose-dependent increase in MMP-2, extracellular signal-related kinases (ERK) activity, and elevation in advanced AGE-specific receptor (RAGE) mRNA expression, which all could lead to enhanced NF-κB activation.[132] Inhibiting RAGE-induced disc degeneration offers an accessible possible therapeutic target; both the antiinflammatory pentosan-polysulfate and AGE inhibitor pyridoxamine are already Food and Drug Administration (FDA) approved compounds and have been shown to reduce the deleterious effects of streptozotocin-induced diabetes on disc health in mice.[133] Independent of the aberrant reactions caused by hyperglycemia leading to AGE production, elevated blood glucose concentration, common to diabetes, has been shown to inhibit nucleus pulposus cell proliferation in vitro, which could further alter cellular homeostasis in the disc.[134] Although in vitro data and in vivo studies suggest that diabetes contributes to disc degeneration, the clinical data have not been as conclusive. A study evaluating nine pairs of monozygotic twins discordant for insulin-dependent diabetes mellitus did not show increased incidence of disc degeneration in the diabetic twin.[134a] A larger study focusing on non–insulin-dependent diabetes showed no increase in diabetic patient disc disease when controlled for body mass index.[134b] Taken together these studies suggest that diabetes, obesity, and their mechanical and metabolic consequences may compromise disc health and promote degeneration.

Effect of Disc Degeneration on Nerves

Degradative changes can occur within nerve roots exposed to nuclear material even in the absence of mechanical compression.[90,135-137] Weinstein et al.[138] investigated the reproduction of pain on discography and concluded that various neurochemical changes within the disc are expressed by sensitized anular nociceptors. These nociceptors are terminal nerve endings of sensory neurons that selectively respond to painful stimuli by the release of substance P.[139] These chemicals are leaked into the epidural space and transported into the axons of the exiting nerve roots. Within the nerve root they alter the excitability of type C nerve fibers and initiate the production of inflammatory agents such as prostaglandins as well as inflammatory cytokines, which results in radicular pain.[68,140,141]

In addition to material from the nucleus pulposus many other substances in the degenerated disc have been implicated in pain generation. The role of nitric acid and phospholipase A_2 in irritation of nerve roots has been well documented.[140,142-145] Phospholipase A_2 has been implicated in multiple aspects: direct activation of nociceptors, nerve injury from degradation of cell membrane phospholipids, and nerve injury from inflammatory mediators created from the arachidonic acid cascade (i.e., prostaglandins and leukotrienes).[146-148] Burke et al.[149] reported on the elevation of inflammatory mediators within the disc such as IL-6, IL-8, and prostaglandin E_2. Other studies have demonstrated the presence of inflammatory cytokines in the facet joints,[150] suggesting facet involvement of a pain generator via a biochemical mechanism as well. Ohtori et al.[151] reported on ingrowth of nerve tissue immunoreactive for TNF and neuronal marker protein gene peptide 9.5 (PGP) in 18 surgically harvested vertebral end plates of patients with Modic type 1 and 2 changes who had undergone surgery. Their findings suggest that axon ingrowth into the vertebral end plate in association with Modic changes was induced by TNF and may be related to pain generation.

Neurovascular proliferation within and around degenerated disc elements has been proposed as another mechanism

of pain generation. Normal IVDs have sparse innervation and vascularity that is solely distributed within the outer lamellae (3 mm) of the anulus fibrosus,[152,153] whereas degenerated discs have significant neurovascular ingrowth within the inner anulus and nucleus pulposus,[154] although this observation remains a subject of controversy with the field. Immunoreactive staining and acetylcholinesterase studies have demonstrated penetration of nerve fibers within the inner third of the anulus in association with neovascularized granulation tissue.[142,152] Peng et al.[155] recently reported on a histological study of 19 IVDs harvested from surgery compared with normal control discs. The distinctive histologic characteristic of painful discs was a zone of richly innervated vascular granulation tissue extending from the outer anulus to the nucleus along the edges of fissures. Proliferation of vascular channels and sensory nerve endings rich in the calcitonin gene-related peptide (CGRP) has also been observed in the end plate region and vertebral body adjacent to the degenerated disc. These findings suggest a role for the vertebral end plate and body as additional pain generators in DDD.[156]

Other recent studies suggest that the sensory nerve supply within the IVD is similar to visceral innervation patterns,[157] with CGRP immunoreactive fibers that pass through the sympathetic trunks.[158] This visceral pattern of innervation is potentially susceptible to central sensitization, which may further complicate chronic LBP with psychosomatic overtones.[159] Psychosocial and chronic non–back pain syndromes have been implicated in recent publications as having a significant effect in patients with LBP.[160-164]

Clinical Picture

Internal Disc Disruption

The diagnosis of IDD is not readily apparent on a routine clinical workup. The patient is typically a younger individual between the ages of 20 and 50 years, with recurrent or persistent back pain. There may be a history of antecedent trauma or a forceful provocative event such as heavy lifting, or unexpected flexion or compression force on the lumbar spine, but more often the pain is gradual in onset with no associated event or date.

The pain is characterized as a deep, dull ache in the lower lumbar region, exacerbated by rotation, flexion, and side-bending movements and partially relieved by rest. Sitting intolerance may be a primary complaint, and pain is often relieved in a lateral recumbent position. Occasionally there is a complaint of pain in the buttock or posterior thigh, but there is a conspicuous lack of radiculopathic symptoms. In the rare instances of associated leg pain it is usually a late finding and pain does not follow any dermatomal pattern. O'Neill et al.,[165] in a study involving intradiscal electrothermal annuloplasty in 25 patients, showed that stimulation of the IVD may result in low back and referred leg pain in patients presenting with symptoms of IDD. The distal distribution of pain was found to depend on the intensity of stimulation, and occasional pain extending below the knee was produced.

Physical examination of these patients reveals decreased range of motion of the back and tenderness of the paraspinal musculature but is otherwise normal. The straight-leg raise test may reproduce back pain but not leg pain. LBP may also be reproduced at 20 to 30 degrees of flexion when rising from a flexed position. The sensorimotor examination is unremarkable, and deep tendon reflexes are normal and symmetric.

Degenerative Disc Disease

Patients with DDD typically present with a history of persistent LBP over the lumbosacral spine, sacroiliac joints, and radiating into the buttocks and posterior thighs. Symptoms are often exacerbated with sitting and prolonged walking; signs of neurologic claudication in the legs are not seen unless associated with concomitant lumbar stenosis. Radicular symptoms are rarely seen in the early stages of the disease. In end-stage DDD significant disc collapse may result in foraminal stenosis and late-onset radicular symptoms.

The physical examination is typically unremarkable except for point tenderness over the lumbar spine in the midline and over the sacroiliac joints. Range of motion of the lumbar spine may be reduced, most specifically in flexion. Extreme flexion usually causes significant discomfort as well as returning to upright from a flexed position. Extension is usually the least painful maneuver and may actually relieve pain. The straight-leg raise test may elicit some posterior thigh pain, which is often described as a stretching or pulling sensation, but there is no true radicular pain distal to the knee unless there is coexisting foraminal stenosis. The sensorimotor examination is usually unremarkable, and deep tendon reflexes are normal and symmetric.

Diagnostic Imaging

Plain Radiography

Plain radiographs are the recommended initial imaging modality for patients with LBP. Classic comparative and cost benefit studies have been performed to determine when and what radiographs to obtain.[166,167] In 1982 Liang et al.[168] published a comparison study between performing radiographs on all patients versus only on patients whose pain did not improve within 8 weeks of presentation. They found that risks and costs did not justify obtaining radiographs on initial presentation. Scavone et al.[169] reviewed the radiographs of 782 patients and found that spot lateral and oblique films only added diagnostic information in 2% of patients. They recommended that a spine series in patients with LBP should consist only of anteroposterior and lateral films. In general, flexion-extension and oblique views are only necessary in patients suspected of having instability or a pars fracture. The presence of so-called red flags increase the chances of diagnostic radiographic findings and may prompt the physician to obtain early radiographic studies (Box 46.1).[170]

Typical radiographic findings for patients with DDD include narrowing of the disc space (loss of height), end plate

BOX 46.1 Practice Guidelines: Red Flags

Anteroposterior and lateral radiographs are generally not useful in the acute setting but may be warranted with the following:

- Unrelenting night pain or pain at rest (increased incidence of clinically significant pathology)
- History or suspicion of cancer (rule out metastatic disease)
- Fever above 38°C (100.4°F) for >48 hours
- Osteoporosis
- Other systemic diseases
- Neuromotor or sensory deficit
- Chronic oral steroid administration
- Immunosuppression
- Serious accident or injury (fall from heights, blunt trauma, motor vehicle accident), not including twisting or lifting injury unless other risk factors are present (e.g., history of osteoporosis)
- Clinical suspicion of ankylosing spondylitis

Other conditions that may warrant anteroposterior or lateral radiographs:

- Age >50 years (increased risk of malignancy, compression fracture)
- Failure to respond to 4 to 6 weeks of conservative therapy
- Drug or alcohol abuse (increased incidence of osteomyelitis, trauma, fracture)

Oblique radiographs are not recommended; they add only minimal information in a small percentage of cases and more than double the exposure to radiation.

From Institute for Clinical Systems Improvement (ICSI). *Adult low back pain.* Bloomington, MN: ICSI; 2008.

sclerosis, and the presence of osteophytes. These are, however, late changes occurring when the degeneration is advanced. Degenerative spondylolisthesis and scoliosis may occur as degeneration progresses. Advanced stages of disc degeneration may demonstrate vacuum phenomenon within the discs, a finding that represents nitrogen collection within voids in the disc.

The radiographs in patients with IDD typically show well-preserved height in the IVD and are normal in appearance other than occasional benign spinal alignment changes. Nonstructural scoliosis and loss of lumbar lordosis may safely be observed in patients with sciatic list and paraspinal spasm.

Computed Tomography

Computed tomography (CT) is an excellent method to assess osseous pathology, but it is generally not the imaging modality of choice for either IDD or DDD because they are primarily soft tissue disorders. Injecting contrast material into the vertebral canal (CT myelography) significantly improves the accuracy of the CT scan for demonstrating pathology within the canal such as masses or stenosis; although they are not a primary feature of DDD, they frequently occur secondarily. CT myelography is the diagnostic imaging study of choice in patients with significant scoliosis or those who are unable to undergo MRI examination due to implanted metal, aneurysm clips, pacemaker, obesity, or claustrophobia.

CT scanning has largely been replaced by MRI scanning because the disc is not adequately imaged, and CT exposes the patient to radiation. As is discussed later, CT is also used in combination with discography.

Magnetic Resonance Imaging

T1- and T2-weighted MRI is used in standard protocols. A semiquantitative method is often used to classify degenerative grades. The 5-scale grading system by Pfirrman combines structural changes with distinction of nucleus and anulus, signal intensity, and height of the disc. Quantitative MRI techniques such as relaxation times and T1ρ have the potential to biochemically assess disc tissue but are currently rarely used in clinical practice. Diffusion of water protons and contrast agents are other quantitative methods primarily used in research. MRI spectroscopy is challenging in vivo but may in the future provide important information about the source of pain.

MRI is the best imaging modality for visualization and evaluation of the neuronal and discal elements and is the most valuable adjunctive diagnostic tool in assessing disc pathology. The IVDs are a highly unlikely cause of pain if the patient's MRI is completely normal and all discs are well hydrated. General MRI findings indicative of DDD include loss of water, loss of disc height, disc bulges, and signal or morphologic irregularity within the nucleus pulposus and end plates. In addition, MRIs are often examined for three specific types of findings: a high-intensity zone (HIZ) in the posterior anulus, dark disc with or without loss of height, and end plate signal changes.

The MRI finding of an HIZ was originally described by Aprill and Bogduk[171] in 1992 and is believed to represent an anular tear (see Fig. 46.1). Postmortem studies have demonstrated three types of tears that can occur in the anulus: concentric, transverse, and radial.[172,173] A concentric tear is a crescentic or oval cavity created by a disruption in the short transverse fibers interconnecting the anular lamellae and is usually not visible on MRI. These concentric tears are occasionally referred to as *delamination*. A transverse tear represents a rupture of the Sharpey's fibers near their attachments to the ring apophysis at the disc periphery; these tears are typically thought to be clinically insignificant. A radial tear extending from the nucleus pulposus to the outermost surface of the posterior anulus is manifest on MRI as an HIZ.[174] The HIZ is visualized on T2-weighted spin-echo images as high-intensity signal located within the anulus fibrosus that is clearly distinguishable from the nucleus pulposus.

Decreased signal within the IVD on T2-weighted images with relative preservation of disc height is a relatively common finding in asymptomatic individuals. Such a disc appearance is frequently referred to as *dark disc disease*; however, whether these discs constitute a potential pain generator is unclear. In the absence of any psychometric abnormalities, an isolated dark disc in a patient with no other identifiable causes of back pain is considered by many clinicians to be a source of back pain even though the evidence is weak to absent.

End plate changes (see Fig. 46.2) that occur with disc degeneration have been well described by Modic.[175] Stage 1 change represents edema and is characterized by decreased signal on T1-weighted images and bright signal on T2-weighted

images within the end plate. In stage 2, fatty degeneration in the bone adjacent to the end plates is represented by bright signal on T1-weighted images and intermediate signal on T2-weighted images. Lastly, stage 3 changes correspond with advanced degenerative changes and end plate sclerosis and are characterized on MRI by decreased signal intensity on both T1- and T2-weighted images.

When interpreting MRI findings, the clinician must be careful to consider the high prevalence of clinically false-positive findings. Abnormal disc findings on MRI are often found in clinically asymptomatic individuals. Boden et al.[176] showed that approximately 30% of asymptomatic individuals have a major finding on lumbar MRIs. In patients older than 60 years those abnormal findings are almost universally present irrespective of symptoms. Jensen et al.[177] reported on 98 asymptomatic patients aged 20 to 80 years and found that 52% overall had disc bulge in at least one level on MRI. Stadnik et al.[178] showed an unusually high rate of disc bulge (81%) and anular tears (56%) on MRI in their 30 asymptomatic volunteers.

Abnormal MRI findings in asymptomatic patients are not indicators of future problems. Borenstein et al.[179] reported on 50 of the 67 patients from the Boden study at a 7-year follow-up interval and found that incidental MRI findings were not predictive of the development or duration of LBP. Jarvik et al.[180] studied 148 veterans who had been asymptomatic of LBP for at least 4 months. They found an incidence of moderate to severe desiccation in at least one disc in 83%, disc bulge in 64%, and loss of disc height in 58%. In a 3-year follow-up of the same cohort, the investigators found no association between the development of new back pain and incidental MRI findings such as Modic changes, disc degeneration, anular tears, or facet degeneration. The single greatest risk factor for developing LBP in the 3-year interval was depression.[160]

Jarvik et al.[181] also published a report on the use of early MRI in the primary care setting. A total of 380 patients with LBP were randomized to receive either initial spine imaging via rapid MRI or plain radiography. These authors reported that substituting rapid MRI for radiographic studies in the primary care setting offered little additional benefit to patients in terms of secondary outcomes measures at 1 year and had the potential to increase the cost of care by $320 per patient (in 2002 dollars). Carragee et al.[182] performed a prospective study of 200 asymptomatic patients to determine the rate at which new episodes of LBP are associated with changes on MRI. On follow-up MRI in 51 patients who had an episode of LBP, 84% had no new finding. The most common new findings were disc signal loss (dark disc), progressive facet arthrosis, and increased end plate changes. New findings were not more common in patients developing back pain after minor trauma. The conclusion was that new findings on MRI within 12 weeks of onset of a serious episode of LBP were unlikely to represent any significant structural change and preexisted the onset.

In consideration of the high prevalence of false-positive MRI findings, the clinician does well to remember that the MRI does not stand alone in the evaluation of spinal pathology. Together with the patient's history, physical findings, and plain radiographs, selective use of MRI can provide valuable information on the source of a patient's lumbar complaints.

Contrast-Enhanced Magnetic Resonance Imaging

The use of intravenous gadolinium diethylenetriaminepentaacetic acid (DTPA) contrast with MRI in the setting of discogenic pain has also been explored. The addition of gadolinium to a lumbar MRI is known to be useful for differentiating scar tissue from recurrent disc herniation, as the latter fails to enhance while the vascular scar tissue will take up the contrast. It appears unlikely that gadolinium-enhanced MRI helps determine if a degenerative disc is painful. Lappalainen et al.,[183] in an animal study of surgically created anular tears, showed that gadolinium-enhanced MRI did not detect all tears; specifically the peripheral, small tears were not visualized. Yoshida et al.[184] investigated the relationship between T2-weighted gadolinium-DTPA–enhanced MRI and a positive pain response with discography of 56 lumbar discs in 23 patients with chronic LBP. The sensitivity, specificity, positive predictive value, and negative predictive value of the unenhanced T2-weighted images in detecting the symptomatic disc were 94%, 71%, 59%, and 97%, respectively. With enhancement the corresponding values were 71%, 75%, 56%, and 86%, respectively.

High-Intensity Zone

The presence of an HIZ indicates the presence of an anular fissure. Aprill and Bogduk[185] correlated the finding of an HIZ with CT discography and found an 86% positive predictive value for a positive discogram; however, the predictive value and clinical significance of the HIZ on MRI has more recently been brought into question. The results vary among publications. Multiple authors have found a positive correlation between the finding of an HIZ and concordant pain on discography similar to the findings of Aprill and Bogduk,[186-189] whereas others have documented the correlation but found unacceptably low sensitivity.[190,191]

Kang et al.,[192] in a study of 62 patients aged 17 to 68 years, found that only an HIZ in association with disc protrusion correlated with concordant pain on discography. The specificity was 98% and positive predictive value was 87%; however, the sensitivity was low at 46%. An HIZ in association with either a normal or bulging disc on MRI was not found to be associated with a positive discogram. Ricketson et al.,[193] in a 30-patient study, found no correlation between the presence of an HIZ on MRI and a concordant pain response on discography; however, they did note that an HIZ was never visualized in a disc found to be morphologically normal on discography. Further studies[144,187,194-196] attempting to correlate positive HIZ findings on MRI and painful discography suggest that, although lumbar IVDs with posterior combined anular tears are likely to produce pain, the validity of these signs for predicting discogenic lumbar pain is limited.

Although the prevalence is unknown, an HIZ is frequently seen in asymptomatic individuals.[139] Carragee et al.[162] reported the presence of an HIZ in 59% of their symptomatic patient

population and in 24% of asymptomatic individuals. In the asymptomatic group, 69% of the discs with an HIZ were positive on discography, whereas 10% of the discs without an HIZ were positive. The authors also reported that 50% of the discs with an HIZ were positive on discography in patients with normal psychometric testing compared with 100% positive discography results in patients with abnormal psychometric testing and chronic pain. They concluded that the presence of an HIZ does not reliably indicate the presence of symptomatic IDD due to the high prevalence of the HIZ in asymptomatic people.

In 2004 Mitra et al.[197] followed 56 LBP patients with the finding of an HIZ longitudinally for 6 to 72 months with MRI. Changes in the HIZ on follow-up MRI—either an increase in intensity or spontaneous resolution—were not correlated to changes in Visual Analog Scale (VAS) score, Oswestry Disability Index (ODI), or symptoms, which again calls into question the clinical significance of the HIZ. Although the finding of an HIZ on MRI has been found in some studies to have good specificity and positive predictive value for concordant pain generation on discography, it has low sensitivity, high false-positive rates, and therefore questionable clinical significance.

Dark Disc

It is quite clear that the majority of patients with a dark disc are asymptomatic. Dark disc is, however, clearly the sign of a degenerative process. Milette et al.[198] found that loss of disc height or abnormal signal intensity were highly predictive of symptomatic tears extending beyond the anulus. Horton and Daftari[199] reported a positive discogram in 50% of patients with dark discs without evidence of an anular tear. An isolated dark disc with concordant pain on provocative discography is often considered to be pathologic in the absence of other potential sources of pain and in the absence of confounding psychosocial issues; however, as discussed previously, this evidence is weak.

Modic End Plate Changes

The various stages of Modic change are thought to be specifically linked with phases of the degenerative disc process. Toyone et al.[200] evaluated the MRIs of 74 patients with Modic changes and found that type 1 changes tended to be associated with complaint of LBP and correlated to segmental hypermobility. Other investigators have also described Modic 1 changes as specifically associated with LBP.[201,202] In a recent large retrospective review by Thompson et al.,[203] Modic changes in 736 patients were correlated to provocative discogram. The authors found that Modic type 1 changes had a high positive predictive value (0.81) for a positive discogram. Modic type 2 had a lower positive predictive value (0.64), and the predictive value of Modic type 3 was not statistically significant.

In the original Modic et al.[175] description of vertebral body marrow changes, conversion between signal characteristics from type 1 to type 2 was described in five of six patients over the course of 14 months to 3 years. Mitra et al.[204] performed a prospective evaluation of 48 patients with Modic type 1 changes. At 12-month to 3-year follow-up, 37% were found to have progressed to Modic type 2, 15% partially progressed, and 40% had no change in type but more extensive Modic 1 changes. Type 1 changes are believed by many to represent an unstable, dynamic phase of the degenerative process and tend to either convert to a type 2 pattern or become more pervasive. Modic type 2 changes are thought to be stable and less associated with painful episodes, but there have been reports of type 2 converting back to type 1.[205] Kuisma et al.[206] reported the prevelance of Modic changes in 60 patients treated nonoperatively for sciatica to be 23%. In a longitudinal follow-up of the same patients at 3 years, 14% were noted to have changed type. Those levels that did not convert to type 2 were found to have more extensive type 1 changes. Development of a Modic change at previously unaffected levels was found in 6%.

Many authors have explored the correlation between Modic changes on MRI with positive concordant pain on discography. Sandhu et al.[207] found that while both were relatively specific for discogenic pain, there was no significant correlation between them. Braithwaite et al.[208] found that Modic changes did not predict a positive response on discography; they concluded that Modic changes may represent a specific but relatively insensitive sign of discogenic LBP. Kokkonen et al.[209] observed that contrast injection during discography reflected pain of discogenic origin well, whereas the pain associated with end plate damage was usually not demonstrated by CT discography. The authors found a stronger association between end plate degeneration and disc degeneration than between end plate degeneration and anular tears, which may explain why Modic changes have been found to be less sensitive for discogenic pain than discography.

Conversely, other studies have found better correlation between back pain and Modic changes than the correlation between back pain and discography. Carragee et al.[161] reported on 100 prospectively followed patients recruited from a study population of asymptomatic persons at high risk for developing disabling back pain. Of all the incidental diagnostic findings, only moderate or severe Modic changes of the vertebral end plates were found to be weakly associated with subsequent development of a disabling episode of back pain. Other structural MRI findings as well as concordant pain with discography correlated only weakly with previous back pain episodes and had no association with future disability or medical consultations for back pain. Interestingly, psychosocial, neurophysiologic (chronic nonlumbar pain), and occupational factors strongly predicted future disabling episodes and consultations for back pain.

Schenk et al.,[210] in a cross-sectional study of 109 women from two groups (nursing or administrative professions), found that Modic changes and nerve root compromise were the only MRI findings that were statistically significant predictors of LBP. Disc degeneration, disc herniation, HIZs, and facet arthritis were found in both groups but were not significant risk factors for LBP.

Similar findings were reported in a study by Kjaer et al.,[211] in which LBP was correlated to MRI findings in a random selection of 412 Danish subjects. Although Modic

changes occurred in less than 25% of subjects (16% Modic type 1 and 7% Modic type 2), this finding had the strongest correlation with complaints of back pain. When the subjects were evaluated clinically, the authors found that patients with both radiographic evidence of DDD and Modic changes had the best clinical evidence of disc disease. Clinical findings in patients with radiographic evidence of disc degeneration without Modic changes were not significantly different from the baseline population. The authors concluded that a Modic change was a critical finding in relation to history of LBP and clinical findings.[212] In a follow-up study of the same Danish population, Modic changes correlated with type of occupation, history of smoking, and overweight body habitus. The odds ratio for heavy labor combined with smoking was 4.9 for the presence of Modic changes on MRI.[213]

A recent meta-analysis review of Modic changes by Jensen et al.[214] found that the median prevalence of Modic changes from all studies was 43% in patients with nonspecific LBP. Seven of 10 studies reported a positive association between LBP and Modic changes with odds ratios between 2.0 and 19.9.

Axially and Vertically Loaded Magnetic Resonance Imaging

Axially loaded MRIs have been used to evaluate patients afflicted with lumbar spinal diseases. The idea is to better reproduce the anatomy of the disc under physiologic load. The utility of axially loaded MRI has been primarily studied in the spinal stenosis and spondylolisthesis patient populations.[215-218] Danielson and Willén[219] observed a significant decrease in dural cross-sectional area between a psoas-relaxed position and axial compression in extension in 56% of asymptomatic individuals. The decrease was most pronounced at L4–L5 and greater in older individuals. Saifuddin et al.[220] postulated that lumbar spine MRI with axial loading may increase the sensitivity for the detection of HIZs; however, this hypothesis remains untested.Vertical MRI has also been introduced to represent a loaded spine situation, but no evidence suggests a role in pure DDD.

Discography

Discography is another diagnostic modality for the evaluation of the integrity of the lumbar disc. There is significant controversy surrounding its usefulness. Some investigators consider discography to be the single most important tool in the diagnosis of IDD,[138,221] but recent outcome studies[222] and a practice guideline by the American Pain Society[223] have recommended against the use of provocative discography in the diagnosis of discogenic back pain.

Discography is the only widely available physiologic modality used to determine if a specific disc is a pain generator. Although several attempts have been made to explain the pathogenesis of pain provocation during discography, the precise pathomechanism is not well understood. There are four components to the evaluation of a discogram: (1) the pressure and volume of fluid injected into the disc, (2) the morphology of the disc being injected, (3) the subjective pain response at the level of interest, and (4) the pain response when adjacent control levels are injected.[224,225] The subjective pain response to low-pressure provocation is believed to be the most important determinant of disc derangement; reproduction of the patient's symptoms upon injection of the diseased level is essential to a positive test. A normal disc nucleus can accept 1.0 to 1.5 mL of contrast media. If 2.0 mL or more of contrast is easily introduced, some degree of disc degeneration is assumed with contrast leakage from the nucleus. The use of postdiscography CT increases the sensitivity for the diagnosis of radial tears of the anulus[226]; however, because of low specificity and sensitivity, postdiscography CT is not as helpful in the diagnosis of IDD. Most authors feel that to be diagnostic the pain should be concordant on low-pressure injection and a normal control disc should be pain free.

Despite being used since 1948, discography remains controversial. In the 1960s, Holt et al.[221] and Massie et al.[227] reported on the high false-positive rate of lumbar discography, which was found to be as high as 26% by Holt. Walsh et al.[228] later published a rigorous study on the reliability of lumbar discography. Ten normal volunteers were compared with seven symptomatic patients. Although 17% of the normal discs were found to be morphologically abnormal, there were no positive pain responses. They concluded that with modern techniques the false-positive rate of lumbar discography is not as high as reported by Holt. Derby et al.[229] found similar results in a more recent study of 90 LBP patients and 16 controls. Morphologically, the prevalence of grade III anular tears was 58% among the asymptomatic control population. Presumably asymptomatic discs in symptomatic individuals on pressure-controlled discography demonstrated pain levels and responses similar to the control group, whereas patients with true-positive discography demonstrated pain characteristics concordant with their usual symptoms. The authors concluded that pressure-controlled discography can differentiate between asymptomatic discs and morphologically abnormal discs.

Carragee et al.[163] studied the false-positive rate of low-pressure discography in a comparison of 69 volunteers with no significant LBP and 52 patients undergoing discography in consideration for treatment of discogenic pain. Low-pressure discography was positive in at least one level in 27% of the LBP patients and in 25% of the controls. The false-positive rate of discography was 25% and correlated with psychosocial factors and history of chronic pain of a non–lumbar spine origin. In another publication from Carragee's group,[164] psychosocial factors and chronic nonlumbar pain, such as cervical pain and somatization disorder, also correlated with positive discography in patients asymptomatic for LBP. The authors concluded that false-positive rates can be low with strict application of the Walsh protocol[228] in patients who do not have positive psychometric issues or other chronic pain syndromes.

In contrast to reports of high false-positive rates, two recent meta-analyses of low-pressure discography reported strong evidence to support the role of discography in identifying

patients with discogenic pain.[230,231] Combined data from all studies demonstrated an overall false-positive rate of 9.3% per patient and 6.0% per disc. False-positive rates among asymptomatic patients was 3.0% per patient and 2.1% per disc. Chronic pain was not found to be a confounder, and strength of evidence was reported as level 2 in support of the diagnostic accuracy of discography.

Finding a gold standard to which discography results can be compared remains a problem. Few studies have compared the use of discography and outcomes after surgical fusion, which is perhaps the best measure for the validity of discography. Colhoun et al.,[232] in a study of 137 patients, reported 89% favorable outcomes in patients with positive concordant pain on discography versus 52% favorable outcomes among those who had no painful response. Madan et al.[233] had different findings; 81% of 41 patients who underwent fusion based on MRI findings had satisfactory outcomes versus 76% of 32 patients who had surgery based on discography. Perhaps the most rigorous study to date was published by Carragee et al.[234] Success of surgical fusion was compared in 32 patients with single-level positive discogram and a matched cohort of 34 patients with single-level spondylolisthesis. Seventy-two percent of the spondylolisthesis patients met the highly effective success criteria for surgery versus only 27% of patients with discogenic pain. Minimal acceptable success criteria were 91% and 43%, respectively. The authors calculated a best-case positive predictive value for discography of 50% to 60% and concluded that provocative discography was not highly predictive of single-level discogenic back pain.

In an attempt to improve on the poor reliability of discography, interest has turned to functional anesthetic discograms, also called discoblocks. This is a modification of discography in which a local anesthetic, usually bupivacaine, is infused with the contrast agent into the disc to enhance the diagnostic capability of the procedure. Relief of pain after discoblock is considered diagnostic for discogenic pain. A recent randomized controlled study comparing standard provocative discogram to discoblock in diagnosing discogenic LBP was published by Ohtori et al.[235] Anterior lumbar interbody fusion procedures were performed in 15 patients who were diagnosed with discogenic pain by discography and 15 patients diagnosed by discoblock. Outcome measures (ODI, VAS, and Japanese Orthopedic Association score) at 3 years' follow-up showed statistically significantly better results in the group diagnosed by discoblock.

Regardless of the details of how discography is performed, some authors have posed the question of potential ill effects resulting from perforating the lumbar disc. Carragee et al.[222] recently published a report on the effect of lumbar discography in precipitating accelerated degeneration in a matched cohort study. Ten-year follow-up demonstrated that discs that had been punctured had a greater progression of disc degeneration (35% vs. 14% in the control group). There were 55 new disc herniations in the discography group versus 22 in the control group. The authors concluded that despite utilizing modern discography techniques with small-gauge needles, there is still an increased risk of disc degeneration, disc herniation, changes in disc and end plate signal, and loss of disc height when discography is performed.

Although discography has the potential for diagnosing disc derangement, its reliance on the patient's subjective pain response can also be problematic when secondary gain may be an issue. Psychosocial factors and chronic nonlumbar pain have also been shown to alter the diagnostic capabilities of the procedure. Finally, consideration of the consistent reports of the high false-positive rates, as well as new findings of accelerated degeneration in discs that undergo discography, make it difficult to recommend the procedure for the diagnosis of discogenic back pain. Indeed, the validity of lumbar discography is very much in doubt, which is underscored by a recent practice recommendation published by the American Pain Society. The society's current recommendation is that provocative lumbar discography should not be used for making the diagnosis of a discogenic source of pain in the setting of nonradicular LBP.[223] The value of using discography to assess the levels to be operated on in patients with multilevel disc degeneration has not been adequately established scientifically.

Treatment

Once a clinician has gathered all the data from the history and physical examination along with appropriate diagnostic studies, decisions must be made regarding treatment. All available information should be used in formulating a treatment plan to ensure a successful outcome. Sole reliance on individual clinical findings or imaging studies drastically lowers the success rate because the incidence of disc abnormality in asymptomatic patients approaches 30% to 40% and increases with advancing age.

In 2009, the American Pain Society published five practice guidelines regarding the management of chronic nonradicular back pain based on the best available evidence for the various diagnostic and treatment modalities available. Those recommendations are summarized in Box 46.2.[223] These treatment modalities, along with others not mentioned in the treatment recommendations, are discussed in detail along with brief summaries of the current supporting and opposing literature.

Nonoperative Treatment

Nonoperative treatment of lumbar disc disorders has been extensively discussed in the literature.[236,237] Physical therapy, pharmcology, and spinal manipulations have all been supported by mutliple studies of reasonable quality, but it is difficult to fully evaluate most of these studies because of a generalized lack of randomized control design, blind observers, compliance measures, and cointerventions. Additionally, very little of the literature on these nonoperative treatments is specific for the diagnosis of IDD or DDD, but rather is generalized to chronic and acute LBP, which may have multiple etiologies.

BOX 46.2 American Pain Society Recommendations Regarding Management of Chronic Nonradicular Low Back Pain

Recommendation 1

- Strong recommendation against use of provocative discography as a procedure for diagnosing discogenic low back pain (moderate-quality evidence).
- Insufficient evidence to evaluate validity of diagnostic selective nerve root block, facet joint block, medial branch block, or sacroiliac joint block as diagnostic procedures.

Recommendation 2

- In patients who do not respond to usual, noninterdisciplinary interventions, clinicians should consider intensive interdisciplinary rehabilitation with a cognitive/behavioral emphasis (high-quality evidence).
- Clinicians should counsel patients about interdisciplinary rehabilitation as an initial treatment option.

Recommendation 3

- Facet joint corticosteroid injection, prolotherapy, and intradiscal corticosteroid injection are not recommended (moderate-quality evidence).
- Insufficient evidence to adequately evaluate benefits of local injections, botulinum toxin injection, epidural steroid injection, intradiscal electrothermal therapy, therapeutic medial branch block, radiofrequency denervation, sacroiliac joint steroid injection, or intrathecal therapy with opioids or other medications.

Recommendation 4

- Clinicians should discuss risks and benefits of surgery including a specific discussion about intensive interdisciplinary rehabilitation as a similarly effective option, the small to moderate average benefit of surgery over noninterdisciplinary nonsurgical therapy, and the fact that the majority of patients who undergo surgery do not experience an optimal outcome (moderate-quality evidence).

Recommendation 5

- Insufficient evidence to adequately evaluate long-term benefits and harms of vertebral disc replacement.

From Chou R, et al. Interventional therapies, surgery, and interdisciplinary rehabilitation for low back pain: an evidence-based clinical practice guideline from the American Pain Society. *Spine.* 2009;34:1066–1077.

Bed Rest and Advice to Stay Active

The use of bed rest and its duration has long been debated in the literature. Treatment schedules ranging from 2 days to 6 weeks have been described.[238-240] The currently accepted recommendation[170] is limited bed rest for a maximum of 2 days in patients with acute severe pain because longer durations of bed rest may be detrimental to the patient's general health while offering no benefit to the back pain. Even a short period of bed rest may not be beneficial. Allen et al.[241] published a review of studies of bed rest as treatment for 15 different conditions and found that for patients with acute LBP there was significant worsening of outcome measures. A Cochrane Review of bed rest for treatment of acute LBP reported high-quality evidence that advice to rest in bed is less effective than advice to stay active.[242] Progressive return to activity and the initiation of a formal physical therapy or home exercise program are recommended after any initial short period of rest.

Verbunt et al.[243] explored reasons why patients sometimes use prolonged bed rest in the setting of acute episodes of LBP. Among the study population of 282 patients, 33% reported using bed rest, and 8% remained in bed for longer than 4 days. Behavioral factors, catastrophizing, and fear of injury were associated with use of prolonged bed rest. History of back pain and pain intensity was not associated with patient use of prolonged bed rest. Additionally, patients who used prolonged bed rest in the early phase of acute LBP were more disabled after 1 year.

Patient education and advice to stay active is now the favored recommendation. A Cochrane Review[244] of patient education and advice to stay active demonstrated strong evidence that individual instructional sessions of 2.5 hours are more effective in returning patients to work than no intervention; however, in the setting of chronic back pain, patient education was less effective than more intensive interventions. Education sessions of shorter duration or written information was no more effective than no intervention. Another meta-analysis[245] of 39 randomized controlled studies evaluated whether advice to stay active alone was as effective as advice in combination with other interventions such as "back school" or specific exercise routines. Advice as an adjunct to a specific exercise program was the most common form of treatment in the reviewed studies and was best supported for chronic LBP. Outcomes among acute LBP patients were generally poor, but advice to stay active alone was found to be the best recommendation.

Brox et al.[246] published a systematic review of brief education in the clinical setting involving examination, information, reassurance, and advice to stay active. The authors found strong evidence that brief education was more effective for return to work but was no more effective than usual care for reduction of pain. There was limited evidence that exercise was more effective than dissemination of a back book or an educational internet session.

Orthotics

Another common conservative management technique involves the use of lumbar supports. Calmels et al.,[247] based on the results of a randomized clinical trial, recommended the limited use of a lumbar belt to improve functional status and pain and reduce medication use. Oleske et al.[248] performed a randomized clinical trial of back supports and patient education in work-related back pain. The authors found no effect on patient self-report of recovery or lost work time between brace use and controls, but back supports were found to have value in preventing recurrence of work-related back pain. A Cochrane systematic review[249] of brace treatment for LBP failed to find sufficient evidence to support the use of lumbar supports to treat LBP. Moderate evidence was found that braces are no more effective than no treatment or physical training in preventing episodes of back pain.

Shoe insoles have been recommended in the past for both treatment and prevention of nonspecific LBP. The most recent Cochrane systematic review[250] of six randomized control trials reported strong evidence that use of insoles does not prevent

episodes of LBP. Limited evidence was found that insoles alleviated LBP, but no conclusions or recommendations were made for use in the treatment of patients with LBP.

Physical Therapy

A large number of physical therapy modalities and routines have been described in the literature. They include land-based and aquatic programs, specific protocols and exercise routines, and group treatment programs—so-called *back schools*. Adjunctive modalities include ultrasound, iontophoresis, transcutaneous electrical nerve stimulation, and heat and cold therapy. Exercise programs commonly use aerobic exercise, stretching, flexion and extension routines, core conditioning, and back stabilization protocols. The goal is to improve core strength, flexibility of the trunk and hip muscles, and conditioning. Patients often respond differently to physical therapy so treatment programs must be tailored to the individual. Periods of activity modification may be necessary. Patients should also be educated on proper body biomechanics, lifestyle, and healthy living habits such as weight control, proper nutrition, stress relaxation, and cessation of smoking.

Several published randomized controlled trials have supported different therapy routines or programs. Although a comprehensive review of all the various programs is not in the scope of this chapter, some critical updates in recent years are worthy of discussion. Recent prospective randomized trials comparing physical therapy to fusion have emphasized the importance of a multidisciplinary approach with cognitive therapy, fear-avoidance counseling, and intensive exercise programs.[251-253] A recent systematic review[246] found moderate evidence that fear-avoidance training emphasizing exposure is more effective than graded activity increase for improvement of pain, disability, and fear avoidance.

Intensive interdisciplinary rehabilitation with emphasis on cognitive and behavioral intervention is one of the treatment recommendations by the American Pain Society.[223] Interdisciplinary rehabilitation was defined as an integrated intervention with rehabilitation and a psychological and/or social or occupational component. Noninterdisciplinary or "traditional" physical therapy is also efficacious in this patient population, but no one specific program, method, or technique is significantly better than another. A recent study of 3094 patients treated with physical therapy for back pain concluded that the treatment is safe but did not reach minimally effective clinical level.[254]

Back schools are another commonly discussed therapy modality, and there is some indication that low-intensity back schools may have some efficacy. Heymans et al.,[255] in a randomized controlled trial, found that low-intensity back school patients experienced fewer sick leave days (68 days) than usual care patients (75 days) and those who attended high-intensity back school (85 days). Functional status and kinesiophobia were improved at 3 months, but there was no difference in pain intensity and perception of recovery among the groups. In another randomized controlled trial, however, Kaapa et al.[256] found no significant benefit of back school compared with physical therapy combined with cognitive therapy at 6-month, 1-year, and 2-year follow-up.

A 2004 systematic Cochrane Review[257] concluded there was moderate evidence suggesting that back schools in an occupational setting reduce pain and improve function and return-to-work status compared with other forms of therapy such as exercises, manipulation, myofascial therapy, advice, placebo, and waiting list controls. Brox et al.[246] published a separate systematic review of back schools and found moderate evidence that back schools were no better than waiting lists, no intervention, placebo, or general exercises for reduction of pain.

A European economic evaluation of a randomized controlled study[258] of intensive group therapy found no significant cost difference between intensive group therapy and standard physiotherapy. There was also no difference in clinical effect between the groups at 1 year follow-up.[259] To date there are no economic studies of group therapy back schools in the United States. Although low-intensity back school and programs in a work setting may have a benefit versus other forms of nonoperative treatment, most of the current literature demonstrates that back schools offer little benefit over standard physiotherapy and cognitive therapy.

Adjunctive Modalities

Another treatment option for LBP includes adjunctive physical therapy modalities such as transcutaneous electrical nerve stimulation (TENS), electrical muscle stimulation, ultrasound, and iontophoresis. Poitras and Brosseau[260] published a review of randomized controlled data on the use of TENS and found that it may be useful for immediate short-term pain reduction but has little impact on patient perception of disability or long-term pain control. A 2008 Cochrane Review of TENS versus placebo[261] concluded there is currently not enough evidence to support the routine use of TENS for the management of chronic LBP.[262] There is even less literature available on the use of iontophoresis and ultrasound in the setting of discogenic back pain. The few randomized controlled trials that exist focus on ultrasound in conjunction with other physical therapy regimens. The efficacy of these modalities as well as heat and cold treatments in isolation has not been determined.

Manual Therapy and Complementary/Alternative Medicine Therapies

Several studies have reported beneficial effects of chiropractic treatment for acute nonspecific LBP.[263-265] The role of chiropractic manipulations for the treatment of IDD or DDD of the lumbar spine has not been studied. Chiropractic manipulation is generally not considered effective in the treatment of chronic back pain resulting from disorders of the IVDs.[266] A Cochrane Review[267] reported there was no evidence that spinal manipulative therapy was superior to general practioner care, analgesics, physical therapy, exercises, or back school in the treatment of both acute and chronic LBP.

Eisenberg et al.[268] published a randomized trial of usual care therapy (nonsteroidal antiinflammatory drugs [NSAIDs], educational and activity modification) versus the addition of the patient's choice of alternative therapy—chiropracty, acupuncture, or therapeutic massage—in the treatment of acute LBP. Outcomes using the Roland-Morris scale and subjective assessment of symptoms demonstrated no statistically significant improvement in patients who underwent alternative therapies. The study did, however, demonstrate an increase in patient satisfaction with alternative therapy.

Hurwitz et al.[269] had similar findings in a randomized prospective study of 681 patients with chronic LBP comparing chiropractic care to medical treatment with 18 months of follow-up. Although less than 20% of the patients experienced overall relief of pain and differences in outcome measures were not clinically significant, patients in the chiropractic group were more likely to perceive that their symptoms had improved.

Andersson et al.[270] compared osteopathic manual therapy to usual care in patients with a 3- to 6-month history of back pain and found that the overall results were similar, but the manual therapy group required fewer medications.

Other alternative medical therapies such as acupuncture, prolotherapy, and massage have also been evaluated. A Cochrane Review of acupuncture[271] showed superiority to placebo sham therapy and also a short-term benefit that did not extend beyond first follow-up when acupuncture was used in conjunction with other conventional therapies. However, a more recent systematic review by Ammendolia et al.[272] questioned inconclusive evidence of the success of acupuncture versus sham acupuncture and called for further randomized trials to rule out the possibility of a placebo effect.

Prolotherapy is a technique that attempts to regenerate ligamentous and tendinous structures of the spine via injections of various irritant solutions. The treatment is usually performed in conjunction with spinal manipulation. There is no consensus on method, type of solution injected, or frequency of sessions. Most practitioners use various combinations of saline, dextrose, glycerin, phenol, and lidocaine. Reports of the efficacy of prolotherapy are conflicted among many randomized trials and systematic reviews.[273-275] No evidence has been reported for the efficacy of prolotherapy without cointerventions such as spinal manipulation or exercise.

The efficacy of complementary and alternative modalities for the treatment of chronic LBP remains in question. The benefit of spinal manipulative therapy is also controversial but may improve patient satisfaction with care and perception of symptoms.

Pharmacotherapy

Judicious use of narcotic pain medications, oral steroids, and NSAIDs in patients with severe, acute back pain can provide good pain relief. The majority of patients with painful degenerative discs can be treated adequately on an outpatient basis. NSAIDs and acetaminophen are common over-the-counter medications used to treat back pain. A Cochrane Review[276] included 65 studies on NSAID use in LBP. NSAIDs were found to be superior to placebo but had significantly more side effects. There is no documented difference between type of NSAID, including cyclooxygenase-2 inhibitors. Acetaminophen has an effect similar to NSAIDs, but it has less risk of associated side effects when taken as directed and generally should be tried before NSAIDs. A Cochrane group concluded that NSAIDs are effective for short-term treatment of acute and chronic LBP, but the size of the effect is small.

Opioid formulations are also commonly used to treat back pain, but considering their widespread use there is a surprising paucity of high-quality randomized controlled data available on their efficacy. A Cochrane meta-analysis[277] of opioid use found only four studies, three of which focused on the use of tramadol. Pooled data found that tramadol, an atypical opioid, was more effective than placebo for pain relief and showed a slight improvement in functional scores. The only randomized controlled study of classic opioids[278] was a comparison to naproxen. Opioids were found to be more effective for pain relief but were not more effective for improving function than naproxen. The Cochrane authors concluded that the benefits of opioids for the treatment of chronic LBP are questionable, and further well-designed randomized controlled studies need to be performed. Two systematic reviews[279,280] of opioid use in the setting of chronic LBP have concluded there is evidence to support the efficacy of opioids for short-term relief of pain only. There is little evidence for long-term opioid use, which is fraught with an incidence of aberrant consumptive behavior approaching 25%.

Opioid pain medication use has many problems, ranging from minor side effects such as constipation and nausea to severe complications including respiratory depression, altered mental status, and insidious issues with tolerance and addiction. Another concern is the combination of opioids and acetaminophen in commonly prescribed formulations.[281] Hepatotoxicity and death from acetaminophen overdose is rare when the dose is less than 7.5 to 10 g in an 8-hour period,[282] but concern arises when patients inadvertently take larger doses in the setting of prescription drug abuse. An FDA advisory committee[283] recommended the addition of a boxed warning on the risk of acetaminophen overdose and also suggested elimination of combination opioid-acetaminophen formulations. Opioid pain medications should be given for only a few days in the setting of severe acute back pain. Opioid prescriptions for patients with chronic back pain are not recommended.

Oral tapering courses of steroids have been found to decrease symptoms of LBP in patients with radiculopathy from disc herniations.[175,284] In patients with axial LBP, steroids are not recommended.[285] Steroids can cause gastrointestinal bleeding; simultaneous use of gastrointestinal protective agents with oral steroids can reduce the risk of this complication.

Muscle relaxants are another class of medication routinely used in the treatment of muscle spasm associated with LBP. Their use should also be limited to very short courses due to their addictive potential. A Cochrane Review[286] of muscle relaxants for the treatment of back pain included 30 trials evaluating the use of benzodiazepines, nonbenzodiazepines,

and antispasmotic muscle relaxants. Strong evidence for the efficacy of muscle relaxants over placebo was reported for short-term pain relief in the setting of acute back pain. No difference between the various drugs and classes was discerned. More trials to determine the efficacy of muscle relaxants compared with other analgesics and NSAIDs were recommended.

The last class of medications commonly prescribed in the setting of back pain are antidepressants. Their use may be particularly beneficial in patients presenting with chronic LBP in association with altered mental status, depression, anhedonia, sleep disturbances, agitation, and anorexia. Clinical studies[287-289] supporting the use of tricyclic antidepressants (TCAs) have shown an improvement in mood and sleep patterns. Low doses of TCAs also affect membrane potentials of peripheral nerves, which may be a mechanism by which they produce pain reduction. A 2003 review[290] of antidepressants in the treatment of chronic LBP found TCAs have a moderate effect on pain reduction in patients with no history of depression but reported conflicting evidence for improvement in functional outcomes. Physicians prescribing TCAs should be aware of potentially serious side effects involving orthostatic hypotension and cardiovascular perturbations. Selective serotonin reuptake inhibitors, another common class of antidepressants, failed to show efficacy in the treatment of chronic LBP and should be reserved for emotional or psychiatric disturbances related to back pain, not as a primary treatment for symptoms of back pain.[291]

Keller et al.[292] published a recent meta-analysis of nonsurgical management options for LBP. The authors reported that behavioral therapy, exercise therapy, and NSAIDs had the largest effect of those modalities studied. Machado et al.[293] published a separate large meta-analysis of placebo-controlled randomized trials of various forms of nonoperative treatment for nonspecific LBP. Small improvements in pain were found in patients treated with traction, physical therapy, antidepressants, and NSAIDs; moderate improvements were reported in patients treated with opioid analgesics, muscle relaxants, facet injections, and nerve blocks.

Nonsurgical Interventional Therapies

Nonsurgical treatment alternatives range from short-term temporizing measures, such as epidural injections, to procedures designed to be definitive treatments, such as intradiscal electrothermal therapy (IDET).

Epidural Spinal Injection

The advantage of epidural injections over oral steroids is the ability to achieve higher concentrations of steroid at the suspected site of pain while minimizing systemic effects. Epidural steroids typically work well when administered in the setting of radicular pain and not well in the setting of axial pain. Patients with foraminal stenosis secondary to loss of disc height may benefit from selective nerve root blocks either as a diagnostic or a therapeutic tool. Many clinicians recommend epidural steroid injections as second-line therapy in the treatment of lumbar disc disorders. Epidural steroids are commonly administered by three different routes: caudal, interlaminar, and transforaminal. The transforaminal approach is generally considered best because it achieves a better anterior epidural distribution. Complications from injection exist but are uncommon.[294,295]

Reports on the efficacy of epidural injections in the literature are contradictory. Manchikanti et al.[296] published preliminary results of a randomized trial of serial caudal epidural injections in patients with discogenic pain without disc herniation or radiculitis. The authors reported greater than 50% pain relief in 72% to 81% of patients and 40% reduction in ODI scores in 81% of patients. They concluded that caudal epidural injections with or without steroid are effective in treating discogenic back pain in more than 70% of patients. Two other observational studies[297,298] by the same authors had similar findings for the beneficial effects of caudal epidural injections in the specific setting of discogenic LBP.

Buttermann[299] studied patients with DDD and back pain of greater than 1 year duration who were candidates for fusion. There was initial success of treatment in greater than 50% of patients, but the success rate declined to between 23% and 29% by 1- to 2-year follow-up. The study had a high dropout rate, with more than two-thirds of the patients seeking another invasive treatment within 2 years. The authors concluded that patients with DDD but without spinal stenosis may experience a short-term benefit from epidural injections, with only one-fourth to one-third experiencing long-term improvement in pain and function. Other earlier studies of both caudal and transforaminal approaches have reported similar good short-term results, with up to 59% of patients having greater than 50% improvement in symptoms and function at a 1-year interval.[297,300]

A systematic review[301] criticized the literature on epidural injections for a lack of careful control of route of administration and patient diagnosis. In one evaluation of the pooled data, the only evidence found to support epidural injections was for short-term symptom relief in nonspecific LBP. No well-designed randomized trials were found specific to discogenic back pain. A 2008 Cochrane Review[302] of injection therapy for LBP failed to find sufficient evidence to make a recommendation. A systematic review by Chou et al.,[303] as part of the American Pain Society practice recommendations, found fair evidence that epidural steroid injection is moderately effective for short-term pain relief; however, the literature supporting its use in nonradicular LBP is sparse and has not shown significant benefit. No specific recommendation for the use of epidural steroid injections or the route of administration was made by the pain society.

Intradiscal Injection

Direct intradiscal injection, usually with a steroid solution, is another intervention that has been described in the literature for IDD. The desired effect is suppression of an inflammatory process within the disc, which is thought to be the cause of the discogenic pain. Intradiscal steroid injections were

reported in an early case series by Feffer,[304] in which 47% of patients reportedly had remission of discogenic symptoms. Similar results were found by Wilkinson and Schuman.[305] Fayad et al.[306] reported short-term improvement in VAS score at a 1-month follow-up with intradiscal steroid injection in patients with Modic types 1 and 1 to 2 changes on MRI, but there was no long-term benefit. The only two major prospective randomized trials[307,308] of intradiscal steroid injection have failed to find a statistically significant benefit versus placebo in the treatment of discogenic back pain. Other authors have attempted intradiscal injection of various other substances, including solutions of chondroitin and dextrose,[309] hypertonic dextrose,[310] methylene blue,[311] and oxygen-ozone gas mixtures.[312,313] Although these studies report promising results, they have yet to be proven efficacious by rigorous randomized controlled trials.

Thermal Annuloplasty

Intradiscal electrothermal therapy (IDET) involves percutaneous insertion of a thermally controlled catheter into the IVD, usually the posterior anulus, and heating the tissue to a specific temperature (90°C) for a prescribed period of time (e.g., 20 minutes).

The proposed mechanism of action for these procedures is twofold: (1) elimination of nociceptive pain fibers and aberrant painful responses to the disrupted disc, and (2) collagen rearrangement in the anulus with resultant spinal segment stabilization. The biologic effects are not well understood and there is a lack of clear consensus regarding the effects on neuronal deafferentiation, collagen modulation, and spinal stability. Freeman et al.[314] studied the effect of nociceptor destruction via IDET on experimentally created anular tears in a sheep model. The authors failed to find any difference in the amount of neoinnervation in the anulus between specimens that underwent IDET and those that did not, which calls into question the theory of deafferentiation of the anulus. Whether collagen rearrangement with resultant shrinkage and stabilization of the discal element is a viable mechanism for IDET also remains in question.[315,316] Cadaveric studies of the effect of IDET on anular collagen have been performed by Kleinstueck et al.,[316] which showed a 10% to 16.7% reduction in tissue volume immediately adjacent to the electrode.

To destroy nociceptors in the anulus fibrosus temperatures must be raised to a minimum of 42°C to 45°C.[317,318] It is not possible to generate sufficient temperatures in the anulus with a radiofrequency probe placed in the center of the disc, as demonstrated by Houpt et al.[319] Temperature changes at distances further than 11 mm were insufficient to raise the tissue temperature of the outer anulus to the 42°C needed for neuronal ablation. Ashley et al.[320] compared temperature distribution in the disc between a radiofrequency needle and a navigable Spinecath. Using this method, they were able to deliver thermal energy to the anulus more effectively and achieved sufficient temperatures to cause denervation. Karasek and Bogduk[321] have recommended inserting the IDET electrode so as to remain within 5 mm of the outer surface of the anulus. Placement of the probe in the interlamellar plane rather than inside the innermost layer of the anulus allows for sufficient heat generation to destroy the nociceptors in the outer layers of the anulus.

Complications secondary to any of the thermal annulopasty procedures are rare. There has been one reported case of postoperative cauda equina syndrome caused by inadvertent placement of the catheter in the spinal canal,[322] and a few reports of broken catheters with no resultant adverse effect. There have been no reports of infection, bleeding, or other equipment- or technique-related complications.

Early uncontrolled clinical trials of IDET were promising, with improvement in 50% to 70% of patients,[137,321,323,324] but randomized controlled trials have produced conflicting results. Freeman et al.[325] found no significant improvement in outcome measures compared with sham surgery at 6-month follow-up. The opposite findings were reported by Pauza et al.[326] in patients with discographically diagnosed LBP of greater than 6 months' duration. The authors found that 40% of their patients who underwent IDET experienced at least 50% relief of pain, whereas a significant portion of the control group experienced symptom progression. They concluded that the IDET procedure is an effective intervention for a selective patient population and reported a needed-to-treat number of five to achieve 75% relief of pain. Barendse et al.[327] reported on a trial of intradiscal radiofrequency thermocoagulation in patients with chronic discogenic back pain. An 8-week follow-up assessment showed no difference from sham surgery in VAS score, global perceived effect, and ODI outcome measures.

Andersson et al.[328] published a systematic review of IDET versus spinal fusion in patients with disc degeneration and disruption. Similar median percentage improvement was noted between the two interventions for pain severity and quality-of-life outcomes. Fusion demonstrated better functional improvement but had a higher rate of complications. The authors concluded that IDET offers similar symptom relief with less risk of complications compared with fusion. Derby et al.,[329] in a systematic review, concluded that IDET is generally safer and cheaper than more invasive surgical techniques despite the fact that the best evidence available demonstrates only modest improvement in pain relief and functional outcomes.

Other systematic reviews of IDET have been more critical. Helm et al.[330] reported level 2 evidence in support of IDET in the setting of discogenic back pain based on two of the above randomized trials and a number of observational studies. Two observational studies were found by the authors in support of radiofrequency intradiscal thermocoagulation for level 3 evidence. Evidence in support of biacuplasty was lacking and was assigned as level 3 evidence. Freeman[331] published a systematic review of the literature that criticized generally poor outcomes even among studies in support of IDET. The author concluded that evidence for the efficacy of IDET is weak and has not passed the standard of scientific proof.

In summary of all nonoperative interventional therapies, Chou et al.[303] published a systematic review as part of the American Pain Society practice recommendations published in 2009. The authors reported fair evidence that epidural

steroid injections are effective for short-term relief of pain. Good evidence was reported that prolotherapy, facet injection, intradiscal steroid, and intradiscal radiofrequency thermocoagulation are not effective. For IDET, no conclusions were made due to the fact that available randomized controlled trials are conflicting. IDET may best be indicated for less functionally impaired patients with well-maintained disc heights and discogenic pain from anular tears.[329]

Surgical Treatment

Once all conservative measures have been exhausted or if symptom nature warrants, surgical intervention may be required. The most common surgical treatment used for recalcitrant discogenic back pain and DDD is arthrodesis (fusion). Lumbar disc arthroplasty is another method approved by the FDA but is not currently in widespread use. Other motion-preserving options being investigated include dynamic stabilization of the motion segment and biologic disc repair.

Chou et al.[332] published a systematic review of surgical treatment for nonradicular LBP as part of the American Pain Society's practice recommendations. The authors found fair evidence that surgical fusion is no better than intensive rehabilitation with a cognitive behavioral emphasis. Surgically treated patients were noted as performing poorly, with less than 50% obtaining optimal outcome with fusion. The benefits of instrumented fusion compared with noninstrumented fusion were not clear. Fair evidence was found that arthroplasty performs as well as fusion for single-level DDD, but long-term outcome data were lacking.

The American Pain Society[223] practice recommendations, published in 2009, encourage clinicians to offer intensive interdisciplinary rehabilitation as an option with outcomes similar to surgery in the setting of nonradicular LBP. The report states that the majority of patients with nonradicular pain who undergo surgery do not experience an optimal outcome, which was defined by the pain society as (1) minimal or no pain, (2) discontinuation of or only occasional use of pain medications, and (3) return to high-level function. The society also suggested that there is insufficient evidence at this time to support disc arthroplasty for patients with nonradicular LBP. Other treatment guidelines also take a cautious view on spinal fusion for DDD, yet in some patients the symptoms are so severe that the chance for a good result makes surgical management attractive, especially when nonoperative treatment has failed.

Spinal Fusion

Surgical treatment for unremitting discogenic back pain has traditionally been spinal fusion. Most clinicians find that it is acceptable to perform spinal fusion for DDD in patients who have not responded to conservative care. The role of spinal fusion in the management of IDD is more controversial.[333]

Three high-quality randomized controlled studies have evaluated spinal fusion compared with nonoperative treatment in the setting of chronic LBP and DDD. Fritzell et al.[334] published a randomized controlled multicenter study of severe chronic LBP comparing fusion of the lower lumbar spine with nonsurgical therapy. The study involved a total of 222 operative and 72 nonoperative patients between the ages of 25 and 65 years with chronic LBP of at least 2 years' duration and radiologic evidence of disc degeneration at L4–L5, L5–S1, or both. The nonsurgical group received physical therapy, patient education, and alternative pain control modalities, such as TENS units, acupuncture, and injections. Results at 2-year follow-up were found to be significantly better in the fusion group, with back pain reduced by 33% compared with 7% in the nonsurgical group. Pain improvement was most significant during the first 6 months postoperatively but then gradually deteriorated thereafter. Disability according to ODI was reduced by 25% compared with 6% among nonsurgical patients, and 63% of surgical patients rated themselves as "much better" or "better" compared with 29% of nonsurgical patients. The "net back to work rate" was 36% in the surgical group and 13% in the nonsurgical group. The early complication rate in the surgical group was 17%. The authors concluded that surgical treatment of severe chronic LBP provides improved results compared with nonoperative treatment in carefully selected patients.

Brox et al.[251] published another randomized trial comparing outcomes of lumbar instrumented fusion versus cognitive intervention and exercise in 64 patients with chronic LBP and DDD. The critical component of this study was the addition of cognitive therapy to an intensive rehabilitation program. The mean change in ODI for the surgical fusion group was from 41 preoperatively to 26 at 1-year follow-up; mean change for the rehab group was from 42 to 30. The authors reported no significant difference in back pain, use of analgesics, emotional distress, and life satisfaction between the groups. Return-to-work rate at 1 year was 22% in the surgical group and 33% in the rehab group. The rehab group experienced greater improvement in fear-avoidance beliefs and fingertip-to-floor distance, while the surgical group had greater improvement in associated symptoms of leg pain. The overall success rate for surgical intervention was rated at 70% and 76% for nonoperative cognitive therapy. The authors concluded that there were near-equivalent outcomes between the groups, which was offset by an 18% complication rate among the surgical group.

The last major randomized clinical trial of surgery versus nonoperative therapy was published by Fairbank et al.[253] The MRC Spine Stabilization Trial was a randomized controlled trial comparing surgical treatment and intensive rehabilitation in 349 patients with chronic LBP. Similar to the Brox study, the intensive physical therapy program in the MRC trial also incorporated principles of cognitive behavioral therapy. At 1-year follow-up the mean ODI scores decreased from 46.5 to 34.0 in the surgical group and from 44.8 to 36.1 in the rehabilitation group. No significant differences were found between the groups in the shuttle walking test and Short Form-36 outcomes. The authors concluded that although the surgical group enjoyed a small—but statistically significant—benefit in one of the primary outcome measures (ODI), this was contradicted by the additional cost and potential risk of complication associated with surgery.

In a separate publication on the MRC trial, Rivero-Arias et al.[335] performed a cost analysis at 2-year follow-up. The cost per patient over the study time frame in the surgical group was estimated to be £7830 ($12,450), versus £4526 ($7200) in the rehabilitation group. There was no significant difference in mean quality-adjusted life-years between the groups. The authors concluded that surgical treatment was not a cost-effective use of health care funds compared with therapy, although the authors pointed out that ultimate costs could vary depending on the number of patients in either group that require subsequent intervention after the 2-year follow-up period.

Meta-analyses of surgical versus nonoperative treatment have paralleled the findings of Brox et al.[251] and the MRC trials.[253] Ibrahim et al.[336] pooled the data from these three randomized trials and found that a modest improvement in mean ODI scores among surgical patients should not be used as justification for routine operative treatment in light of a 16% early complication rate. Mirza et al.,[337] in a separate systematic review, concluded that surgical outcomes are equivalent to a structured rehabilitation program with cognitive behavioral therapy.

Phillips et al.[338] performed a systematic review of fusion in the treatment of DDD. They concluded that comparing surgery to nonoperative treatment obviates the fact that the treatments generally are performed in sequence, with surgery occurring when nonoperative treatment has failed. They further concluded that lumbar spine fusions result in meaningful improvements in pain and function.

Fusion Technologies

Over the years there has been a change from posterolateral and anterior stand-alone fusions to circumferential fusions. In recent years lateral fusion techniques have grown in popularity, as have minimally invasive fusion techiques. There is little question that minimally invasive approaches will grow in use; in fact, all procedures today are done with less-invasive techniques than in the past.

The use of new materials in implants and osteobiologics are discussed elsewhere in this text. Iliac crest bone grafts are today rarely used in the United States.

Adjacent-Segment Degeneration

A serious adverse effect of fusion surgery is adjacent-segment pathology. Sometimes it is an imaging finding without clinical importance, but sometimes it results in pain and may result in an extension of the fusion.[339,340]

As a consequence motion-preservation techniques have developed such as disc replacements and posterior motion preservation systems. These techniques are discussed in other chapters of this text.

Biologic Treatment of Degenerative Disc Disease

Over the past few decades research into biologic repair of disc degeneration has grown substantially. Molecular therapy, gene therapy, and stem cell disc regeneration are all viable alternatives but are not yet at the stage where they can be used clinically with predictable success.[341-343] Tissue engineering approaches are challenged by the complexity and stresses of the IVD.[344] Biologic repair will undoubtedly succeed at some time in the future but is not an immediate solution.

Summary

Lumbar disc disease is a common problem that affects many people at various ages in the form of IDD and DDD. Detailed history and physical examination are vital components in harmony with imaging modalities to make an accurate diagnosis. Recent practice guidelines have reaffirmed that the first line of treatment for those who have LBP of a discogenic source, with or without radicular symptoms, is conservative therapy. New emphasis has been placed on multidisciplinary therapy incorporating cognitive and behavioral treatment. Intradiscal therapy remains controversial, and many patients who undergo this procedure may eventually require arthrodesis. Surgical fusion, in all the various forms, is an appropriate option for patients who do not improve with appropriate nonoperative therapy. Preliminary studies of lumbar total disc replacement report equivalence to arthrodesis for the management of this patient population. Development of new motion-preserving techniques will likely change the treatment approach, as will emerging biologic techniques.

KEY POINTS

1. Detailed history and physical examination in conjunction with radiographic and MRI findings such as loss of disc height, disc signal changes, HIZs, and Modic changes are the best means available for diagnosing IDD and DDD.
2. Routine use of lumbar discography is not recommended for diagnosing a discogenic LBP.
3. Recent practice guidelines have reaffirmed that the first line of treatment for patients with LBP of a discogenic source, with or without radicular symptoms, is conservative therapy, and new emphasis has been placed on multidisciplinary therapy incorporating cognitive and behavioral treatment.
4. IDET remains controversial, and many patients who undergo this procedure still require arthrodesis. Other forms of less-invasive therapy, such as prolotherapy and intradiscal corticosteroid injections, are not recommended in this patient population.
5. Surgical fusion is an appropriate option for patients who do not improve with exhaustive nonoperative therapy.
6. No one method for achieving segmental fusion has clearly been shown to be better than another.
7. Preliminary studies of lumbar total disc replacement report equivalence to arthrodesis for the surgical management of this patient population, but there is still insufficient evidence to evaluate the long-term benefits and complications.

CHAPTER 47

Lumbar Disc Herniations

SECTION VI

Amandeep Bhalla
Christopher M. Bono
Andrew J. Schoenfeld
Steven R. Garfin

Lumbar disc herniations are a common manifestation of degenerative disease.[1-3] They tend to occur early within the degenerative cascade, representing the tensile failure of the anulus to contain the gel-like nuclear portion of the disc. With improvements in advanced imaging techniques, lumbar disc herniations have been increasingly recognized in symptomatic and asymptomatic individuals.[4]

Treatment decision making for patients with herniated discs can be challenging. Nonoperative treatment can be effective in most cases.[5–9] Other authors have indicated that surgery leads to superior results, especially in short-term pain relief.[1,7–10] Several authors have highlighted the influence of fragment location and pattern, as well as social and psychological factors on outcomes.[7–9,11–13] The exact natural history and complex interaction of biologic, psychosocial, ergonomic, and cultural variables have not been well established.

In the best-case scenario, the clinician can radiologically identify a single culprit disc that positively correlates with clinical findings. In patients who do not respond to nonoperative management, disagreement remains concerning the optimal period of observation, timing of surgery, method of excision, and type of postoperative rehabilitation. In less evident cases, one or more minor disc bulges may be identified that are difficult to attribute to the patient's signs and symptoms. The use of diagnostic injections can be helpful in localizing symptomatic regions. Empiricism and reliance primarily on intuition may lead to inferior results. Strict agreement between a patient's signs, symptoms, and correlative diagnostic tests needs to exist when predicating treatment recommendations.

To address these questions, the wealth of classic and contemporary contributions made to the understanding of lumbar disc herniations has been reviewed. This chapter synthesizes the information and organizes it to help clinicians' understanding and recommendations of management of this seemingly simple, but realistically challenging, problem.

Pathoanatomy

Effective evaluation is based on an intimate understanding of the relationship of the lumbar intervertebral disc to its surrounding structures. The disc is the anterior border of the spinal canal at the facet joint level. It is covered by the thin posterior longitudinal ligament, which is concentrated in the midline, from which small bands extend laterally to cover the inferior aspect of the disc (Fig. 47.1). This configuration leaves the superior part of the posterolateral disc bare, and is thought to contribute to the fact that posterolateral (or paracentral) herniations are the most frequent location for herniations to occur. Cumulative degenerative changes occur in this region of the disc from concentration of torsional, axial loading, and flexion-induced biomechanical strains.

The spinal cord ends at approximately the L1 level in adults to form the conus medullaris. The cauda equina is located within the lumbar spinal canal. It contains the lumbar and sacral nerve roots bathed in cerebrospinal fluid contained—or encapsulated—by the pia, arachnoid, and dural membranes (meninges). Nerve roots branch from the cauda equina one level above their exiting foramen (Fig. 47.2). The L5 nerve root leaves the cauda equina approximately at the level of the L4 vertebral body. It descends inferolaterally to pass anterior to the L4–L5 facet joint and posterior to the L4–L5 disc. Intimately associated with the inferomedial aspect of the L5 pedicle, the root turns lateral to enter the L5–S1 intervertebral (neural) foramen just proximal to the L5–S1 disc. Within the foramen, sensory cell bodies form the dorsal root ganglion. The root, now called a *postganglionic spinal nerve,* exits the neural foramen, where it is in close proximity to the lateral aspect of the L5–S1 disc. Fibrous bands (called *Hoffman ligaments*) often tether the nerve to the disc in this region.[14,15] After a short extraspinal course, the nerve divides into a ventral and dorsal primary ramus.

The location of the disc herniation determines which root is primarily affected. The spinal canal can be divided into longitudinal zones (Fig. 47.3). The *central zone* is delineated by the lateral borders of the cauda equina. The *lateral recess* is between the lateral border of the cauda equina and the medial border of the pedicle. Although the term *lateral recess* is frequently used to describe stenosis from bony encroachment (*lateral recess stenosis*), it sufficiently describes the location of *paracentral, posterolateral,* or *juxtacentral* herniations. Within the lateral recess, fragments medial to the nerve root,

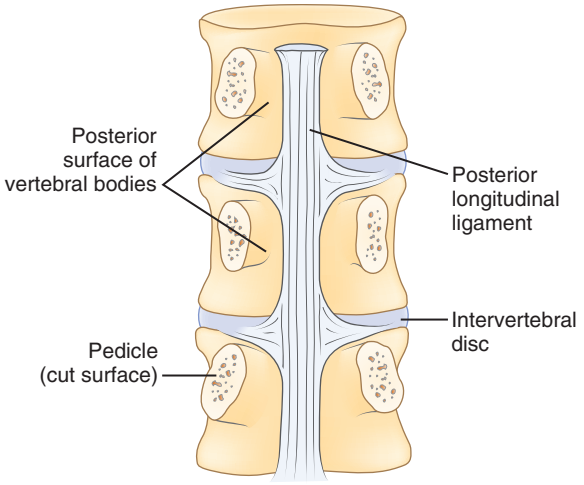

FIG. 47.1 The posterior longitudinal ligament incompletely covers the posterior portion of the disc. Specifically, the superolateral aspect of the disc remains uncovered, which may help explain why disc herniations are most common in this region.

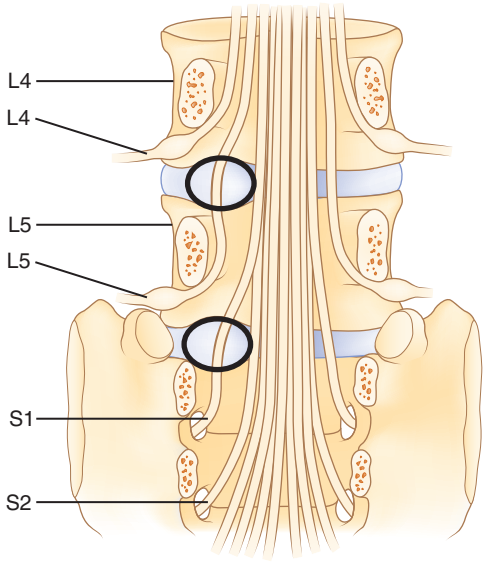

FIG. 47.2 Lumbar nerve root branches exit the dural sac one vertebral level above their respective foramen. Paracentral disc herniations tend to affect the traversing nerve root as it crosses the intervertebral disc.

interposed between it and the cauda equina, are called *axillary* herniations (Fig. 47.4). The *foraminal* zone is between the medial and lateral borders of the pedicle. Herniations beyond the lateral border of the pedicle are within the far-lateral or *extraforaminal* zone. Herniations in the foraminal or extraforaminal zones usually affect the exiting nerve.

Fragments can displace cranially or caudally. Axillary herniations have a tendency to migrate distally, lying inferior to the disc space. Superior migration of the fragment can position it behind the adjacent cranial vertebral body. Locating the fragment preoperatively is crucial to successful operative excision.

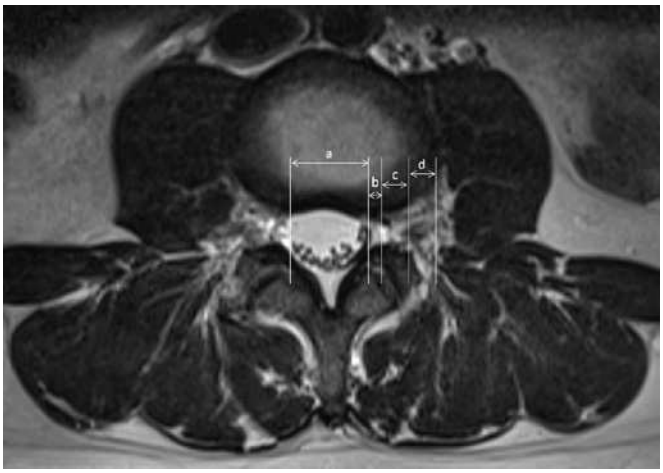

FIG. 47.3 Considered in cross-section, the spinal canal can be divided into anatomic zones to describe better the location of lumbar disc herniations. *The central zone* (*a*) is within the borders of the cauda equina dural sac. The *lateral recess* (*b*), which paracentral disc herniations can compromise, is bordered by the lateral aspect of the dural sac and the medial aspect of the pedicle and neural foramen. In this zone, the nerve root descends within the spinal canal toward its respective foramen. The *foraminal zone* (*c*) is the space between adjacent ipsilateral pedicles. The *extraforaminal zone* (*d*) is the space lateral to the pedicles. Disc herniations in this region, commonly referred to as *far lateral,* affect the exiting nerve root.

Pathophysiology

Disc Degeneration and Herniation

Disc herniation is one stage of the lumbar degenerative cascade. It is considered one of the earlier stages, following internal disc disruption. Herniation occurs through a tear in the anulus fibrosus. The anulus is the thick outer layer that normally withstands tensile forces transferred from the compressed nucleus pulposus (Fig. 47.5).[16,17] Force transfer works only if the nucleus-anulus-endplate complex acts as a closed-volume system.[18] Normally, compression across the disc space leads to increased pressure within the nucleus. The soft nucleus deforms and flattens, pushing against the annular fibers, which then generates tensile hoop stresses. The circumferential fibers are placed under tension, dissipating stresses and containing the anulus.

With disruption of the anulus, the soft nucleus can be pushed through (i.e., herniated) if placed under sufficient pressure. The nucleus must be fluid, or "dynamic," enough to permit herniation to occur. Discs in younger individuals that have a well-hydrated nucleus are more likely to herniate. Older patients with desiccated discs are less prone to herniation. The ejected portion is typically a fibrocartilaginous fragment.[19] In some cases, a piece of anulus or endplate fibrocartilage can be associated with it. In juveniles, an apparent herniation may represent a Salter type II fracture of the vertebral ring apophysis with its attached anulus.

When a portion of the nucleus is ejected, disc mechanics are altered. Frei and colleagues[17] showed that nucleotomy alters the loading pattern across the disc space, with the anulus sustaining higher compression forces than normal.

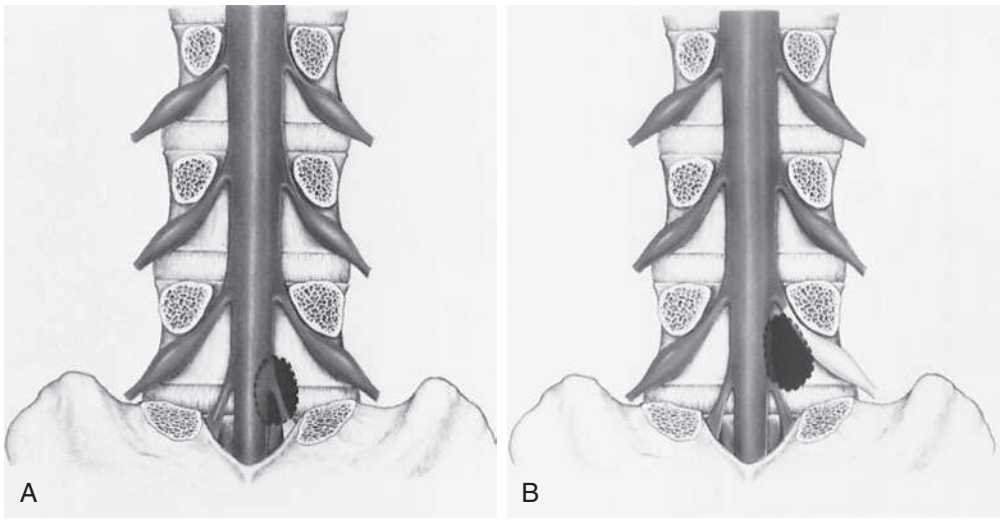

FIG. 47.4 (A) Most commonly, paracentral disc herniations compress the traversing (descending) nerve root along its lateral aspect. (B) In some cases, the disc fragment can be interposed between the nerve root and lateral border of the cauda equina sac. These are known as *axillary disc herniations*.

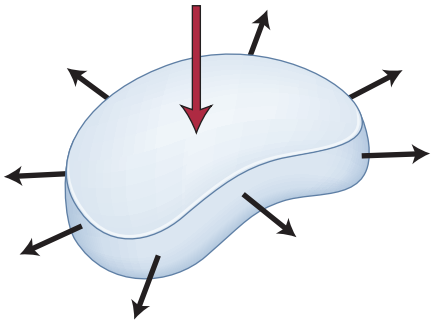

FIG. 47.5 The thick, outer anulus normally withstands tensile forces transferred from a compressed nucleus pulposus. This force transfer works, however, only if the nucleus-anulus-endplate acts as a closed-volume system. An annular defect disrupts this closed-volume system and can allow a portion of the nucleus to escape (or herniate).

This situation can lead to increases in endplate pressures along the periphery where the anulus attaches to the bone. Chondro-osseous metaplastic changes such as osteophytes or sclerosis in these regions are a response to long-standing abnormal loading patterns.

The exact inciting event leading to disc herniation is unknown. Some authors believe that an acute traumatic episode leads to displacement of the disc, although this is most likely related to force imparted onto a previously degenerated disc, which has developed a focal annular weakness. Acute sciatica from a disc herniation is often associated with a prodromal history of back pain.

Postural variations can influence intradiscal pressures. The highest pressures have been recorded in patients with the torso forward flexed with weight in hand. In an elegant biomechanical study, Wilder and colleagues[16] found that combined lateral bend, flexion, and axial rotation with 15 minutes of exposure to vibration can lead to tears extending from the nucleus across the anulus. This finding may have significance for occupations with exposure to long periods of vibratory stimuli, such as truck drivers and machine workers.

Disc Herniation and Sciatica

The most classic symptom of a herniated disc is radicular pain in the lower extremity following a dermatomal distribution. Focal neurologic deficits attributable to the same nerve root are sometimes present and lend further diagnostic accuracy. The relationship between disc herniation and sciatica is incompletely understood, however.

In animals and humans, pure compression of a noninflamed nerve produces sensory and motor changes without pain, whereas pain is elicited with manipulation of inflamed nerves.[20] These findings suggest that herniated discs large enough to cause mechanical compression of a nerve root may produce focal deficits, but that associated sciatic-type pain is produced only if the nerve root is concurrently irritated or inflamed. Inflammation may be produced by prolonged neuroischemia of the microvasculature of the nerve root from mechanical compression or by nonmechanical, possibly biochemical, factors. This phenomenon helps explain why some patients with small bulges or protrusions contacting inflamed nerves have pain that does not seem to be consistent with the "small" degree of neural compression. Additionally, these patients frequently do not have demonstrable sensory or motor deficit.

Neurochemical factors also have a role in the production of sciatic pain. This role may be related to initiation of an immune response locally or systemically, or both. Spiliopoulou and colleagues[21] examined immunoglobulin G (IgG) and IgM levels in discs excised from patients with sciatica and controls. Although IgG levels were equivalent, elevated levels of IgM were found in discs from sciatica patients but not in controls, suggesting a local and humoral antigenic inflammatory reaction as a contributor to pain. Other investigators have shown the role of cytokines in the mediation of root pain. Olmarker and Rydevik[22] studied the effects of selective inhibition of tumor necrosis factor-α (TNF-α) in a herniated disc model in pigs. They found preservation of nerve conduction velocity and decreased nerve root injury in treated animals versus

controls, suggesting a role of TNF-α in potentiating nerve dysfunction.

Similarly, research has suggested that matrix metalloproteinase, nitric oxide, prostaglandin E_2, and interleukin-6 in discs excised from patients with herniation and radiculopathy may have a causative role in pain production.[23] A more recent investigation was unable to confirm the presence of these inflammatory markers in the epidural space of patients with symptomatic disc herniations, however.[24] Other investigators have shown that in extruded or sequestered discs, a cellular inflammatory reaction may be locally mediated via T cells and macrophages[25]; this has been postulated to play a role in herniated disc regression.[26]

There is evidence of systemic inflammatory responses to disc herniations as well. Brisby and colleagues[27] detected elevated levels of glycosphingolipid antibodies in the serum of patients with sciatica and disc herniation compared with healthy volunteers. Elevations were equivalent to those found in patients with autoimmune neurologic disorders, such as Guillain-Barré syndrome. Brisby and colleagues[27] suggested that a systemic autoimmune response to disc tissue may result in damage, or alteration, of nerve tissue. After age 12 years, the endplate apophyseal vessels close, which may facilitate an amnestic antigenic response to exposure to extruded nucleus pulposus tissue. These findings are helpful in considering patients who have severe sciatic pain with minimal mechanical compression and patients who seem to have persistent symptoms despite surgical decompression.

Disc Herniation and Back Pain

Most patients with symptomatic disc herniations present with leg and back pain (Table 47.1). The mechanism of degenerative back pain remains elusive, although many authors have suggested mechanisms. Accepting that herniation is a stage within the continuum of lumbar degeneration, discogenic pain generators may be a factor. Innervation of the posterior anulus by branches of the sinuvertebral nerve have been well documented and are a suggested pathway of nociceptive pain transmission from disc degeneration. An annular tear and nuclear herniation could result in similar pain transmission.

The concept of *vertebrogenic pain* has also been suggested. Jinkins and colleagues[28] studied the contribution of anterior disc herniations to back pain. They believed that the pain was neurally mediated through branches of the ventral ramus and paravertebral autonomic plexus. Because the herniations were outside the spinal canal, they were not associated with compression of the cauda equina or nerve roots, but most patients complained of lower extremity paresthesias, mostly bilateral, in addition to low back pain. A direct causal relationship between anterior disc herniations and leg symptoms has not been clarified.

TABLE 47.1 Prevalence of Back Pain and Sciatica in Adults

Characteristic	Prevalence (%)
Any low back pain	60–80
Any low back pain persisting at least 2 wk	14
Low back pain persisting at least 2 wk at a given time (point prevalence)	7
Back pain with features of sciatica lasting at least 2 wk	1.6
Lumbar spine surgery	1–2

Classification of Disc Herniations

Classification of any disorder should be based on identifiable features that have some influence on prognosis or treatment decision making. Many classification systems have been proposed for lumbar disc herniations, although none are all-inclusive or ideal.[29,30] It is more appropriate to consider them as tools to describe the herniation.

Morphology

Disc herniations can be described by their morphology. Before the introduction of advanced imaging, morphology was difficult to assess preoperatively. Currently, and to a lesser extent, computed tomography (CT) can differentiate disc morphology with reasonable reliability. Spengler and colleagues[13] divided herniations into three types (Fig. 47.6). A *protruded* disc was defined as eccentric bulging through an intact anulus fibrosus. An *extrusion* was defined as disc material that crosses the anulus but is in continuity with the remaining nucleus within the disc space. A *sequestered* disc represents a herniation that is not continuous with the disc space; this is the typical "free fragment."

Other authors have classified discs as either contained or uncontained.[31] *Contained* disc herniations are subligamentous. It is presumed that they have not passed beyond the limits of the posterior longitudinal ligament or the outer layer of the anulus. *Uncontained* disc herniations have crossed this boundary. Advocates of this system describe contained and uncontained extrusions, with the former remaining beneath the outer layers of the anulus.[31]

Location

Herniations can be described topographically according to anatomic location (see Fig. 47.3). The herniation can be located within the central zone, lateral recess, foraminal, or extraforaminal regions. Herniations can also exhibit cranial or caudal migration in relation to the disc space.

Timing

Lumbar disc herniations can be organized according to the time from initial symptom onset. These may be arbitrarily divided as acute or chronic. Acute herniations are present for less than 3 to 6 months, whereas chronic discs cause symptoms for a longer time. Breakdown according to this time frame is based on our sense of what is a reasonable cutoff point. Because

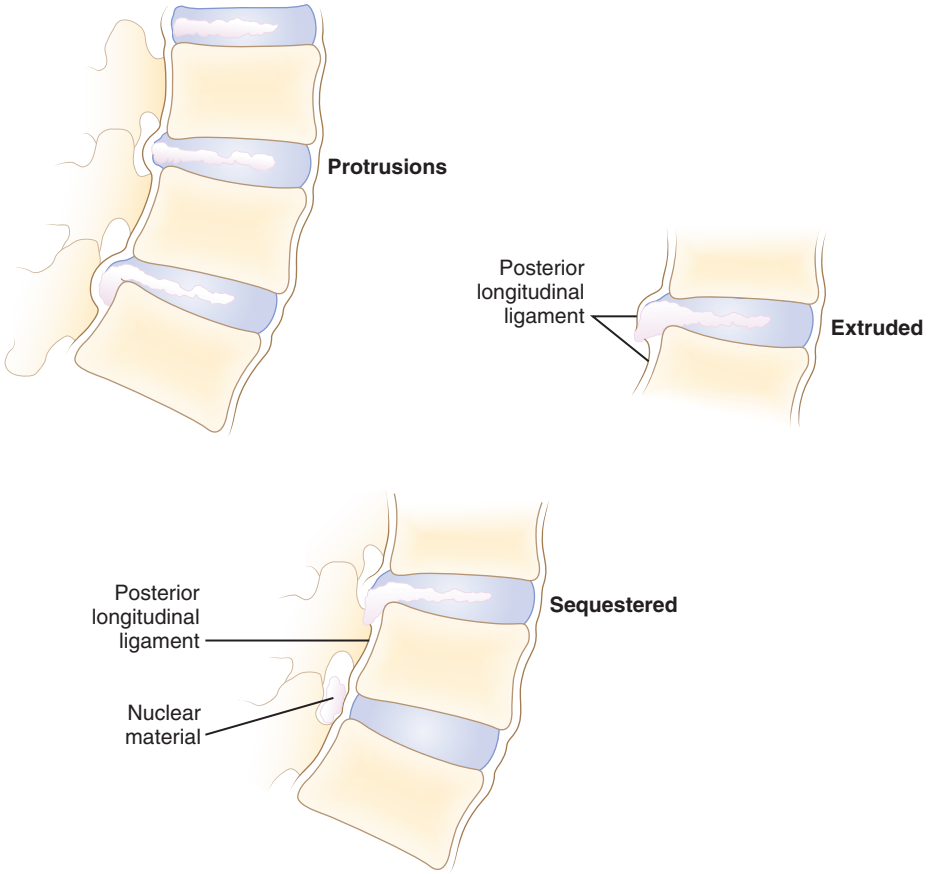

FIG. 47.6 Classification of disc herniations as described by Spengler and colleagues.[13] *Disc protrusion* is defined as a bulging, displaced nucleus that has not extended beyond the limits of the anulus fibrosus. *Extrusion* extends beyond the anulus fibrosus but is still in continuity, at least partially, with the parent disc. *Sequestered* disc herniation implies that a fragment has broken free (i.e., free fragment) and is no longer in continuity with the parent disc. In some cases, in which disc herniation lies immediately behind the vertebral body, it is difficult to tell from which disc the herniated fragment originated.

the results of disc excision seem to be influenced by the timing of surgery, this categorization is important. From a survey of the literature, it seems that the results of disc excision are compromised if delayed more than 2 to 16 months from symptom onset.[12,32–34]

History and Symptoms

Many patients describe a prodromal history of long-standing mild to moderate back pain. Although trauma is not the only component leading to a disc herniation, some patients describe a specific incident attributable to the onset of leg and back pain. This incident may be a fall, a twist, or lifting of a heavy item. Specific postures can lead to exponential increases in intradiscal pressure, which can predispose to disc injury.[18] Exposure to vibrational energy combined with sustained lateral flexion and rotation may also predispose to herniation.[16] The exact history of the incident and the presence of preexistent back or leg pain must be explored; this is particularly important in work-related injuries.

Pain is the most common complaint. Axial back pain is typically present, although some patients do not have this complaint. Radicular pain is more typical and often the more "treatable" of the complaints. The pattern of lower extremity radiation depends on the level of the herniation. Lower lumbar or lumbosacral disc herniations can lead to the classic symptoms of pain radiating below the knee. Often pain extends into the foot and can follow a dermatomal distribution. S1 radicular pain may radiate to the back of the calf or the lateral aspect or sole of the foot. L5 radicular pain can lead to symptoms on the dorsum of the foot (Fig. 47.7). Radiculopathy from involvement of the upper lumbar roots can lead to more proximal symptoms. L2 and L3 radiculopathy can produce anterior or medial thigh and groin pain. Groin pain may also be indicative of L1 pathology. Radicular pain can be difficult to discern and is often not "classic." Many patients do not exhibit pain in a specific dermatomal distribution, or the radiation does not extend along the entire leg. It may radiate only into the hip region or just the foot or any portion of the leg.

The character of radicular pain can be sharp, dull, burning, or dysesthetic. It can be exacerbated by coughing, bending, or lifting. A relieving maneuver may be lying supine with the knees and hips flexed, particularly with lower lumbar herniations. In contrast to patients with lumbar stenosis, patients

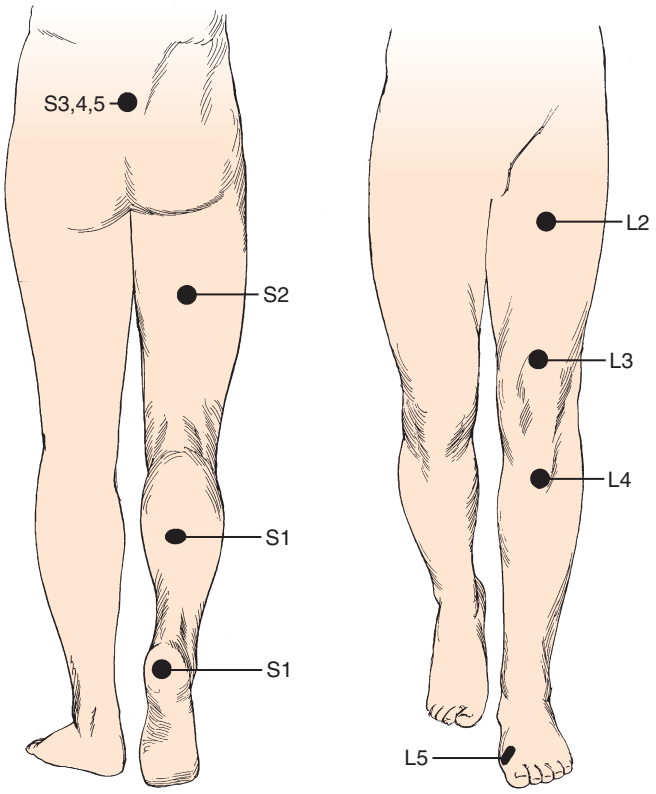

FIG. 47.7 The location of the pain can help localize the nerve root involved. Pain may radiate to small, isolated areas along the course of the dermatome.

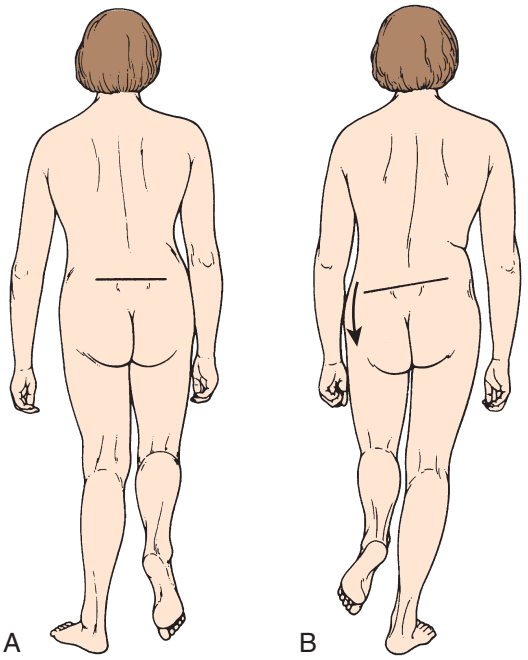

FIG. 47.8 (A) With normal L5 nerve root function, hip abductors are strong and able to support body weight. (B) With L5 nerve root compression, hip abductors can be weakened, leading to positive Trendelenburg sign. This sign is seen when the iliac crest (pelvis) tilts down onto the side where the leg is raised, indicating contralateral hip abductor (L5) weakness.

with disc herniations more typically complain of constant pain that is not exacerbated by ambulation. Buttock pain is also common and can be referred or radicular in nature. Patients may interpret this as back pain, but the pathoanatomic significance of pain in this area is different than true axial pain. Pain is one component of radiculopathic complaints. Nerve compression can lead to motor and sensory deficits. Weakness may be reported as a slapping gait, footdrop, knee buckling, or imbalance when walking.

It is important to ask questions pertaining to bowel and bladder function. The examiner should inquire about urgency and frequency and fecal and urinary incontinence. Questions must be direct because most patients report constipation, which is often related to narcotic usage or inactivity, as a change in bowel habits. Acute bowel or bladder symptoms can be the sign of a cauda equina syndrome, which should mandate urgent surgical decompression.

The influence of social and psychological factors on the outcomes of disc surgery has been well documented. It is highly recommended to obtain a social and at least cursory psychiatric history. Prescription use of antidepressants is an important clue, although depression is often undiagnosed and untreated at the time of initial presentation. Other personality factors—such as chronic headaches, hysteria, hypochondriasis, nervous disorders, and impulsivity—can also be influential.[13,35] Work history, pending litigation, and type of work should be obtained. A history of smoking is an independent risk factor for low back pain and a risk factor for a poor result after back surgery.[35,36]

Physical Examination

Inspection

Inspection is the first step in the physical examination. As the patient walks into the examining room, gait should be observed. A sciatic list may be present, usually manifested as the patient leaning away from the side of leg pain. This sciatic list is thought to be associated with a paracentral herniation lateral to the nerve root. Axillary herniations may cause a list toward the side of herniation. The list is an attempt to relieve neuromeningeal tension by drawing the nerve root away from the herniated fragment. Another feature of gait that should be noted is a wide-based gait, indicative of lumbar or more cranial canal stenosis. A footdrop or foot slapping gait may occur with L4 or L5 paresis. A Trendelenburg gait can suggest hip abductor weakness (Fig. 47.8), which may be a clue to L5 nerve root compression because the gluteus medius is most often an L5 dominant muscle.

Alignment of the spine should be noted. There can be loss of normal lumbar lordosis from muscular spasm. Hip flexion can relieve pain, leading some patients to lean forward or be reluctant to place the affected foot flat on the floor. In some cases, a nonstructural "sciatic scoliosis" can be noted on radiographs or examination of the back.

Palpation and Percussion

Examination should include a systematic examination of the back. The spinous processes are palpated individually and in stepwise fashion. Tenderness to palpation of one or two levels is more consistent with bony pathology than tenderness at multiple levels. In some cases, pressure on the spinous processes can reproduce sciatic symptoms. Continuing caudally, the lumbosacral junction and the sacral prominences and sacroiliac joint area can be palpated and percussed. Inflammation in these regions can manifest with sciatica, feigning disc herniation.
